Transference and Countertransference Patients with dissociative identity disorder often manifest a complex multilayered transference as a whole, as a system of personality states, and as individual alter personality states. Commonly, transference is dominated by themes of trauma and abuse with the therapist most commonly experienced as potentially exploitative and abusive, uninvolved or uncaring about the patient's difficulties, or a helpless victim like the patient faced with an implacable other. Countertransference responses may vary accordingly with overinvolvement, detached hostile skepticism, or a sense of being overwhelmed and unskilled being quite common. Burnout and “secondary” posttraumatic stress disorder has been reported for therapists and treatment teams; adequate attention must be paid to limit-setting, boundaries, and assistance to clinicians who experience reports of extremely abusive trauma adversely.

Therapeutic Resolution Over the course of treatment significant unification of dissociated mental processes may be observed. Alter personalities lose distinctness and decrease compartmentalization of thoughts, memories, and affects and the patient develops a more unified sense of self. Transference is modified consistent with these changes. Amnesia and switching become less apparent. Fusion of alter personalities results in psychological merging of two or more entities at a point in time with a subjective experience of loss of all separateness. Some patients proceed to what appears to be a complete fusion of all alter identities, with a shift in self-representation from that of a dissociated individual to one with a consistent and continuous sense of self across all behavioral states. Many patients never attain a full integration of their alter personalities but leave treatment when they have achieved relative stability, adequate function, and some measure of internal harmony.

As this integrative process occurs, symptoms of posttraumatic stress disorder usually improve significantly. Patients often experience a freeing of energy towards everyday life and away from trauma-focused ways of living. At the same time, nondissociative and integrative coping strategies must be identified and substituted for dissociative responses to life stressors. Losses must be mourned and the patient must be helped to connect and to cope with the larger world in a more functional manner.

Hypnosis Despite the controversy about its use, hypnosis was endorsed by approximately two thirds of respondents as a psychotherapeutic adjunct. Hypnotherapeutic interventions can often alleviate self-destructive impulses or reduce symptoms such as flashbacks, dissociative hallucinations, and passive-influence experiences. Teaching the patient self-hypnosis may help with crises that occur outside of sessions. Hypnosis may be useful for accessing specific alter personality states and their sequestered affects and memories. Hypnosis is also used to create relaxed mental states in which negative life events can be examined without overwhelming anxiety. Clinicians using hypnosis should be trained in its use in general and in trauma populations. Clinicians should be aware of current controversies over the impact of hypnosis on accurate reporting of recollections and obtain appropriate informed consent for its use.

Pharmacotherapy Pharmacotherapy was the third most commonly endorsed treatment modality. Although double-blind, controlled clinical trials have not been conducted, a variety of medications are considered clinically effective with many patients with dissociative identity disorder. Guidelines for the use of medications with dissociative patients emphasize the need to identify specific treatment-responsive symptoms rather than attempting to treat the dissociation per se. Medications may be helpful in attenuating symptoms to assist the patient in stabilizing in treatment. Patients should be advised that medication response is likely to be partial. In general, success is more likely if medication target symptoms are present across a range of alter personality states rather than confined to one or a few personality states.

Among the target symptoms considered most responsive to medication are affective symptoms. In many instances, these are secondary and show a more heterogeneous and less robust response than primary mood disorders. Nonetheless, antidepressant medications are often important in the reduction of depression, and stabilization of mood. A variety of symptoms of posttraumatic stress disorder, especially intrusive and hyperarousal symptoms, are partially responsive to medication. Guided by clinical experience and research on patients with posttraumatic stress disorder, clinicians report some success with antidepressant medications, b-adrenergic receptor antagonists, clonidine (Catapres), anticonvulsants, and benzodiazepines in reducing intrusive symptoms, hyperarousal, and anxiety in these patients. Sleep disturbances and traumatic nightmares may also be improved by these medications, although patients should be cautioned that sleep disturbances may be particularly refractory to medications. Case reports suggest that aggression may respond to carbamazepine (Tegretol) in some individuals if EEG abnormalities are present. Many patients show significant obsessive-compulsive symptoms, and they may preferentially respond to antidepressant medications that have antiobsessive efficacy. Open-label studies suggest that naltrexone (ReVia) may be helpful for amelioration of recurrent self-injurious behaviors in a subset of traumatized patients.

Questions are often raised about the efficacy of antipsychotic medications, particularly for symptoms such as hallucinations. Although these drugs are only minimally effective for quasipsychotic symptoms such as hallucinations in many patients with dissociative identity disorder, low doses may be useful in some cases for severe anxiety and for the subtle cognitive slippage sometimes seen. The newer drugs, such as risperidone (Risperdal) and olanzapine (Zyprexa), may be more effective and better tolerated for overwhelming anxiety and intrusive posttraumatic stress disorder symptoms. Dissociative memory and process symptoms have proven refractory to medication in general. Dissociative-like symptoms and behaviors, however, can be induced in some patients with posttraumatic stress disorder and in normal individuals with drugs (e.g., phencyclidine, cannabinoids), suggesting the presence of pharmacologically sensitive neurobiological mechanisms that may lead to future medications specifically targeting dissociative symptoms per se.

Inpatient Treatment Inpatient treatment is most commonly used for stabilization of patients in acute crisis and, less often, for providing a safe environment in which to do intensive work with painful moods and memories. For a number of reasons, patients with overt dissociative identity disorder can have disruptive effects on the milieu of general psychiatric units and often stimulate splitting and conflict among staff about the best way in which to relate to the patient and the alter personalities. Inpatient programs specializing in the treatment of dissociative and posttraumatic disorder patients may be more successful because they provide a unified treatment approach in which rigorous boundaries and firm limit-setting are combined with specific supportive treatment interventions to assist with symptoms. Inpatient treatment on general hospital units is most successful if “special” treatment is avoided for the dissociative patient with a focus on a unified approach to managing specific target symptoms.

Partial hospital treatment can be a very effective modality for the dissociative patient if clinical interventions target trauma-based issues and adaptations. Specialized trauma-partial hospital programs with groups emphasizing symptom containment, cognitive-behavioral interventions, and psychoeducation can be very effective in helping to stabilize the more severely and persistently ill dissociative patients as well as in providing an intensive stabilization experience for higher-functioning dissociative patients.

Adjunctive Treatments Authorities agree that in therapy groups that include general psychiatric patients, the emergence of alter personalities can be disruptive to the group process by eliciting excess fascination or by frightening other patients. Therapy groups composed only of dissociative patients are reported to be more successful, although the groups must be carefully structured, set firm limits, and should generally focus only on here-and-now issues of coping and adaptation. Family or couples therapy is often important for long-term stabilization and to address pathological family and marital processes that are common in these patients and their family members. Family therapy with the family of origin of the dissociative patient may be helpful in clarifying on resolving the conflictual emotions these patients frequently experience towards family members. Care must be exercised in setting up such meetings since some interactions with family members may lead to a decompensation in the patient. Confrontation of family members about past traumas in an accusatory manner almost invariably has a disastrous outcome both for the dissociative patient and family members. Accordingly, there is usually little place for such interventions in treatment of dissociative identity disorder.

Expressive and occupational therapies, such as art and movement therapy, have proven particularly helpful in treatment of dissociative patients. Art therapy may permit patients to safely express thoughts, feelings, mental images, and conflicts that they have difficulty verbalizing. Movement therapy may facilitate normalization of

body image for these severely traumatized patients.

Outcome Studies Single case descriptions of successful treatments for dissociative identity disorder date back more than a century. Systematic outcome studies, however, have only appeared since the 1980s. The first such study followed up 20 patients an average of 3 years after intake. The majority were being treated by therapists who were unfamiliar with this disorder. Nonetheless, two thirds of the clinicians reported moderate to great improvement in their patients. A history of severe retraumatization during the course of treatment was associated with poorer outcomes. In the Netherlands a chart review study of 101 dissociative disorder patients in outpatient treatment for an average of 6 years found that clinical improvement was related to the intensity of the treatment, with more comprehensive therapies having better outcomes. A study using the DES to track treatment progress of 21 dissociative inpatients found a significant drop in overall scores over a 4-week hospitalization.

The largest and most systematic treatment outcome study re-evaluated 54 inpatients 2 years after discharge to outpatient treatment. As a group, there were significant overall decreases in psychopathology including number of Axis I and Axis II disorders, decreased DES scores, decreased depression on the Beck Depression Inventory and Hamilton Rating Scales for Depression and decreased dissociative symptoms on all of the DDIS subscales. Patients who were reported integrated according to the criteria defined by Richard Kluft in 1984 were the most improved. Two studies investigating cost efficacy of treatment for dissociative identity disorder have concordant findings suggesting that outcome depends on clinical subgroup. The more treatment-responsive group of patients showed significant remission of symptoms within 3 to 5 years of beginning appropriate treatment. A second group with more alter identities and more personality disorder features showed good outcome but required hospitalizations in addition to outpatient treatment. A third group, characterized by the longest period of treatment before diagnosis, largest number of alter identities, and most personality disorder problems, had a much longer, more expensive, and more difficult course. Overall, however, treatment approaches specifically targeting this disorder showed reductions in overall psychiatric treatment cost after the first year compared with prior treatment for these patients. Some health maintenance organizations report that more intensive treatment benefits for dissociative patients has not only reduced overall psychiatric costs but has also reduced costs for medical utilization for somatoform symptoms.

These preliminary studies have notable limitations including the diverse and nonstandardized nature of the therapy and lack of comparison groups. Nonetheless, in aggregate they indicate that many patients with dissociative identity disorder improve with treatments focused on their dissociative symptoms and that overall treatment costs may be saved in the long term with better treatment for these patients.

FORENSIC ISSUES

The intersection between the diagnosis dissociative identity disorder and the legal system has proven exceedingly controversial. The contentious dispute over its existence, the often sensationalized media attention, and the need to rule out simulation or malingering have made the forensic evaluation of the disorder difficult to perform and to defend. Issues of competency to stand trial and degree of responsibility for the behavior of different alter personality states have received contradictory judicial opinions. The most common defenses are: (1) dissociative defendants do not have control over or are not conscious of their alter personalities and therefore cannot be held responsible for their actions; (2) these defendants cannot recall the actions of their alter personalities and therefore cannot participate in their own defense; and (3) a diagnosis of dissociative identity disorder makes it impossible for a defendant to conform to the law or to know right from wrong. Evidentiary questions, such as the admissibility of hypnotic or amobarbital (Amytal) interviews and the independence of testimony by different alter personalities have proven problematic.

In assessing possible dissociative identity disorder in criminal defendants, a number of guidelines may be helpful: (1) Follow basic principles of forensic assessment; (2) undertake a comprehensive assessment of all available documentary materials concerning the defendant and the case; (3) review all available past psychiatric, social service, and related materials; (4) perform a standard diagnostic assessment on the defendant before introducing specialized testing; where possible, videotape the interview following forensic guidelines for videotaping; (5) conduct a longitudinal life-history interview, which may be useful in cases where malingered amnesia or dissociative identity disorder are suspected: ask for the defendant's entire life history beginning with the first memory and proceeding to the present time, following up information as necessary in a neutral manner; (6) after completion of the basic clinical assessment, psychological testing, specialized dissociative interviews (e.g., the SCID-D), or neuropsychiatric testing may be done; (7) corollary sources (e.g., friends and family) may be necessary to corroborate the history in addition to written records; and (8) use forensic guidelines for hypnotically facilitated or drug-facilitated interviews; avoid performing these unless you have been trained in forensic hypnosis.

There is no pathognomonic presentation of dissociative identity disorder in the forensic setting. However, authorities suggest that genuine defendants are more likely to show a complex alter system, not just a good-or-bad alter dichotomy. Individuals with bonafide dissociative identity disorder may have bizarre explanations for why and how they (in alter identities) committed crimes, not just that “the bad one did it.” Authorities also state that a number of these defendants minimize their psychiatric symptoms and attempt to avoid being labeled psychiatrically ill, although a few will exaggerate their symptoms.

Clinicians may find themselves treating patients who face criminal charges for minor crimes such as shoplifting, check forgery, credit card fraud, or driving while intoxicated. It may be impossible for the patient to hire an independent forensic expert. In these cases the clinician may have to provide a written report or appear for court testimony at the request of the patient or the patient's attorney. The clinician should clarify with the patient on the differing roles of the forensic expert and the therapist. It may be difficult for the therapist to separate the roles of the advocate for a disturbed patient from that of a forensic examiner. However, the clinician should take seriously the importance of protecting the public from the patient. Clinically, the forensic situation may be useful to underscore for the patient the responsibility of the whole person for behavior committed in dissociated states of consciousness and to gain better adherence to responsible behavior from acting-out alter identities.

In general, most courts have not found dissociation sufficient grounds for a claim of legal incompetence. Also, the clinical standard of holding the whole human being responsible for the behavior of any part should be the foundation for any legal consideration of diminished responsibility for criminal conduct in the dissociative patient. An affirmative case should be made that the defendant fails to meet the standard for legal sanity or has diminished capacity, just as would be done for any psychiatric defense.

SUGGESTED CROSS-REFERENCES

Further descriptions of the nature and the function of dissociative mechanisms are found in Chapter 6, dealing with the theories of personality and psychopathology, and in Chapter 9, dealing with the classification of mental disorders. The diagnostic distinction between dissociative disorders and other mental disorders is clarified in Chapter 12 on Schizophrenia and in Chapter 15 on anxiety disorders. Chapter 16 on the Somatoform disorders provides a detailed description of the somatic symptoms that in this chapter are viewed as manifestations of dissociation. Expanded descriptions of the various psychotherapeutic approaches appears in Chapter 30.

18.4 DEPERSONALIZATION DISORDER

MARLENE STEINBERG, M.D.

Although listed as a dissociative disorder in the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders*, (DSM-IV), coverage of depersonalization in the scientific literature has until recent years been limited. However, interest in the dissociative disorders has steadily increased since the 1970s, and many advances have recently been made in the study of depersonalization and the other dissociative disorders, including the development of reliable diagnostic instruments.

DEFINITION

DSM-IV defines depersonalization as “a feeling of detachment or estrangement from one's self,” in which “The individual may feel like an automaton or as if he or she is living in a dream or movie.” This may be accompanied with “a sensation of being an outside observer of one's mental processes, one's body, or parts of one's body.” Additional examples of depersonalization include emotional and mental numbness, not recognizing oneself in the mirror, the feeling of lack of control over emotions, and feeling as if body parts are detached or unreal.

HISTORY

Although first described by M. Krishnaber in 1872, depersonalization was not named as such until 1898, when L. Dugas coined the term to contrast “the feeling of loss of ego” with a “real loss.” While various other nineteenth- and early–twentieth-century scholars in psychology—such as Eugén Bleuler, Sigmund Freud, Josef Breuer, and Pierke Janet—referred to the phenomenon in passing or listed it as a symptom in their celebrated case studies, relatively little attention was paid to it until 1980, when *depersonalization disorder* was officially listed as a psychiatric diagnosis in the third edition of DSM (DSM-III). However, a few notable studies on depersonalization occurred during this time. W. Mayer-Gross, in his classical paper of 1935, began the modern study of depersonalization and was followed by H. Shorvonn in 1946 and J. Saperstein in 1949. The next major contributor to the study of depersonalization was C. Ackner, who in his 1954 paper noted that the phenomenon lacked clear boundaries and therefore described four salient features that continue to be widely accepted: (1) the feeling of unreality or strangeness apropos the self; (2) the retention of insight and lack of delusional elaboration; (3) the lack of affective response (“numbness”) except for the discomfort regarding depersonalization; and (4) the unpleasant property that may vary in intensity inversely with the subject's familiarity with the phenomenon.

In recent years interest in depersonalization has been increasing. An extensive and systematic investigation of depersonalization has been performed based on the administration of the *Structured Clinical Interview for DSM-IV Dissociative Disorders–Revised* (SCID-D-R), a diagnostic tool for the assessment of specific dissociative symptoms and disorders. SCID-D-R research indicates that the range and severity of depersonalization distinguishes dissociative identity disorder from the occasional occurrence of depersonalization, which may be seen in patients with other psychiatric disorders. In addition, depersonalization has been included as one of the five core symptoms of dissociation, the others being amnesia, derealization, identity confusion, and identity alteration. In the evaluation of patients experiencing depersonalization, it is essential to assess the presence of the other core symptoms of dissociation in order to arrive at an accurate diagnosis.

COMPARATIVE NOSOLOGY

With each edition of DSM, the thrust has been toward a more specific definition of depersonalization disorder and a greater emphasis on subjective stress. The most recent (fourth) edition of DSM (DSM-IV), is the most useful in that its wording better clarifies the criteria and presents terminology and examples that are easily understood.

While depersonalization disorder was classified as a dissociative disorder in DSM-III and all subsequent editions, the International Classification of Diseases (ICD) does not list it as such. In its most recent incarnation, the 10th revision of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10), depersonalization-derealization syndrome is listed under other neurotic disorders. This distinction is fairly arbitrary, but some scholars support this exclusion because memory disturbance, which is found in the other dissociative disorders, is absent (Table 18.4-1).

A. Either of the following must be present:
   (1) *Depersonalization*. The patient complains of a feeling of being distant or "not really here." For example, individuals may complain that their emotions, feelings or experience of the inner self are detached, strange, not their own, or unpleasantly lost, or that they feel as if acting in a play.
   (2) *Derealization*. The patient complains of a feeling of unreality. For example, there may be complaints that the surroundings or specific objects look strange, distorted, flat, colorless, lifeless, dreary, uninteresting, or like a stage upon which everyone is acting.
B. There is retention of insight, in that the patient realizes that the change is not imposed from outside by other persons or forces.

Table 18.4-1 ICD-10 Diagnostic Criteria for Depersonalization-Derealization disorder

EPIDEMIOLOGY

Transient depersonalization has been reported to be the third most common complaint among psychiatric patients, following depression and anxiety; in fact, it is experienced to some degree by 80 percent of the psychiatric population. However, the symptom of depersonalization often occurs in association with other disorders and may not be the predominant syndrome. Recurrent depersonalization is a common occurrence in the context of dissociative identity disorder and dissociative disorder not otherwise specified. The sex ratio, while inadequately documented and unclear, seems to favor females. It has been reported widely in adults and adolescents, but few cases have been reported in children. There is no known pattern of inheritance for depersonalization disorder.

ETIOLOGY

The etiology for depersonalization is diverse and symptoms are probably produced by an array of biological and psychological factors. Several biological and psychodynamic theories have been proposed. First, depersonalization may result from temporal lobe dysfunction and various metabolic and toxic states. This theory has associated depersonalization with epilepsy and other diseases of the central nervous system, as well as the ingestion of psychotomimetic drugs like mescaline and lysergic acid diethylamide (LSD). Second, depersonalization may result from a predetermined functional brain response adaptive to overwhelming trauma, as

evidenced by its occurrence in a variety of other psychiatric disorders and in nonpsychiatric populations. Third, depersonalization may be a defense against painful conflictual affects such as guilt, phobic anxiety, anger, rage, paranoia, conflictual ego identifications, primitive fusion fantasies, and exhibitionism. Systematic research into these theories is limited, and further research is necessary to clarify and provide conclusive support for any current theories of etiology.

Research has documented the psychological triggering of depersonalization. Depersonalization frequently appears as a response to life-threatening danger such as accidents, serious illnesses, cardiac arrests, anaphylactic reactions, and complications of surgery, as well as a response to emotional stress from a variety of situations such as overwhelming anxiety, anger, or severe conflict. Depersonalization appears to occur commonly in conjunction with posttraumatic stress disorder, dissociative identity disorder and hallucinogen persisting perception disorder (flashbacks) and is frequently reported by survivors of severe physical, emotional, or sexual abuse; political imprisonment; torture; and cult indoctrination.

DIAGNOSIS AND CLINICAL FEATURES

Depersonalization, in the sense of detachment from the self, occurs as a transient symptom of a variety of Axis I and Axis II disorders. However, it is important to distinguish between this mild and episodic depersonalization and the more severe, prolonged, and recurrent syndrome of depersonalization disorder. The DSM-IV diagnostic criteria of depersonalization disorder are listed in Table 18.4-2.

A. Persistent or recurrent experiences of feeling detached from, and as if one is an outside observer of, one's mental processes or body (e.g., feeling like one is in a dream).
B. During the depersonalizing experience, reality testing remains intact.
C. The depersonalization causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
D. The depersonalization experience does not occur exclusively during the course of another mental disorder, such as schizophrenia, panic disorder, acute stress disorder, or another dissociative disorder, and is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition (e.g., temporal lobe epilepsy).

Table 18.4-2 DSM-IV Diagnostic Criteria for Depersonalization Disorder

Although the central characteristic of depersonalization is the quality of unreality and estrangement from the self—wherein both internal mental processes and external worldly events remain unchanged while their relation and meaning to the patient alter or even appear to lose all coherence—this disorder can manifest itself in a variety of ways. Common manifestations of depersonalization include a feeling of being unreal, of being dead, of parts of the body being disconnected, or of observing a movie of the self. The depersonalization experience is evident in the following excerpt from a patient interview:

> It's really weird. It's sort of like I'm here, but I'm really not here and that I kind of stepped out of myself, like a ghost... . I feel really light, you know. I feel kind of empty and light, like I'm going to float away... . Sometimes I really look at myself that way... . It's kind of a cold, eerie feeling. I'm just totally numbed by it.

Many people who suffer from chronic depersonalization do not report these experiences spontaneously. Patients often are reluctant to relate these experiences for fear that the clinician will think that they are crazy; some even adapt to and learn to accept their chronic condition, and may actually find it comforting. This makes detection and diagnosis particularly difficult, since depersonalization disorder is marked only by an altered internal state of consciousness and perception, not by any apparent change in external social behavior. Even those who do report feelings of depersonalization often find that their experiences are difficult to put into words. For example, they may describe their feelings as follows: “[It's like] being high on drugs,” “I would have the ability to fly, to escape from my body for a short period of time,” “I can see myself [from the outside] and what I must look like [to others] or what I'm doing or how I'm walking,” or “It's like feeling like you're floating in space and watching [yourself].” Due to the elusive nature of depersonalization, and to the fact that it is rarely the patient's presenting complaint, it is essential that clinicians assess for the varied manifestations of depersonalization in mental status examinations.

Bodily Perceptions Parts of one's body or one's entire body may feel insubstantial, unreal, or foreign.

> ... it just doesn't seem real. Everything to me doesn't seem real, my body included... . I was looking in the mirror and all of a sudden it just felt as if the image in the mirror was looking back out upon myself.

Emotional, Mental and Behavioral Perceptions One's internal mental and emotional operations may seem altered or foreign, sometimes resulting in behavioral transformations or limitations.

> You just feel like you're never being yourself, uh, you're not thinking as you normally do. You just feel strange... . I need to concentrate on things a lot more... . I feel as if most people have their brain on automatic. I feel like I have to crank it, like I'm always working at it and always consciously trying to remember things, trying to concentrate... . It's almost as if I can't visualize things in my mind the way you normally would, when you actually see things ... I can't do that very well.

External Perceptions Feelings of unreality, strangeness, and discontinuity may pervade one's perceptions of objects and people in the outside world. Thus, individuals experiencing depersonalization may experience it in conjunction with derealization.

> [Everything] just feels different, just like it's in a dream, in a daze, things are dulled... . I remember when this first started and I was in college and I went home and the thing that kept going over in my mind was I want to go home, I want to go home and I was home, but that just kept coming into my mind... . everything always seems unreal... . Other people, myself, just everything... .

Anxiety Although many patients report a sense of numbness or emotional detachment, this lack often does not extend to fear of depersonalization itself; in fact, many patients become upset by the sense of unreality. They may have attacks of panic as a result of either hampered interaction with the outside world or fear of encroaching insanity.

> Um well, yeah, I guess you'd call it a panic attack... . if someone's talking to me [and] I can't understand what they're saying or I'm just not thinking clearly, then it's kind of a panic that they're going to notice that, or if I'm driving. Sometimes I'd have problems with driving for a while.

Reality Testing Although patients may report feeling as if they were unreal or automated, reality testing—that is, the ability to distinguish between the real and the unreal—always remains intact; depersonalization is typified by the “as if” quality of the experience.

> I know what is really real... . [things] just don't seem real... . I'm used to it now. I'm used to compensating... . I know pretty much what it's going to do, how bad it is at its worst or how good it is at its best... . everything you're saying feels like it's not real, but yet you know it's real and you know what you really just said.

Screening Tools and Diagnostic Interviews Until recently, the diagnosis of depersonalization disorder and of the rest of the dissociative disorders was difficult to make because of the multiple causes for transient depersonalization and the lack of tools for systematic assessment. In recent years, however, the development of structured interviews for diagnosis have improved the accuracy of diagnoses. Screening instruments for dissociative symptoms include the Questionnaire of Experiences of Dissociation, which consists of 26 true-false items, the Dissociative Experiences Scale, which consists of 28 questions, and the Perceptual Alteration

Scale, which includes items from the Minnesota Multiphasic Personality Inventory relative to dissociation. The Dissociative Disorders Interview Schedule is a structured interview for the assessment of dissociative disorders. Poor inter-examiner reliability has been reported for depersonalization on this tool.

Because screening tools cannot diagnose depersonalization disorder, individuals who have dissociative symptoms should be evaluated further with a thorough clinical evaluation and a more comprehensive, structured interview, such as SCID-D-R in order to rule out the presence of a dissociative disorder. The SCID-D-R is a semistructured interview that evaluates the severity of five dissociative symptoms (amnesia, depersonalization, derealization, identity confusion, and identity alteration) and diagnoses dissociative disorders, including depersonalization disorder. The average duration of the interview is 45 to 90 minutes, and contains 40 items specific to depersonalization, with follow-up items if the examiner wishes to obtain additional information. Good to excellent reliability and discriminant validity have been reported for the SCID-D-R, with the symptom of depersonalization receiving the highest rating for inter-examiner reliability. The *Interviewer's Guide to the SCID-D-R* provides guidelines for the administration, scoring and interpretation of SCID-D-R.

Proper treatment of depersonalization depends upon accurate diagnosis of its presence and severity, as well as the symptom constellation surrounding it, as the following a case study of a patient diagnosed with depersonalization disorder on the SCID-D-R demonstrates. This case is presented in the form of a report suitable for inclusion in the patient's records, in order to demonstrate the utility of the SCID-D-R in patient education and treatment planning as well as diagnostic assessment. Figure 18.4-1 is a visual outline of the process of differential diagnosis.

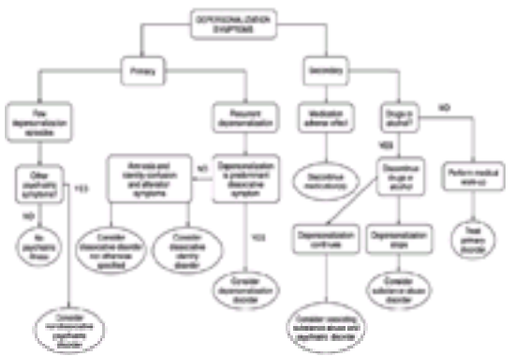

FIGURE 18.4-1 Differential diagnosis decision tree of depersonalization. (Reprinted with permission from Steinberg M: *Interviewer's Guide to the Structured Clinical Interview for DSM-IV Dissociative Disorders-Revised [SCID-D-R].* American Psychiatric Press, Washington, DC, 1994.)

SCID-D-R Psychological Report Ms. Walker

Dates of Evaluation: 8/11/94 and 8/18/94

Referral Source: present therapist

Reason for Referral: diagnostic evaluation

Information obtained from: Ms. Walker; present therapist

Brief Summary: Ms. Walker is a 31-year-old unmarried Caucasian woman who presented with the complaint of “feeling detached” from herself. Ms. Walker currently commutes to her job as an administrative assistant at a nearby community college. Her present therapist, from whom she has been receiving outpatient treatment for the past 3 years, referred her.

Past Psychiatric History: The patient has no history of hospitalization for psychiatric disturbance. In 1995 she began receiving treatment with her present therapist when periods of depression began to interfere with both her job and her social relationships. Although she had experimented with marijuana during college, she has never required treatment for a substance abuse disorder. While she indicates that the severity of her depression has diminished somewhat, she still describes her feelings as those of being “detached.”

Family History: Ms. Walker is the older of two siblings. Her family is intact but is in general emotionally unsupportive. She claimed that there is no history of alcohol or drug abuse in her family. While she also stated that neither of her parents had been treated for a psychiatric disorder, she indicated that her mother and father experienced episodes of emotional instability. She said that both her parents were prone to mood swings and spontaneous temper outbursts.

Mental Status Exam: Dressed neatly in a sweater and skirt, Ms. Walker was calm and cooperative. She spoke fluently and answered questions with cogent replies. Though she appeared mildly depressed, her affect seemed to be full range. Ms. Walker denied the presence of auditory or visual hallucinations and did not display any symptoms of psychotic thinking. Furthermore, she claimed not to have experienced any suicidal or homicidal ideation. For a summary of her dissociative symptoms, see the SCID-R Evaluation below.

SCID-D-R Evaluation: In addition to a routine mental status examination, the SCID-D-R was administered in order to systematically evaluate the patient's dissociative symptoms (chronic feelings of detachment from self) and the presence of dissociative disorders. The SCID-D-R interview was then scored according to the guidelines described in the Interviewer's Guide to the SCID-D-R. A review of the significant findings from the SCID-D-R interview includes the following:

Ms. Walker denied experiencing amnestic episodes. However, she endorsed experiencing recurrent episodes of detachment from herself. These feelings of depersonalization cause her considerable distress and inhibit her ability to function effectively in either an occupational or a social environment. This ongoing feeling of depersonalization began at age 18 and has continued since. The patient describes her depersonalization as occurring “all the time”; however, she noted that these feelings vary directly with her overall level of stress. Her experience of depersonalization entail feelings of detachment from life and psychic numbing. Her depersonalization does not manifest itself in disturbances in body image or a sense of a split between participating and observing parts of the self. She endorsed only one out-of-body experience, which she considers an isolated occurrence. With respect to the symptom of derealization, Ms. Walker endorsed experiences of derealization, which vary in intensity together with her depersonalization. However, she reported that her derealization was secondary to her depersonalization, and she never experiences the former without the latter. Her feelings of depersonalization trigger episodes of anxiety and panic, which in turn affect her ability to drive. Ms. Walker entered therapy in 1995, when the combination of depersonalization and panic attacks overwhelmed her, causing feelings of depression. Ms. Walker stated that the depersonalization has negatively affected her ability to function at her job and in life in general. With respect to the symptoms of identity confusion or alteration, Ms. Walker denied experiencing puzzlement regarding her identity, severe mood changes, on alterations in her sense of identity. In addition, Ms. Walker denied experiencing internal dialogues, feelings of being possessed, or the acquisition of unexplained possessions or skills.

Assessment: Based on the SCID-D-R evaluation, Ms. Walker's symptoms are consistent with a primary diagnosis of a dissociative disorder. More specifically, her recurrent episodes of depersonalization with associated derealization, in the absence of amnesia, identity confusion, or alteration is characteristic of SCID-D-R symptom profiles for patients with depersonalization disorder. Her chronic feelings of detachment and unreality towards herself, associated with dysfunction, in the absence of substance abuse disorder or temporal lobe epilepsy, are consistent with DSM-IV criteria for depersonalization disorder. In addition, her descriptions of internal struggle are focused on feelings of unreality, which are characteristic of patients with depersonalization disorder, rather than on conflicts between different personalities, as is described by patients with dissociative identity disorder. Ms. Walker's recurrent depersonalization has in turn resulted in episodes of secondary panic, which interfere with driving, as well as recurrent feelings of depression.

Recommendations: (1) a follow-up interview for review of the findings of the SCID-D-R evaluation, and for educating the patient regarding the nature of her symptoms; (2) continuation of individual psychotherapy. Initial treatment goals should include identification of specific triggers of depersonalization episodes and review of specific techniques for alleviation of the symptom. Longer-range goals should include decrease in the frequency and severity of symptom

disorder, rather than on conflicts between different personalities, as is described by patients with dissociative identity disorder. Ms. Walker's recurrent depersonalization has in turn resulted in episodes of secondary panic, which interfere with driving, as well as recurrent feelings of depression.

Recommendations: (1) a follow-up interview for review of the findings of the SCID-D-R evaluation, and for educating the patient regarding the nature of her symptoms; (2) continuation of individual psychotherapy. Initial treatment goals should include identification of specific triggers of depersonalization episodes and review of specific techniques for alleviation of the symptom. Longer-range goals should include decrease in the frequency and severity of symptom episodes and resultant dysfunction. Trial administration of an antidepressant or antianxiety medication may alleviate this patient's coexisting symptoms of depression and anxiety.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of patients who experience depersonalization should take into account both psychological and organic causes of depersonalization. Patients who present with recurrent depersonalization should receive a comprehensive psychiatric evaluation, including a specialized diagnostic interview in order to rule out the presence of a dissociative disorder.

Medical Etiology If the depersonalization is isolated and coexists with other medical or neurological symptoms, a medical work-up including physical and neurological examination is essential. Blood screening chemistries—such as thyroid function tests, chemical profiles, and a complete blood count—may be necessary. An index of suspicion for temporal lobe epilepsy requires that an electroencephalogram (EEG) be performed. Drug toxicology tests may be helpful in ruling out substance-induced depersonalization, including prescribed medication that may produce depersonalization as an adverse effect.

Individuals with the following disorders may experience depersonalization: (1) seizure disorders such as temporal lobe epilepsy, postconcussional syndrome, structural pathology (i.e., brain tumor), cerebral arteriopathy, and meningioma; (2) infectious causes (i.e., encephalitis); (3) metabolic abnormalities (i.e., hyperglycemia); (4) other conditions, including migraine headaches, vestibular dysfunction, Meniere's disease, and Korsakoff's syndrome.

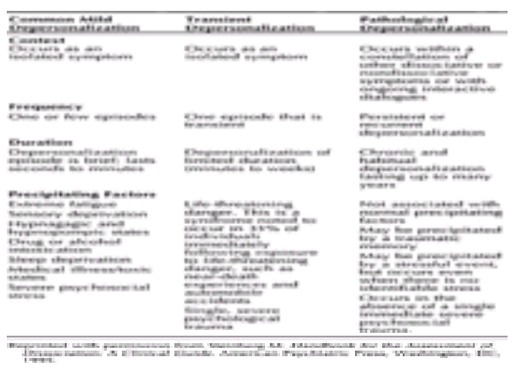
In addition, depersonalization may occur as an adverse effect of both drug abuse and prescribed medications (including the antipsychotic agent haloperidol [Haldol], the anti-inflammatory agent indomethacin [Indocin], methyldopa [Aldomet], and the amphetamine-like agent fenfluramine). Drug-induced depersonalization is typically transient and disappears on discontinuation of the medication. Since case reports of drug-induced depersonalization have not evaluated the baseline level of depersonalization prior to pharmacotherapy, it is unclear whether the drugs caused the depersonalization, worsened pre-existing depersonalization, or whether the association is coincidental.

It is important to note that organically induced depersonalization typically has a repetitive content, in contrast to the elaborate descriptions and internal dialogues associated with depersonalization in individuals who suffer from dissociative disorders.

Spectrum of Depersonalization Research using SCID-D-R indicates that the severity of depersonalization ranges from isolated episodes experienced by normal subjects under stress or sleep deprivation to recurrent and persistent depersonalization in individuals with dissociative disorders and posttraumatic stress disorder. Patients with a variety of nondissociative psychiatric disorders, including the anxiety disorders (particularly panic disorders, obsessive-compulsive disorder, agoraphobia), mood disorders (depressive disorders, bipolar I disorder), psychotic disorders (schizophrenia, psychotic disorder not otherwise specified), the personality disorders (particularly borderline personality disorder), and the substance-related disorders (particularly those involving marijuana and hallucinogens such as LSD and mescaline, although depersonalization may also occur with alcohol, cocaine, phencyclidine, opioids, sedatives, and stimulants), may also experience occasional depersonalization episodes. On the other hand, patients with dissociative disorders exhibit the most severe depersonalization, including individuals with depersonalization disorder and dissociative identity disorder.

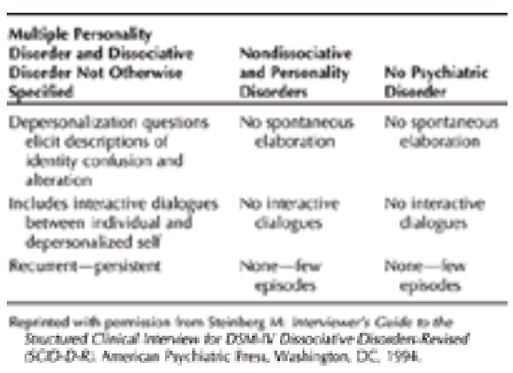
Investigations based on SCID-D-R have found that depersonalization that occurs as a part of depersonalization disorder will occur in the relative absence of other dissociative symptoms. However, in individuals with dissociative identity disorder, depersonalization can occur along with the other four dissociative symptoms—amnesia, derealization, identity confusion, and identity alteration. In addition, research has found that depersonalization that exists within the context of dissociative identity disorder is often distinguished by the occurrence of ongoing, interactive dialogues that occur between the observing and the participating self. It is also important to note that depersonalization occurring in an individual with a dissociative disorder typically has an “as if” quality and that reality testing is intact. In patients with schizophrenia, the depersonalization typically occurs in a psychotic context and reality testing is impaired. In order for a diagnosis of depersonalization disorder to be made, depersonalization must be chronic and of long duration. Once an organic cause has been ruled out, systematic evaluation of depersonalization, including its severity and nature, can distinguish dissociative disorders from other psychiatric disorders.

Table 18.4-3 presents a summary of the diagnostic distinctions between normal and pathological depersonalization, Table 18.4-4 is a summary of the spectrum of depersonalization, and Figure 18.4-1 is a visual summary of the differential diagnosis of depersonalization.



Common Mild Depersonalization	Transient Depersonalization	Pathological Depersonalization
Context		
Occurs as an isolated symptom	Occurs as an isolated symptom	Occurs within a constellation of other dissociative or nondissociative symptoms or with ongoing interactive dialogues
Frequency		
One or few episodes	One episode that is transient	Persistent or recurrent depersonalization
Duration		
Depersonalization episode is brief; lasts seconds to minutes	Depersonalization of limited duration; minutes to weeks)	Chronic and flattened depersonalization lasting up to many years
Precipitating Factors		
Extreme fatigue Sensory deprivation Hypnagogic and hypnopompic states Drug or alcohol intoxication Sleep deprivation Medical illness/toxic states Severe psychosocial stress	Life-threatening danger. This is a syndrome noted to occur in 35% of individuals immediately following exposure to life-threatening danger, such as near-death experiences and automobile accidents Single, severe psychological trauma	Not associated with normal precipitating factors May be precipitated by a traumatic memory May be precipitated by a stressful event, but occurs even when there is no identifiable stress Occurs in the absence of a single immediate severe psychosocial trauma.

Table 18.4-3 Distinguishing Between Normal and Pathological Depersonalization



Multiple Personality Disorder and Dissociative Disorder Not Otherwise Specified	Nondissociative and Personality Disorders	No Psychiatric Disorder
Depersonalization questions elicit descriptions of identity confusion and alteration	No spontaneous elaboration	No spontaneous elaboration
Includes interactive dialogues between individual and depersonalized self	No interactive dialogues	No interactive dialogues
Recurrent—persistent	None—few episodes	None—few episodes

Table 18.4-4 The Spectrum of Depersonalization on the SCID-D-R

COURSE AND PROGNOSIS

Depersonalization usually begins between age 15 and age 30 although there have been reports of its onset in childhood. The symptoms typically begin abruptly, after which point they tend to continue on a steady course without significant changes in intensity. However, in some cases the symptoms occur as a series of repeated attacks, with symptom-free intervals in between. In individuals who are exposed to life-threatening trauma or near-death experiences, depersonalization may develop instantaneously upon the onset of trauma and usually remits after the traumatic experience has ended. The prognosis of individuals with depersonalization disorder has not been investigated systematically.

TREATMENT

Therapy for depersonalization is usually indicated if the depersonalization is recurrent or if it results in distress or functional impairment; if depersonalization is secondary to an underlying primary disorder, then that primary disorder should be treated. If depersonalization is the primary disorder, therapy can be directed at alleviating the depersonalization. A variety of treatments have been reported, including supportive psychodynamic psychotherapy, pharmacological treatment, behavioral and directive techniques, and hypnosis.

Psychodynamic Psychotherapy Traditional psychotherapy that teaches the patient to identify the underlying dynamics of and to achieve control over the symptoms has been reported to be effective. For this treatment to be successful, it is important for the patient to learn to accept and tolerate the depersonalization; hence patients should be encouraged to accept the experience rather than to attempt to change it directly.

Cognitive Therapies In patients with depersonalization and a trauma history, cognitive restructuring approaches may be particularly useful. As depersonalization may be triggered by feelings of loss of control or victimization, cognitive therapies that counteract anxiety can help to alleviate anxiety as well as the depersonalization.

Patient Education and Specific Techniques The patient should be educated regarding depersonalization, its onset, development, triggers, and treatment. A review of the defensive nature of this symptom and its triggers can be the first step in reducing anxiety and minimizing future episodes of depersonalization. In addition, techniques are used to reduce recurrent depersonalization.

Review of techniques specific to symptom alleviation.

Grounding (reorienting) is a method in which the patient can make contact with objects in the environment (e.g., touching a chair where they are sitting) during a depersonalization episode and state his or her name, location, and a statement of self-support (e.g., “I'm John, I'm in the library in my house; it is safe here”).

In creative visualization the patient is taught to visualize a safe place as an attempt to manage their depersonalization episodes.

Distraction techniques may be used to focus the patient's attention to an external activity that they enjoy (e.g., drawing, exercising, talking to a friend) in an attempt to divert their attention from the episodes of depersonalization.

In controlled dissociation patients are taught to rate their episodes of depersonalization on a scale of 1 to 10. They are then asked to increase or decrease the intensity of an episode, so that they can regain a sense of control over their symptom.

Hypnosis Since dissociation is a feature of the hypnotic trance, this treatment may help to demonstrate to patients how to control their own dissociation. When combined with well-designed psychotherapy, hypnosis can lead to a reduction in depersonalization symptoms. In addition, hypnosis is an effective tool for gaining access to and reintegrating dissociated traumatic memories. Because dissociative symptoms can occur secondary to hypnosis, it has been recommended that clinicians should document their patients' baseline level of dissociative symptoms prior to induction using the SCID; preferably, the interview should be audiotaped.

Behavior Therapy Reports have indicated successful response mostly to positive reinforcement, although a few report good results with negative reinforcement. Flooding treatment through fantasy and paradoxical intention has also been reported successfully.

Pharmacotherapy In addition to psychological and social factors, biological factors also seem to contribute to dissociation. Some patients may have a physiological predisposition toward depersonalization. While preliminary data on pharmacological treatments is encouraging, systematic research is limited and current treatment of patients with depersonalization should include a flexible individualized approach.

Their have been no double-blind trials of medications for the treatment of depersonalization. Case reports have found antidepressant and antianxiety medications helpful in alleviation of depersonalization, including the tricyclic desipramine (Norpramin) the selective serotonin reuptake inhibitor fluoxetine (Prozac), and the benzodiazepine clonazepam (Klonopin). One study found fluoxetine to be helpful in decreasing depersonalization in patients with coexisting panic or obsessive-compulsive symptoms. In addition, a variety of biological therapies used to treat depersonalization disorder, because of their significant adverse effects, were previously reported to be effective in studies on patients suffering from severe depersonalization. These medications include pentylenetetrazole, methamphetamine (Desoxyn), electroconvulsive therapy (ECT), dextroamphetamine (Dexed), amobarbitol (Amytal), and thiopental (Pentathol). ECT has also been reported to worsen symptoms of depersonalization, as has caffeine. Mixed results have been reported for antipsychotic agents.

Further research is necessary in the form of controlled double-blind studies utilizing reliable tools comparing the efficacy of pharmacotherapeutic agents. Pharmacotherapy trials can now evaluate baseline and postmedication severity levels of depersonalization using recently developed diagnostic tools that allow for the assessment of the severity of depersonalization based on operationalized criteria.

SUGGESTED CROSS-REFERENCES

Dissociative identity disorder is discussed in Section 18.3, dissociative disorder not otherwise specified in Section 18.5, and posttraumatic stress disorder in Chapter 15. Hypnosis is covered in Section 30.3, behavior therapy in Section 30.2, and biological therapies in Chapter 31.

18.5 DISSOCIATIVE DISORDERS NOT OTHERWISE SPECIFIED

DAPHNE SIMEON, M.D., AND ERIC HOLLANDER, M.D.

The category of *dissociative disorders not otherwise specified* includes all the dissociative conditions whose manifestations do not meet diagnostic criteria for the better delineated, specific dissociative disorders from the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-I) that is, dissociative amnesia, dissociative fugue, dissociative identity disorder, and depersonalization disorder. The DSM-IV criteria for dissociative disorder not otherwise specified are presented in Table 18.5-1. Given the surge of interest and the return of dissociation to the mainstream of psychiatry in recent years after many decades of relative neglect, it is hoped that this residual category of dissociative pathology will encourage further detection and research into dissociative syndromes that are less well understood. Importantly represented in this group are nonwestern dissociative ailments that until recently were considered more the subject of folklore and medical anthropology. It is widely known that dissociation is common in the third world, probably more so overall than in industrialized societies, and comprises an important ingredient of various culturally defined ritual and healing practices. Dissociation is culturally more accepted as a idiom of distress in these countries and therefore is often the medium through which significant dysfunction and distress may be expressed, frequently qualifying as psychiatric nosology by the criteria of mental illness. These non-Western dissociative disorders, which fall under the rubric of *dissociative trance disorder*, are to a great extent unfamiliar to Western clinicians and researchers, limiting cross-cultural understanding as well as the universal applicability of the nosological system. With the inclusion of dissociative trance disorder in the appendix of the latest edition of DSM-IV, the elucidation of these widespread, variable, and fascinating conditions appears closer.

This category is included for disorders in which the predominant feature is a dissociative symptom (i.e., a disruption in the usually integrated functions of consciousness, memory, identity, or perception of the environment) that does not meet the criteria for any specific dissociative disorder. Examples include:

1. Clinical presentations similar to dissociative identity disorder that fail to meet full criteria for this disorder. Examples include presentations in which (a) there are not two or more distinct personality states, or (b) amnesia for important personal information does not occur.
2. Depersonalization unaccompanied by derealization in adults.
3. States of dissociation that occur in individuals who have been subjected to periods of prolonged and intense coercive persuasion (e.g., brainwashing, thought reform, or indoctrination while captive).
4. Dissociative trance disorder: single or episodic disturbances in the state of consciousness, identity, or memory that are indigenous to particular locations and cultures. Dissociative trance involves narrowing of awareness of immediate surroundings or stereotyped behaviors or movements that are experienced as being beyond one's control. Possession trance involves replacement of the customary sense of personal identity by a new identity, attributed to the influence of a spirit, power, deity, or other person, and associated with stereotyped "involuntary" movements or amnesia. Examples include *latah* (Indonesia), *bebainan* (Indonesia), *latah* (Malaysia), *pibloktoq* (Arctic), *ataque de nervios* (Latin America), and possession (India). The dissociative or trance disorder is not a normal part of a broadly accepted collective cultural or religious practice.
5. Loss of consciousness, stupor, or coma not attributable to a general medical condition.
6. Ganser's syndrome: the giving of approximate answers to questions (e.g., "2 plus 2 equals 5") when not associated with dissociative amnesia or dissociative fugue.

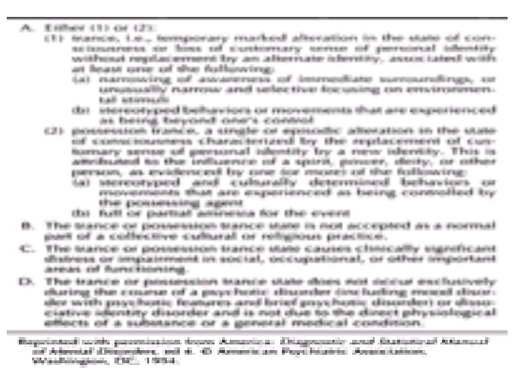
Table 18.5-1 DSM-IV Diagnostic Criteria for Dissociative Disorder Not Otherwise Specified

DISSOCIATIVE TRANCE DISORDER

Definition The diagnostic criteria for dissociative trance disorder are presented in Table 18.5-2. It encompasses a variety of dissociative phenomena that share an alteration of normal consciousness, or trance state, which is distressing, impairing, and beyond the nonpathological trance manifestations that may be indigenous to particular cultures. Dissociative trance involves a narrowing of awareness of the immediate surroundings with stereotypical behaviors or movements that are experienced as involuntary and for which there may be partial or total amnesia. The most widely written about dissociative trance of this sort is the *ataque de nervios* encountered in South America. Alternatively, *possession trance* is characterized by a transient alteration in identity whereby one's normal identity is temporarily replaced (possessed) by a spirit, ghost, deity, or other person. Descriptions of possession trance are to be found in a variety of cultures and have been most studied in India.



A. Either (1) or (2):
   (1) trance, i.e., temporary marked alteration in the state of consciousness or loss of customary sense of personal identity without replacement by an alternate identity, associated with at least one of the following:
      (a) narrowing of awareness of immediate surroundings, or unusually narrow and selective focusing on environmental stimuli
      (b) stereotyped behaviors or movements that are experienced as being beyond one's control
   (2) possession trance, a single or episodic alteration in the state of consciousness characterized by the replacement of customary sense of personal identity by a new identity. This is attributed to the influence of a spirit, power, deity, or other person, as evidenced by one (or more) of the following:
      (a) stereotyped and culturally determined behaviors or movements that are experienced as being controlled by the possessing agent
      (b) full or partial amnesia for the event
B. The trance or possession trance state is not accepted as a normal part of a collective cultural or religious practice.
C. The trance or possession trance state causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
D. The trance or possession trance state does not occur exclusively during the course of a psychotic disorder (including mood disorder with psychotic features and brief psychotic disorder) or dissociative identity disorder and is not due to the direct physiological effects of a substance or a general medical condition.

Table 18.5-2 DSM-IV Research Criteria for Dissociative Trance Disorder

ATAQUE DE NERVIOS

Diagnosis and Clinical Features *Ataque de nervios* is characterized by a number of somatic symptoms including trembling, heart palpitations, a sense of heat rising to the chest and head, faintness, paresthesias, and darkened vision. There can be difficulty moving or seizure-like convulsive movements, falling to the ground, or lying still as if dead. Individuals also typically cry, shout, moan, or swear uncontrollably; become hysterical; and attempt to harm themselves or strike out at others or throw objects. The episode ends suddenly or gradually, sometimes with the intervention of others who attempt to calm down the victim, pray, or perform alcohol rubs *(alcoholado)*. During the episode there is typically a narrowing of attention and general lack of awareness of the surroundings, and after the episode there can be partial or total amnesia for what transpired. After the episode there is a return to normal consciousness or a prolonged period of exhaustion that can last for hours. Acute family conflict appears to comprise the hallmark trigger of this condition. The episode typically commences with a sense of brooding, feeling overwhelmed, and of shock, followed by the acute shift in consciousness and the narrowing of attentional focus. Overall affective and somatic alterations are pronounced in the context of a dissociated state. *Ataque de nervios* may occur as isolated incidents, lasting minutes to hours, or can become long-term and recurring, sometimes lasting for years and causing significant disability.

The inclusion of *ataque de nervios* in the dissociative disorders, with their characteristic alterations in sensorimotor control, broadens the traditional Western concept of dissociative disorders, which focuses primarily on alterations in perception, memory, and identity. It begs the broader question of whether conversion syndromes are more closely related to the dissociative disorders than their current DSM classification under the somatoform disorders would suggest. In addition, this broadened spectrum of dissociation more closely approximates the 10th revision of *International Statistical Classification of Diseases and Related Health Problem* (ICD-10), in which dissociative (conversion) disorders are grouped together. Trance and possession disorders are classified in this section of the ICD-10, and the specific criteria

are given in Table 18.5-3.

Table 18.5-3 ICD-10 Diagnostic Criteria for Dissociative (Conversion) Disorders

Etiology *Ataque de nervios* is precipitated by acute traumatic stressors, typically loss, grief, danger, fear, or vulnerability, which may vary from relatively mild to extreme. Typical triggers are arguments with a spouse, death of a close relative, drunkenness and threats from a spouse, physical or sexual abuse, an accident, or even natural disasters.

Epidemiology *Ataque de nervios* has best been studied in Puerto Rico, and a recent epidemiological study estimated their lifetime prevalence at 13.8 percent of the population. The demographic characteristics of the sufferers have been consistent in the various reports and include female sex, age over 45, low socioeconomic status (education less than high school and unemployment) and divorced, separated, or widowed marital status.

Differential Diagnosis Although there is some overlap between the symptoms of *ataque de nervios* and those of panic attacks, *ataque de nervous* is additionly characterized by alterations in consciousness and sensorimotor dissociation that render them clearly distinct. There is significant comorbidity between *ataque de nervios* and other Axis I disorders, in approximately 60 percent of sufferers, including depressive disorders, generalized anxiety disorder, panic disorder, agoraphobia, and posttraumatic stress disorder. *Ataque de nervios* largely accounts for the high rates of somatization found in these cultures, and the expression of distress in such a somatic form appears to be more culturally sanctioned and accepted than the stigma of mental illness. Nevertheless, individuals who suffer from *ataque de nervios* commonly experience high levels of distress and dysfunction and the high rates of associated psychopathology contradict the notion that these are normal cultural expressions of suffering.

Treatment Typically, others perceive the victim of *ataque de nervios* as being in significant distress and requiring some form of assistance. If the trigger was overwhelming, such as death or marital abuse, home-based remedies may be attempted, such as emotional support, concrete assistance, or interventions to resolve the conflict. However, if the stressor is not deemed to be as significant, it is more likely that professional help will be sought, either in nonpsychiatric or in psychiatric settings, and *ataque de nervios* patients may frequently be prescribed antidepressant or antianxiety medications or may receive some type of spiritual healing or counseling.

POSSESSION TRANCE

Diagnosis and Clinical Features Possession trance is a category of dissociative disorders that encompasses a variety of different cultural presentations throughout the world, best characterized in African and South Asian cultures. It is defined by the presence of alterations in consciousness, behavior, memory, and, in particular, identity that go beyond the culturally accepted norms and bring dysfunction and distress to the sufferer.

During the trance state a variety of behaviors similar to those seen in *ataque de nervios* can occur: uncontrolled bodily movements such as shaking, flailing, or falling to the ground; moaning and shrieking; violent behaviors directed at the self or others; and derogatory or menacing verbalizations. Paresthesias, dizziness, and other somatic symptoms may also occur, although they may be less pronounced and intense than in *ataque de nervios*. A personality emerges that is distinct from that characteristic of the individual, and these personalities are typically regarded as arising outside of the person. This is in contrast to dissociative identity disorder, in which the identities are experienced and viewed as distinct aspects of some sense of self. The possessing personalities may not disclose their identity immediately, until tricked into doing so by family members or healing practitioners, and they typically involve deities, demons, spirits, ghosts, or deceased family members, neighbors, or friends who were known to the particular individual and underwent similar stress. The individual then takes on their particular attributes. Demands are often made by this possessing personality for specific changes in the individual's circumstances and for better treatment, and the possessing entity may agree to recede if these demands are met. These verbalizations tend to be more purposeful, organized, and coherent than the affective storm quality that characterizes *ataque de nervios*. After the episode the individual almost always collapses, loses consciousness, is disoriented, and has partial or total amnesia for the events that occurred and may remain dazed, exhausted, and confused for a number of hours. This aftermath tends to be more pronounced than in *ataque de nervios*.

In contrast to the individualistic character and the stricter personal boundaries of western cultures, it has been proposed that the more porous and fluid characteristics of Indian culture, which is more open to external human and spiritual influences, contribute to this particular pathological manifestation. Rurality and lack of formal education also probably contribute to the phenomenon and permit the often helpless and powerless individual to express, in a dissociated form, feelings of fear, anger, vulnerability, and grief that may be more effectively heard and attended to than otherwise. Indeed, the very low standing of women in the low strata of these cultures, whose worth is often at best equated with a dowry, often renders it very unlikely that their distress would merit attention in other shapes or forms. Typically the episodes recur at variable durations and intervals, may involve different consecutive possessing personalities, and may continue for days or weeks until the underlying stressors are addressed, such as by a visit to the young bride's hometown or by more respectful treatment by her in-laws. If not attended to in some fashion the possession attacks can in some cases become severely disabling.

Etiology Possession trance in India typically occurs in young adult women of underpriviledged socioeconomic status and low caste in the context of prolonged subacute stress usually surrounding the transition from the family of origin to wedlock in the absence of a solid support network. The transition typically demands a multitude of difficult adaptations, including leaving one's home town, family, and prior status and adjusting to the demands made upon a new bride by her in-laws, forced marriages, consummation of the marriage, as well as marital conflict, abuse, or neglect. Other circumstances that have been described in relation to possession include a variety of traumas, such as death of the husband or children; discovery of incest, sexual abuse, murder, or suicide of close female friends; or natural disasters. Although much has been written about earlier antecedents to these states, including an underlying primitive hysterical personality, oedipal dynamics, or the possibility of reactivated early childhood abuse, none of these is well substantiated. The most obvious determinant is the largely culturally determined prolonged and subacute trauma that precedes the condition.

Epidemiology Possession trance disorders have been described in India, Bangladesh, Nepal, Taiwan, Japan, Hong Kong, Malaysia, Niger, and Brazil; they have been most extensively described in the standard psychiatric literature in India. A review of 2651 case records of all patients seen in the adult outpatient clinic of a large Indian hospital found that 62 patients definitely suffered from dissociative disorders. Of those, the vast majority (90 percent) were atypical dissociative disorders that would not fit criteria for the established Western category of major dissociative disorders, and at least 10 percent were cases of possession trance. The prevalence of possession syndromes has been estimated at 1 to 4 percent of the population in community surveys, although the methodologies may be flawed.

Differential Diagnosis In terms of associated psychopathology and not studied in a systematic fashion, hysterical or paranoid states are more commonly diagnosed in Indian possession in contrast to the high prevalence of anxiety and depression in Puerto Rican *ataque de nervios*; in both, some associated psychopathology is often present.

Possession trance has been compared to Western dissociative identity disorder, and it appears that although the disorders have similarities they comprise distinct entities. Possession trance is a more time-limited condition that relates to more current stressors, and the basic organization of the underlying personality is more intact. Indeed, cases of dissociative identity disorder have been found to be much rarer in India than in the United States, with the first case reported in 1956 and a recently estimated prevalence of 0.15 of 1000 psychiatric patients. However, the degree to which these two disorders are distinct remains not fully understood. It may

be due to a true difference in childhood abuse, as the neglect of children is probably more common in India. Alternatively, it may be that the presence of possession in a patient from the West is more likely to be diagnosed as a psychotic state whereas Indian patients with dissociation are unlikely to manifest different personal identities because of cultural and religious beliefs that emphasize external influences.

Treatment Treatment is commonly obtained within the family setting, as family members attempt to provide support and appease the possessing spirits by meeting some of their demands. Professional intervention is more likely be sought from traditional healers who perform different types of exorcism that are often successful in ridding the individual of the possession. Sometimes professional psychiatric help may be sought.

BRAINWASHING

Definition The DSM-IV describes this dissociative disorder not otherwise specified as "states of dissociation that occur in individuals who have been subjected to periods of prolonged and intense coercive persuasion (e.g., brainwashing, thought reform, or indoctrination while captive)" (Table 18.5-1). The 10th edition of *Merriam Webster's Collegiate Dictionary* defines brainwashing as "a forcible indoctrination to induce someone to give up basic political, social or religious beliefs and attitudes and to accept contrasting regimented ideas." The term *brainwashing* was first coined by an American journalist in the 1950s from Chinese ideographs that would more accurately have been translated as "thought reform." Indeed, the terms *brainwashing, thought reform, coercive persuasion*, and *mind control* are for all practical purposes used synonymously and interchangeably. Depending on differing perspectives, the degrees and methods of what constitutes brainwashing vary. In general, psychiatrists have largely stayed outside of such issues, which involve larger ideological, societal, political, and religious implications. The average psychiatrist is typically not better informed in this area than an educated lay person, and with few exceptions, psychiatrists have for the most part been uncomfortable with this issue.

Diagnosis and Clinical Features Brainwashing occurs largely in the settings of political reform, as has been lengthily described with the cultural revolution in communist China, war imprisonment, torture of political dissidents, terrorist hostages, and, more familiarly in Western culture: totalitarian cult indoctrination. It implies that under conditions of adequate stress and duress, individuals can be made to comply with the demands of those in power, thereby undergoing major changes in their personality, beliefs, and behaviors. People submitted to such conditions can undergo considerable harm, including loss of health and life, and typically manifest a variety of posttraumatic and dissociative symptoms. The first stage in coercive processes has been likened to the artificial creation of an identity crisis, with the emergence of a new pseudoidentity that manifests characteristics of a dissociative state. Under circumstances of extreme and malignant dependency, overwhelming vulnerability, and danger to one's existence, individuals develop a state characterized by extreme idealization of their captors, with ensuing identification with the aggressor and externalization of their superego, regressive adaptation known as *traumatic infantilism*, paralysis of will, and a state of frozen fright. The coercive techniques that are typically employed to induce such a state in the victim have been amply described and include isolation of the subject, degradation, control over all communications and basic daily functions, induction of fear and confusion, peer pressure, assignment of repetitive and monotonous routines, unpredictibility of environmental supplies, renunciation of past relationships and values, and various deprivations. Even though physical or sexual abuse, torture, and extreme sensory deprivation and physical neglect can be parts of this process, they need not necessarily occur to define a coercive process. As a result, victims who have been extensively studied manifest extensive posttraumatic and dissociative symptomatology, including a drastic alteration of their identity, values, and beliefs; a reduction of cognitive flexibility with a regression to simplistic perceptions of good-evil and dominance-submission; a numbing of experience and blunting of affect; trance-like states and diminished environmental responsiveness; and in some cases more severe dissociative symptoms such as amnesia, depersonalization, and shifts in identity.

It has been suggested that an individual subjected to severe inescapable coercion can have three distinctive response patterns: to sham compliance, to submit and identify, or to defend against persuasion. Individuals capable of the latter option appear more able to spontaneously use autohypnotic techniques, to become involved in restitutive hypnotic fantasy, and to dissociate from their suffering as if it were happening to someone else. Thus, in a paradoxical fashion the use of such dissociative techniques might be protective against the development later of more severe psychopathology and deterioration and has been proposed as a preventive training technique for those who are at risk of becoming victims of coercion (e.g., military personnel).

Proponents of religious freedom and the right to choose membership in cults and new religious movements have argued that in the absence of physical coercion and in the presence of a real option to depart, the term *brainwashing* is misapplied. They further argue that any set of beliefs, religious or otherwise, involves an element of arbitrary faith and a background of indoctrination that may be sanctioned by the general culture, thus blurring the boundaries of coercion. As members of such groups, some individuals may find a sense of stability and direction that society may otherwise not be able to offer them. Opponents of this view argue that coercion is primarily a mental process that need not involve extreme physical means, and that adoption of the former view approaches blaming the victim. Individuals who have greater predisposing psychopathology; identity issues; family conflicts; difficulties negotiating their aggressive, sexual, or individuating needs; or are in transitional stressful phases of life are then in effect held wholly responsible for submitting to the coercion. No one disputes that predisposing psychopathology is one of the factors that can affect the outcome of the coercive process, but the process nonetheless remains the same.

Treatment The treatment of the victims of coercion can vary considerably depending on their particular background, the circumstances involved, and the setting in which help is sought. Although there are no systematic studies in this domain, basic principles involve validation of the traumatic experience and coercive techniques used, cognitive reframing of the events that transpired, exploration of preexisting psychopathology and vulnerabilities where this is applicable, and general techniques used in treating posttraumatic and dissociative states. In addition, family interventions and therapy may be required, at least in cases of cult indoctrination, as significant family duress and disruption is a common occurrence.

GANSER'S SYNDROME

Definition *Ganser's syndrome* is a fascinating, poorly studied, and uncommon dissociative condition whose exact etiology, classification, and symptom constellation are still debated in the literature. Based on the gradual accumulation of relatively limited data and a clearer conceptualization of the disorder, Ganser's syndrome was moved from its status as a factitious disorder in the third edition of DSM (DSM-III) to that of dissociative disorders not otherwise specified in the revised third edition (DSM-III-R), and has remained so in DSM-IV (Table 18.5-1).

Diagnosis and Clinical Features The hallmark symptom of Ganser's syndrome is paralogia, the giving of approximate answers to questions, as originally described by Sigbert Ganser in 1897 in a paper entitled "Concerning an Unusual Hysterical Confusional State." Although afflicted individuals typically know their names, they often only approximate other key personal information such as age, address, and occupation. They also give approximate answers to questions like the number of days in a week or months in a year, to simple calculations (e.g., 3 + 1 = 5), and perform approximate naming of objects (e.g., pencil for pen, picture for stamp). It is generally agreed that for the diagnosis of the syndrome additional dissociative symptoms must be present, including disorientation, dazing or clouding of consciousness, and amnesia for past events or typically, once the episode clears, for prior responses. Various case reports and literature reviews tend to concur that the presence of these additional symptoms may be variable so that the Ganser phenomenon may occur on a continuum, at times possibly warranting the diagnosis of *Ganser's symptoms* instead of the full-blown Ganser's syndrome. The current edition of DSM does not specify criteria for the severity, duration, number, and types of symptoms that must be present to definitively make the diagnosis of Ganser's syndrome, probably because conclusive data are lacking.

Epidemiology According to all reports, Ganser's syndrome is much more common in men than in women. One study reported the mean age of subjects as 35 years old and the mean duration of the episode as 1 month. In addition to Western cultures, it has been described in the Far East and in India. Its incidence in the West may have declined over the past century, paralleling the generally accepted decline in hysteria.

Etiology Precipitating stressors can often be identified, including an organic or mental illness, personal conflicts, and, not uncommonly, litigation, imprisonment, and disability claims. The latter have given rise to considerable debate about whether the syndrome may involve conscious faking or secondary gains, such as in factitious disorders or malingering. However, extensive review of this topic has fairly consistently excluded this as a significant component of the syndrome in the large majority of cases.

Differential Diagnosis Part of the difficulty in making the discrete diagnosis is the very common overlap with major organic or psychiatric disorders, most commonly psychosis, organic brain syndromes such as head trauma, seizures, or other of the central nervous system diseases major depressive disorder, use disorders. A careful review of all convincing cases of Ganser's syndrome in the literature revealed that the majority of patients suffer such comorbidity. At other times, Ganser's syndrome has been described as the prelude to an acute and severe psychotic or depressive decompensation. It does appear, however, that these underlying disorders are not adequate in accounting for the manifestations of Ganser's syndrome, as these patients do not manifest them before or after the resolution of the episode, are in a dissociated state at the time, and have normal enough intelligence to intellectually know the correct answers. Rather, it has been conceptualized that the underlying condition may serve as an acute stressor that in vulnerable individuals precipitates a hysterical overlaid reaction.

In considering the differential diagnosis of Ganser's syndrome, Ganser's paralogia must be differentiated primarily from simple hysterical or depressive pseudodementia, from the organic dysphasias or dementias, from the thought disorders of psychosis, and from the confabulation of Korsakoff's syndrome. In addition to the general consideration of the clinical picture, this differential is based on the presence of the other accompanying acute dissociative symptoms that are typically absent in other conditions. A comprehensive review of the literature has found that amnesia is present in 69 percent of subjects, disorientation or confusion in 62 percent, conversion symptoms in 54 percent, fugue in 29 percent, and loss of personal identity in 23 percent. In addition, hallucinations occur in about half the subjects, leading some to speculate that the syndrome might be a type of brief reactive psychosis to stress although hallucinations are well known to also occur in severe dissociative conditions. The types of amnesia can be variable, including amnesia for past events prior to the episode, amnesia during the episode, anterograde amnesia, and most typically amnesia for the episode as the person recovers and the sensorium clears.

Treatment It has been speculated that the paralogia of Ganser's syndrome, consistent with the variety of other dissociative symptoms present, is based on trance logic, that is, a processing of information that is reminiscent of primary process, that is unaffected by inherent contradictions, and that allows the subject to simultaneously know and not know troubling realities. Consequently, the indicated treatment parallels that of other dissociative states. An insistent confrontation of the presenting contradictions is probably not fruitful, and can lead either to an intensification of the paralogia or to a compliant suppression of the paralogia, which may further confuse the presentation. A structured, protective, and supportive environment; treatment of the comorbid conditions; and exploration of the precipitating stressors have been advocated and may lead to a rapid resolution of the syndrome.

SUGGESTED CROSS-REFERENCES

Further descriptions of the nature and the function of dissociative mechanisms are found in Chapter 6 dealing with the theories of personality and psychopathology, and in Chapter 9, dealing with the classification of mental disorders. The diagnostic distinction between dissociative disorders and other mental disorders is clarified in Chapter 12 on schizophrenia and in Chapter 15 on posttraumatic stress disorder and anxiety disorders. Chapter 16 on the somatoform disorders, provides a detailed description of the somatic symptoms that in this chapter are viewed as manifestations of dissociation. Expanded descriptions of the various psychotherapeutic approaches appear in Chapter 30 which is devoted to psychotherapies.

CHAPTER 19. NORMAL HUMAN SEXUALITY AND SEXUAL AND GENDER IDENTITY DISORDERS

19.1 NORMAL HUMAN SEXUALITY

19.1A NORMAL HUMAN SEXUALITY AND SEXUAL DYSFUNCTIONS

VIRGINIA A. SADOCK, M.D.

Sexuality is determined by anatomy, physiology, psychology, the culture in which one lives, one's relationships with others, and developmental experiences throughout the life cycle. It includes the perception of being male or female and all those thoughts, feelings and behaviors connected with sexual gratification and reproduction including the attraction of one person to another.

The 1990s have seen advances in the field of sexuality in the areas of pharmacology and psychology and in the study of the interaction of sex and the social milieu. Significant new developments are the availability of medications that enable men to gain and maintain erections later in their lives and hormonal therapies that allow women to have pleasurable coitus postmenopausally. These medications have helped breach the taboo against sex in elderly adults. Theories on the psychology of sex have examined compulsive sexual behavior, which is not currently an official diagnosis in the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV). Finally, a 1994 study of sex in the United States (discussed below) yielded the most authoritative survey of sexual practices to date and placed the sexual behavior of Americans in a social context.

HISTORY

Cultural mores regarding sexual behavior have varied throughout the history of Western civilization. Attitudes have oscillated between the liberal and the puritanical, between the acceptance and the repression of human sexuality. During the past several decades, the prevalent attitudes toward sex in the United States have been markedly liberal. However, recent studies indicate a trend toward accepting more-conservative values. That shift is attributed largely to the fear of acquired immune deficiency syndrome (AIDS). One poll reported that 40 percent of Americans are concerned about contracting AIDS and are altering their sexual behavior because of that fear. The greatest concern was expressed by young adults, who are now more likely to use condoms as a precaution and to choose their sexual partners with greater care. In 1997 the rate of teenage pregnancy declined for the first time in 40 years, and in 1998 the number of teenagers who had sexual intercourse fell below 50 percent for the first time in a decade. Conservative segments of society emphasize abstinence before marriage as the answer to the fear of AIDS. The recurrence of conservative attitudes in response to the threat of illness has parallels in history. The sexual liberality of the Renaissance ended when syphilis swept the European continent and became a major argument for chastity among proponents of the Reformation. Other factors that predispose to more-restrictive mores are periods of economic recession that tend to bring people to more puritanical positions and limited gratification when sexual freedom is used as a substitute for intimate relationships. Few of these issues have been resolved definitively in the form of new social mores, however, and the legacies of the sexual revolution of the 1960s and 1970s exert a strong effect on current sexual behavior.

That particular sexual revolution derived from social and scientific sources. The advent of effective birth control methods and legalized abortion clearly differentiated the pleasure of sexual activity from its procreative function. The feminist movement attacked the double standard for acceptable sexual behavior for men and women, encouraged women to accept sexual responsibility for the gratification of their needs, and challenged society to reevaluate stereotyped male and female roles. The women's movement also focused attention on rape and incest. Gerontologists and elderly people alike have drawn attention to the sexual needs of the aged. Middle-class adolescents became sexually active, and gay rights groups urged acceptance of their sexual orientation, and succeeded in 1980 in having homosexuality dropped as a diagnostic category in the revised third edition of DSM (DSM-III-R).

Concurrent with the cultural changes of the sexual revolution there was growth in scientific research into sexual physiology and sexual dysfunctions. William Masters and Virginia Johnson published their pioneering work on the physiology of sexual response in 1966 and reported on their program for treating sexual complaints in 1970. Most medical centers now have programs specifically geared to the treatment of sexual dysfunctions.

Historically, problems of sexual conflict and sexual dysfunction have always been the province of psychiatry. Such pioneers as Havelock Ellis (Fig. 19.1a-1), Richard Krafft-Ebing (Fig. 19.1a-2), and Sigmund Freud focused broadly on human sexuality. Later workers focused more intensively on sexual physiology and dysfunctions. Dysfunction problems are particularly distressing to patients and have often been resistant to treatment. The current approach to sexual dysfunctions reflects the cultural and scientific developments of recent years, the development of specific techniques for the treatment of these problems, the historical interest of psychiatry in this area, and the recognition of its importance in psychiatric practice.

FIGURE 19.1a-1 Havelock Ellis, 1859–1939. In his book *Studies in the Psychology of Sex* (1896), Ellis recorded examples of normal and abnormal sexuality. It remains a classic in the field of sexology. (Courtesy of New York Academy of Medicine.)

FIGURE 19.1a-2 Richard von Krafft-Ebing (1840–1903), a psychiatrist who published a classic text, *Psychopathia Sexualis* (1898), in which he documented every variation in sexuality, including zoophilia, necrophilia, urolagnia, and lust murder among others. Case reports were so lurid and detailed that early editions were published in Latin. (Courtesy of New York Academy of Medicine.)

NORMAL SEXUALITY

Anatomical and Physiological Bases Knowledge about the organs of sexuality and the normal physiological sequence of male and female response is necessary for an informed understanding of the sexual dysfunctions. In fact, over the past decade greater emphasis has been placed on the genetic, neuroanatomical, and neurochemical model of human sexuality than on psychological and social factors.

Anatomy of the Male The external genitalia of the normal adult male include the penis, scrotum, testes, epididymis, and parts of the vas deferens. Internal components include the vas deferens, ejaculatory ducts, and prostate gland.

Freud referred to the penis as the executive organ of sexuality. Since antiquity, culture has represented the penis in a variety of art forms. In ancient Greece, the cults of Dionysus, Priapus, and the satyrs used the phallus as a recurrent symbol of fertility and rejuvenation. The word “penis” has been traced from the Latin, meaning variously “tail” or “to hang,” and refers to the pendant position of the organ in its resting or flaccid state. The size of the penis varies within a fairly constant range, but sex researchers over the years have disagreed on the dimensions of the range. All agree, however, that concern over the size of the penis is practically universal among men. Masters and Johnson report a range of 7 to 11 cm in the flaccid state, and 14 to 18 cm in the erect state. Of particular interest was their observation that the flaccid dimension bears little relation to the erect dimension: the smaller penis erects proportionally more than the larger one.

Circumcision, in which the prepuce is surgically removed, has been practiced for centuries as a religious rite by Jews and Moslems and is a common medical procedure in the United States today. The circumcised penis with its exposed glans was once believed to be less sensitive because of cornification of the epithelium. In laboratory studies, however, researchers have found no difference in tactile threshold between the circumcised penis and the uncircumcised penis. Intravaginally the prepuce of the uncircumcised penis remains retracted behind the glans during penile thrusting, dispelling the myth that premature ejaculation may be more common in uncircumcised men because of increased stimulation caused by preputial movements. In 1999, the American Academy of Pediatrics recommended that male circumcision not be performed as a routine procedure except for religious reasons.

Ejaculation is the forceful propulsion of semen and seminal fluid from the epididymis, vas deferens, seminal vesicles, and prostate into the urethra. The dilation of the prostatic urethra and the passage of fluid into the penile urethra provide the man with a sensation of impending climax, the emission phase of the ejaculatory process. Indeed, once the prostate contracts, ejaculation is inevitable. The ejaculate is then propelled through the penile urethra by contractions of the striated pelvic and perineal muscles. This phase of ejaculation is essentially under somatic efferent control. The ejaculate consists of about 1 teaspoon (2.5 mL) of fluid and contains about 120 million sperm cells. It is believed that the larger the ejaculate, the more pleasurable the orgasm—but this belief is highly subjective. *Orgasm*, the sense of pleasure usually associated with ejaculation, is thought to be a cortical experience.

Anatomy of the Female The external genitalia of the normal female, also called the *vulva*, include the mons pubis, major and minor lips, clitoris, glans, vestibule of the vagina, and vaginal orifice. The internal system includes the ovaries, fallopian tubes, uterus, and vagina.

The word *vagina* comes from the Latin word meaning “sheath.” The vagina is usually collapsed, a potential rather than an actual space. About 8 cm long, the vagina extends from the cervix of the uterus above to the vestibule of the vagina or vaginal opening below. In most virgins a membranous fold, the hymen, separates the vestibule and opening from the rest of the vaginal canal. The mucous membrane lining the vaginal walls rests in numerous transverse folds. To accommodate the penis during sexual intercourse, the vagina expands in both length and width. After menopause, because circulating estrogen concentrations decrease, the vagina loses much of its elasticity.

Hippocrates first described the clitoris in the medical literature, referring to it as the site of sexual excitation. Masters and Johnson described the clitoris as the primary female sexual organ, because orgasm depends physiologically on adequate clitoral stimulation. Anatomically, the clitoris has a nerve net that is proportionally three times as large as that of the penis.

Alfred Kinsey found that when women masturbate, most prefer clitoral stimulation. That finding was refined further by Masters and Johnson, who reported that women prefer the shaft of the clitoris to the glans, because the glans is hypersensitive if stimulated excessively.

The clitoral prepuce is contiguous with the labia minora and during coitus, the penis does not stimulate the clitoris directly. Rather, penile thrusting exerts traction on the minor lips, which in turn stimulate the clitoris sufficiently for orgasm. During heightened excitement, just before orgasm, the clitoris retracts under the clitoral hood because of contraction of the ischiocavernosus muscles. Retracting, the clitoris moves away from the vaginal barrel, which makes clitoral-penile contact impossible. The size of the clitoris varies considerably and is unrelated to the sexual responsiveness of a particular female.

G SPOT In 1950 Ernst Graefenberg described an area surrounding the female urethra in the anterior wall of the vagina that has come to be called the G spot. About 0.5 to 1 cm in size, it becomes engorged during sexual stimulation. Many women report that stimulation of the area is highly pleasurable and in some, can induce orgasm. Graefenberg believed that the tissue here was analogous to the prostate and might account for the spurt of fluid during orgasm reported by some women, similar to male ejaculation.

Innervation of Sex Organs Innervation of the sexual organs is mediated primarily through the autonomic nervous system (ANS). Penile tumescence occurs through the synergistic activity of two neurophysiologic pathways. A parasympathetic (cholinergic) component mediates reflexogenic erections via impulses that pass through the pelvic splanchnic nerves (S2, S3, and S4). A thoracolumbar, mainly sympathetic pathway transmits psychologically induced impulses. Both parasympathetic and sympathetic mechanisms are thought to play a part in relaxing the smooth muscles of the penile corpora cavernosa, which allow the penile arteries to dilate and cause the inflow of blood that results in penile erection. Relaxation of cavernosal smooth muscles is aided by the release of nitric oxide, an endothelium-derived relaxing factor. Clitoral engorgement and vaginal lubrication also result from parasympathetic stimulation that increases blood flow to genital tissue. Adrian Zorgniotti has compared the erection phenomenon that results from increased penile blood inflow and decreased blood outflow with the inflation of an automobile tire, which requires an inflow of air and an intact casing.

Evidence indicates that the sympathetic (adrenergic) system is responsible for ejaculation. Through its hypogastric plexus the adrenergic impulses enervate the urethral crest, the muscles of the epididymis, and the muscles of the vas deferens, seminal vesicles, and prostate. Stimulation of the plexus causes emission. In women the sympathetic system facilitates the smooth muscle contraction of the vagina, urethra, and uterus that occurs during orgasm.

The ANS functions outside of voluntary control and is influenced by external events (e.g., stress, drugs) and internal events (hypothalamic, limbic, and cortical stimuli). It is not surprising, therefore, that erection and orgasm are so vulnerable to dysfunction.

Endocrinology From the time of conception, hormones play a major role in human sexual development (Fig. 19.1a-3). Unlike the fetal gonads, which are under chromosomal influence, the fetal external genitalia are very susceptible to hormones. Recently a gene was found on the X chromosome that is believed capable of disrupting the normal development of male genitals. The finding requires replication.

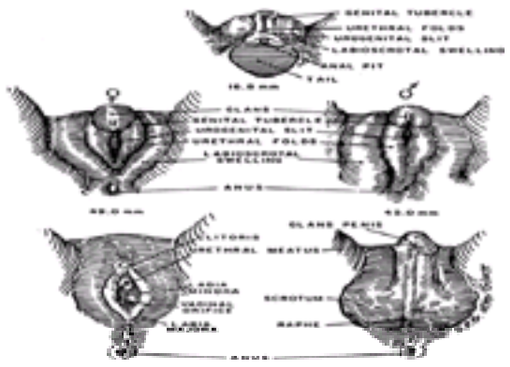

FIGURE 19.1a-3 Differentiation of male and female external genitalia from indifferent primordia. Male differentiation occurs only in the presence of androgenic stimulation during the first 12 weeks of fetal life. (From Van Wyk and Grumbach, 1968. Reprinted with permission from Brobeck JR, editor: *Best and Taylor's Physiological Basis of Medical Practice*, ed 9. Williams & Wilkins, Baltimore, 1973.)

Exogenous hormonal administration can cause external genital development inconsistent with the fetal sex gland development. For instance, if the pregnant mother receives sufficient exogenous androgen, a female fetus possessing an ovary can develop external genitalia resembling those of a male. Fetal, maternal, or exogenous hormones administered to a pregnant woman may all affect development of the external genitalia of the fetus. Deprived of male and female gonads and the respective hormones testosterone and estrogen, the human adult does not develop normal secondary sexual characteristics, is incapable of reproduction, and, in the case of the female, does not develop a menstrual cycle.

Testosterone is the hormone believed to be connected with libido in both men and women. In men stress is inversely correlated with testosterone blood concentration. Other factors, such as sleep, mood, and lifestyle, influence circulating levels of the hormone.

The release of testosterone in men is under the control of the hypothalamic-gonadal-pituitary axis. The hormone is secreted in a pulsatile manner and in a diurnal rhythm, with the highest levels occurring in the morning and the lowest levels in the evening. Normal concentrations range from 270 to 1100 ng/dL. Decreased testosterone concentrations are apparent by age 50 and proceed at the rate of about 100 ng/dL per decade. However, many healthy, aging men never become hypogonadal. It has also been suggested that the sensitivity of androgen receptor sites decreases in the aging male.

Administration of androgens to patients complaining of sexual dysfunction is usually futile if normal hormonal function is present. Androgen administered to men complaining of loss of potency and loss of libido is usually unsuccessful unless testosterone concentrations are below normal, and administration to women may precipitate disturbing virilization. Many clinicians correct the hormone deficiency of the postmenopausal period with estrogen replacement therapy. Testosterone has been used in combination with estrogen in women who do not respond to estrogen alone. The combination is especially useful in treating headache, depression, and reduced libido. Oxytocin, secreted by the hypothalamus, stimulates lactation and uterine contractions. It may enhance sexual activity. Plasma oxytocin concentrations increase in men and women during orgasm.

Diethylstilbestrol Diethylstilbestrol (DES), an androgenic steroid, was prescribed in the 1950s and 1960s for pregnant women with threatened abortion. However, the drug had untoward effects on the children (especially female children) born to these mothers. Reports of cervical and uterine abnormalities were reported in women and reproductive tract abnormalities in men. The children (called DES daughters and sons) organized a National DES Education Program sponsored by the National Cancer Institute to provide information on the potential medical problems confronting those born to DES mothers.

Brain and Sexual Behavior Experimentation with animals has demonstrated that the limbic system is directly involved with elements of sexual functioning. In all mammals the limbic system is involved in behavior required for self-preservation and the preservation of the species.

Chemical or electrical stimulation of various sites of the limbic system—the lower part of the septum and the contiguous medial preoptic area, the fimbria of the hippocampus, the mammillary bodies, and the anterior thalamic nuclei—have all elicited penile erection. The hippocampus is believed to influence genital tumescence and affect the regulation of the release of gonadotropins. Stimulation of the amygdala in primates initiates first oral (chewing, lip smacking) and then genital (penile erection) behavior. Researchers have stated that the closeness of those functions may derive from the evolutionary fact that the olfactory sense was strongly involved in both feeding and mating. They speculate that the evolution of the third subdivision of the limbic system may reflect a shift in importance from olfactory contact to visual communication in sociosexual behavior.

Brain Neurotransmitters A vast array of neurotransmitters are produced by the brain. They include dopamine, epinephrine, norepinephrine, and serotonin. All affect sexual function. For example, an increase in dopamine is presumed to increase libido. Serotonin produced in the upper pons and midbrain is presumed to have an inhibitory effect on sexual function. Basic science and clinical research on brain neurotransmitters and their effects on behavior (including sex) is one of the most rapidly expanding fields. Some of those findings are summarized in Table 19.1a-1.

	Adrenergic Impulses		Cholinergic Impulses
Effector Organs	Receptor Type	Responses	Responses
Urinary bladder			
Detrusor	β_2	Relaxation (usually) +	Contraction +++
Trigone and sphincter	α_1	Contraction ++	Relaxation ++
Ureter			
Motility and tone	α_1	Increase	Increase (?)
Uterus	α_1, β_2	Pregnant: contraction (α_1), relaxation (β_2); nonpregnant: relaxation (β_2)	Variable
Sex organs, male	α_1	Ejaculation +++	Erection +++
Skin			
Pilomotor muscles	α_1	Contraction ++	
Sweat glands	α_1	Localized secretion +	Generalized secretion +++

Table 19.1a-1 Responses of Sex Organs to Autonomic Nerve Impulses

PSYCHOSEXUALITY

Sexuality and total personality are so entwined that to speak of sexuality as a separate entity is virtually impossible. The term “psychosexual” is therefore used to describe personality development and functioning as these are affected by sexuality. *Psychosexual* applies to more than sexual feelings and behavior, and it is not synonymous with libido in the broad Freudian sense.

Freud's generalization that all pleasurable impulses and activities are originally sexual has given lay people a somewhat distorted view of sexual concepts and has given psychiatrists a confused picture of motivation. For example, some oral activities are directed toward obtaining food, and others are directed toward achieving sexual gratification. Both activities are pleasure seeking and use the same organs, but they are not, as Freud contended, both necessarily sexual. Labeling all pleasure-seeking behaviors *sexual* obviates specifying precise motivation. People may also use sexual activities to gratify nonsexual needs, such as dependency, aggression, power, and status. Although sexual and nonsexual impulses may jointly motivate behavior, the analysis of behavior depends on understanding the underlying individual motivation and their interactions. Sexuality is something more than physical sex, coital or noncoital, and something less than all behaviors directed toward gaining pleasure.

Psychosexual Factors Sexuality depends on four interrelated psychosexual factors: sexual identity, gender identity, sexual orientation, and sexual behavior. These

factors affect personality, development, and functioning.

Sexual identity is the pattern of a person's biological sexual characteristics: chromosomes, external and internal genitalia, hormonal composition, gonads and secondary sex characteristics. In normal development, these characteristics form a cohesive pattern that leaves persons in no doubt about their sex.

Gender identity is a person's sense of maleness or femaleness. By the age of 2 or 3 years, almost everyone has a firm conviction that “I am male” or “I am female.” Gender identity results from an almost infinite series of clues derived from experiences with family members, peers and teachers and from cultural phenomena. For instance, male infants tend to be handled more vigorously and female infants to be cuddled more. Fathers spend more time with their infant sons than with their daughters, and they also tend to be more aware of their sons' adolescent concerns than of their daughters' anxieties. Boys are more likely than girls to be physically disciplined. A child's sex affects parental tolerance for aggression and reinforcement or extinction of activity and of intellectual, aesthetic, and athletic interests. Physical characteristics derived from a person's biological sex (e.g., physique, body shape and physical dimensions) interrelate with an intricate system of stimuli, including rewards, punishment, and parental gender labels, to establish gender goals.

Sexual orientation describes the object of a person's sexual impulses: heterosexual (opposite sex), homosexual (same sex), or bisexual (both sexes). The overwhelming majority of people have a heterosexual orientation. In the United States, 2.8 percent of men and 1.4 percent of women identify themselves as homosexual. These numbers are compatible with figures from Western European countries as well. However, a higher percentage of persons have had at least one same-sex experience in their lives. Additionally, homosexuals congregate in urban areas, so the incidence of homosexuality in some large cities is as high as 8 or 9 percent.

Sexual behavior includes desire, fantasies, pursuit of partners, autoeroticism, and all the activities engaged in to express and gratify sexual needs. It is an amalgam of psychological and physiological responses to internal and external stimuli.

SEXUAL LEARNING AND SEXUAL BEHAVIOR

The sex drive is innate and varies in intensity in different people, but much sexual behavior is learned. Early sexual experiences, particularly those during puberty and early adolescence, can have an imprinting effect. If they are strongly associated with pleasure and release of tension they are likely to be repeated and the person is conditioned to a particular form of sexual expression. In the normal person sexual learning and experimentation continue throughout the life cycle, the repertoire of sexual behavior expands, and the behaviors are compatible with cultural norms.

Childhood Sexual learning begins in childhood. In a broad sense, that learning occurs through parent-child interaction, including the meeting of the infant's needs, cuddling, and the reinforcement or discouragement of gender-associated activities. Cuddling and physical touching engender emotional security and positive feelings in infants toward their bodies. That physicality lays the groundwork for a healthy body image that is a component of sexual self-esteem. A good body image also derives from mastery of early physical activity and a positive parental approach to tasks such as toilet training.

Genital self-stimulation is a normal activity of babies. It is particularly pronounced between the ages of 15 and 19 months, and it is part of the general interest of children in their bodies. The activity is reinforced by the pleasurable sensations it produces. As youngsters acquire playmates, curiosity about their own and others' genitalia motivates episodes of exhibitionism or genital exploration. Unless the child is unduly shamed, such experiences contribute to continued pleasure from sexual stimulation.

Children also learn by watching the interaction of their parents. They observe demonstrations of physical affection (although usually not the sex act itself), and they are sensitive to the sexual undertone of flirtation, bantering, or seductive interchange.

Adolescence With the approach of puberty, the upsurge of sex hormones, and the development of secondary sex characteristics, sexual curiosity is intensified. Adolescents are physically capable of coitus and orgasm but are usually inhibited by social restraints. The dual, often conflicting pressures of establishing their sexual identities and controlling their sexual impulses produce a strong physiological sexual tension in teenagers that demands release, and masturbation is a normal way to reduce sexual tension. In general, males learn to masturbate to orgasm earlier than females and masturbate more frequently. Consequently, many males integrate their sexuality as an autonomous characteristic earlier than some females. An important emotional difference between the adolescent and the younger child is the presence of coital fantasies during masturbation in the adolescent. These fantasies are an important adjunct to the development of sexual identity; in the comparative safety of the imagination, the adolescent learns to perform the adult sex role. Fantasies that accompany masturbation vary and reflect individual psychodynamics; however, in general, fantasies differ for the sexes. Males respond to visual stimuli of nude or barely dressed women and images of explicit physical acts. Females report responding to romantic stories in which a man demonstrates intense passion for, and commitment to, a woman. Their fantasies focus more on touching, emotions, and the partner's response than on visualizing an explicit sexual act.

In addition to masturbation, adolescents learn sexually through caressing and kissing with partners. In early adolescence, sex play may involve a partner of the same sex for a short period of time for heterosexuals as well as for homosexuals. Adolescence is also when one's body image becomes more definitive and a sense of sexual adequacy and sexual desirability begins to develop. Peer acceptance by the same sex and the opposite sex is of paramount importance. Engaging in sexual talk and jokes, kissing, touching genitalia, experimenting with degrees of nudity, experimenting with different partners or with one partner are part of the process of learning about sexuality. These experiences reinforce the adolescent's sense of being a sexual male or female.

First Coitus The first coitus is a rite of passage for both sexes. The modal age for first coitus is 16 for males and 17 for females. Currently, both considerable peer pressure and individual sex drive impel adolescents or young adults to their first coital experience. In the past, virginity conferred status on the young person. Today, many young people feel embarrassed or inadequate about being virgins. A small backlash is present in some groups in which adolescents sign premarital chastity pledges in a public forum. Also, a survey by the Centers for Disease Control reported that 49 percent of male teenagers had intercourse in 1998, down from 57 percent in 1991. The corresponding number for girls was 48 percent, down from 51 percent.

For the male, anxiety involved in his first coitus relates to performance. Will he be able to get an erection, to penetrate the vagina, to last for some period of time before he ejaculates? He is vulnerable in his masculine pride and may fear being judged inadequate by his female partner and his male peers.

First coitus for a female has been surrounded by cultural ambivalence and concern about the meaning of her loss of virginity and her assumption of the risk of pregnancy and responsibility for the next generation. That risk has been eased by the availability of contraceptive methods. Development of the birth control pill in the 1960s changed societal attitudes toward premarital sex for women and created a more permissive climate. The cohort of females who came of age sexually after the late 1960s report a much higher frequency of premarital intercourse than women before that time. However, only 30 percent of young women use contraception with their first sexual mate and many use it inconsistently. In effect, many young women deny that they are planning to have sex by not being prepared in terms of contraception, reflecting cultural ambivalence about their sexual activity.

Studies have shown that first coitus is most likely to be a positive experience for girls with strong feelings for their partners. In general, women report a greater need to experience sex in the context of an affectionate relationship.

Adulthood By their late 20s, 70 percent of men and 85 percent of women have formed a union, either exclusive cohabitation or marriage. The sexual impulse is catalytic in forming and maintaining adult love relationships. Ideally, a mature sexual relationship encompasses the capacity for intimacy and love for one's partner.

As sexual access ceases to be problematic, more attention is focused on the activity itself. Interference with sexual activity arises from the time and energy required by the pursuit of careers, child rearing, and other family and community obligations. Nonetheless, studies reveal a much higher frequency of sexual interaction among married persons than among single persons. The modal frequency for married persons is three times a month with many couples relating sexually twice a week. The highest frequency of sexual interaction, 4 or more times a week, exists among cohabiting couples.

Kissing, intercourse, and masturbation are frequent sexual activities. Even after a permanent sexual relationship has been established, masturbation remains a healthy practice during the illness or absence of a partner or when intercourse is unsatisfactory. Only when it is a compulsive activity or when it is preferred to partner interaction should it be considered maladaptive. Many adults have some experience with oral sex. Studies show that although it is not a regular activity for most couples, many people are likely to engage in it occasionally throughout their lifetimes. The incidence of the practice of cunnilingus and fellatio are the same; the lifetime prevalence is 75 percent of sexually active people. Anal sex is not part of the repertoire of regular sexual activities for most men and women in the United

States. Although a sizeable minority (25 percent of men and 20 percent of women) report one experience of anal sex, very few repeat the practice. In general, a graph of sexual practices does not form a bell curve. Most curves of sexual behavior are strongly skewed, with many persons indulging in a particular behavior or, conversely, very few people doing so.

Middle Age During middle age the frequency of marital intercourse may decline. The rates of interaction depend more on male interest, and the middle-aged man may devote much of his energy to his career at this point. The decline in sexual interaction often reflects deeroticization of the woman because of her wife-mother role. Familiarity also contributes to a decreased passion, and some men have difficulty connecting marital sexual activity with the erotic scripts they elaborated during their adolescence. Conversely, a couple's experience of each other makes them comfortable and augments their skill at mutual arousal. For women, interest in sexual competence typically increases at this time. A woman's erotic pleasure and sexual commitment are strongly connected to feelings of attachment toward her partner and the security of being in a loving relationship.

With late middle age the biological drive decreases in intensity. It takes the man longer to reach orgasm, he has a longer refractory period, and he requires more stimulation to achieve an erection. The woman must adjust to the hormonal fluctuations of her perimenopausal years, and she too requires more stimulation to become aroused. Although medications are available to address these specific physiological changes, they do not eliminate all need to adjust to the aging process. In terms of family dynamics, children often leave the house for work or further education at this time. That fact plus freedom from concern over unwanted pregnancy may enhance sexual activity for persons who have more time to direct attention toward each other and renew their life as a couple.

However, middle age is the period of rising extramarital activity, although the frequencies of such occurrences are low; 75 percent of men and 85 percent of women remain faithful throughout the lifetime of their marriages. Daniel Offer has explained that the patterning of extramarital sexual activity for both sexes continues to express earlier patterns of psychosexual development:

> For men, it predominantly has the capacity for detachment that in adolescence was directly related to the pursuit of sexual fantasies and the homosocial validation of masculinity. For women, on the other hand, it resembles a quest for circumstances that justify and confirm a romantic self-image rather than a quest for orgasms.

In the context of a loving, communicative, and committed relationship, a decreased frequency of sexual interaction does not herald the onset of extramarital affairs or threaten the stability of the marriage.

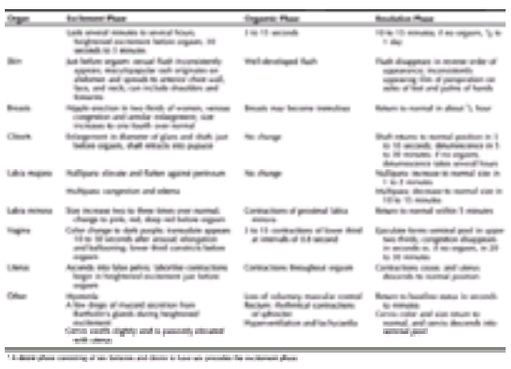
SEX IN AMERICA

A 1994 study conducted by the University of Chicago is the latest sex survey and the most authoritative. Based on a representative United States population between the ages of 18 and 59, it found the following:

1. Eighty-five percent of married women and 75 percent of married men are faithful to their spouses.
2. Forty-one percent of married couples have sex twice a week or more, compared with 23 percent of single persons.
3. Cohabiting single persons have the most sex of all, twice a week or more.
4. The median number of sexual partners over a lifetime for men is six; for women, two.
5. A homosexual orientation was reported by 2.8 percent of men and 1.4 percent of women, with 9 percent of men and 5 percent of women reporting that they had at least one homosexual experience after puberty.
6. Vaginal intercourse was considered the most appealing type of sexual experience by 83 percent of men and 78 percent of women.
7. Among married partners, 93 percent are of the same race, 82 percent are of similar educational level, 78 percent are within 5 years of each other's age, and 72 percent are of the same religion.
8. Both men and women who as children had been sexually abused by an adult were more likely as adults to have had more than 10 sex partners, to engage in group sex, to report a homosexual or bisexual identification, and to be unhappy.
9. Less than 8 percent of the participants reported having sex more than four times a week; about two thirds said they had sex a few times a month or less, and about 3 in 10 have sex a few times a year or less.
10. About 1 man in 4 and 1 woman in 10 masturbates at least once a week, and masturbation is less common among those 18 to 24 years of age than among those 24 to 34 years old.
11. Three quarters of the married women said they usually or always had an orgasm during sexual intercourse, compared with 62 percent of the single women. Among men, married or single, 95 percent said they usually or always had an orgasm.
12. More than half of the men said that they thought about sex every day or several times a day, compared with only 19 percent of the women.
13. More than four in five Americans had only one sexual partner or no partner in the past year. Generally, African-Americans reported the most sexual partners and Asian-Americans the fewest.

PHYSIOLOGICAL RESPONSES

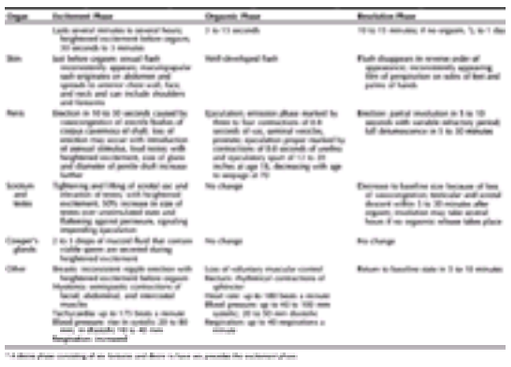
Normal men and women experience a sequence of physiological responses to sexual stimulation. In the first detailed description of these responses, Masters and Johnson observed that the physiological process involves increasing vasocongestion and myotonia tumescence and subsequent release of the vascular activity and muscle tone as a result of orgasm detumescence. Table 19.1a-2 and Table 19.1a-3 describe the female and male sexual response cycles, respectively. DSM-IV defines a four-phase response cycle: phase I, desire; phase II, excitement; phase III, orgasm; phase IV, resolution.



Organ	Excitement Phase	Orgasmic Phase	Resolution Phase
	Lasts several minutes to several hours; heightened excitement before orgasm; 10 seconds to 3 minutes	3 to 15 seconds	10 to 15 minutes; if no orgasm, ½ to 1 day
Skin	Just before orgasm: sexual flush inconsistently appears; maculopapular rash originates on abdomen and spreads to anterior chest wall, face, and neck; can include shoulders and forearms	Well-developed flush	Flush disappears in reverse order of appearance, inconsistently appearing; film of perspiration on soles of feet and palms of hands
Breasts	Nipple erection in two thirds of women; venous congestion and areolar enlargement; size increases by one fourth over normal	Breasts may become meteoritous	Return to normal in about ½ hour
Clitoris	Enlargement in diameter of glans and shaft just before orgasm; shaft retracts into prepuce	No change	Shaft returns to normal position in 1 to 10 seconds; detumescence in 5 to 30 minutes; if no orgasm, detumescence takes several hours
Labia majora	Nullipara: elevate and flatten against perineum Multipara: congestion and edema	No change	Nullipara: decrease to normal size in 1 to 5 minutes Multipara: decrease to normal size in 10 to 15 minutes
Labia minora	Size increase two to three times over normal; change to pink, red, deep red before orgasm	Contractions of proximal labia minora	Return to normal within 5 minutes
Vagina	Color change to dark purple; transudate appears 10 to 30 seconds after arousal; elongation and flattening; lower third constrict before orgasm	3 to 15 contractions of lower third at intervals of 0.8 second	Ejaculate forms seminal pool in upper two thirds; congestion disappears in seconds or, if no orgasm, in 20 to 30 minutes
Uterus	Ascends into false pelvis; ballooning contractions begin in heightened excitement just before orgasm	Contractions throughout orgasm	Contractions cease, and uterus descends to normal position
Other	Myotonia A few drops of mucoid secretion from Bartholin's glands during heightened excitement	Loss of voluntary muscular control Reclam: rhythmical contractions of sphincter Hyperventilation and facial grimacing	Return to baseline status in seconds to minutes Cervix color and size return to normal, and cervix descends into

* A dotted phase consisting of sex hormone and desire to have sex precedes the excitement phase.

Table 19.1a-2 Female Sexual Response Cycle*



Organ	Excitement Phase	Orgasmic Phase	Resolution Phase
	Lasts several minutes to several hours; heightened excitement before orgasm; 30 seconds to 3 minutes	3 to 15 seconds	10 to 15 minutes; if no orgasm, ½ to 1 day
Skin	Just before orgasm: sexual flush inconsistently appears; maculopapular rash originates on abdomen and spreads to anterior chest wall, face, and neck; can include shoulders and forearms	Well-developed flush	Flush disappears in reverse order of appearance, inconsistently appearing; film of perspiration on soles of feet and palms of hands
Penis	Erection in 10 to 30 seconds caused by vasocongestion of erectile bodies of corpus cavernosa of shaft; loss of erection may occur with introduction of sexual stimulus, loud noise, with heightened excitement, size of glans and diameter of penile shaft increase further	Ejaculation, emission phase marked by three to four contractions of 0.8 seconds of vas, seminal vesicles, prostate; ejaculation proper marked by contractions at 0.8 seconds of urethra and ejaculatory spurt of 12 to 30 inches at age 18, decreasing with age to seepage at 70	Erection: partial resolution in 5 to 10 seconds with variable refractory period; full detumescence in 5 to 30 minutes
Scrotum and testes	Tightening and lifting of scrotal sac and retraction of testes; with heightened excitement, 50% increase in size of testes over unstimulated state and flattening against perineum, signaling impending ejaculation	No change	Decrease to baseline size because of loss of vasocongestion; testicular and scrotal descent within 5 to 30 minutes after orgasm; resolution may take several hours if no orgasmic release takes place
Cowper's glands	2 to 3 drops of mucoid fluid that contain visible sperm are secreted during heightened excitement	No change	No change
Other	Erratic, inconsistent nipple erection with heightened excitement before orgasm Myotonia: semispastic contractions of facial, abdominal, and extremities muscles Tachycardia: up to 175 beats a minute Blood pressure: rise in systolic 20 to 80 mm; in diastolic 10 to 40 mm Respiration: increased	Loss of voluntary muscular control Reclam: rhythmical contractions of sphincter Heart rate: up to 180 beats a minute Blood pressure: up to 40 to 100 mm systolic; 20 to 50 mm diastolic Respiration: up to 40 respirations a minute	Return to baseline state in 5 to 10 minutes

* A dotted phase consisting of sex hormone and desire to have sex precedes the excitement phase.

Table 19.1a-3 Male Sexual Response Cycle.*

Phase I: Desire Phase I is distinct from any identified solely through physiology and reflects the psychiatrist's fundamental concern with motivations, drives, and personality. It is characterized by sexual fantasies and the desire to have sexual activity.

Phase II: Excitement Phase II is brought on by psychological stimulation (fantasy or the presence of a love object), physiological stimulation (stroking or kissing), or a combination of the two. It consists of a subjective sense of pleasure. The excitement phase is characterized by penile tumescence leading to erection in the man and vaginal lubrication in the woman. The nipples of both sexes become erect, although nipple erection is more common in women than in men. The woman's clitoris becomes hard and turgid, and her labia minora become thicker as a result of venous engorgement. Initial excitement may last several minutes to several hours. With continued stimulation, the man's testes increase in size 50 percent and elevate. The woman's vaginal barrel shows a characteristic constriction along the outer third known as the orgasmic platform. The clitoris elevates and retracts behind the symphysis pubis; hence it is not easily accessible. However, stimulation of the area causes traction on the labia minora and the prepuce, and there is intrapreputial movement of the clitoral shaft. Breast size in the woman increases 25 percent. Continued engorgement of the penis and vagina produces specific color changes, particularly in the labia minora, which become bright or deep red. Voluntary contractions of large muscle groups occur, rate of heartbeat and respiration increases, and blood pressure rises. Heightened excitement lasts 30 seconds to several minutes.

Phase III: Orgasm Phase III consists of peaking sexual pleasure, with release of sexual tension and rhythmic contraction of the perineal muscles and pelvic reproductive organs. A subjective sense of ejaculatory inevitability triggers the man's orgasm. Forceful emission of semen follows. The male orgasm is also associated with four to five rhythmic spasms of the prostate, seminal vesicles, vas, and urethra. In the woman orgasm is characterized by 3 to 15 involuntary contractions of the lower third of the vagina and by strong, sustained contractions of the uterus, flowing from the fundus downward to the cervix. Both men and women have involuntary contractions of the internal and external sphincter. Those and the other contractions during orgasm occur at 0.8-second intervals. Other manifestations include voluntary and involuntary movements of the large muscle groups, including facial grimacing and carpopedal spasm. Blood pressure rises 20 to 40 mm (both systolic and diastolic), and the heart rate increases up to 160 beats a minute. Orgasm lasts from 3 to 25 seconds and is associated with a slight clouding of consciousness.

Phase IV: Resolution Resolution consists of the disgorgement of blood from the genitalia (detumescence), which brings the body back to its resting state. If orgasm occurs, resolution is rapid; if it does not occur, resolution may take 2 to 6 hours and be associated with irritability and discomfort. Resolution through orgasm is characterized by a subjective sense of well-being, general relaxation, and muscular relaxation. After orgasm men have a refractory period that may last from several minutes to many hours; in that period they cannot be stimulated to further orgasm. The refractory period does not exist in women, who are capable of multiple and successive orgasms.

Sexual response is a true psychophysiological experience. Arousal is triggered by both psychological and physical stimuli, levels of tension are experienced both physiologically and emotionally, and with orgasm, there is normally a subjective perception of a peak of physical reaction and release. Psychosexual development, psychological attitude toward sexuality, and attitudes toward one's sexual partner are directly involved with, and affect, the physiology of human sexual response.

ABNORMAL SEXUALITY AND SEXUAL DYSFUNCTIONS

Seven major categories of sexual dysfunction are listed in DSM-IV: (1) sexual desire disorders, (2) sexual arousal disorders, (3) orgasm disorders, (4) sexual pain disorders, (5) sexual dysfunction due to a general medical condition, (6) substance-induced sexual dysfunction, and (7) sexual dysfunction not otherwise specified.

Definition In DSM-IV sexual dysfunctions are categorized as Axis I disorders. The syndromes listed are correlated with the sexual physiological response, which is divided into the four phases discussed above. The essential feature of the sexual dysfunctions is inhibition in one or more of the phases, including disturbance in the subjective sense of pleasure or desire or disturbance in the objective performance (Table 19.1a-4 and Table 19.1a-5). Either type of disturbance can occur alone or in combination. Sexual dysfunctions are diagnosed only when they are a major part of the clinical picture. They can be lifelong or acquired, generalized or situational, and due to psychological factors, physiological factors or combined factors. If they are attributable entirely to a general medical condition, substance use, or adverse effects of medication, then sexual dysfunction due to a general medical condition or substance-induced sexual dysfunction is diagnosed.

Phase	Characteristics	Dysfunction
1. Desire	Distinct from any identified solely through physiology and reflects the patient's motivations, drives, and personality; characterized by sexual fantasies and the desire to have sex	Hypoactive sexual desire disorder, sexual aversion disorder, hypoactive sexual desire disorder due to a general medical condition (male or female); substance-induced sexual dysfunction with impaired desire
2. Excitement	Subjective sense of sexual pleasure and accompanying physiological changes; all physiological responses noted in Masters and Johnson's excitement and plateau phases are combined in this phase	Female sexual arousal disorder, male erectile disorder (may also occur in stages 3 and 4); male erectile disorder due to a general medical condition; dyspareunia due to a general medical condition (male or female); substance-induced sexual dysfunction with impaired arousal
3. Orgasm	Peaking of sexual pleasure, with release of sexual tension and rhythmic contraction of the perineal muscles and pelvic reproductive organs	Female orgasmic disorder, male orgasmic disorder, premature ejaculation; other sexual dysfunction due to a general medical condition (male or female); substance-induced sexual dysfunction with impaired orgasm
4. Resolution	A sense of general relaxation, well-being, and muscle relaxation; men are refractory to orgasm for a period of time that increases with age, whereas women can have multiple orgasms without a refractory period	Postcoital dysphoria, postcoital headache

* DSM-IV-TR consolidates the Masters and Johnson excitement and plateau phases into a single excitement phase, which is preceded by the desire (appetitive) phase. The orgasm and resolution phases remain the same as originally described by Masters and Johnson.

Table 19.1a-4 DSM-IV Phases of the Sexual Response Cycle and Associated Sexual Dysfunctions*

Category	Dysfunctions
Sexual pain disorders	Vaginismus (female) Dyspareunia (female and male)
Other	Sexual dysfunctions not otherwise specified. Examples: 1. No erotic sensation despite normal physiological response to sexual stimulation (e.g., orgasmic anhedonia) 2. Female analogue of premature ejaculation 3. Genital pain occurring during masturbation

Table 19.1a-5 Sexual Dysfunction Not Correlated With Phases of the Sexual Response Cycle

According to the 10th revision of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10), sexual dysfunction refers to a person's inability to "participate in a sexual relationship as he or she would wish." This dysfunction is expressed in various ways: as a lack of desire or of pleasure or as a physiological inability to begin, maintain, or complete sexual interaction. Because sexual response is psychosomatic, it may be difficult to determine "the relative importance of psychological and/or organic factors."

Sexual dysfunction such as lack of desire can occur in both men and women, but women more often complain of the "subjective quality" of the experience than of the "failure of a specific response." ICD-10 advises looking "beyond the presenting complaint to find the most appropriate diagnostic category." Table 19.1a-6 presents the ICD-10 diagnostic criteria.

Table 19.1a-6 ICD-10 Diagnostic Criteria for Sexual Dysfunction, Not Caused by Organic Disorder or Disease

With the possible exception of premature ejaculation, sexual dysfunctions are rarely found separate from other psychiatric syndromes. Sexual disorders may lead to or result from relational problems, and patients invariably develop an increasing fear of failure and self-consciousness about their sexual performance. Sexual dysfunctions are frequently associated with other mental disorders, such as depressive disorders, anxiety disorders, personality disorders, and schizophrenia. In many instances, a sexual dysfunction may be diagnosed in conjunction with another psychiatric disorder; in other cases, however, it is only one of many signs or symptoms of the psychiatric disorder.

A sexual disorder can be symptomatic of biological problems, intrapsychic conflicts, interpersonal difficulties, or a combination of these factors. The sexual function can be affected by stress of any kind, by emotional disorders, and by a lack of sexual knowledge.

Taking a Sexual History As with all psychiatric interviews, sexual history taking is not only an information-gathering time, it also permits the development of a positive doctor-patient relationship. The development of confidence and rapport requires an accepting atmosphere and a nonjudgmental attitude on the part of the therapist toward the patients' sexual values, ideas, and practices.

The sexual history is more structured than the rest of the psychiatric interview, although patients are encouraged to take their own lead in areas of great personal significance. In general, the therapist structures the interview so that both recent and early sexual histories are covered. The therapist must ascertain the specific current sexual complaint, the person's sexual practices and pattern of interaction with partners, the person's sexual goal and fantasies, the masturbatory history, the presence or extent of extramarital relationships, and the degree of commitment to the marriage or the partner. Patients describe their view of the problem and when it began. If married, the courtship, honeymoon, and reproductive history are examined in detail. Premarital expectations, mutual physical attraction, periods of separation, the type of contraception used, and the effect of children on the couple's sexual life are covered. The satisfying aspects of the marriage must also be discussed. The patient is particularly asked to evaluate the partner's contribution to the present distress.

Early sexual development and education are also thoroughly discussed. The interviewer asks for the patient's view of the parents' marriage as seen in retrospect and as perceived in childhood. Relationships to peers, siblings, and important familial figures other than parents are also explored. Particular attention is paid to ways in which affection was expressed in the family and the degree of physical contact between family members. The sexual climate in which the patient grew up is seen through reported parental attitudes, memories of sexual games played as a child, the way in which the patient learned sexual facts, the specifics of religious training, reactions to masturbation and nocturnal emissions or the menarche, dating patterns, an adolescent rebellious phase, and any significant premarital involvements. Ethnic background and the socioeconomic level of the patient's primary family are also taken into account. As the interview progresses, the patient's self-image emerges. The interviewer must be sensitive to any event that was exceptional in the patient's sexual life in either a destructive or a highly pleasant manner and should take particular note of the people who contributed to the patient's sexual education, identity, and mores.

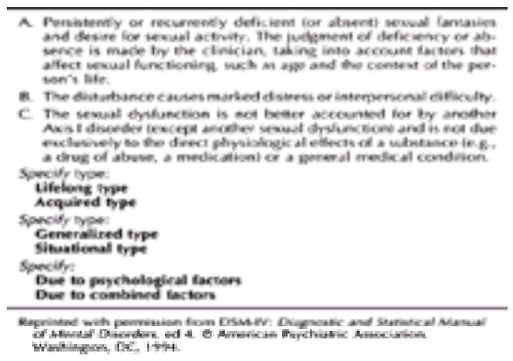
The interviewer must also ask specific questions to elicit information that may be outside the patient's view of the socially acceptable, such as premarital and extramarital affairs, group sex, homosexual involvements, and abortions. The sexual orientation of the person being interviewed should be ascertained, and questions related to same-sex interactions explored. All interviews should review high-risk sexual behavior regardless of sexual orientation, since transmission of the human immunodeficiency virus (HIV) is increasing rapidly in all groups. Additionally, the issue of sexual abuse must be explored, particularly since a history of abuse predisposes to the development of sexual dysfunction.

Similar disorders exist among both homosexual and heterosexual partners, with variations imposed by anatomical differences. For example, although penile-vaginal dysfunction cannot be described among homosexuals, penile-anal dysfunction may occur. In spite of sexual orientation, each phase of the sex cycle applies equally to same-sex and heterosexual partners, and the methods and principles for treatment are essentially similar.

Rating Scales In addition to the interview, several questionnaires are available to assess sexual function. They were developed primarily to evaluate illness or medication-related effects on sexual functioning. The most commonly used scales are the Arizona Sexual Experience Scale, the Brief Sexual Function Questionnaire, the Changes in Sexual Functioning Questionnaire, the Derogatis Sexual Function Inventory, and the Rush Sexual Inventory. The scales vary in length, reliability, validity, and method of administration. Some are rated by the patients themselves, others by the therapist. The formats include structured and semistructured approaches. The scales differ in number of symptoms assessed, in the dysfunctions they target, and in the time frame they cover.

Sexual Desire Disorders DSM-IV divides sexual desire disorders into two classes: hypoactive sexual desire disorder, characterized by a deficiency or lack of sexual fantasies and desire for sexual activity, and sexual aversion disorder, characterized by an aversion to, and avoidance of, genital sexual contact with a sexual partner. The former condition is more common than the latter.

Hypoactive Sexual Desire Disorder Hypoactive sexual desire disorder (Table 19.1a-7) is experienced by both men and women; however, they may not be hampered by any dysfunction once they are involved in the sex act. Conversely, hypoactive desire may be used to mask another sexual dysfunction. Lack of desire may be expressed by decreased frequency of coitus, perception of the partner as unattractive, or overt complaints of lack of desire. Upon questioning, the patient is found to have few or no sexual thoughts or fantasies, a lack of awareness of sexual cues, and little interest in initiating sexual experiences.



A. Persistently or recurrently deficient (or absent) sexual fantasies and desire for sexual activity. The judgment of deficiency or absence is made by the clinician, taking into account factors that affect sexual functioning, such as age and the context of the person's life.
B. The disturbance causes marked distress or interpersonal difficulty.
C. The sexual dysfunction is not better accounted for by another Axis I disorder (except another sexual dysfunction) and is not due exclusively to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition.

Table 19.1a-7 Diagnostic Criteria for Hypoactive Sexual Desire Disorder

Sometimes biochemical correlates are associated with hypoactive desire. A recent study found markedly low serum testosterone concentrations in men complaining of this dysfunction when they were compared with normal controls in a sleep-laboratory situation. Also, a central dopamine blockage is known to decrease desire (Table 19.1a-7). The need for sexual contact and satisfaction varies among different persons, as well as in the same person over time. In a group of 100 couples with stable

marriages, 8 percent reported having intercourse less than once a month. In another group of couples, one third reported lack of sexual relations for periods averaging 8 weeks. In a survey of a general medical practice in England, 25 percent of that sample reported no sexual activity most of the time. It has been estimated that 20 percent of the total population have hypoactive sexual desire disorder. The complaint is more common among women.

Patients with desire problems often have good ego strengths and use inhibition of desire defensively to protect against unconscious fears about sex. Lack of desire can also result from chronic stress, anxiety, or depression. Abstinence from sex for a prolonged period sometimes suppresses the sexual impulse. Desire problems may also be an expression of hostility or signal a deteriorating relationship.

The presence of desire depends on several factors: biological drive, adequate self-esteem, previous good experiences with sex, the availability of an appropriate partner, and a good relationship in nonsexual areas with one's partner. Damage to any of those factors may result in diminished desire.

Hypoactive sexual desire disorders often become manifest during puberty and may remain a lifelong condition. A general medical workup is always indicated to rule out a medical cause, which would be diagnosed as male or female sexual desire disorder due to a general medical condition according to DSM-IV.

Mr. and Mrs. L. were a professional couple in their mid-40s who presented with a chief complaint of lack of desire on the wife's part. Although Mrs. L. stated she never found her husband “a terrific turn-on”; she had felt sufficiently attracted to him for the couple to have sustained a satisfactory sex life up to the year before they entered therapy. She agreed to seek help because of his increasing complaints about their lack of sexual interaction.

They were both Ph.D.s and taught at different colleges. To juggle her obligations at home and work, Mrs. L. had been forced to reduce her teaching hours and resign from academic committees, and she had been unable to complete several scholarly articles she had outlined for publication. Mr. L. took time for conferences, networking, and writing, He felt he could not put his career on hold. Also, he objected to his wife's wish to have him as available to her as he had been during their time as graduate students.

Mrs. L. was diagnosed as having hypoactive sexual desire disorder, acquired type. She had experienced desire in the past and was a sexually responsive woman. Her current lack of desire was associated with anger at her husband whom she perceived as no longer willing to support her career and needing “to have everything go his way.”

Sexual Aversion Disorder Sexual aversion disorder (Table 19.1a-8) is defined in DSM-IV as a “persistent or recurrent and extreme aversion to, and avoidance of, all or almost all, genital sexual contact with a sexual partner.” Some researchers consider the line between hypoactive desire disorder and sexual aversion disorder blurred, and in some cases both diagnoses are appropriate. Low frequency of sexual interaction is a symptom common to both disorders. The clinician should think of the words “repugnance” and “phobia” in relation to the patient with sexual aversion disorder. Freud conceptualized sexual aversion as the result of inhibition during the phallic psychosexual phase and unresolved oedipal conflicts. Some men, fixated at the phallic stage of development, fear the vagina and believe that they will be castrated if they approach it (a concept Freud called *vagina dentata*), because they believe unconsciously that the vagina has teeth. Hence they avoid contact with the female genitalia entirely.

A. Persistent or recurrent extreme aversion to, and avoidance of, all (or almost all) genital sexual contact with a sexual partner.
B. The disturbance causes marked distress or interpersonal difficulty.
C. The sexual dysfunction is not better accounted for by another Axis I disorder (except another sexual dysfunction).

Table 19.1a-8 Diagnostic Criteria for Sexual Aversion Disorder

The disorder may result from a traumatic sexual assault, such as rape or childhood abuse, from repeated painful experiences with coitus, or from early developmental conflicts that have left the patient with unconscious connections between the sexual impulse and overwhelming feelings of shame and guilt. The disorder may also be a reaction to a perceived psychological assault by the partner and to relationship difficulties.

Mr. and Mrs. J. were 38 and 36 years old, respectively, when they presented for treatment stating they had not had coitus for 3 years. Three years previously Mrs. J. revealed that she had been having an extramarital affair of 2 months duration, which she then ended. At that time, she told her husband that she had been unhappy with their lovemaking.

Upon hearing of her affair, the husband was angry and refused to approach his wife sexually. When he finally did so, she would allow caressing of her body but not her genitalia although she was willing to stimulate him sexually. At this point the husband also had an affair but stopped when he realized it would not solve his problems with his wife, and she then agreed to enter sex therapy. When they presented for sex therapy their sexual interaction consisted of mutual kissing and her manual stimulation of his penis until he reached orgasm.

In the individual interviews that were part of the evaluation of the case, Mrs. J. reiterated that she found her husband's lovemaking unsatisfactory; but that she did not have a problem allowing other men to caress her genitalia and that she could have coitus with other men. Mr. J. had been traumatized by his wife's rejection and sexual betrayal, and he in turn was averse to touching her genitalia or attempting intromission.

This was a case in which both partners suffered from sexual aversion disorder. The husband feared touching his wife in an explicitly sexual way; the wife was averse to his touching her genitalia, and both spouses avoided coitus. For both partners the dysfunction was acquired and situational.

Sexual Arousal Disorders DSM-IV divides the sexual arousal disorders into (1) female sexual arousal disorder, characterized by the persistent or recurrent partial or complete failure to attain or maintain the lubrication-swelling response of sexual excitement until the completion of the sexual act, and (2) male erectile disorder, characterized by the recurrent and persistent partial or complete failure to attain or maintain an erection until the completion of the sex act. The diagnosis takes into account the focus, the intensity, and the duration of the sexual activity in which the patient engages. If sexual stimulation is inadequate in focus, intensity, or duration, the diagnosis should not be made.

Female Sexual Arousal Disorder Women who have excitement-phase dysfunction often have orgastic problems as well. In one series of relatively happily married couples, 33 percent of the women described difficulty in maintaining sexual excitement. Numerous psychological factors are associated with female sexual inhibition. Those conflicts may be expressed through inhibition of excitement or orgasm and are discussed under orgasmic phase dysfunctions. In some women arousal disorders are associated with dyspareunia or lack of desire.

Less research has been done on physiological components of dysfunction in women than in men, and there have been conflicting results. Masters and Johnson found normally responsive women to particularly desire sex premenstrually. A recent study found that dysfunctional women tended to be more responsive immediately following their periods. A third group of dysfunctional women felt the greatest sexual excitement at the time of ovulation. Some evidence indicates that dysfunctional women are less aware of such physiological responses of their bodies as vasocongestion, during arousal.

There are some organic causes for female sexual arousal disorder. Alterations in testosterone, estrogen, prolactin, and thyroxine concentrations have been implicated. Medications with antihistaminic or anticholinergic properties lessen vaginal lubrication and interfere with arousal. Also, postmenopausal women require

longer stimulation for lubrication to occur, and there is generally less vaginal transudate after menopause. An artificial lubricant is frequently useful in that situation.

Table 19.1a-9 presents the diagnostic criteria for female sexual arousal disorder.

A. Persistent or recurrent inability to attain, or to maintain until completion of the sexual activity, an adequate lubrication-swelling response of sexual excitement.
B. The disturbance causes marked distress or interpersonal difficulty.
C. The sexual dysfunction is not better accounted for by another Axis I disorder (except another sexual dysfunction) and is not due exclusively to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition.

Table 19.1a-9 Diagnostic Criteria for Female Sexual Arousal Disorder

Male Erectile Disorder Male erectile disorder (Table 19.1a-10) is also called *erectile dysfunction* and *impotence*. A man with lifelong male erectile disorder has never obtained an erection sufficient for vaginal insertion. In acquired male erectile disorder, the man successfully achieved vaginal penetration at some time in his sexual life but later cannot do so. In situational male erectile disorder, the man can have coitus in certain circumstances but not in others; for example, a man may function effectively with a prostitute but not with his wife. Kinsey estimated that a few men (2 to 4 percent) are dysfunctional at age 35 but 77 percent are at age 80. Ten percent of the men in the University of Chicago study reported an experience with erectile dysfunction in the past year, and between 15 and 20 percent experienced anxiety about performing. More recently it was estimated that the incidence of erectile dysfunction in young men is about 8 percent. However, that sexual dysfunction may first appear later in life. Masters and Johnson reported a fear of impotence in all men over 40, which the researchers believed reflects the masculine fear of loss of virility with advancing age. (As it happens, however, erectile dysfunction is not a regularly occurring phenomenon in aged men; good health and an available sexual partner are more closely related to continuing potency than is age per se.) From 35 to 50 percent of all men treated for sexual disorders have erectile dysfunction as the chief complaint.

A. Persistent or recurrent inability to attain, or to maintain until completion of the sexual activity, an adequate erection.
B. The disturbance causes marked distress or interpersonal difficulty.
C. The erectile dysfunction is not better accounted for by another Axis I disorder (other than a sexual dysfunction) and is not due exclusively to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition.

Table 19.1a-10 Diagnostic Criteria for Male Erectile Disorder

Many recent studies have focused on the relative incidences of psychological and organic erectile dysfunction. Physiologically, erectile dysfunction may be due to a variety of medical causes (Table 19.1a-11). In the United States it is estimated that two million men cannot gain erections because they suffer from diabetes mellitus; an additional 300,000 are dysfunctional because of other endocrine diseases; 1.5 million are dysfunctional as a result of vascular disease; 180,000 because of multiple sclerosis; 400,000 because of traumas and fractures leading to pelvic fractures or spinal cord injuries; and another 650,000 as a result of radical surgery, including prostatectomies, colostomies, and cystectomies. In addition, the clinician should be aware of the possible pharmacological effects of medication on sexual functioning. The increased incidence of organic causes for erectile dysfunction in the past 15 years may partly reflect the increased use of psychotropic and antihypertensive medications. Statistics indicate that 50 to 80 percent of men with erectile dysfunction have a medical basis for their problem. The following case is an example of male erectile dysfunction.

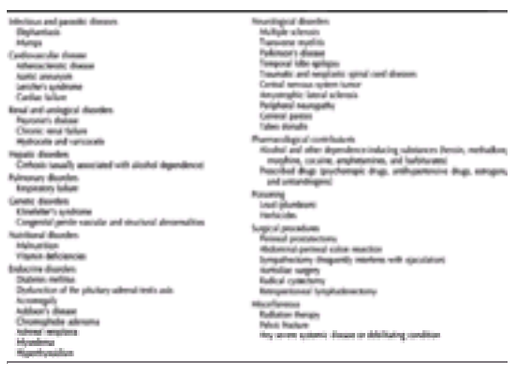

Table 19.1a-11 Diseases and Other Medical Conditions Implicated in Erectile Dysfunction

Mr. R., a 45-year-old doctor, presented with a chief complaint of difficulty gaining and maintaining erections. He had been suffering from erectile dysfunction for the past 4 years, with a few exceptions, ever since he divorced his wife. At the age of 29 he had married a woman to whom he was very attracted. He never experienced any dysfunction with her, and they had frequent intercourse. However, he described her as very passive during their sex play and stated that she rarely caressed him or directly stimulated his genitals. After the birth of their child his wife began complaining about the amount of time he spent working. At the same time she began rebuffing his sexual overtures. Their sex life dwindled and then ceased. The patient stated the reason he divorced his wife was his dissatisfaction with her social skills—he described her as withdrawn and shy—and his unhappiness with her demands and coldness.

Mr. R.'s sexual experience prior to his marriage consisted of masturbation and four or five visits to prostitutes. As a youngster and adolescent he felt unattractive to girls, short and homely, and he was convinced his penis was smaller than average. Although he was the spouse who terminated the marriage, his wife's sexual rejection of him revived his sense of sexual inadequacy. All his earlier sexual anxiety resurfaced, and he became unable to function.

He was diagnosed as having male erectile disorder, acquired type.

Orgasmic Disorders Female orgasmic disorder (also known as *inhibited female orgasm*, or anorgasmia) is defined as the recurrent and persistent inhibition of the female orgasm, as becomes manifest by the absence or delay of orgasm after a normal sexual excitement phase that the clinician judges to be adequate in focus, intensity, and duration. Women who can achieve orgasm with noncoital clitoral stimulation but cannot experience it during coitus in the absence of manual clitoral

stimulation are not necessarily categorized as anorgasmic.

Physiological research on the female sexual response has demonstrated that orgasms caused by clitoral stimulation and those caused by vaginal stimulation are physiologically identical. Freud's theory that women must give up clitoral sensitivity for vaginal sensitivity to achieve sexual maturity is now considered misleading, although some women say that they gain a special sense of satisfaction from an orgasm precipitated by coitus. Some workers attribute that to the psychological feeling of closeness engendered by the act of coitus, but others maintain that the coital orgasm is a physiologically different experience. Many women achieve orgasm during coitus by a combination of manual clitoral stimulation and penile vaginal stimulation.

Lifelong female orgasmic disorder exists when the woman has never experienced orgasm by any kind of stimulation. Acquired orgasmic dysfunction exists if the woman has previously experienced at least one orgasm regardless of the circumstances or means of stimulation, whether by masturbation or during sleep while dreaming. Kinsey found that the proportion of married women over 35 years of age who had never achieved orgasm by any means was only 5 percent. The incidence of orgasm increased with age. According to Kinsey, the first orgasm occurs in late adolescence in about 50 percent of women. The rest usually experience orgasm by some means as they get older. Lifelong female orgasmic disorder is more common among unmarried women than among married women; 39 percent of the unmarried women over age 35 in Kinsey's study had never experienced orgasm. Increased orgasmic potential in women over 35 has been explained on the basis of less psychological inhibition, greater sexual experience, or both. Also, orgasmic consistency has been correlated with marital happiness, although cause and effect have not been determined. In the University of Chicago study, three quarters of the female respondents usually or always experienced orgasm during sex, compared with two thirds of the single women. One woman in 10 complained of difficulty in achieving orgasm.

Mr. and Mrs. Z. were a childless couple, both in their late 20s. She was a college instructor, and he was a free-lance writer. The couple had been married for 4 years and came to therapy with a mutual complaint of steadily lessening sexual frequency. During the year before they were seen, they had had intercourse six times. In the initial interview, Mrs. Z. stated that she had never been able to have an orgasm with her husband and had never experienced an orgasm during intercourse. Her frustration made her increasingly reluctant to have coitus and rejecting of her husband sexually. Mrs. Z. could masturbate to orgasm while indulging in masochistic fantasies, but she did so very infrequently.

She was the oldest of four children, raised by rigid and intellectual, but undemonstrative, parents. She stated that she had been a very docile child and adolescent but openly rebelled in marrying her husband. Her parents disapproved of him, since he came from a different religious background. Mrs. Z.'s father particularly objected, and relations between Mr. Z. and his father-in-law were strained. Mrs. Z. stated that she often felt caught between them.

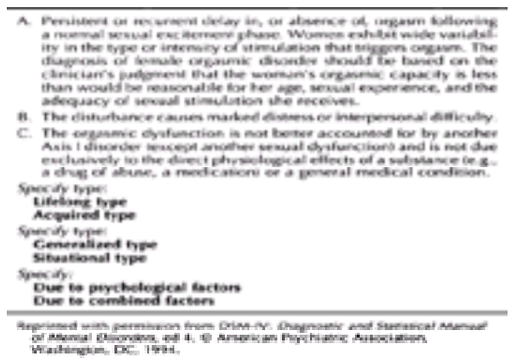
Mr. Z. was the middle child and the only boy in a family of three sisters. There was a 20-year age difference between his parents, and the father was not actively involved with the children. He felt he had always been his mother's favorite.

Mr. and Mrs. Z. met in college, and although neither was sexually experienced, they were strongly attracted to one another and indulged in enjoyable sexual play, short of intercourse. Mrs. Z. perceived her husband as a very assertive man and was impressed by the way he stood up to her family. When he completed school, a year ahead of Mrs. Z., he broke off the relationship with her. During that year Mrs. Z. became involved with another man and enjoyed sexual play with him. She did not have intercourse with him but sometimes came to orgasm through manual manipulation. At the time of her graduation, she terminated this relationship and managed to regain Mr. Z.'s attention. The couple married 6 months after her graduation. Intercourse was a disappointment to Mrs. Z. from the beginning. She felt unfulfilled, and her husband felt rejected and inadequate.

In therapy, the couple's premarital expectations were discussed. In effect, each had expected more assertiveness from the other, and in reality, each had some problem with passivity. Several sessions were also spent dealing with relations with in-laws. Mrs. Z. was encouraged to give priority to her relationship with her husband, and Mr. Z. was encouraged to face and restrain his competitiveness with her father. They responded to the behavioral exercises that were prescribed. At the time of their discharge from therapy, the couple was having intercourse 1 to 2 times a week. Mrs. Z. could not reach orgasm during intercourse but could frequently achieve climax after coitus through manual stimulation.

Acquired female orgasmic disorder is a common complaint in the clinical population. One clinical treatment facility described nonorgasmic women as about four times more common in its practice than patients with all other sexual disorders. In another study 46 percent of the women complained of difficulty in reaching orgasm, and 15 percent described an inability to have orgasm. The overall prevalence of inhibited orgasm in women is estimated to be 30 percent.

Numerous psychological factors are associated with female sexual inhibition. They include fears of impregnation, rejection by the sexual partner, or damage to the vagina; hostility toward men; and feelings of guilt regarding sexual impulses. Some women equate orgasm with loss of control or with aggressive, destructive, or violent behavior. Fear of those impulses may be expressed through inhibition of excitement or orgasm. The expression of orgasmic inhibition varies. Some women feel unentitled to gratify themselves and cannot masturbate to climax. Others enjoy self-stimulation but cannot reach orgasm with a partner present. Cultural expectations and societal restrictions on women are also relevant. Nonorgasmic women may be otherwise symptom free or may experience frustration in a variety of ways, including such pelvic complaints as lower abdominal pain, itching, and vaginal discharge, as well as increased tension, irritability, and fatigue. The diagnostic criteria for female orgasmic disorder are presented in Table 19.1a-12.



A. Persistent or recurrent delay in, or absence of, orgasm following a normal sexual excitement phase. Women exhibit wide variability in the type or intensity of stimulation that triggers orgasm. The diagnosis of female orgasmic disorder should be based on the clinician's judgment that the woman's orgasmic capacity is less than would be reasonable for her age, sexual experience, and the adequacy of sexual stimulation she receives.
B. The disturbance causes marked distress or interpersonal difficulty.
C. The orgasmic dysfunction is not better accounted for by another Axis I disorder (except another sexual dysfunction) and is not due exclusively to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition.

Table 19.1a-12 Diagnostic Criteria for Female Orgasmic Disorder

Male Orgasmic Disorder In male orgasmic disorder (previously inhibited male orgasm and called *retarded ejaculation*), the male achieves climax during coitus with great difficulty, if at all. A man suffers from lifelong orgasmic disorder if he has never ejaculated during coitus. The disorder is diagnosed as acquired if it develops after previous normal functioning.

Some workers suggest that orgasm and ejaculation should be differentiated. Certainly, inhibited orgasm must be differentiated from retrograde ejaculation, in which ejaculation occurs but the seminal fluid passes backward into the bladder. This condition always has an organic cause. Retrograde ejaculation can develop after genitourinary surgery and is also associated with medications that have anticholinergic adverse effects, such as the phenothiazines, particularly thioridazine (Mellaril).

The incidence of male orgasmic disorder is much lower than those of premature ejaculation and erectile dysfunction. Masters and Johnson reported only 3.8 percent in one group of 447 sex-dysfunction cases. This problem is more common among men with obsessive-compulsive disorders than among others. Male orgasmic disorder may have physiological causes and can occur after surgery of the genitourinary tract, such as prostatectomy. Male orgasmic dysfunction may also be associated with Parkinson's disease and other neurological disorders involving the lumbar or sacral sections of the spinal cord. The antihypertensive drugs guanethidine monosulfate (Esmelin) and methyldopa (Aldomet) have been implicated in retarded ejaculation. Phenothiazines have also been associated with the disorder, as have almost all the antidepressants. Transient retarded ejaculation may occur with excessive alcohol intake or with hyperglycemia, whether caused by drugs or by pituitary adenoma. Strictly organic cases and problems that are symptomatic of other Axis I psychiatric syndromes are not to be included in the diagnosis.

Primary male orgasmic disorder indicates more-severe psychopathology. The man often comes from a rigid, puritanical background; he perceives sex as sinful and the genitals as dirty, and he may have conscious or unconscious incest wishes and guilt. Usually difficulties with closeness exist that extend beyond the area of

sexual relations.

In an ongoing relationship, secondary ejaculatory inhibition frequently reflects interpersonal difficulties. The disorder may be the man's way of coping with real or fantasized changes in the relationship. Those changes may include plans for a pregnancy about which the man is ambivalent, the loss of sexual attraction to the partner, or demands by the partner for greater commitment as expressed by sexual performance. In some men the inability to ejaculate reflects unexpressed hostility toward women.

In a version of the dysfunction, some men experience partial inhibition of ejaculation. Those men experience a slow dribbling of ejaculation (not related to age) rather than an ejaculatory spurt. They usually do not experience the pleasurable sensations of orgasm.

The following case is an example of ejaculatory inhibition.

> Mr. and Mrs. G. presented with the chief complaint of the man being unable to achieve climax and ejaculate. The problem had begun some 10 weeks prior to the couple's entering treatment. The man denied having masturbated during that time, but after being instructed to do so in the privacy of his home as part of the therapeutic evaluation, he reported having no difficulty reaching orgasm and ejaculating with masturbation.
>
> The couple (male aged 46 and female aged 39) had been married for 2 years. Mr. G. had a child from a previous marriage. This was Mrs. G.'s first marriage and she had no children. Although Mr. G. did not want more children, he felt it would be unfair to deprive his wife of them, and he had agreed to have a new family prior to the marriage. Ten months after they were married, Mrs. G. suffered a miscarriage. The couple decided to wait before trying to have her conceive again but had resumed trying 3 months before entering therapy.
>
> It was clear following the initial interviews that Mr. G. felt he had made “a good faith effort” with his wife's first conception. His genuine distress for her at the time of the miscarriage had increased his ambivalence about having her conceive again. His current problem of retarded ejaculation was a dysfunctional attempt to resolve the conflict of fulfilling his promise to his wife with his desire to have no more children. He was diagnosed with male orgasmic disorder, acquired.

The diagnostic criteria for male orgasmic disorder are presented in Table 19.1a-13.

A. Persistent or recurrent delay in, or absence of, orgasm following a normal sexual excitement phase during sexual activity that the clinician, taking into account the person's age, judges to be adequate in focus, intensity, and duration.
B. The disturbance causes marked distress or interpersonal difficulty.
C. The orgasmic dysfunction is not better accounted for by another Axis I disorder (except another sexual dysfunction) and is not due exclusively to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition.

Table 19.1a-13 DSM-IV Diagnostic Criteria for Male Orgasmic Disorder

Premature Ejaculation In *premature ejaculation* the man recurrently achieves orgasm and ejaculates before he wishes to do so. There is no definite time frame within which to define the dysfunction. The diagnosis is made when the man regularly ejaculates before or immediately after entering the vagina or following minimal sexual stimulation. The clinician should consider actors that affect duration of the excitement phase, such as age, novelty of the sexual partner, and the frequency and duration of coitus. Masters and Johnson conceptualized the disorder in terms of the couple and consider a man a premature ejaculator if he cannot control ejaculation long enough during intravaginal containment to satisfy his partner in at least half of their episodes of coitus. That definition assumes that the female partner is capable of an orgasmic response. As with other dysfunctions, the disturbance is diagnosed only if it is not caused exclusively by medical factors or is not symptomatic of any other Axis I syndrome.

Premature ejaculation is more common today among college-educated men than among men with less education and is thought to be related to their concern for partner satisfaction. It is estimated that 30 percent of the male population have the dysfunction, and about 40 percent of men treated for sexual disorders have premature ejaculation as the chief complaint.

Difficulty in ejaculatory control may be associated with anxiety regarding the sex act. Both anxiety and ejaculation are mediated by the sympathetic nervous system. Other psychological factors that have been noted include sexual guilt, a history of parent-child conflict, interpersonal hypersensitivity, and perfectionism or unrealistic expectations about sexual performance.

Current research also suggests that a subgroup of premature ejaculators (particularly those with a lifelong history of premature ejaculation) may be biologically predisposed to this dysfunction. Some researchers believe that certain males are constitutionally more vulnerable to sympathetic stimulation, hence they ejaculate rapidly. Other workers have found a shorter bulbocavernosus reflex nerve latency time in men with lifelong premature ejaculation than in men who had acquired the dysfunction.

Premature ejaculation also may result from negative cultural conditioning. The man who has most of his early sexual contacts with prostitutes who demand that the sex act proceed quickly or in situations in which discovery would be embarrassing, such as in an apartment shared with roommates or in the parental home, may become conditioned to achieving orgasm rapidly. In ongoing relationships the partner has been found to have great influence on the premature ejaculator. A stressful marriage exacerbates the disorder. Table 19.1a-14 gives the diagnostic criteria for premature ejaculation.

A. Persistent or recurrent ejaculation with minimal sexual stimulation before, on, or shortly after penetration and before the person wishes it. The clinician must take into account factors that affect duration of the excitement phase, such as age, novelty of the sexual partner or situation, and recent frequency of sexual activity.
B. The disturbance causes marked distress or interpersonal difficulty.
C. The premature ejaculation is not due exclusively to the direct effects of a substance (e.g., withdrawal from opioids).

Table 19.1a-14 Diagnostic Criteria for Premature Ejaculation

Sexual Pain Disorders

Dyspareunia *Dyspareunia* refers to recurrent and persistent pain during intercourse in either a man or a woman. In women the dysfunction is related to and often coincides with vaginismus. Repeated episodes of vaginismus may lead to dyspareunia and vice versa, but in either case somatic causes must be ruled out. Dyspareunia should not be diagnosed as such when a medical basis for the pain is found or when (in a woman) it is associated with vaginismus or with lack of lubrication.

The true incidence of dyspareunia is unknown, but it has been estimated that 30 percent of surgical procedures on the female genital area result in temporary dyspareunia. Additionally, among women seen in sex therapy clinics, the complaint is more common in women with a history of rape or childhood sexual abuse.

Dynamic factors are usually considered causative, although situational factors probably account for more secondary dysfunction. Painful coitus may result from tense vaginal muscles. The pain is real and makes intercourse unbearable or unpleasant. Anticipation of further pain may cause the woman to avoid coitus altogether. If the partner proceeds with intercourse regardless of the woman's state of readiness, the condition is aggravated.

Dyspareunia can also occur in men, but it is uncommon and usually associated with a medical condition such as Peyronie's disease, prostatitis, or gonorrheal or herpetic infections. Vasocongestion during sexual activity without orgasmic release also may lead to discomfort. Rarely, some men experience pain upon ejaculation (postejaculatory pain disorder). This pain is caused by an involuntary spasm of the perineal muscles that may be due to physiological conflicts about the sex act or be an adverse effect of some antidepressant medications. Table 19.1a-15 lists the diagnostic criteria for dyspareunia. In DSM-IV, dyspareunia due to a general medical condition is used when the medical condition is the sole or major causal factor.

A. Recurrent or persistent genital pain associated with sexual intercourse in either a male or a female.
B. The disturbance causes marked distress or interpersonal difficulty.
C. The disturbance is not caused exclusively by vaginismus or lack of lubrication, is not better accounted for by another Axis I disorder (except another sexual dysfunction), and is not due exclusively to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition.

Table 19.1a-15 DSM-IV Diagnostic Criteria for Dyspareunia

Vaginismus *Vaginismus* is an involuntary and persistent constriction of the outer one third of the vagina that prevents penile insertion and intercourse. The response may be demonstrated during a gynecological examination when involuntary vaginal constriction prevents introduction of the speculum into the vagina, although some women only have vaginismus during coitus. The diagnosis is not made if the dysfunction is caused exclusively by medical or surgical factors or if it is symptomatic of another Axis I psychiatric syndrome (Table 19.1a-16). Vaginismus is less prevalent than anorgasmia. It most often afflicts highly educated women and those in the higher socioeconomic groups. A milder form of the dysfunction in which some vaginal tightness makes penile entry difficult is experienced by more women on an intermittent or chronic basis.

A. Recurrent or persistent involuntary spasm of the musculature of the outer third of the vagina that interferes with sexual intercourse.
B. The disturbance causes marked distress or interpersonal difficulty.
C. The disturbance is not better accounted for by another Axis I disorder (e.g., somatization disorder) and is not due exclusively to the direct physiological effects of a general medical condition.

Table 19.1a-16 DSM-IV Diagnostic Criteria for Vaginismus

A woman suffering from vaginismus may consciously wish to have coitus but unconsciously prevent penile entrance into her body. A sexual trauma, such as rape, may result in vaginismus. Women who have experienced pain with nonsexual bodily traumas, through accidents or because of illness or surgery, may become sensitized to the idea of penetration. Women with psychosexual conflicts may perceive the penis as a dangerous weapon. Pain or the anticipation of pain at the first coital experience causes vaginismus in some women. A strict religious upbringing that associates sex with sin is frequently noted in such cases. Others have problems in the dyadic relationship; a woman who feels emotionally abused by her partner may protest in this nonverbal fashion.

Miss M. was a 31-year-old accountant who presented for therapy stating that she was afraid to have intercourse. She was increasingly distressed by this problem as she was becoming more interested in forming a serious, loving relationship with a man. Miss M. was a virgin who had never had a serious boyfriend and who had little dating experience. However, she had experienced some petting sessions with men in which she allowed them to stimulate her genitally over her underwear, and she reported becoming excited. She also had sexual fantasies and masturbated to climax.

As a girl, the patient had been squeamish about menstruation, and she was unable to use tampons. Prior to therapy the she had never gone for a gynecological examination. A gynecological consultation was included in her workup. The gynecologist reported no abnormal findings, with the exception of extreme difficulty performing the examination even using the smallest available speculum. The patient reported anxiety and pain associated with the examination and felt light headed for some time after its completion.

She was given the diagnosis of vaginismus, lifelong type.

Sexual Dysfunction Due to a General Medical Condition The category sexual dysfunction due to a general medical condition covers sexual dysfunction that results in marked distress and interpersonal difficulty when there is evidence from the history, the physical examination, or the laboratory findings of a general medical condition judged to be causally related to the sexual dysfunction (Table 19.1a-17).

A. Clinically significant sexual dysfunction that results in marked distress or interpersonal difficulty predominates in the clinical picture.
B. There is evidence from the history, physical examination, or laboratory findings that the sexual dysfunction is fully explained by the direct physiological effects of a general medical condition.
C. The disturbance is not better accounted for by another mental disorder (e.g., major depressive disorder).

Select code and term based on the predominant sexual dysfunction:

Female hypoactive sexual desire disorder due to a general medical condition: if deficient or absent sexual desire is the predominant feature.

Male hypoactive sexual desire disorder due to a general medical condition: if deficient or absent sexual desire is the predominant feature.

Male erectile disorder due to a general medical condition: if male erectile dysfunction is the predominant feature.

Female dyspareunia due to a general medical condition: if pain associated with intercourse is the predominant feature.

Male dyspareunia due to a general medical condition: if pain associated with intercourse is the predominant feature.

Other female sexual dysfunction due to a general medical condition: if some other feature is predominant (e.g., orgasmic disorder) or no feature predominates.

Other male sexual dysfunction due to a general medical condition: if some other feature is predominant (e.g., orgasmic disorder) or no feature predominates.

Coding note: Include the name of the general medical condition on Axis I (e.g., male erectile disorder due to diabetes mellitus; also code the general medical condition on Axis III.

Table 19.1a-17 DSM-IV Diagnostic Criteria for Sexual Dysfunction Due to a General Medical Condition

Male Erectile Disorder Due to a General Medical Condition Many studies have focused on the relative incidences of psychological and organic male erectile disorder. Statistics indicate that 50 to 80 percent of men with erectile disorder have an organic basis for the disorder. The medical causes of male erectile dysfunction are listed in Table 19.1a-11. Adverse effects of medication may impair male sexual functioning in a variety of ways. Castration (removal of the testes) does not always lead to sexual dysfunction, depending on the person. Erection may still occur after castration, via a reflex arc fired when the inner thigh is stimulated that passes through the sacral cord erectile center.

PHYSIOLOGICAL TESTS A number of procedures, benign and invasive, are used to help differentiate psychogenic erectile dysfunction. The procedures include monitoring nocturnal penile tumescence (erection that occur during sleep) normally associated with rapid eye movement; monitoring tumescence with a strain gauge; measuring blood pressure in the penis with a penile plethysmograph or an ultrasound (Doppler) flow meter, both of which assess blood flow in the internal pudendal artery; and measuring pudendal nerve latency time. Neurological impairment of penile function may be indicated by decreased vibratory perception in the penis. Other diagnostic tests that delineate organic bases for erectile disorder include glucose tolerance test, plasma hormone assays, liver and thyroid function tests, prolactin and follicle-stimulating hormone (FSH) determinations, and cystometric examinations. Invasive diagnostic studies include penile arteriography, infusion cavernosography, and radioactive xenon penography. Invasive procedures require expert interpretation and are used only for patients who are candidates for vascular reconstructive procedures.

MEDICAL VERSUS PSYCHOGENIC CAUSES A good history is crucial to determining the cause of the male erectile disorder. If a man reports having spontaneous erections at times when he does not plan to have intercourse, having morning erections or only sporadic erectile dysfunction, or having good erections with masturbation or with partners other than his usual one, then organic causes for his disorder can be considered negligible, and costly diagnostic procedures can be avoided. When a medical basis for erectile dysfunction is found, psychological factors often contribute to the dysfunction, and psychiatric treatment may be helpful. Some diabetics, for instance, may experience psychogenic erectile dysfunction.

In general, the psychological conflicts that cause erectile dysfunction are related to an inability to express the sexual impulse because of fear, anxiety, anger, or moral prohibition. Lifelong dysfunction is a more serious, but less common, condition than acquired erectile disorder, and is less amenable to treatment.

Many developmental factors have been cited as contributing to erectile disorder. Any experience that hinders the ability to be intimate, that leads to a feeling of inadequacy or distrust, or that develops a sense of being unloving or unlovable may result in this problem. Erectile dysfunction in an ongoing relationship may reflect difficulties between the partners, particularly if one person cannot communicate his or her needs or angry feelings in a direct and constructive way. Successive episodes of impotence are reinforcing, with the man becoming increasingly anxious about his next sexual encounter. Regardless of the original cause of the dysfunction, his anticipatory anxiety about achieving and maintaining an erection interferes with his pleasure in sexual contact and his ability to respond to stimulation, thus perpetuating the problem.

Dyspareunia Due to a General Medical Condition An estimated 30 percent of all surgical procedures on the female genital area result in temporary dyspareunia. In addition, 30 to 40 percent of women with the complaint who are seen in sex therapy clinics have pelvic pathology. Organic abnormalities leading to dyspareunia and vaginismus include irritated or infected hymenal remnants, episiotomy scars, Bartholin's gland infection, various forms of vaginitis and cervicitis, and endometriosis. Postcoital pain reported by women with myomata and endometriosis is attributed to the uterine contractions during orgasm. Postmenopausal women may have dyspareunia because of thinning of the vaginal mucosa and reduced lubrication.

Dyspareunia can also occur in men, but it is uncommon and is usually associated with an organic condition such as Peyronie's disease, which consists of sclerotic plaques on the penis that cause penile curvature.

Hypoactive Sexual Desire Disorder Due to a General Medical Condition Desire commonly decreases after major illness or surgery, particularly when the body image is affected after such procedures as mastectomy, ileostomy, hysterectomy, and prostatectomy. Illnesses that deplete a person's energy, chronic conditions that require physical and psychological adaptation, and serious illnesses that may cause the person to become depressed can all result in a marked lessening of sexual desire in both men and women. In some cases, biochemical correlates are associated with hypoactive sexual desire disorder (Table 19.1a-18). A recent study found markedly lower serum testosterone concentrations in men complaining of low desire than in normal controls in a sleep-laboratory situation. Drugs that depress the CNS or decrease testosterone production can decrease desire.

	Dopamine	Serotonin	Adrenergic	Cholinergic	Clinical Correlation
Erection	++	+/-	α, β - +	+/-	Antipsychotics (dopamine receptor antagonists) may lead to erectile dysfunction; dopaminergic drug agonists may lead to enhanced erection and libido; yohimbine (α2 blocks), β-adrenergic receptor antagonists may lead to impotence
Ejaculation and orgasm	+/-	+	+ α1	+/-	α-adrenergic receptor antagonists, tricyclic drugs, MAOIs, thioridazine may lead to impaired ejaculation; serotonergic agents

* +/- = minimal or no effect; + = facilitates effect; - = inhibits effect.

Table 19.1a-18 Neurotransmitter Effects on Sex Function*

Other Male Sexual Dysfunction Due to a General Medical Condition The category other male sexual dysfunction due to a general medical condition is used when some other dysfunctional feature predominates (e.g., orgasmic disorder) or no feature predominates. Male orgasmic dysfunction may have physiological causes and can occur after surgery on the genitourinary tract, such as prostatectomy. It may also be associated with Parkinson's disease and other neurological disorders involving the lumbar or sacral sections of the spinal cord. The antihypertensive drug guanethidine monosulfate, methyldopa, the phenothiazines, the tricyclic drugs, and serotonin reuptake inhibitors, among others, have been implicated in retarded ejaculation. Male orgasmic disorder must also be differentiated from retrograde ejaculation, in which ejaculation occurs but the seminal fluid passes backward into the bladder. Retrograde ejaculation always has an organic cause. It can develop after genitourinary surgery and is also associated with medications with anticholinergic adverse effects, such as the phenothiazines.

Other Female Sexual Dysfunction Due to a General Medical Condition The category other female sexual dysfunction due to a general medical disorder is used when some other feature (e.g., orgasmic disorder) predominates or no feature predominates.

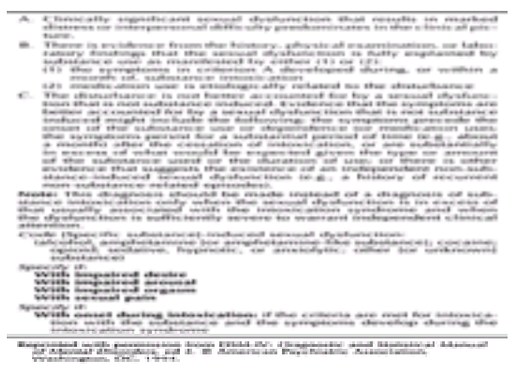
Some medical conditions—specifically such endocrine diseases as hypothyroidism, diabetes mellitus, and primary hyperprolactinemia—can affect a woman's ability to have orgasms. Also, a number of drugs affect some women's ability to have orgasms. Antihypertensive medications, CNS stimulants, tricyclic drugs, serotonin reuptake inhibitors, and frequently monoamine oxidase inhibitors (MAOIs) have interfered with female orgasmic capacity (Table 19.1a-19). However, one study of women taking MAOIs found that after 16 to 18 weeks of pharmacotherapy, that adverse effect of the medication disappeared, and the women could reexperience orgasms, although they continued taking an undiminished dosage of the drug.

Tricyclic antidepressants
Imipramine (Tofranil)
Clomipramine (Anafranil)
Nortriptyline (Aventyl)
Monoamine oxidase inhibitors
Tranylcypromine (Parnate)
Phenelzine (Nardil)
Isocarboxazid (Marplan)
Dopamine receptor antagonists
Thioridazine (Mellaril)
Trifluoperazine (Stelazine)
Selective serotonergic receptor inhibitors
Fluoxetine (Prozac)
Paroxetine (Paxil)
Sertraline (Zoloft)
Fluvoxamine (Luvox)
Citalopram (Celexa)

* The interrelation between female sexual dysfunction and pharmacological agents has been less extensively evaluated than have male reactions. Oral contraceptives are reported to decrease libido in some women, and some drugs with anticholinergic side effects may impair arousal as well as orgasm. Benzodiazepines have been reported to decrease libido, but in some patients the diminution of anxiety caused by these drugs enhances sexual function. Both increase and decrease in libido have been reported with psychoactive agents. It is difficult to separate these effects from the underlying condition or from improvement of the condition. Sexual dysfunction associated with the use of a drug disappears when the drug is discontinued.

Table 19.1a-19 Some Psychiatric Drugs Implemented in Inhibited Female Orgasm*

Substance-Induced Sexual Dysfunction The diagnosis substance-induced sexual dysfunction is used when evidence from the history, physical examination, or laboratory findings indicates substance intoxication or withdrawal when dysfunction follows the use of prescribed medication. Distressing sexual dysfunction occurs within a month of significant substance intoxication or withdrawal (Table 19.1a-20). Specified substances include alcohol; amphetamines or related substances; cocaine; opioids; sedatives, hypnotics, or anxiolytics; and other or unknown substances.



A. Clinically significant sexual dysfunction that results in marked distress or interpersonal difficulty predominates in the clinical picture.

B. There is evidence from the history, physical examination, or laboratory findings that the sexual dysfunction is fully explained by substance use as manifested by either (1) or (2):
(1) the symptoms in criterion A developed during, or within a month of, substance intoxication
(2) medication use is etiologically related to the disturbance

C. The disturbance is not better accounted for by a sexual dysfunction that is not substance induced. Evidence that the symptoms are better accounted for by a sexual dysfunction that is not substance induced might include the following: the symptoms precede the onset of the substance use or dependence or medication use; the symptoms persist for a substantial period of time (e.g., about a month) after the cessation of intoxication or are substantially in excess of what would be expected given the type or amount of the substance used or the duration of use; or there is other evidence that suggests the existence of an independent non-substance-induced sexual dysfunction (e.g., a history of recurrent non-substance-related episodes).

Note: This diagnosis should be made instead of a diagnosis of substance intoxication only when the sexual dysfunction is in excess of that usually associated with the intoxication syndrome and when the dysfunction is sufficiently severe to warrant independent clinical attention.

Code (Specify substance-induced sexual dysfunction):
(alcohol; amphetamine (or amphetamine-like substance); cocaine; opioid; sedative, hypnotic, or anxiolytic; other (or unknown) substance)

Specify (if):
With impaired desire
With impaired arousal
With impaired orgasm
With sexual pain

Specify (if):
With onset during intoxication: if the criteria are met for intoxication with the substance and the symptoms develop during the intoxication syndrome

Table 19.1a-20 DSM-IV Diagnostic Criteria for Substance-Induced Sexual Dysfunction

Abused recreational substances affect sexual function in various ways. In small doses many substances enhance sexual performance by decreasing inhibition or anxiety or by temporarily elevating mood. However, continuous use impairs erectile, orgasmic, and ejaculatory capacities. The abuse of sedatives, anxiolytics, and particularly opiates and opioids nearly always depresses desire. Alcohol may foster the initiation of sexual activity by removing inhibitions, but it impairs performance. Cocaine and amphetamines produce similar effects. Although no direct evidence indicates that sexual drive is enhanced, the user initially has a feeling of increased energy and may become sexually active. Ultimately, dysfunction occurs. Men usually go through two stages: prolonged erection without ejaculation and then a gradual loss of erectile capacity.

Recovering substance-dependant patients may need therapy to regain sexual function. In part, this is one piece of psychological readjustment to a nondependent state. Many substance abusers have always had difficulty with intimate interactions. Others have missed the experience that would have enabled them to learn social and sexual skills because they spent their crucial developmental years under the influence of some substance.

Pharmacological Agents Implicated in Sex Dysfunction Many pharmacological agents, particularly those used in psychiatry, have been associated with an effect on sexuality. In men those effects include decreased sex drive, erectile failure (impotence), decreased volume of ejaculate, and delayed or retrograde ejaculation. In women decreased sex drive, decreased vaginal lubrication, inhibited or delayed orgasm, and decreased or absent vaginal contractions may occur. Drugs may also enhance the sexual response and increase the sex drive, but that effect is less common than are adverse effects.

Antipsychotic Drugs Most antipsychotic drugs are dopamine receptor antagonists that also block adrenergic and cholinergic receptors, which accounts for their adverse sex effects. Chlorpromazine (Thorazine), thioridazine, trifluoperazine (Stelazine), and haloperidol (Haldol) are potent anticholinergic agents that impair erection and ejaculation in men and inhibit vaginal lubrication and orgasm in women. Chlorpromazine and thioridazine also block adrenergic receptors. Thioridazine has a particular adverse effect of causing retrograde ejaculation in which the seminal fluid backs up into the bladder rather than being propelled through the penile urethra. Patients still have a pleasurable sensation of orgasm, but it is dry. When urinating after orgasm, the urine may be milky white since it contains the ejaculate. The condition is startling but harmless and may occur in up to 50 percent of patients taking the drug. Paradoxically, rare cases of priapism have been reported with antipsychotics.

Antidepressant Drugs The antidepressant drugs may be subdivided into heterocyclic drugs, such as imipramine (Tofranil); the SSRIs, such as fluoxetine; and the MAOIs, such as phenelzine (Nardil).

Sexual dysfunction has been reported with almost all antidepressants, including changes in libido, impaired erectile capacity, and such ejaculatory/orgasmic dysfunction as associated discomfort and delayed or inhibited ejaculation or orgasm. The sexual adverse effects of these drugs are of particular concern since over 65 million prescriptions a year for antidepressants have been dispensed since 1997.

The most commonly prescribed group of antidepressants are the selective serotonin reuptake inhibitors (SSRIs). Adverse sexual effects may occur with this group of drugs because of increased serotonin concentration. A lowering of the sex drive and difficulty reaching orgasm occur in both sexes. Of the SSRIs, the most frequent sexual adverse effects are seen with paroxetine (Paxil), next with fluoxetine (Prozac) and the least with sertraline (Zoloft). Similar symptoms have been associated with fluvoxamine (Luvox) and citaloprom (Celexa). Reversal of negative effects has been achieved with cyproheptadine (Periactin), an antihistamine with antiserotonergic effects; amantadine (Symmetrel), a dopamine agonist; yohimbine, (Yocon) a central a_2 adrenergic receptor antagonist used in treating male erectile disorder, and methylphenidate (Ritalin), or dextroamphetomine which are dopaminergic and have adrenergic effects. There have been anecdotal reports of sildenafil (Viagra), a nitric oxide enhancer used to treat erectile dysfunction, overcoming orgasmic problems associated with the SSRIs. However, this remedy has not been systematically studied.

The tricyclic and tetracyclic antidepressants have anticholinergic effects that interfere with erection and delay ejaculation. Since the anticholinergic effects vary among the cyclic antidepressants, those with the fewest side effects (e.g., desipramine [Norpramin]) produce the fewest sexual side effects. The effects of the heterocyclic drugs in women have not been studied sufficiently; however, few women seem to complain of any effects. Selegiline (Eldepryl) is a selective monoamine oxidase type B (MAO_B) inhibitor reported to increase sex drive, possibly by dopaminergic activity and increased production of norepinephrine.

Some men reported a pleasurable increased sensitivity of the glans that does not interfere with erection, although it delays ejaculation. In some cases, however, the tricyclic drug causes a painful ejaculation, perhaps as the result of interference with seminal propulsion caused by interference with urethral, prostatic, vas, and epididymal smooth muscle contractions. Clomipramine (Anafranil) has been reported to increase sex drive in some persons. Buspirone (Buspar) helps some patients overcome adverse sexual effect of SSRI's, possibly because it is an 5-HT_A agonist or because it suppresses SSRI induced elevation of prolactin.

The MAOIs affect biogenic amines broadly. Accordingly, they produce impaired erection, delayed or retrograde ejaculation, vaginal dryness, and inhibited orgasm. Tranylcypromine (Parnate) has a paradoxical sexually stimulating effect in some persons, possibly as a result of its amphetamine-like properties.

GENERAL EFFECTS Since depression is associated with a decreased libido, varying levels of sexual dysfunction and anhedonia are part of the disease process. That phenomenon makes assessment of dysfunction as a result of sexual side effects in patients taking the drugs difficult. Some patients report improved sexual function as their depression improves with antidepressant medication. Sometimes sexual side effects disappear with time, perhaps because a biogenic amine homeostatic mechanism comes into play. In many cases, antidepressants without associated side effects of sexual dysfunction are substituted, such as bupropion (Wellbutrin), nefazadone (Serzone), or mirtazapine (Remeron). There have been rare, individual reports of orgasmic dysfunction with the latter two drugs.

Lithium Lithium regulates mood and in the manic state may reduce hypersexuality, possibly by a dopamine antagonist activity. Others have reported impaired erection.

Psychostimulants Psychostimulants are sometimes used in the treatment of depression and include amphetamine, methylphenidate, and pemoline (Cylert), which raise plasma concentrations of norepinephrine and dopamine. Libido is increased; however, with prolonged use, men may experience a loss of desire and erections. One study found that ephedrine sulfate facilitated arousal in functional women.

a-Adrenergic and b-Adrenergic Receptor Antagonists Adrenergic receptor antagonists are used to treat hypertension, angina, and certain cardiac arrhythmias. They diminish tonic sympathetic nerve outflow from vasomotor centers in the brain. As a result, they can cause impotence, decrease the volume of ejaculate, and produce retrograde ejaculation. Changes in libido have been reported in both sexes. Suggestions have been made to use the side effects of drugs therapeutically. Thus a drug that delays or interferes with ejaculation (such as fluoxetine) might be used to treat premature ejaculation.

Anticholinergics The anticholinergics block cholinergic receptors and include such drugs as amantadine and benztropine (Cogentin). They can produce dryness of the mucous membranes (including those of the vagina) and erectile dysfunction.

Antihistamines Drugs such as diphenhydramine (Benadryl) have anticholinergic activity and are mildly hypnotic. They may inhibit sexual function as a result. Cyproheptadine, although an antihistamine, also has potent activity as a serotonin antagonist. It is used to block the serotonergic sexual adverse effects produced by SSRIs, such as delayed orgasm and erectile dysfunction.

Antianxiety Agents The major class of antianxiety drugs is the benzodiazepines (e.g., diazepam [Valium]). They act on the g-aminobutyric (GABA) receptors, which are believed to be involved in cognition, memory, and motor control. Because they decrease plasma epinephrine concentration, they diminish anxiety; thus they improve sexual function in persons inhibited by anxiety.

Alcohol Alcohol suppresses CNS activity generally and hence can produce erectile disorders in men. Alcohol has a direct gonadal effect that decreases testosterone concentrations in men; paradoxically, it can produce a slight increase in testosterone concentrations in women. This may account for increased libido in women after drinking small amounts of alcohol. Long-term use of alcohol reduces the ability of the liver to metabolize estrogenic compounds; in men this produces signs of feminization (e.g., gynecomastia as a result of testicular atrophy).

Opioids Opioids such as heroin have such adverse sexual effects as erectile failure and decreased libido. Altered consciousness may enhance the sexual experience in occasional users.

Hallucinogens The hallucinogens include lysergic acid diethylamide (LSD), phencyclidine (PCP), psilocybin (from some mushrooms), and mescaline (from peyote cactus). In addition to inducing hallucinations, the drugs cause loss of contact with reality and an expanding and heightening of consciousness. Some users report that the sexual experience is similarly enhanced; others experience anxiety, delirium, or psychosis, which clearly interferes with sex function.

Cannabis The altered state of consciousness produced by cannabis may enhance sexual pleasure for some persons. Its prolonged use depresses testosterone concentrations.

Barbiturates and Similarly Acting Drugs Barbiturates are sedative-hypnotics that may enhance sexual responsiveness in persons who are sexually unresponsive because of anxiety. They have no direct effect on the sex organs; however, they do alter consciousness, which some persons find pleasurable. They are subject to abuse and may be fatal when combined with alcohol or other CNS depressants. Methaqualone (Quaalude) acquired a reputation as a sexual enhancer that had no biological basis in fact. It is no longer marketed in the United States.

Sexual Dysfunction and Sexual Disorder Not Otherwise Specified DSM-IV uses two categories-sexual dysfunction not otherwise specified and sexual disorder not otherwise specified. The diagnostic criteria are listed in Table 19.1a-21 and Table 19.1a-22, respectively. The distinction between the two categories is unclear, however, and there is overlap between them. Many sexual disorders are not classifiable as sexual dysfunctions or as paraphilias. These unclassified disorders are rare, poorly documented, not easily classified, or not specifically described in DSM-IV. ICD-10 has a similar residual category for problems related to sexual development or preference (Table 19.1a-23).

This category includes sexual dysfunctions that do not meet criteria for any specific sexual dysfunction: Examples include.

1. No (or substantially diminished) subjective erotic feelings despite otherwise normal arousal and orgasm
2. Situations in which the clinician has concluded that a sexual dysfunction is present but is unable to determine whether it is primary, due to a general medical condition, or substance induced

Table 19.1a-21 DSM-IV Diagnostic Criteria for Sexual Dysfunction Not Otherwise Specified

This category is included for coding a sexual disturbance that does not meet the criteria for any specific sexual disorder and is neither a sexual dysfunction nor a paraphilia. Examples include

1. Marked feelings of inadequacy concerning sexual performance or other traits related to self-imposed standards of masculinity or femininity
2. Distress about a pattern of repeated sexual relationships involving a succession of lovers who are experienced by the individual only as things to be used
3. Persistent and marked distress about sexual orientation

Table 19.1a-22 DSM-IV Diagnostic Criteria for Sexual Disorder Not Otherwise Specified

This section is intended to cover those types of problems that derive from variations of sexual development or orientation, when the sexual preference per se is not necessarily problematic or abnormal.

Sexual maturation disorder
The patient suffers from uncertainty about his or her gender identity or sexual orientation, which causes anxiety or depression.

Ego-dystonic sexual orientation
The gender identity or sexual preference is not in doubt, but the individual wishes it were different.

Sexual relationship disorder
The abnormality of gender identity or sexual preference is responsible for difficulties in forming or maintaining a relationship with a sexual partner.

Other psychosexual development disorders

Psychosexual development disorder, unspecified

Table 19.1a-23 ICD-10 Diagnostic Criteria for Psychological and Behavioral Disorders Associated With Sexual Development and Orientation

Examples include persons who experience the physiological components of sexual excitement and orgasm but report no erotic sensation or even anesthesia and the male experience of orgasm with a flaccid penis. The orgasmic female who desires, but has not experienced, multiple orgasms can be classified under this heading as well. Also, disorders of excessive rather than inhibited function, such as compulsive masturbation, might be diagnosed under atypical dysfunction. Other sexual practices exist that are not listed in DSM-IV, for example, behaviors that attempt to enhance sexual arousal by oxygen deprivation (hypoxyphilia) or other deviant methods. Atypical dysfunction also might be used to cover complaints engendered by couple, rather than individual, dysfunction; for example, a couple in which one partner prefers morning sex and the other functions more readily at night or a couple with unequal frequencies of desire.

Compulsive Sexual Behavior The concept of compulsive sexual behavior, or sex addiction, developed over the past two decades to describe persons who compulsively seek out sexual experiences and whose behavior becomes impaired if they cannot gratify their sexual impulses. The concept of sex addiction derived from the model of addiction to such drugs as heroin, or addiction to behavioral patterns, such as gambling. Addiction implies psychological dependence, physical dependence, and a withdrawal symptom if the substance (e.g., the drug) is unavailable or the behavior (e.g., gambling) is frustrated.

DSM-IV does not use the terms *sex addiction* or *compulsive sexual behavior*, nor is this disorder universally recognized or accepted. Nevertheless, the person whose entire life revolves around sex-seeking behavior and activities, who spends an excessive amount of time in such behavior, and who often tries to stop such behavior but cannot do so is well known to clinicians. Such persons show repeated and increasingly frequent attempts to have a sexual experience, and deprivation evokes symptoms of distress. In the author's view sex addiction is a useful concept heuristically because it can alert the clinician to seek an underlying cause for the manifest behavior.

DIAGNOSIS Sex addicts cannot control their sexual impulses, which can involve the entire spectrum of sexual fantasy or behavior. The need for sexual activity increases, and the person's behavior is motivated largely by the persistent desire to experience the sex act. The history usually reveals a long-standing pattern of such behavior, which the person repeatedly tried to stop without success. Although feelings of guilt and remorse may exist after the act, they do not prevent its recurrence. The patient may report that the need to act out is most severe during stressful periods or when angry, depressed, anxious, or otherwise dysphoric. Most acts culminate in a sexual orgasm, although a sense of excitement (a high) usually accompanies the sex-seeking behavior even in the absence of orgasm. Eventually, the sexual activity interferes with the person's social, vocational, or marital life, which begins to deteriorate.

The signs of sexual addiction are listed in Table 19.1a-24.

1. Out-of-control behavior
2. Severe adverse consequences (medical, legal, interpersonal) due to sexual behavior
3. Persistent pursuit of self-destructive or high-risk sexual behavior
4. Repeated attempts to limit or stop sexual behavior
5. Sexual obsession and fantasy as a primary coping mechanism
6. Need for increasing amounts of sexual activity
7. Severe mood changes related to sexual activity (e.g., depression, euphoria)
8. Inordinate amount of time spent in obtaining sex, being sexual, or recovering from sexual experience
9. Interference of sexual behavior in social, occupational, or recreational activities

Data from Carnes P: *Don't Call It Love*. Bantam Books, New York, 1991.

Table 19.1a-24 Signs of Sexual Addiction or Compulsive Sexual Behavior

TYPES OF BEHAVIORAL PATTERN Compulsive sexual behavior is seen in males more than females in a ratio of 4 to 1. The paraphilias constitute the behavioral patterns frequently found in the sex addict. As defined in DSM-IV, the essential features of a paraphilia are recurrent intense sexual urges or behaviors, including exhibitionism, fetishism, frotteurism, sadomasochism, cross-dressing, voyeurism, and pedophilia. Paraphilias are associated with clinically significant distress and almost invariably interfere with interpersonal relationships; they often lead to legal complications. In addition to the paraphilias, however, sex addiction can also include behavior considered normal, such as coitus and masturbation, except that it is promiscuous and uncontrolled. Paradoxically, the sex addict may suffer from a sexual disorder such as erectile dysfunction or orgasmic inhibition.

In the nineteenth century Krafft-Ebing reported several cases of abnormally increased sexual desire. One involved a 36-year-old married teacher, the father of seven children, who masturbated repeatedly while sitting at his desk in front of his pupils, after which he was “penitent and filled with shame.” He indulged in coitus three or four times a day in addition to his repeated masturbatory acts. In another case, a young woman masturbated almost incessantly and was unable to control her impulses. She had frequent coitus with many men, but neither coitus or masturbation sufficed, and she eventually was placed in an institution. Krafft-Ebing referred to the condition as *sexual hyperaesthesia*, which he believed could occur in otherwise normal persons.

In many cases sex addiction is the final common pathway of a variety of other disorders. In addition to the paraphilias that are frequently present, there may be an associated major mental disorder, such as anxiety, depressive disorder, bipolar disorder, or schizophrenia. Antisocial personality disorder and borderline personality disorder are common.

COMORBIDITY Comorbidity (dual diagnosis) refers to the presence of an addiction that coexists with another psychiatric disorder. For example, about 50 percent of patients with substance-use disorder also have an associated psychiatric disorder. Dual diagnosis implies that the psychiatric illness and the addiction are separate disorders; one does not cause the other. The diagnosis of comorbidity is often difficult to make because addictive behavior (of all types) can produce extreme anxiety and severe disturbances in mood and affect, especially while the addictive behavior is treated. If symptoms of a psychiatric disorder remain after a period of abstinence, the comorbid condition is more easily recognized and diagnosed. Finally, sex addiction and substance-use disorders are highly correlated (up to 80 percent in some studies), which complicates both diagnosis and treatment.

MANAGEMENT Self-help groups based on the 12-step concept used in Alcoholics Anonymous (AA) have been employed successfully with many sex addicts. They

include such groups as Sexaholics Anonymous (SA), Sex and Love Addicts Anonymous (SLAA), and Sex Addicts Anonymous (SAA). The groups differ in that some are for men or women or for married persons or couples. All advocate some abstinence from either the addictive behavior or sex in general. If a substance-use disorder is also present, the patient often requires referral to AA or Narcotics Anonymous (NA) as well. Patients may enter an impatient treatment unit when they lack sufficient motivation to control their behavior on an outpatient basis or are a danger to self or others. Additionally, medical or psychiatric symptoms may require careful supervision and treatment best carried out in a hospital.

Mr. P., a 44-year-old man, was married for the second time. He presented with feelings of depression. His history revealed a pattern of chronic dissatisfaction in his intimate relationships, a persistent problem of orgasmic inhibition in his sexual interactions, and a need to masturbate four or five times a day. He had no problem ejaculating with masturbation. He would get up at 4 o'clock in the morning to watch pornography without his wife knowing and masturbate, He would interrupt work several times a day to go to the men's room and masturbate, historically with pornographic magazines, and after computers were installed in his office, following pornographic interchange with unknown women on the computer. He constantly fantasized about women he would see at work or on the street and occasionally followed them, although he did not accost them. The patient believed that one of the women that appealed to him sexually would turn out to be the love of his life. However, he had felt that way initially about both wives and about many women with whom he had had affairs. All his interactions ended with his feeling dissatisfied and disappointed.

Mr. P. was one of four children in a middle-class family. His father became disabled when the patient was 6 years old, and he remembers his father either lying in bed or sitting alone in the basement. He died when the patient was 10. The mother was described as caring but stressed by the responsibility of raising the family herself and not emotionally available. Mr. P. masturbated “incessantly” throughout his adolescence and married the first woman with whom he had coitus, during his senior year in college. She was 2 years old than he. He interrupted his habit of masturbation only to allow his wife to conceive when she pressured him to have a baby. However, after the couple had a child he had a series of affairs, one involving the woman who became his second wife.

Mr. P., an intelligent and successful man, continually put his relationships and career in jeopardy with his sexual compulsivity. He would not stop masturbation even though he knew he might be caught at work; he had experienced sex as an anodyne for his depression and emotional needs during adolescence and could not give it up. Therapy for Mr. P. entailed a multimodal approach including insight-orientated psychotherapy, group work with other sex addicts, couple therapy, and the use of a specific serotonin reuptake inhibitor, both to treat his depression and for its side effect of decreasing libido.

PSYCHOTHERAPY Insight-oriented psychotherapy may help patients understand the dynamics of their behavioral patterns. Supportive psychotherapy can help repair the interpersonal, social, or occupational damage that occurs. Cognitive-behavioral therapy helps the patient recognize dysphoric states that precipitate sexual acting out. Marital therapy or couples therapy can help the couple establish or reestablish communication, which is usually severely impaired by the time a treatment program is begun. Finally, psychotherapy may help in the treatment of any associated psychiatric disorder.

PHARMACOTHERAPY Most specialists in general addiction avoid the use of pharmacological agents, especially in the early stages of treatment. Substance-dependent persons tend to abuse these agents, especially those with a high abuse potential, such as benzodiazepines. Pharmacotherapy is of use in the treatment of such associated psychiatric disorders as major depressive disorder and schizophrenia.

Certain medications may help the sex addict, however, because of their specific effects on reducing the sex drive. Fluoxetine and other SSRIs reduce libido in some persons, a side effect that is used therapeutically. Compulsive masturbation is an example of a behavioral pattern that may benefit from such medication. Medroxyprogesterone acetate (Depo-Provera) diminishes libido in men and thus helps them control sexually addictive behavior. However, this medication is rarely prescribed by therapists.

The use of antiandrogens to control hypersexuality in women has not been sufficiently tested, but since androgenic compounds contribute to the sex drive in women, antiandrogens could be of benefit. Antiandrogenic agents are not available in the United States but are used in Europe with varying success.

Postcoital Dysphoria Postcoital dysphoria is not listed in DSM-IV. It occurs during the resolution phase of sexual activity, when persons normally experience a sense of general well-being and muscular and psychological relaxation. Some persons, however, experience postcoital dysphoria; after an otherwise satisfactory sexual experience, they become depressed, tense, anxious, and irritable and show psychomotor agitation. They often want to get away from the partner and may become verbally or even physically abusive. The incidence of the disorder is unknown, but it is more common in men than in women. Its several causes relate to the person's attitude toward sex in general and the partner in particular. It may occur in adulterous sex and with prostitutes or when individuals cannot experience sex without consequential strong feelings of guilt. The fear of AIDS causes some persons to experience postcoital dysphoria. Treatment requires insight-oriented psychotherapy to help patients understand the unconscious antecedents to their behavior and attitudes.

Unconsummated Marriage A couple involved in an unconsummated marriage have never had coitus and are typically uninformed and inhibited about sexuality. Their feelings of guilt, shame, or inadequacy are increased by their problems, and they experience conflict between their need to seek help and their need to conceal their difficulty. Couples present with the problem after having been married several months or several years. Masters and Johnson reported an unconsummated marriage of 17 years duration.

Frequently, the couple does not seek help directly, but the woman may reveal the problem to her gynecologist on a visit ostensibly concerned with vague vaginal or other somatic complaints. On examining her, the gynecologist may find an intact hymen. In some cases though, the wife may have undergone a hymenectomy to resolve the problem. That surgical procedure is another stress and sometimes increases the feelings of inadequacy in the couple. The wife may feel put upon, abused, or mutilated, and the husband's concern about his manliness may increase. Inquiry by a physician who is comfortable in dealing with sexual problems may be the first opening to a frank discussion of the couple's distress. Often, the pretext of the medical visit is a discussion of contraceptive methods or—even more ironically—a request for an infertility workup. Once presented, the complaint can often be successfully treated. The duration of the problem does not significantly affect the prognosis or the outcome of the case.

The causes of unconsummated marriage are varied: lack of sex education, sexual prohibitions overly stressed by parents or society, problems of an oedipal nature, immaturity in both partners, overdependence on primary families, and problems in sexual identification. Religious orthodoxy, with severe control of sexual and social development or the equation of sexuality with sin or uncleanliness has also been cited as a dominant cause. Many women involved in an unconsummated marriage have distorted concepts about their vaginas. They may fear that the vagina is too small or too soft, or they may confuse the vagina with the rectum, leading to feelings of being unclean. The man may share in those distortions about the vagina and, in addition, perceive it as dangerous to himself. Similarly, both partners may have distortions about the man's penis, perceiving it as a weapon, as too large, or as too small. Many patients can be helped by simple education about genital anatomy and physiology, by suggestions for self-exploration, and by correct information from a physician. The problem of the unconsummated marriage is best treated by seeing both members of the couple. Dual-sex therapy has been markedly effective. However, other forms of conjoint therapy, marital counseling, traditional psychotherapy on a one-to-one basis, and counseling from a sensitive family physician, gynecologist, or urologist are all helpful.

Body Image Problems Some persons are ashamed of their bodies and experience feelings of inadequacy related to self-imposed standards of masculinity or femininity. They may insist on sex only during total darkness, not allow certain body parts to be seen or touched, or seek unnecessary operative procedures to deal with their imagined inadequacies. Body dysmorphic disorder should be ruled out.

Don Juanism Some men who appear to be hypersexual, as shown by their need to have many sexual encounters or conquests, use their sexual activities to mask deep feelings of inferiority. Some have unconscious homosexual impulses, which they deny by compulsive sexual contacts with women. After having sex, most Don Juans are no longer interested in the woman. The condition is also referred to as satyriasis or a form of sex addiction.

Nymphomania Nymphomania signifies excessive or pathological desire for coitus in a woman. There have been few scientific studies of the condition. Those patients who have been studied usually have had one or more sexual disorders, usually including female orgasmic disorder. The woman often has an intense fear of loss of love. She attempts to satisfy her dependency needs, rather than to gratify her sexual impulses through her actions. It is sometimes classified as a form of sex addiction.

Fantasies Other atypical disorders are found in persons who have one or more sexual fantasies about which they obsess, feel guilty, or are otherwise dysphoric. As indicated in Table 19.1a-25 however, the range of common sexual fantasies is broad.

Men	Women
Heterosexual	
Replacement of established partner	Replacement of established partner
Forced sexual encounters with woman	Forced sexual encounters with man
Observing sexual activity	Observing sexual activity
Sexual encounters with man	Idyllic encounters with unknown man
Group sex	Sexual encounters with woman
Homosexual	
Images of male anatomy	Forced sexual encounters with women
Forced sexual encounters with men	Idyllic encounters with established partner
Sexual encounters with women	Sexual encounters with man
Idyllic encounters with unknown men	Memories of past sexual experiences
Group sex	Sadistic imagery

* Listed in order of occurrence. A 1994 study found that one in five persons experienced a same-sex sexual fantasy at some time in their lives.
Adapted with permission from Masters WF, Johnson VE: The Masters and Johnson treatment program for dissatisfied homosexual men. Am J Psychiatry 145:173, 1988.

Table 19.1a-25 Common Sexual Fantasies*

Persistent and Marked Distress About Sexual Orientation Distress about sexual orientation is characterized by a dissatisfaction with homosexual arousal patterns, a desire to increase heterosexual arousal, and strong negative feelings about being homosexual. Occasional statements to the effect that life would be easier if the person were not homosexual do not constitute persistent and marked distress about sexual orientation.

Treatment of sexual orientation distress is controversial. One study reported that with a minimum of 350 hours of psychoanalytic therapy, about a third of about 100 bisexual and homosexual men achieved a heterosexual reorientation at 5-year follow-up, but that study was challenged and was never replicated. Behavior therapy and avoidance conditioning techniques have also been used, but a basic problem with behavioral technique is that the behavior may be changed in the laboratory setting but not outside the laboratory. Prognostic factors weighing in favor of heterosexual reorientation for men include being under 35 years of age, having some experience of heterosexual arousal, and having a high motivation for reorientation.

Another style of intervention is directed at enabling the person with persistent and marked distress about sexual orientation to live comfortably as a homosexual without shame, guilt, anxiety, or depression. Gay counseling centers are engaged with patients in such treatment programs. At present, outcome studies of such centers have not been reported in detail.

Few data are available about the treatment of women with persistent and marked distress about sexual orientation, and those are primarily single-case studies with variable outcomes.

Postcoital Headache Postcoital headache is a headache immediately after coitus and may last for several hours. It is usually described as throbbing, and it is localized in the occipital or frontal area. The cause is unknown but may be vascular, muscle contraction (tension), or psychogenic. Coitus may precipitate migraine or cluster headaches in predisposed persons.

Orgasmic Anhedonia Orgasmic anhedonia is a condition in which the person had no physical sensation of orgasm, even though the physiological component (e.g., ejaculation) remains intact. Medical causes, such as sacral and cephalic lesions that interfere with afferent pathways from the genitalia to the cortex, must be ruled out. Psychic causes usually relate to extreme guilt about experiencing sexual pleasure. Those feelings produce a type of dissociative response that isolates the affective component of the orgasmic experience form consciousness.

Female Premature Orgasm Data on female premature orgasm are lacking; no separate category of premature orgasm for women is included in DSM-IV. However, in the University of Chicago study, 10 percent of women felt they reached orgasm too quickly.

Masturbatory Pain Some persons may experience pain during masturbation. Organic causes should always be ruled out. A small vaginal tear or early Peyronie's disease may produce a painful sensation. The condition should be differentiated from compulsive masturbation. People may masturbate to the extent that they do physical damage to their genitals and eventually experience pain during subsequent masturbatory acts. Such cases constitute a separate sexual disorder and should be so classified.

Autoerotic Asphyxiation Certain masturbatory practices have resulted in what has been called autoerotic asphyxiation. The practices may involve masturbating while hanging by the neck to heighten erotic sensations and the intensity of the orgasm through the mechanism of mild hypoxia. Although they intend to release themselves from the noose after orgasm, an estimated 500 to 1000 persons a year accidentally kill themselves by hanging. Most who indulge in the practice are men; transvestism is often associated with the habit, and most deaths occur among adolescents. Such masochistic practices are usually associated with severe mental disorders such as schizophrenia and major mood disorders.

TREATMENT

The treatment of sexual disorders has evolved significantly since the 1970s when Masters and Johnson refocused the attention of the psychiatric community on sexual disorders. Innovations in treatment reflect the results of research and changes in the patient population. For example, in the late 1960s most cases of erectile dysfunction were considered psychological in origin, with about 20 percent of erectile problems having an organic cause. Currently, the numbers are reversed, with the majority of cases considered to result from a physiological problem. Actually, many cases are of mixed origin. Similarly, early patients in sex therapy were assumed to suffer in part from lack of sexual information and culturally reinforced negative attitudes toward sex. In the past 30 years the public has received a great deal of accurate information about sex through the media, and cultural attitudes regarding sexual behavior have become markedly more liberal. Patients now have more knowledge and greater sexual sophistication. Their dysfunctions have a complex etiology frequently involving psychodynamic and relational issues. Problems of desire are seen with increasing frequency and are among the most challenging cases for therapists. Couple issues involve problems of trust, intimacy, lack of sexual attraction, and struggles for dominance. Finally, along with the rest of psychiatry, sex therapy has experienced medicalization. Biological treatment approaches have developed rapidly. An eclectic approach that allows the use of several techniques sequentially or in combination may be necessary.

Before entering therapy, the patient should have a thorough medical evaluation, including a medical history, physical examination, and appropriate laboratory studies when necessary. If a medical cause for the disorder is found, treatment should be directed toward ameliorating that cause.

Prior to 1970 the most common treatment of sexual dysfunction was individual psychotherapy. Classic psychodynamic theory considers sexual inadequacy to have its roots in early developmental conflicts, and the sexual disorder is treated as part of a more pervasive emotional disturbance. Treatment focuses on the exploration of unconscious conflicts, motivation, fantasy, and various interpersonal difficulties. Therapy assumes that removal of the conflicts will allow the sexual impulse to become structurally acceptable to the patient's ego and thereby find appropriate means of satisfaction in the environment. Unfortunately, the symptom of sexual dysfunction frequently becomes secondarily autonomous and persists after resolution of the other problems evolving from the patient's pathology. The addition of behavioral techniques are often necessary to cure the sexual problem.

Dual-Sex Therapy The theoretical basis of the dual-sex therapy approach is the concept of the marital unit or dyad as the object of therapy. The method of dual-sex therapy was originated and developed by Masters and Johnson. Dual-sex therapy does not accept the idea of a sick half of a patient couple. Both are involved in a relationship in which there is sexual distress, and thus both must participate in the therapy program.

The sexual problem often reflects other areas of disharmony or misunderstanding in the marriage. The marital relationship as a whole is treated, with emphasis on sexual functioning as a part of that relationship. Improved communication in sexual and nonsexual areas is a specific goal of treatment. Psychological and physiological aspects of sexual functioning are discussed with an educational attitude. Suggestions are followed in the privacy of the couple's home.

Initial histories are taken to determine suitability for this type of treatment. Evidence of major underlying psychopathology suggests further psychiatric evaluation, and participation in the program may be deferred until the patient seems better able to benefit from it. Concurrent psychotherapy with a psychiatrist while participating in

dual-sex therapy is sometimes recommended.

Each patient is interviewed individually early in the course of treatment. A complete sexual history is obtained, which is later reflected back to the couple, to help them understand their present problem. The individual sessions also help the therapist understand the patients' lifestyle and make suggestions that fit into that lifestyle.

Behavioral Exercises Treatment is short term and behaviorally oriented. Specific exercises are prescribed to help the couple with their particular problem. Sexual dysfunction often involves a fear of inadequate performance; thus couples are specifically prohibited from any sexual play other than that prescribed by the therapist. Initially, intercourse is interdicted, and couples learn to give and receive bodily pleasure without the pressure of performance. Beginning exercises usually focus on heightening sensory awareness to touch, sight, sound, and smell.

During those exercises, called *sensate focus exercises*, the couple is given much reinforcement to lessen anxiety. They are urged to use fantasies to distract them from obsessive concerns about performance, which is termed *spectatoring*. The needs of both the dysfunctional partner and the nondysfunctional partner are considered. If either partner becomes sexually excited by the exercises, the other is encouraged to bring him or her to orgasm by manual or oral means. That procedure is important to keep the nondysfunctional partner from sabotaging the treatment. Open communication between the partners is urged, and the expression of mutual needs is encouraged. Resistances, such as claims of fatigue or not enough time to complete the exercises, are common and must be dealt with by the therapist. Genital stimulation is eventually added to general body stimulation. The couple is sequentially taught to try various positions for intercourse without necessarily completing the act, and to use varieties of stimulating techniques before they are permitted to proceed with intercourse.

The specific exercises vary with differing presenting complaints, and special techniques are used to treat the various dysfunctions. In cases of vaginismus, for instance, the woman is advised to dilate her vaginal opening with her fingers or with size-graduated vaginal dilators as part of the therapy. In cases of premature ejaculation an exercise known as the *squeeze technique* is used to raise the threshold of penile excitability. In that exercise the man or the woman stimulates the erect penis until the earliest sensations of impending orgasm and ejaculation are felt. Penile stimulation is then stopped abruptly, and the coronal ridge of the penis is forcibly squeezed for several seconds. The technique is repeated several times. A variation is the *stop-start technique* in which stimulation is interrupted for several seconds but no squeeze is applied. Masturbation to the point of imminent orgasm raises the threshold of excitability to a more tolerant stimulation level. The man is encouraged to focus on sensations of excitement rather than distract himself from them. This makes him more familiar with his excitement pattern and lets him feel in control rather than overwhelmed by sensations of arousal. Communication between the partners is improved, because the man must let his partner know his level of sexual excitement so that she can squeeze the penis before the ejaculatory process has started. Sex therapy has been successful with some premature ejaculators; however, a subgroup of dysfunctional men may need pharmacotherapy as well.

A man with sexual desire disorder or erectile disorder is sometimes told to masturbate to demonstrate that full erection and ejaculation are possible. A woman with lifelong female orgasmic disorder is directed to masturbate, sometimes using a vibrator. Kegel's exercises may be introduced to strengthen the pubococcygeal muscles; that is, the woman is encouraged to contract her abdominal and perineal muscles during masturbation and coitus. When a man has erectile disorder, the woman may be instructed to stimulate or tease his penis. The same technique is used with men who suffer from retarded ejaculation, with stimulation sometimes involving a vibrator. Retarded ejaculation is managed by extravaginal ejaculation initially and gradual vaginal entry after stimulation to the point of near ejaculation.

Treatment Goals The overall goal of treatment is to initiate an educational process, to diminish the fears of performance felt by both sexes, and to facilitate communication in sexual and nonsexual areas. Therapy sessions follow each new exercise period, and problems and satisfactions (both sexual and nonsexual) are discussed. Specific instructions and new exercises geared to the individual couple's progress are reviewed in each session. Gradually, the couple gains confidence and learns (or relearns) to communicate verbally and sexually. Dual-sex therapy is most effective when the sexual dysfunction exists apart from other psychopathology.

Hypnotherapy Hyponterapists focus specifically on the anxiety-producing symptom, that is, the particular sexual dysfunction. Successful use of hypnosis helps the patient gain control over the symptom that has been lowering self-esteem and disrupting psychological homeostasis. Patient cooperation is first obtained and encouraged during a series of nonhypnotic sessions with the therapist, designed to develop a secure doctor-patient relationship and a sense of physical and psychological comfort on the part of the patient and establish mutually desired treatment goals. During that time, the therapist assesses the patient's capacity for the trance experience. The nonhypnotic sessions also permit the clinician to take a careful psychiatric history and do a mental status examination before beginning hypnotherapy. Treatment focuses on symptom removal and attitude alteration. In a trance state, patients can entertain ideas incongruent with their usual (nonhypnotized) perceptions of reality. Patients are instructed in developing alternative means of dealing with the anxiety-provoking situation (i.e., the sexual encounter).

For example, a woman suffering from vaginismus is given the posthypnotic suggestion that she will feel no pain during intercourse and will be able to relax the muscles surrounding her vagina. If compliance with the suggestion is successful, she can deal with the anxiety produced by the sex act. She is also taught new attitudes, such as being entitled to sexual pleasure. Under hypnosis, her fear or anger at sexual contact can be examined, and she learns how her emotions are expressed by involuntary vaginal spasms.

Some patients respond particularly well to the use of self-hypnosis and indirect suggestion. These techniques allow them to retain a greater sense of control over their situation. Typically, patients are instructed to conjure up images and develop ideas antithetical to their dysfunctional responses. For example, a woman with an arousal disorder may first agree to concentrate on imagery that causes her to salivate. She is then told that just as she has made her mouth water by focusing on stimulating images, she can effect the lubricating response of her vagina by focusing on images she finds erotic or romantic. At the same time, the therapist helps her deal with her anxieties about a positive sexual response. Patients are also taught relaxing techniques to use before sexual relations. With these methods to alleviate anxiety, the physiological responses to sexual stimulation can more readily result in pleasurable excitation and discharge. Hypnosis may be added to a basic individual psychotherapy program to accelerate the impact of psychotherapeutic intervention.

Behavior Therapy Behavior therapists assume that sexual dysfunction is learned, maladaptive behavior. Behavioral approaches were initially designed to treat phobias. In cases of sexual dysfunction the therapist sees the patient as phobic of sexual interaction. Using traditional techniques, the therapist sets up a hierarchy of anxiety-provoking situations for the patient, ranging from the least threatening to the most threatening. Mild anxiety may be experienced at the thought of kissing, and massive anxiety may be felt when imagining penile penetration. The behavior therapist helps the patient master the anxiety through a standard program of systematic desensitization. The program is designed to inhibit the learned anxious response by encouraging behaviors antithetical to anxiety. The patient first deals with the least anxiety–producing situation in fantasy and progresses by steps to the most anxiety–producing situation. Medication, hypnosis, or special training in deep muscle relaxation is sometimes used to help with the initial mastery of anxiety.

Assertiveness training helps teach patients to express their sexual needs openly and without fear. Exercises in assertiveness are given in conjunction with sex therapy, and patients are encouraged both to make sexual requests and to refuse to comply with requests perceived as unreasonable. Sexual exercises may be prescribed for patients to perform at home, and a hierarchy may be established, starting with activities that proved most pleasurable and successful in the past.

One treatment variation involves the participation of the patient's sexual partner in the desensitization program. The partner, rather than the therapist, presents the hierarchical items to the patient. In such situations a cooperative partner is necessary to help the patient carry gains made during treatment sessions to sexual activity at home.

Behavior therapy techniques have been particularly effective in treating women with severe inhibition of excitement and orgasm when such feelings were accompanied by strong feelings of anxiety, anger, or disgust.

Group Therapy Methods of group therapy have been used to examine both intrapsychic and interpersonal problems in patients with sexual disorders. The therapy group provides a strong support system for patients who feel ashamed, anxious, or guilty about a particular sexual problem. It is a useful forum in which to counteract sexual myths, correct misconceptions, and provide accurate information regarding sexual anatomy, physiology, and varieties of behavior.

Groups for the treatment of sexual disorders can be organized in several ways. Members may all share the same problem, such as premature ejaculation; members may all be of the same sex with different sexual problems; or groups may be composed of both men and women who are experiencing different sexual problems. Group therapy may be an adjunct to other forms of therapy or the prime mode of treatment. Groups organized to cure a particular dysfunction usually have a behavioral approach. For example, patients suffering from anorgasmia may participate with others suffering from the same problem in a short-term, intensive group experience. Sexual histories, feelings of inadequacy, and concerns about body image are shared. Specific physiological information, sometimes with the aid of

audiovisual materials, is presented to the group members. Members are given homework assignments (e.g., they may be instructed to masturbate). A combination of group support and group pressure helps some of the participants complete assignments they might otherwise avoid. As the short-term group process nears termination, members are encouraged to talk about their experiences with their partners.

Groups have also been effective when composed of sexually dysfunctional married couples. The group provides an opportunity to gather accurate information, provides consensual validation of individual preferences, and enhances self-esteem and self-acceptance. Such techniques as role playing and psychodrama may be used in treatment. These groups are not indicated for couples in which one partner is uncooperative, a patient is suffering from a severe depression or psychosis, or a strong repugnance for explicit sexual audiovisual materials or a strong fear of groups exists.

Integrated Sex Therapy One of the most effective treatment modalities is the use of sex therapy integrated with supportive, psychodynamic, or insight-orientated psychotherapy. Adding psychodynamic conceptualizations to the behavioral techniques used to treat sexual dysfunctions allows treatment of patients with sex disorders associated with other psychopathology. Also, the therapy is appropriate for patients suffering from hypoactive desire disorders. Insight-oriented therapy helps them deal with problems in their interpersonal relationships or intrapsychic conflicts that frequently are at the root of the problem. The themes and dynamics that emerge in patients in analytically oriented sex therapy are the same as those seen in psychoanalytic therapy, such as relevant dreams, fear of punishment, aggressive feelings, difficulty with trusting the partner, fear of intimacy, oedipal feelings, and fear of genital mutilation.

A 34-year-old widow presented for therapy with a chief complaint of vaginismus. Her marriage of 3 years, which had been unconsummated, ended when her husband was killed in a car accident. Approximately 1 year after she lost her husband, the patient became involved with a married man. She was very attracted to him and became highly aroused during their sexual encounters. Although she could reach orgasm through manual or oral stimulation, she could not tolerate penetration. Although she never considered therapy when she was married, in spite of her husband's requests to do so, she was motivated to seek help for her problem because she felt sure her lover would leave his wife for her if they could share a more complete sexual experience.

The patient's vaginismus resulted partly from unresolved developmental conflicts. Her parents had been loving but rigid people who came from different socioeconomic backgrounds. Their values often conflicted, and they frequently fought over their daughter as she entered adolescence. The mother insisted that she take an academic course in high school to prepare for college, whereas the father pushed a more practical business program. The patient sided with her mother and felt that her father, whom she had always perceived as cold, became more distant than before. Some of her difficulties were due to unresolved oedipal problems; both her husband and her lover were more than 20 years older than she was, and her lover (reflecting her parental situation) was married to a woman who was more successful than he was. In addition, she had identified with some of her mother's negative feelings about men. The mother had once told the patient she hoped that she would be spared marriage. Vaginismus protected the patient from the closeness with men that she consciously wanted but unconsciously perceived as hurtful and dangerous.

A 56-year-old man came for treatment because of an erectile disorder. In general, he functioned better in extramarital affairs than in his marriage. Although he loved his wife and considered her an attractive woman, he believed that she was not interested in sex. He could rarely achieve an erection with her and he gradually stopped approaching her sexually. His wife felt deprived by their lack of sexual relations and frequently masturbated.

The patient had been a sickly child, with a mother he described as devoted but smothering. He remembered her cuddling him in bed until he was 8 years old, and he felt that she was inappropriately affectionate in general (“she embarrassed me”). At the same time, he remembered his father as an earthy man and had a childhood recollection of hearing his mother ask his father, “How could you, how could you?” The patient believed it had been his mother's response to a sexual overture or act. In part, his disorder derived from his unconscious oedipal associations to his wife, which made her taboo for him as a sex partner. The women to whom he responded had to be blatantly sexual and signal their acceptance of him before he would risk an advance. Therapy involved both individual sessions with the patient and joint sessions with him and his wife. Communication, which had been strained partly because of the sexual distance between them, was encouraged, and a behavioral approach was used to reestablish some physical interaction. Individual work focused on his deeper psychological problems.

The dynamics and the emotional difficulties evident in the vignettes are seen every day by the psychiatrist. Psychiatrists can readily absorb the techniques of sex therapy into their treatment armamentarium, just as they have modified and absorbed any number of specialized techniques, from classic analytic dynamic formulations to the use of pharmacotherapy, group therapy techniques, and behavioral and other directive modalities. The combined approach of individual and sex therapy is used by the general psychiatrist, who carefully judges the optimal timing of sex therapy and the ability of patients to tolerate the directive approach that focuses on their sexual difficulties.

Biological Treatment Methods Biological treatments, including pharmacotherapy and surgery, have application in specific cases of sexual disorder. Advances in biological treatment methods, particularly pharmacological methods of treating sexual dysfunction have significantly augmented the therapist's catalogue of therapeutic approaches. Most of the recent advances involve male sexual dysfunctions. Current studies are under way to test pharmacological treatment of sexual dysfunctions in women.

Pharmacotherapy A variety of drugs have been explored in the treatment of sexual dysfunction. The major new medications are sildenafil; oral prostaglandin (Vasomax); alprostadil (Caverject), an injectable phentolamine; and a transurethral alprostadil (MUSE), all used in the treatment of erectile disorder.

Sildenafil Sildenafil is a nitric oxide enhancer that facilitates the inflow of blood to the penis necessary for an erection. The physiological mechanism of penile erection involves release of nitric oxide in the corpus cavernosum during sexual stimulation. Nitric oxide activates the enzyme guanylate cyclase, which increases cyclic guanosine monophosphate concentration and produces smooth muscle relaxation in the corpus cavernosum that allows the penile vessels to dilate and admit blood. Sildenafil enhances the effect of nitric oxide by inhibiting the enzyme that degrades cyclic guanosine monophosphate. In short, sidenafil augments the natural process involved in gaining and maintaining an erection during sexual stimulation. The drug takes effect about 1 hour after ingestion, and its effect can last up to 4 hours. Sildenafil has no effect in the absence of sexual stimulation.

The most common adverse events associated with sidenafil are headaches, flushing, and dyspepsia. Some sildenafil users see things in a blue tint for several hours after taking the medication; because of this, airline pilots have been prohibited from taking the drug, so that this visual artifact does not interfere with safe landings. The use of sildenafil is contraindicated for people taking organic nitrates. The concomitant action of the two drugs can result in large, sudden, and sometimes fatal drops in systemic blood pressure. The Food and Drug Administration (FDA) has posted 130 deaths in which sidenafil was listed as an associated medication and advises caution in prescribing sidenafil to men with a recent (6 month) history of myocardial infarction, stroke, life threatening arrhythmia, significant hypotension or hypertension, cardiac failure, angina or retinitis pigmentosa. However, the FDA has reiterated that it is a safe drug. Sildenafil is not effective in all cases of erectile dysfunction. It fails to produce an erection rigid enough for penetration in about 50 percent of men who have had radical prostate surgery or in those with long-standing insulin-dependent diabetes. It is also ineffective in certain cases of nerve damage.

Oral phentolamine has proved effective as a potency enhancer in men with minimal erectile dysfunction. It may prove useful for men with cardiac problems, since sildenafil is contraindicated for men using organic nitrates, but it is not currently approved by the FDA. Apomorphine is also being tested as an oral remedy for erectile dysfunction.

Alprostadil In contrast to the oral medications, injectable and transurethral alprostadil act locally on the penis and can produce erections in the absence of sexual stimulation. Alprostadil contains a naturally occurring form of prostaglandin E. Prostaglandins are composed of complex hydroxy fatty acids, and they have wide biological influences. Although some prostaglandins are vasoconstrictive, prostaglandin E_1 found in alprostadil is a powerful vasodilating agent, especially in local vascular areas such as the corpus cavernosum of the penis. The drug causes direct smooth muscle relaxation of penile vessels and erectile tissue; this reaction lowers the vascular resistance of the corpus and significantly increases blood flow to the penis. The firm erection produced with 2 to 3 minutes by increased blood flow may last as long as 1 hour. Treatment consists of the patient's self-injection of alprostadil into the corpus before coitus. This technique is easily taught and relatively painless. Infrequent adverse effects include penile bruising and changes in liver function test results, which are readily reversible when a man stops the injections. However, possible hazardous sequelae exist, including priapism and sclerosis of the small veins of the penis. Another substance being tried is vasoactive intestinal polypeptide (VIP). Intracavernous injection of VIP causes erection and has a parasympathomimetic effect. Some researchers speculate that this substance, which has been found in the hypothalamus and the female genital organs, is the essential factor in male and female arousal. In Europe phenoxybenzamine (Dibenzyline) is used to produce erections by injection into the penis. Serious adverse effects include priapism and pain accompanying the injection, and the drug is not allowed as a therapy in the United States.

Alprostadil can also be delivered via the urethra, eliminating the need for self-injection. Some men prefer the local, nonsystemic effects of alprostadil to oral sildenafil, others prefer sildenafil because it seems more like a nonpharmacologically aided response to them and their partners. A small trial found a topical cream effective in alleviating erectile dysfunction. The cream consists of three vasoactive substances that are a mixture of ergot alkaloids.

The pharmacological treatments described above are useful in treatment of erectile dysfunction of various causes: psychogenic, neurogenic, arterial insufficiency, venous leakage, and mixed. The following case demonstrates the use of pharmacotherapy to treat erectile dysfunction of psychogenic origin.

> Mr. B. and Ms. C. (his fiancee) presented for sex therapy with Mr. B. having experienced erectile dysfunction for 7 months' as well as having a lifelong history of premature ejaculation. Mr B. was a 42-year-old professional, and Ms. C. was a 38-year-old corporate executive. She had never been married; it was to be his second marriage.
>
> Mr. B.'s sexual history was remarkable for a late first coitus (age 25) and a general sexual insecurity that contrasted with his professional confidence and social poise. Ms. C. was sexually responsive in spite of a history of anxiety attacks for which she had been treated in the past. Their early sexual activity together had been frequent and satisfying to both in spite of his prematurity. After a few months, however, she began to complain about both the premature ejaculation and the secrecy of their relationship. Although Mr. B. was legally separated when they became involved, he was worried about divorce negotiations if his spouse learned about his new relationship. Treatment revealed that he found the secrecy in their relationship exciting.
>
> The two were treated with integrated sex therapy, a combination of behavioral and insight-oriented technique, and made substantial progress. They successfully controlled the premature ejaculation by practicing the squeeze technique (i.e., forcibly squeezing the coronal ridge of the penis before ejaculation, to increase the threshold of penile sensitivity). In genital-caressing sessions Mr. B.'s erections returned, and he could maintain a good erection to climax, with manual and oral stimulation. However, he continued to lose his erection when he attempted vaginal penetration. It was decided to supplement psychotherapy with intracavernosal injections of alprostadil (sildenafil was not yet available). Ms. C. was present when he was instructed in the injection technique and supported the process. Mr. B. was delighted with the results, and after 1 month of pharmacologically assisted coitus, he successfully achieved penetration without assistance. Currently, he has coitus once a week, with occasional use of sildenafil rather than intracavernosal injection when he is feeling stressed. The availability of a medication to treat his erectile problem significantly relieves his performance anxiety.

Erectile dysfunction of psychologic or mixed origin should not be treated by medication alone, even though the dysfunction can be corrected pharmacologically. The drugs should be used in conjunction with, not as a replacement for, sex therapy. In some cases, erectile dysfunction serves as a defense against unconscious conflicts that must be faced when the sexual symptom is removed. Therapeutic intervention is essential in such cases to prepare the patient to deal with his conflicts or to judge that he would be unable to do so and then to postpone pharmacological treatment. Sometimes the patient deals with his conflicts by simply not using the medications prescribed for his erectile problem. Also, patients in long-standing or marital relationships require the cooperation of their partners for this treatment to be effective. Although most women are very accommodating to their partner's desire for treatment, several concerns occur with some frequency: the element of romance is an important part of sexual interaction for many women, and pharmacological assistance of erections may eliminate that sense of romance; the woman, or the couple, may bemoan the lack of spontaneity when pharmacotherapy is part of the sex act; and some women feel deprived of feedback about their desirability. Joint sessions help the couple cope with these issues.

Sildenafil Use in Women The use of sildenafil in women is being researched, but no completed studies have been published. Anecdotal reports describe individual women who have experienced intensified excitement when they have tried sildenafil (presumably their partner's).

The physical sign of sexual excitement in the female is vaginal lubrication. That lubrication is a transudate believed to result from increased vasocongestion of the extensive capillary net in the vaginal walls. The same physiological mechanism, vasocongestion, results in erection in the male. Researchers believe that sildenafil may facilitate blood flow in the female just as it does in the male and thus give women with inhibited excitement of psychological or physiological origin a pharmacological remedy for their dysfunction. However, as in men, pharmacological treatment may need to be combined with psychological modalities to be effective.

Recognition of sexual excitement may be more complex for women than it is for men. For example, in studies of response to pornography, men and women underwent physiological measurements of excitement following visual stimuli. In these studies, men were more accurate in correlating their subjective sense of arousal with the objectively measured physiological response. Also, 50 percent of women experience postpubertal sexual stimulation and orgasm for the first time in the course of sex play with a partner, while most men first experience these sensations with masturbation. Many women face a greater challenge in identifying themselves as autonomously sexual than do men and consequently may not respond to pharmacotherapy alone.

Other Pharmacological Agents Numerous other pharmacological agents have been used to cure the various sexual disorders. Intravenous methohexital sodium (Brevital) has been used in desensitization therapy. Antianxiety agents may have some application in tense patients, although these drugs can also interfere with the sexual response. The side effects of antidepressants, in particular the SSRIs and tricyclic drugs, have been used to prolong the sexual response in patients with premature ejaculation. This approach is particularly useful in patients refractory to behavioral techniques, who may fall in the category now being investigated of physiologically determined premature ejaculation. The use of antidepressants has also been advocated in the treatment of patients who are phobic of sex and in those with a posttraumatic stress disorder following rape. The risks of taking such medications must be carefully weighed against their possible benefits. Bromocriptine is used in the treatment of hyperprolactinemia which is frequently associated with hypogonadism. Such cases are first worked up to rule out pituitary tumors. Bromocriptine (Parlodel), a dopamine agonist, may improve sexual function impaired by hyperprolactinemia. Sometimes the problem requires androgen therapy.

A number of substances have popular standing as aphrodisiacs, for example, ginseng root and yohimbine. However, studies have not confirmed any aphrodisiac properties. Yohimbine, an a-adrenergic receptor antagonist, may cause dilation of the penile artery by that mechanism. Many recreational drugs, including cocaine, amphetamines, alcohol, and cannabis, are considered enhancers of sexual performance. Although they may provide the user with an initial benefit because of their tranquilizing, disinhibiting, or mood-elevating effects, consistent or prolonged use of any of these substances impairs sexual functioning.

Ginseng has been reported to have androgenic effects. One report described the case of a mother who ingested large amounts of ginseng during her pregnancy, resulting in androgenization of the neonate, who was born with pubic hair and enlarged testes.

Dopaminergic agents have been reported to increase libido and improve sex function. Those drugs include L-dopa, a dopamine precursor, and bromocriptine, a dopamine agonist. The antidepressant bupropion has dopaminergic effects and has increased sex drive in some patients. Selegiline, an MAOI, is selective for MAO_B and is dopaminergic. It improves sexual functioning in older persons.

Hormone Therapy Androgens increase the sex drive in women and in men with low testosterone concentrations. Women may experience virilizing effects, some of which are irreversible (e.g., deepening of the voice). In men, prolonged use of androgens produces hypertension and prostatic enlargement. Testosterone is most effective when given parenterally; however, effective oral and transdermal preparations are available.

Gonadotrophin-releasing hormone (GnRH), also known as luteinizing hormone–releasing hormone (LHRH), stimulates the release of luteinizing hormone (LH), which increases testosterone secretion in both sexes. GnRH is used as an inhalant in Europe. It stimulates desire and increases potency. Since GnRH is released normally in a pulsatile fashion, portable infusion pumps have been developed that simulate pulsatile delivery. An excess of GnRH suppresses estrogen and testosterone; thus the therapeutic use of GnRH is limited by a narrow therapeutic window.

Women who use estrogens for replacement therapy or for contraception may report decreased libido; in such cases a combined preparation of estrogen and testosterone has been used effectively. Estrogen, itself, prevents thinning of the vaginal mucous membrane and facilitates lubrication.

Pheromones are sexual scents that are found in animals and may be present in humans. They produce dramatic sex-seeking behavioral patterns in animals (e.g., male deer following female deer in estrus and mounting behavior in primates). Human pheromones are believed to be short-acting fatty acids present in vaginal secretions and male sweat. In one study women were consistently more attracted to items impregnated with a chemical derived from male sweat (a-androstenol) than to control items. In another study, the sweat of women was preserved in underarm pads they changed daily, and the date each pad was worn was correlated with the women's menstrual cycle. A second group of women was asked to smell these pads as they were rubbed above their upper lips, without knowing what they were and recognizing no scent but the alcohol preservative used on the pads. Depending on whether they were exposed to pads from the early or late part of the first group's

(wearers) menstrual cycle, the second group (sniffers) saw their own menstrual cycles shortened or lengthened. This area is still being researched.

Antiandrogens and Antiestrogens Estrogen and progesterone are antiandrogens that have been used to treat compulsive sexual behavior in men, usually in sex offenders. Clomiphene (Clomid) and tamoxifen (Nolvadex) are both antiestrogenic and both stimulate GnRH secretion and increase testosterone concentration, thereby increasing libido. Women being treated for breast cancer with tamoxifen report an increased libido.

Cyprosterone acetate is a strong antiandrogen used in male sex offenders. At doses of 100 to 200 mg a day, the sex drive disappears within 2 weeks. It is available in Europe but is in the investigational stage in the United States.

Mechanical Treatment Approaches

Steal Syndrome In male patients with arteriosclerosis (especially of the distal aorta, known as Leriche's syndrome), the erection may be lost during active pelvic thrusting. The need for increased blood in the gluteal muscles and others served by the ilial or hypogastric arteries takes blood away (steals) from the pudendal artery and thus interferes with penile blood flow. Relief may be obtained by decreasing pelvic thrusting, which is also aided by the woman's superior coital position.

Vacuum Pump Vacuum pumps are mechanical devices that patients without vascular disease can use to obtain erections. The blood drawn into the penis following the creation of the vacuum is kept there by a ring placed around the base of the penis. This device has no adverse effects, but it is cumbersome, and partners must be willing to accept its use. Some women complain that the penis is redder and cooler than when erection is produced by natural circumstances, and they find the process and the result objectionable.

Surgical Treatment

Male Prostheses Surgical treatment is infrequently advocated, but improved penile prosthetic devices are available for men with inadequate erectile response who are resistant to other treatment methods or who have medically caused deficiencies. There are two main types of prosthesis: a semirigid rod prosthesis that produces a permanent erection that can be positioned close to the body for concealment and an inflatable type that is implanted with its own reservoir and pump for inflation and deflation. The latter type is designed to mimic normal physiological functioning. Placing a penile prosthesis in a man who has lost the ability to ejaculate or to have an orgasm as a result of medical causes will not restore those functions. Men with prosthetic devices have generally reported satisfaction with their subsequent sexual functioning, but their wives report much less satisfaction. Presurgical counseling is strongly recommended so that the couple has a realistic expectation of what the prosthesis can do for their sex lives. Postsurgical counseling may also be necessary to help the couple adapt to their rediscovered ability to have intercourse. They may experience a high level of anxiety if their sex life had been inactive for a prolonged period before surgery. Prosthetic devices have been associated with severe adverse effects including perforation, infection, urinary retention, and persistent pain.

Some surgeons are attempting revascularization of the penis as a direct approach to treating erectile dysfunction resulting from vascular disorders. Such surgical procedures are indicated in patients with corporal shunts that allow normally entrapped blood to leak from the corporal spaces, leading to inadequate erections (steal phenomenon). Limited reports exist of prolonged success with the technique. Endarterectomy can be of benefit if aortoiliac occlusive disease is responsible for the erectile dysfunction.

Another medical treatment being studied for erectile disorders is electrostimulation at the base of the penis. Initial reports indicate minimal physical discomfort in patients receiving this therapy. However, response to treatment is inconsistent, and a problem exists in terms of maintaining erections. At the present time, the treatment seems to have no benefits.

Female Procedures Surgical approaches to female dysfunctions include hymenectomy in the case of dyspareunia in an unconsummated marriage, vaginoplasty in multiparous women complaining of lessened vaginal sensations, or freeing clitoral adhesions in women with inhibited excitement. Such surgical treatments have not been carefully studied and should be considered cautiously.

Outcome The results of different treatment methods have varied considerably since Masters and Johnson first reported positive results for their treatment approach in 1970. Masters and Johnson studied the failure rates of their patients (defined as the failure to initiate reversal of the basic symptom of the presenting dysfunction). They compared initial failure rates with 5-year follow-up findings for the same couples. Although some have criticized their definition of the percentage of presumed successes, other studies have confirmed the effectiveness of their approach. Demonstrating the effectiveness of traditional outpatient psychotherapy is just as difficult when therapy is oriented to sexual problems as it is in general. In some cases the patient improves in all areas except the sexual area. The more severe the psychopathology associated with a problem of long duration, the more adverse the outcome is likely to be.

The more difficult treatment cases involve couples with severe marital discord. Cases involving problems of fear of intimacy, excessive dependency, or excessive hostility are also complex. Other challenges are posed by patients with impulse disorders, unresolved homosexual conflicts, or fetishistic defenses. Patients phobic of sex also present treatment difficulties, as do patients diagnosed with lifelong dysfunctions. Desire disorders are particularly difficult to treat. They require longer, more intensive therapy than some other disorders, and their outcomes are very variable.

When behavioral approaches are used, empirical criteria that are supposed to predict outcome are more easily isolated. Using these criteria, for instance, couples who regularly practice assigned exercises appear to have a much greater likelihood of successful outcome than do more-resistant couples or those whose interaction involves sadomasochistic or depressive features or mechanisms of blame and projection. Flexibility of attitude is also a positive prognostic factor. Overall, younger couples tend to complete sex therapy more often than older couples. Couples whose interactional difficulties center on their sex problems, such as inhibition, frustration, or fear of performance failure, are also likely to respond well to therapy.

In general, methods that have proved effective singly or in combination include training in behavioral-sexual skills, systematic desensitization, directive marital counseling, traditional psychodynamic approaches, group therapy, and pharmacotherapy. Although most workers prefer to treat a couple for sexual dysfunctions, treatment of individual persons has also been successful.

The frequency of sessions is not a significant factor in treatment success. Thus, whether patients have intensive daily therapy over a period of 2 weeks, weekly therapy, or biweekly therapy appears to have little effect on the outcome of treatment. Also, the use of one therapist to treat a couple instead of a dual-sex cotherapy team is nearly as effective and certainly more practical.

Patients seen today are frequently older when they present for therapy, more informed about sex, and more likely to have dysfunctions of mixed etiology than those seen 30 years ago. A multimodal treatment regimen is often necessary. Future studies will evaluate results of an eclectic therapeutic approach to sexual disorders.

SUGGESTED CROSS-REFERENCES

Homosexuality is discussed in Section 19.1b , paraphilias in Section 19.2, and gender identity disorders in Section 19.3. The neuropsychological and neuropsychiatric aspects of HIV infection are covered in Section 2.8. Couples therapy is discussed in Section 30.5 and yohimbine and other pharmacological therapies are discussed in Section 31.33. The physical and sexual abuse of children, including incest, is the subject of Section 49.4.

CHAPTER 19. NORMAL HUMAN SEXUALITY AND SEXUAL AND GENDER IDENTITY DISORDERS

19.1 NORMAL HUMAN SEXUALITY

19.1B HOMOSEXUALITY AND HOMOSEXUAL BEHAVIOR

TERRY S. STEIN, M.D.

Perspectives on homosexuality—concerning its origins, social and personal meanings, diagnostic implications, and clinical relevance—have persistently represented one of the most contentious issues within psychiatry during the latter part of the twentieth century. In spite of a remarkable expansion in the understanding of homosexuality and bisexuality since the work of Alfred C. Kinsey, many psychiatrists continue to view sexual orientation as either homosexual, heterosexual, or bisexual and have failed to understand its complex developmental, biological, behavioral, and psychosocial dimensions. This reductionistic viewpoint ignores the richness and diversity of development, experience, and identity associated with sexual orientation in contemporary society. This chapter examines both the experience of homosexuality as it is expressed in individuals and the variety of theories and clinical and research findings available to explain sexual orientation.

DEFINITIONS

Increased understanding of sexuality in general has led to greater specificity in the use of terms related to sex, gender, sexuality, and sexual orientation. Terms such as *gender identity* and *gender* or *sex role* tended to be confused with sexual orientation in early writing about homosexuality; however, it is now recognized that these are related but discrete characteristics that may interact with but are not synonymous with homosexuality and have distinct developmental pathways. It is important to understand the precise meanings of these terms.

Sexual orientation refers to a person's erotic response tendency—homosexual, bisexual, or heterosexual—toward other persons of the same or other sex as reflected in such indicators as the proportion of dreams and fantasies directed to one or the other sex, the sex of one's sexual partners, and the extent of physiological response to erotic stimuli associated with one or both genders. Sexual orientation consists of three components: desire, behavior, and identity, which may or may not be congruent in an individual. The Kinsey heterosexual-homosexual scale—a 7-point continuous scale with 0 representing exclusive heterosexuality, 6 representing exclusive homosexuality, and 3 representing equal amounts of both, or bisexuality—is the scale most widely used to describe sexual orientation. The Kinsey scale has been criticized for its unidimensional and bipolar conceptualization of sexual orientation that suggests a diminished attraction toward one sex in proportion to an increased attraction to the other sex, as opposed to independently describing the degree of erotic attraction in an individual to each sex.

The terms *sexual orientation* and *sexual preference* are often used interchangeably; however, the former term has had a wider currency in contemporary professional and popular usage because it is generally accepted to refer more narrowly to a person's erotic response tendency. In contrast, sexual preference is viewed as implicitly suggesting that an individual prefers and therefore also chooses an erotic attraction toward one sex or the other. Such an association between desire and choice is often thought, particularly by those biological determinists who believe that sexual attractions are irrevocably set by inborn factors, to be inappropriate and potentially politically dangerous because it is seen as open to attempts to forcibly change a sexual attraction that is viewed negatively by society. Neither term necessarily implies anything about the degree of volition persons have with regard to their sexual desire; historically medical, legal, and moral justifications have been used to try to change both personal preferences and biologically determined characteristics. In this section *sexual orientation* is used to refer to erotic response tendency, not because it is semantically a better term, but only because it is more commonly used in the psychiatric literature.

Homosexuality was first used as a term in the second half of the nineteenth century to refer to erotic desire for persons of the same sex. *Heterosexuality* was developed later as a term to describe erotic desire for persons of the opposite sex. A third category of sexual orientation, *bisexuality*, was used by Sigmund Freud and others to describe an attraction to members of both sexes. These terms have not been applied consistently in theoretical, research, or popular discourse; they have been used to refer to a wide range of constructs, including categories of sexual desire, gender role attributes, forms of sexual behavior, personal and social identities, types of personalities and persons, degrees of normality and abnormality, and the presence or absence of mental illness. This conceptual confusion, along with an underlying assumption that sexual orientation as a concept refers to some unitary quality within different individuals, has complicated efforts to understand the complex personal and social meanings of sexual desire and relationships.

In this section *homosexuality* is used solely to refer to an erotic desire for someone of the same biological sex, and its presence in an individual does not imply the concurrent existence of any other characteristics in that individual. When used as an adjective, *homosexual* is intended to refer to sexual ideation or activity involving members of the same sex. Thus, for example, a woman may engage in homosexual behavior, demonstrate typical feminine gender role characteristics, be married to a man, and experience a heterosexual identity; or a man may have homosexual desire, have sex only with women, and show gender role nonconformity. These different characteristics have distinct developmental and expressive pathways in each individual; however, as the result of socialization and because of the possible existence of predisposing biological factors, their development will be interactive and reinforcing in some individuals.

Bisexuality refers to an erotic propensity, an individual identity, and sexual behavior. It may occur both sequentially and simultaneously as an expression of a sexual orientation directed to the same and the other sex. Although bisexuality is often devalued or ignored and has been portrayed as a transitional state in development to a heterosexual or gay or lesbian identity, it describes the sexual behavior and the sexual orientation of a large number of men and women at some point in their lives and is a persistent sexual identity for an increasingly visible group of individuals. There are frequent parallels between the experiences of gay men, lesbian women, and bisexual men and women.

In the latter part of the twentieth century, the terms *gay, gay man, lesbian*, and *bisexual* have been used to refer to men and women who have developed a sexual orientation identity that is homosexual or bisexual. In much of the early psychological and psychoanalytic literature about homosexuality, *homosexual* was used as a noun to designate a person with homosexual desire or behavior, however, at this point the term is used in this manner less often in the scientific and popular literature. When used as a noun the term may have a negative connotation because of its origins in medicine, its historical association with psychopathology, and its reification of the idea of a category of person, generally presented as a negative stereotype, designated solely by sexual orientation. Although *gay* is sometimes used as an inclusive term to refer to both men and women, reference to two distinct groups, gay men and lesbians, is more appropriate because of the significant differences in the development and experiences of these two groups.

Homosexual, or lesbian and gay, and bisexual identities are the subjective experiences of being homosexual or bisexual—being significantly or exclusively attracted to someone of the same sex—with the identities being both self- and other-ascribed. The acquisition of lesbian, gay, and bisexual identities is generally conceptualized as a developmental process that occurs over time. Models of lesbian, gay, and bisexual identity development usually portray a series of linear progressive stages involving tasks such as *coming out* (the process of recognizing one's homosexual or bisexual attraction and acknowledging it to oneself and to others); involvement in lesbian, gay, and bisexual communities; establishing same-sex relationships; and integrating one's sexual identity into other aspects of the self. It is important to understand that not all persons who experience homoerotic desire or participate in homosexual behavior develop a lesbian, gay, or bisexual identity. Thus, the clinician must be careful when evaluating a patient's sexuality to inquire about all of the components of sexual orientation: desire, behavior, and identity. Congruence between these components should not be assumed based upon information about only one or two of them.

Although a *heterosexual identity* refers in theory to the experience of those men and women who primarily are aware of attraction to persons of the other sex, this construct is not as well developed as that of lesbian, gay, and bisexual identities. Heterosexual identity is often not consciously experienced by individuals in our society because it is associated with the dominant sexual orientation. A heterosexual developmental outcome has been described as compulsory and is usually

assumed to be a person's identity unless the individual does something to disavow it or to proclaim an alternative identity. Thus, acquisition of a heterosexual identity cannot by definition involve coming out because it is the default identity in contemporary Western society.

In contrast to sexual orientation, *gender identity* is generally understood to refer to a persistent sense of oneself as being male, female, or ambivalent and is contrasted with *sex*, which refers to the biological attributes of being male or female. *Gender identity* describes an inner experience of being male or female, *gender role* and *social-sex role* are defined as the degree to which an individual's outer behavior or appearance can be described as masculine, feminine, or androgynous. The large majority of persons, regardless of their sexual orientation, have a gender identity and gender role consistent with their biological sex, although sometimes gay and lesbian persons may demonstrate a greater range of gender role attributes.

Sometimes people with variant gender identities and gender roles are diagnosed as having a type of mental disorder. *Transsexualism* consists of a strong and persistent cross-gender identification, discomfort with one's biological sex, and a wish to acquire the characteristics of the other sex. When these characteristics are present in a person, some researchers believe that they should be diagnosed as a *gender identity disorder. Transgendered* is a more recent term that is used to describe a person who identifies with and adopts the gender identity of a member of the other biological sex. *Transvestism* consists of sexual urges and fantasies involving cross-dressing which, when distressing to a patient, may be diagnosed as a *transvestic fetishism*, a type of *paraphilia*. Historically these experiences have often been confused with homosexuality, but they are separate and distinct phenomena.

THEORIES

Prior to the time homosexuality was first studied as a psychiatric condition in the second half of the nineteenth century, the meaning of homosexual behavior was very different than it is today in Western culture. Homosexual practices played an important role for men in ancient Greece and other cultures and homosexual acts have been both ritualized and prohibited in various societies, but the idea of identifying a type of person based on regular participation in homosexual behavior is generally believed to be a product of the medicalization of homosexuality during the nineteenth century. The study of the forms and meanings of homosexual behavior in different cultures is a rich field that has helped to provide information about the range of sexual practices and types of gender-based relationships transculturally and transhistorically. However, the forms of socialization and development of identity associated with homosexual behavior in contemporary society are generally recognized to be unique to this period of time in history and, until recently, to Euro-American culture. The history of the development of these contemporary forms of homosexual expression is the focus of the following review of theoretical perspectives about homosexuality.

History The modern view of homosexuality had its origins in the second half of the nineteenth century when a number of European sexologists, including several prominent psychiatrists, began to study homosexuality from a scientific perspective. Medical and psychiatric views of homosexuality passed through two major periods in the ensuing 100 years: the first from the second half of the nineteenth century through the first half of the twentieth century, marked by the gradual predominance of biological and psychological, largely psychoanalytic, theories of homosexuality over the earlier religious and moral conceptualizations; and the second, roughly from the time of the publication of the two Kinsey volumes on male and female sexuality in 1948 and 1953, respectively, until the removal of homosexuality from the list of mental disorders by the American Psychiatric Association (APA) in 1973, marked by a growing attempt to normalize homosexuality and to study the phenomena of sexual orientation from a wide range of social and scientific perspectives.

Medicalization of Homosexuality: From Morality to Pathology

LATE–NINETEENTH- AND EARLY–TWENTIETH-CENTURY BIOLOGICAL VIEWS During the second half of the nineteenth century researchers in Europe began to study homosexuality scientifically in an effort that reflected a shift away from the previous religious and moral view that homosexual acts were an expression of degeneracy. *Homosexual* was first coined by the Hungarian physician Károli Mária Kertbeny in 1869, and was later adopted by the influential German psychiatrist, Richard von Krafft-Ebing. The conceptual basis for homosexuality arose from the earlier ideological construction of two sexes, male and female, with dichotomous characteristics, and the attempt to find explanations for homosexuality derivative from these male and female categories. Thus, the homosexual was conceived of as a person of one biological sex with the sexual longing of the other sex, as portrayed, for example, in the German jurist and homosexual rights advocate Karl Heinrich Ulrich's description of the male homosexual as a female soul in a male body. Ulrich's belief that because homosexuality was biologically determined it was natural, and his reliance on the idea of separate male and female “love drives” in the brain that developed in *Urninge* (male homosexuals) and *Urninden* (female homosexuals) in opposite directions to their genital sex, continue to be reflected in contemporary efforts to locate an anatomical basis for homosexuality in brain sexual dimorphism.

The psychiatrists Carl Westphal and von Krafft-Ebing adopted many of Ulrich's ideas, but they considered the traits he described to be unnatural. The German physician and sexual emancipator, Magnus Hirschfeld, also believed that there was a genetic basis for homosexuality. Although he understood homosexuality to be a malformation in development and ascribed it to a number of different biological etiologies, he also asserted that it was natural. Similarly, the English sex reformer Havelock Ellis based his efforts to alter attitudes about homosexuality on the belief that homosexuality was an inborn trait. The sexual reforms advocated by Hirschfeld and others in Germany came to an end when the Nazis came to power in 1933. Other biological bases for homosexuality began to be examined during this period, including a variety of constitutional factors, such as different anatomical structures in the brains and nerve structures in the rectums of homosexual men, and endocrinological determinants, including atrophied and abnormal testicles in homosexual men, which led to experiments involving the removal of the testicles of homosexual men and replacement with what were believed to be the normal testicles of heterosexual men.

These early biological theories about the origin of homosexuality, with their emphasis on heredity, endocrinological influences, and anatomical or structural differences between homosexual and heterosexual persons, presage many of the current efforts to find a biological basis for homosexuality. They also served as the justification for subsequent eugenic efforts in Germany to eradicate homosexual persons. Furthermore, the almost exclusive emphasis on the study of homosexuality in men parallels later twentieth-century biological research that has largely ignored homosexuality in women. The historical belief in a biological basis for homosexuality, whether it was viewed as natural or unnatural, has had a major influence on scientific approaches to homosexuality, but from the beginning this belief has been challenged by those who assert that homosexuality results from environmental, psychological, and developmental causes. The biological arguments helped to create the notion of a homosexual person by emphasizing the existence of fundamental constitutional differences between those who are attracted to persons of the same sex and those who are attracted to persons of the other sex. This conflation of behavior and personhood can be seen as the progenitor for the later development of gay and lesbian identities.

PSYCHOANALYTIC APPROACHES Like the biological theorists of his time, Freud believed that heterosexuality was the natural outcome of normal development. However, unlike many of his historic contemporaries and some of his later followers, he did not view homosexuality as a sign of degeneracy and asserted that homosexuality could occur in persons who had no other signs of deviation and no impairment in functioning. For Freud homosexuality represented an arrest in development from an instinctual bisexuality to a mature heterosexuality that could arise as the result of a variety of factors; he presented both biological and environmental explanations for its development. Freud's position on homosexuality, neither completely based in biology or in environment, further influenced the movement away from the moral degeneracy and religious views that predominated prior to the nineteenth century.

Later psychoanalytic theorists, including Sandor Rado, who refuted Freud's model of innate bisexuality and developed his own theory of homosexuality as a type of phobia, heavily emphasized the beliefs that homosexuality is the result of problems in psychosexual development and that its occurrence is a sign of severe psychopathology. However regardless of the degree of pathology homosexuality was believed to represent, psychoanalysis largely derived its theories of homosexuality from a biological and medical model that relied on dichotomous categories of male or female, masculine or feminine, and heterosexual or homosexual. Various etiological theories were hypothesized, but they all were based on the same assumptions of gender, sexual, and sexual orientation polarities that shaped the research in the biological sciences during this period. Although some discussion of the etiology of female homosexuality was presented in the psychoanalytic literature, the primary emphasis in psychoanalysis, like in the biological sciences, was on male homosexuality; often the causes and types of homosexuality in women were simply treated as the opposite of those for male homosexuality.

During the latter part of the nineteenth and the first half of the twentieth century, psychoanalysis, with its emphasis on intrapsychic and interpersonal development, represented an alternative approach to the biological sciences to studying and understanding homosexuality; however, its fundamental assumptions were derived from the same materialistic beliefs upon which the biological sciences rested. Thus, the outcomes of the efflorescence of interest in studying homosexuality within the medical and the psychoanalytic fields during this period were similar: to establish a focus of interest about homosexuality outside of the realms of morality and religion within science and medicine; to reify a category of person, the homosexual, associated with homosexual behavior; and to confirm the abnormality and the pathology inherent in homosexuality. These developments set the stage for the movement toward the normalization of homosexuality that began in the middle part of the twentieth century.

Normalization of Homosexuality: From Diagnosis to Normality

INFLUENCE OF NEWER RESEARCH FINDINGS FROM SEXOLOGY, CROSS-CULTURAL, ANIMAL, AND PSYCHOLOGICAL STUDIES The publication of the two volumes on male and female sexuality by Kinsey and his colleagues in 1948 and 1953, respectively, marked the beginning of the move away from the view of homosexuality as pathology and toward an understanding of homosexuality as a normal variant of sexual desire and behavior. Although Kinsey's studies have subsequently been criticized for their methodology, at the time of their publication their demonstration of the widespread presence of homosexual feelings and behavior among samples of several thousand American men and women suggested that homosexuality was not an isolated and aberrant phenomenon. Kinsey's conceptualization of sexual orientation as a continuum also introduced the idea that homosexuality and heterosexuality were not dichotomous categories but rather occurred in varying degrees in individuals. Reflecting his nominalist view of the world, Kinsey stated that the world cannot "be divided into sheep and goats.... It is a fundamental of taxonomy that nature rarely deals with discrete categories. Only the human mind invents categories and tries to force facts into separated pigeon-holes. The living world is a continuum in each and every one of its aspects."

Cleland Ford and Frank Beach's work, published in 1951, demonstrated that homosexuality was common across cultures and occurred in almost all nonhuman primate species. These findings were interpreted to support the notion that homosexuality was both natural and widespread. The psychologist Evelyn Hooker's publication in 1957 of the results of her groundbreaking study comparing the projective test results from 30 homosexual men and 30 heterosexual men showed that experienced judges could not distinguish between the two groups based on their test results and thereby established for the first time the idea that homosexuality in men was not associated with mental illness. The effect of this significant finding was to require that future views of homosexuality as an illness could only be based on an a priori assumption that homosexuality was itself pathological. By the 1970s influential psychiatrists like Judd Marmor, a psychoanalyst and president of the APA, began to publish works that moved the psychiatric profession away from the perspective of homosexuality as a type of mental illness and toward a consideration of the perspectives offered in these newer research findings.

During this period of transition and in spite of the availability of contradictory findings from empirical studies, other psychologists, particularly behaviorists who attempted to extinguish homosexual expression through aversive techniques, and some psychiatrists and psychoanalysts, espoused a pathological basis of homosexuality and published works in the 1960s that presented homosexuality as the outcome of developmental disturbance and as a sign of severe psychopathology. Such work, often criticized for its methodology, was particularly influential in portraying a pathogenic family type, consisting of a detached and rejecting father and a close-binding and domineering mother, that led to homosexuality in adult men. Ignoring the fact that such family configurations occur for heterosexual men as well and relying on questionable methods for analyzing results, those workers strengthened the belief within psychoanalysis and psychiatry that homosexuality was a sign of severe psychopathology and intensified efforts to attempt to "cure" persons who were homosexual through reconstructive treatment to make them heterosexual. The rate of cure for conversion of men from homosexuality to heterosexuality was in fact quite small and subjects were never independently evaluated to determine if reported changes in behavior were maintained.

Pathologizing views of homosexuality within psychoanalysis and psychiatry reflected the negative attitudes about homosexuality in the larger society, which allowed an assumption of pathology in homosexual persons whether or not it had been demonstrated to exist. The impact of these works was to reinforce the societal association of homosexuality with mental illness and stigma and to increase the experience of guilt and self-hatred in homosexual persons and their families. The clash within psychiatry between these traditional views of homosexuality and the perspectives offered in the newer research and articulated by spokespersons for an increasingly vocal gay rights' movement led to the next phase of development in theory about homosexuality.

DECLASSIFICATION BY THE AMERICAN PSYCHIATRIC ASSOCIATION Homosexuality was classified as a type of mental disorder since the publication of the first edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-I) in 1952, in which it was designated, along with the other conditions labeled as sexual deviations, as a type of sociopathic personality disturbance, defined by the existence of certain behaviors and not by the presence of distress or dysfunction. This classification of homosexuality as a form of mental illness was not controversial at the time DSM-I was published, reflecting as it did the negative societal attitudes about homosexuality and accepting the prevailing medical views of homosexuality as an illness as previously defined in the International Classification of Disease (ICD). In the second edition of DSM (DSM-II), published in 1968, homosexuality continued to be listed as a sexual deviation, but the sexual deviations were no longer categorized as types of sociopathic personality disturbance.

During the next several years the gay rights' movement became more vocal in its opposition to classifying homosexuality as a type of mental disorder, and increasing numbers of psychiatrists were responsive to the research findings that demonstrated its occurrence in large numbers of people, in persons who demonstrated normal adjustment, and in a variety of cultures. The psychiatric view of homosexuality as a disease was now seen as part of a larger historical movement to replace moral and religious judgments of homosexuality with supposedly scientific and objective but equally negative portrayals of homosexuality as a sickness.

Beginning in 1968 gay activists began to confront the APA about its position, and following a series of dramatic encounters between gay rights' advocates and psychiatrists at several annual meetings of the APA, the organization began officially to reevaluate its position of diagnosing homosexuality as a mental disorder. Following considerable political activity and significant scientific study of the issue, a proposal from the Nomenclature Committee of the APA to eliminate homosexuality from DSM was approved by the APA's Council on Research and Development, Reference Committee, and Assembly of District Branches before being accepted by the APA's Board of Trustees in December 1973. As a result, for the first time in modern history homosexuality per se was not classified as a type of illness. This action is viewed as having enormous social significance in shifting the predominant and official view of homosexuality as a sickness to viewing it as acceptable behavior. Psychiatrists who continued to adhere to the traditional views of homosexuality criticized the action taken by the Board of Trustees and challenged it in a referendum of the APA membership, but the decision was upheld by 58 percent majority of voting members.

Other major mental health professional organizations, including the American Psychological Association and the National Association of Social Workers, moved to endorse the action taken by the APA. The decision to declassify homosexuality was accompanied by passage of a position statement by the APA that supported the protection of the civil rights of homosexual persons:

> Whereas homosexuality in and of itself implies no impairment in judgment, stability, reliability, or vocational capabilities, therefore, be it resolved that the American Psychiatric Association deplores all public and private discrimination against homosexuals in such areas as employment, housing, public accomodations, and licensing, and declares that no burden of proof of such judgment, capacity, or reliability shall be placed on homosexuals greater than that imposed on any other persons. Further, the APA supports and urges the enactment of civil rights legislation at local, state, and federal levels that would insure homosexual citizens the same protections now guaranteed to others. Further, the APA supports and urges the repeal of all legislation making criminal offenses of sexual acts performed by consenting adults in private.

The rationale for removing homosexuality from DSM was based in part on the clarification, as formulated by Robert Spitzer, of the definition of a mental disorder as meeting the criteria of either experience of subjective distress or generalized impairment in social effectiveness or functioning as a result of the condition. Neither of these criteria applied to homosexual persons who were satisfied with their sexual orientation and who did not demonstrate impaired functioning. However, in what appeared to be a compromise between opposing views, a new diagnostic category, sexual orientation disturbance, was introduced to apply to those homosexual persons who "are either disturbed by, in conflict with, or wish to change their sexual orientation." When third edition of DSM (DSM-III) was published in 1980, sexual orientation disturbance was replaced with a new diagnostic category, "ego-dystonic homosexuality," a type of general psychosexual disorder that labeled homosexuality as a mental disorder only when it was accompanied by persistent distress. Finally, after further review of the appropriateness and utility of this diagnosis, all reference to homosexuality was removed from the revised third edition of DSM (DSM-III-R), published in 1986, representing the final acknowledgment by the American psychiatric profession that homosexuality by itself is not a type of mental illness. This change in the official view of homosexuality signified not only the acceptance of findings from newer research about homosexuality, but also a dramatic conceptual shift in the cultural meaning and significance of homosexual behavior within American society. This shift set the stage for the publication during the last three decades of the twentieth century of a profusion of new theory and research findings about homosexuality and gay and lesbian persons based on more complex and multidimensional conceptualizations of homosexuality as a normal variant of sexual desire and expression.

Postmodern Theories: Essentialist and Constructivist Arguments The declassification of homosexuality per se as a type of mental illness in 1973 and the elimination of any reference to homosexuality in DSM-III-R paralleled a significant cultural shift in approaches to epistemology and knowledge during the latter part of the twentieth century away from realist and materialist beliefs and toward a way of viewing the world that has been called postmodernism. *Postmodernism* is characterized by an attitude that challenges fixed beliefs and categories of knowledge, uses constructivist methods to unravel the particular historical and social influences that determine language and understanding, and seeks to identify the links between knowledge and social and political influences. Thus, at the same time that a specific paradigm shift in the conceptualization of homosexuality was occurring, signaled by its declassification by the APA as a type of mental illness, a more

fundamental alteration in philosophical and analytic approaches to understanding was taking place.

Postmodernism has had its strongest influence within the humanities and the social sciences whereas the biomedical field—focused as it is on biology and the body—has continued to rely on more traditional materialist approaches to studying and viewing the world. During the latter part of the twentieth century a bridge between traditional and postmodern methods for the study of homosexuality arose from the debate that took place between essentialist and constructivist (also known as social constructionist) theorists. This debate originated within the fields of philosophy, feminism, and identity politics and built upon the critiques of sex, gender, and racial categories developed by feminist and civil rights' thinkers. *Constructivist ideas*, first defined in the 1970s by the French philosopher Michel Foucault and others, maintained with respect to sexuality that there is no inner sexual drive, but rather that the human potential for thinking and acting is shaped by social forces of regulation and categorization into various types of sexual desire at different times in history and in different societies. Constructivist theory critiques classical theories of sexuality that posit inherent and largely immutable qualities that are associated with sex, gender, and sexual orientation. Thus, constructivist methods provide one way of questioning and examining contemporary notions of sexuality, including homosexuality.

In contrast, *essentialism* refers to the view that sexual desires and identities are fixed personal characteristics that are inherent, objective, transcultural, and transhistorical. Essentialism treats sexuality as a biological force that underlies genuine sexual differences, which in turn serve as the basis for sexual categories and identities. With respect to sexual orientation, essentialist theorists believe that fundamental differences in sexual desire are the basis for creating categories of persons known as homosexual, heterosexual, and bisexual.

The debate between essentialists and constructivists reflects the earlier debate within psychiatry regarding the importance of nature and nurture in creating mental illness and in determining the etiology of homosexuality. However, the scope of this postmodern debate encompasses much more than origins or etiology alone and entails challenges to other dimensions of understanding about homosexuality as well. Although these dimensions are often described in terms of oppositional positions representing essentialist or constructivist arguments, a continuum of beliefs about them is contained within both schools of thoughts.

Homosexuality: Innate Versus Constructed One polarity in the debate consists of the contrasting beliefs that homosexuality is innate versus that homosexuality is constructed. These two positions represent a fundamental distinction between essentialist and constructivist views respectively. The essentialist view that homosexuality is innate is represented most directly in attempts to locate a biological basis for homosexuality. Many of these efforts reflect a conceptualization identical to what was in fashion during the nineteenth century when researchers sought to identify a source for homosexuality in the brain and other parts of the body and during the early part of the twentieth century when endocrinologists first began to search for a possible hormonal basis for homosexuality. Corollary essentialist assumptions include the notion that types of persons exist who can be defined by their homoerotic desire and that these persons have shared fundamental characteristics throughout history and in different cultures.

In contrast, constructivist theorists argue that different forms of sexual desire and expression arise as the result of social forces that vary across time and cultures. Thus, while the individual may experience same-sex desire and even some sense of being lesbian or gay, these experiences are viewed as the product of larger social forces—like the market place, urbanization, and government regulation—that influence sexual desire and behavior. The implications of this belief include the idea that homosexual desire and gay and lesbian identity are variable and fluid in their origins and expression.

Homosexuality: Fixed Versus Mutable Another dimension of the debate between essentialists and constructivists involves beliefs about the extent to which homosexuality is fixed or mutable. There is considerable variability in the positions represented by essentialists and constructivists on this matter and any distinction between the two schools cannot be collapsed into disagreement about the possibility of changing sexual orientation. For example, persons believing that homosexuality should be changed through psychotherapy or other means are often essentialists who believe in the essential nature of heterosexuality; those who strongly endorse a constructivist conceptualization of sexuality may at the same time recognize that most individuals are unable to alter their sexual attraction. Nonetheless, a political position has arisen that argues that if sexual orientation is an essential characteristic of a person, it cannot be changed, and this position has been contrasted with constructivist ideas that are believed to imply the possibility for changing sexual orientation. However, neither of these theoretical beliefs necessarily suggests that sexual orientation can either be changed easily or be changed through psychotherapy or other means such as religious conversion. In this debate the fixed-mutable dimension of sexual orientation has often been conflated with two other issues: the political concern about attempts to coercively change a homosexual or bisexual orientation to a heterosexual orientation and the question of the degree of individual freedom in relation to choosing a particular sexual orientation. It is important to understand that discussion of the degree to which underlying sexual orientation is fixed or mutable can be separated from the notions of how change can be accomplished and to what extent individuals have choice in relation to their sexual desire, behavior, and identity.

The belief that homosexuality is a stable phenomenon that is relatively resistant to change derives from several sources, including the experiences of many people who are lesbian, gay, and bisexual concerning the difficulty and undesirability of changing their sexual attractions; the empirical finding that homosexuality rarely changes as the result of psychotherapy or other external attempts to alter it; the idea that sexual orientation is the outer representation of some constitutionally determined inner characteristic; the political stance that external agents should not attempt to alter sexual orientation; and the deterministic assumption that individuals have no choice about the direction of their sexual desire. In contrast, the idea that sexual orientation can change for some persons derives from a different set of observations about sexual orientation: the experiences of some persons who report fluctuations in sexual attractions across the course of their lives; the belief that sexuality is the product of social forces that vary over time and in different cultures; adherence to a belief in the need to protect individual freedom in relation to choosing sexual partners regardless of their sex; and the idea that the acceptance of a potential for change in an individual's sexual orientation can be separated from the concern about the use of coercive and harmful means for attempting such change. Thus, the apparent conundrum present in trying to determine the degree of change in sexual orientation that is possible can only be understood by appreciating the variable origins and values associated with such arguments and defining which of these beliefs is actually the topic of discourse.

Towards an Interactionist Model An important distinction between essentialist and constructivist approaches to homosexuality is the manner in which they conceptually organize the phenomena they address. Strict essentialists often assume that homosexuality is a unitary phenomenon comprised of similar experiences and behaviors that fundamentally represent the same characteristic. As a result, observations that are at variance with a unitary notion of homosexuality may not be viewed by strict essentialists as part of it. For example, people who experience fluctuations in their sexual desire for one or the other sex may be considered to be bisexual, and only persons who go through certain developmental stages or who demonstrate certain biological markers may be described as “true homosexuals.” As a result of demarcating such a conceptual boundary, other essentialist assumptions that homosexuality is innate, fixed, and uniform are reinforced. By excluding variations and focusing on means, a more discrete descriptive category can be created.

In contrast, constructivists tend to focus on variability and to see multiple phenomena within the construct of “homosexuality.” The constructivist methods of analyzing and deconstructing fixed categories and ideas result in the recognition of multiple layers and types of experiences associated with same-sex desire, behavior, and identity in different cultures and periods and which vary for some individuals across the lifespan. The result of this perspective may be that the constructivist sees more clearly the dehumanizing effects of narrow categorization and labeling but may also be speaking about something that is very different from what the essentialist is addressing.

If the differences between the two theoretical stances are understood, the focusing lens of the essentialist and the dispersing crystal of the constructivist can both be used to help view different aspects of what is called homosexuality in contemporary society and together can serve to drive, from different vantage points, new thinking and research that will deepen the understanding of human sexuality. The apparent contradictions between the essentialist and constructivist positions, like those in the earlier arguments about nature and nurture, can then be seen to reflect sometimes complementary aspects of the complex phenomena that are associated with sexual orientation. From this perspective, the biological, genetic, and structural matrix of the human body becomes shaped by volition and external influences into a person's sexual orientation.

FREQUENCY

Studies that purport to demonstrate the extent of homosexuality in a population have generally failed to distinguish between the various components of sexual orientation: desire, behavior, and identity. If an interview or survey question simply asks if a person is gay or lesbian or homosexual, respondents who only have sexual relations with other persons of the same sex but do not identify themselves as gay or lesbian may deny that they are gay or lesbian, and the stigma associated with being a member of a sexual minority group often interferes with full disclosure. Similarly, if persons are not open about their sexual orientation, they may also fail to respond fully or accurately to questions about their sexual behavior or identity. Even when questions about sexual orientation are constructed in a manner that takes into account such problems of definition and disclosure, it may be difficult to obtain a representative sampling of individuals with different sexual orientations. Studies have shown that self-reports of sexual orientation vary significantly across age groups, for example, from early to late teenage years, and in different geographical locations. These variations are compounded when frequency rates are compared cross-culturally because of the variable meanings of sexual behaviors

and practices in different cultures.

Given these limitations in the existing studies of the frequency of homosexuality, it is impossible to determine definitively the number of persons who have same-sex desire, behavior, or identity in the United States today. The 1948 Kinsey study of male sexuality, based on a sample of men between the ages of 16 and 55 years, found that 4 percent of the men were exclusively homosexual, 50 percent were exclusively heterosexual, and 46 percent were somewhere in between. The Kinsey study has subsequently been criticized for its sampling errors, which are believed to have led to inflated estimates of the extent of homosexual and bisexual behavior. Later studies of the frequency of same-sex sexual contacts between men, utilizing results from national surveys conducted in 1970 and 1988, determined that 20 percent of men had sexual contact to orgasm with another man at some time in their lives, and that 5 to 7 percent of men had such behavior in adulthood, but that only one quarter to one half of these men also reported having such contact in the preceding 12 months. Because of problems in reporting and with missing data, these figures were considered to be the lower bounds of actual frequency of same-sex behavior among men. Although reports about the frequency of homosexuality among women in the United States have been almost absent since the publication of Kinsey's 1953 volume on sexuality in women, the number of women reporting same-sex sexual contact or identifying themselves as lesbian is generally considered to be considerably lower than for men, often one half or less than the number of men.

A large scale study of sexuality in the United States published in 1994 by Edward Laumann and his colleagues provides the most reliable current estimates of the prevalence of homosexuality in the United States. This study utilized more precise definitions of homosexuality and heterosexuality, inquiring about individual desire, behavior, and identity, and obtained a carefully stratified representative sampling of the general population. However, because the total number of persons reporting at least one of the components of homosexuality was only 293 in a total sample of 3159, 150 of 1749 women and 143 of 1410 men, the number of persons reporting same-sex desire, behavior, and identity in specific age groups, in different geographical locations, and in other demographic categories was rather small. This study showed that, of the total sample 1.3 percent of the women and 2.7 percent of the men participated in same-sex sexual behavior during the preceding year, and 4.1 percent of women and 4.9 percent of men had done so since age 18; 7.5 percent of women and 7.7 percent of men reported the presence of sexual desire for someone of the same sex; and 1.4 percent of the women and 2.8 percent of the men reported a homosexual or bisexual identity. These figures varied considerably across groups based on age, marital status, education, religion, race, and place of residence.

The frequency figures from these studies of the extent of homosexuality in the United States during the second half of the twentieth century demonstrate that the figure of 1 in 10, or 10 percent often used to describe the number of persons who are gay and lesbian seems to be an overestimate of the actual number of persons who report same-sex desire or behavior or who acknowledge a gay or lesbian identity. However, it is also clear from the results of these studies that a larger number of persons report the existence of same-sex desire and that in certain population groups, for example, individuals living in the twelve largest U.S. cities, the number of gay and lesbian persons does approach the 10 percent figure. The clinician must understand the variable prevalence depending on which component of homosexuality and which social or demographic groups are being considered. Studies of prevalence of homosexuality in other Western countries show similar trends but estimates of the extent of homosexuality in a given country must take into consideration such factors as the degree of repression of homosexuality and the cultural meaning of same-sex desire, behavior, and identity.

ORIGINS OF HOMOSEXUALITY

Prior to the declassification of homosexuality as a form of mental disorder scientific studies into its origins consisted primarily of attempts to understand the nature of biological, psychological, or environmental causation of a pathological condition. Since the declassification of homosexuality in 1973, studies of its origin have been free to examine broader aspects of homosexuality and bisexuality and have largely been conducted with the assumption that homosexuality is a normal variation of human desire and behavior. Four areas in which the origins of homosexuality have been focused are biology, cross-cultural studies, psychological development, and acquisition of gay and lesbian identities.

Biological Studies Studies of the biological origins of homosexuality conducted since the 1960s have been based on the essentialist assumption that the cause of homosexuality, or at least of some of its forms, can be discovered in genetic, endocrinological, or anatomical differences between homosexual and heterosexual persons. Findings from studies into the biology of homosexuality have claimed the attention of the biomedical sciences and much of the general public and have continued to focus on the determination of a single cause or basis for homosexuality.

Genetic studies of homosexuality have been reported within the field of molecular biology through genetic linkage studies that attempt to locate a “gay gene” and within family studies of the twins and siblings of gay and lesbian individuals. One genetic study reported evidence for genetic linkage between alleles on the X chromosome in pairs of gay brothers. A number of studies have reported increased concordance for homosexuality among sets of monozygotic or identical twins and increased presence of homosexuality in the siblings of gay and lesbian subjects. The findings from such family studies vary in the degree of concordance they demonstrate and in the extent to which they reflect environmental or genetic influences. Explanations for discordant phenotypes in genotypically identical individuals have not been accounted for in these studies but suggest the influence of nongenetic factors in determining sexual orientation.

Early studies of a hormonal basis for homosexuality hypothesized a decreased level of testosterone in homosexual men and an increased level in homosexual women. However, there is currently no evidence for hormonal differences between adult homosexual and heterosexual men and women. More recent studies have focused on prenatal hormonal influences. This research has relied on studies in animals involving diminished prenatal exposure to androgens, the so-called male hormones, and comparison of the degree of sex-typed behaviors, primarily mounting and lordosis, in demasculinized rats with normally developing rats. These studies have not reported consistent findings and have been criticized for assuming an animal analog for human sexual orientation that compares demasculinized rodents with homosexual men who have normal testicles and hormones and that equates sex-typed behaviors in animals with sexual orientation in humans.

The final area of current biological studies of homosexuality is of brain function and structure. Based on the arguable assumption that the human brain is sexually dimorphic, these studies attempt to demonstrate that the brains of lesbians and gay men are in some fashion intersex, or intermediary in function or structure, between heterosexual men and women. This research has attempted to find evidence for differences between the brains of homosexuals and heterosexuals based on neuroendocrine function, cognition and lateralization, and brain structure, including in the corpus callosum and in the third interstitial nucleus and the suprachiasmatic nucleus of the hypothalamus. The results of these studies have not been replicated, and none of the criticisms of the studies has been adequately addressed through the design of new studies that correct the theoretical and technical problems that have been identified.

Recent efforts to locate a biological basis for homosexuality have narrowed their focus from the expansive arena of investigation in earlier generations of such research, which hypothesized a wide range of constitutional differences between homosexuals and heterosexuals. Current biological research often continues to rely on nineteenth-century assumptions that conflate sex and gender differences with differences in sexual orientation, that utilize the study of animal models and behavior to explain more complex human phenomena, and that visualize a structural-functional equation between anatomy and behavior. Biological studies have also have been plagued by ongoing problems with definition and methodology, including lack of precise definitions in describing subjects, use of small sample sizes, failure to replicate study results, and generalizations from findings about specific samples to the general population. Virtually all the biological studies have focused on men and results from the few studies of lesbians demonstrate even fewer differences from heterosexual women than for men. Thus far the results of this research at best suggest that some aspects of homosexuality in some individuals may be linked to genetic and familial origins. Carefully designed future research may further clarify the nature of biological contributions to the determination of sexual orientation.

Cross-Cultural Studies Anthropological studies of human sexuality have demonstrated the enormous variation in gender and sexual organization and behavior in different cultures, thereby providing further evidence for the fluidity and complexity of sexual behavior and experience at individual and social levels. The findings from ethnographic studies of gender and sexuality in different cultural groups have helped to dislocate the cultural bias underlying many approaches to examining these phenomena that assumes developmental continuity in individuals and cross-cultural similarities in the definition and expression of sexuality. Building upon the pioneering work of Margaret Mead, Ruth Benedict, and other anthropologists during the first half of the twentieth century in identifying variations in sexual patterns in different societies, more recent researchers have been able to classify structural types of sexual development and forms of homosexual organization in different cultures. Gilbert Herdt in particular has explicated these cross-cultural models based on his study of ritualized homosexuality among the Sambia people in New Guinea and on his review of findings from other anthropological studies of sexual practices. Herdt has incorporated the idea of “discontinuity” in sexual development to explain variation in the psychological experience and symbolic meaning of sexuality, in contrast to the continuity in sexual development across the life span that is assumed in most traditional approaches to understanding sexual development and that underlies important aspects of biological development. He has also explored the cultural aspects of fluidity in experience and expression of sexual orientation that has defined much of the theoretical discourse on bisexuality.

Herdt has identified three types of sexual development—linear, sequential, and emergent—that occur cross-culturally and help to explain variations in patterns of sexual orientation. *Linear development* refers to sexual behavior that occurs without significant change in behavior or orientation across a lifetime. *Sequential development* describes a developmental pattern that incorporates important change at different life stages, for example, in Victorian England, and to some extent modern America, where children were assumed to be sexually naïve but adults were expected to have a fully developed range of sexual practices, and among the

Sambia, who practice ritualized homosexual behavior during childhood and universal heterosexuality as adults. *Emergent development* occurs in societies that allow some degree of ambiguity and uncertainty in adult sexual outcomes based on childhood socialization. It can be identified in societies that have undergone massive social change that has affected sexual norms and values and in segments of modern American society that allow a range of sexual options for adults. Each of these patterns of sexual development can be shown to significantly influence the forms and expression of sexual orientation that exist in different cultures.

Herdt has also described a typology of homosexuality based on the organization of same-sex sexual behavior cross-culturally. The first type is *age-structured homosexuality*, usually involving older and younger males and generally including a sequential pattern of childhood same-sex practices that yield to primarily heterosexual behaviors in adults. Another form of homosexuality is *gender-reversed homosexuality*, which consists of a reversal in the normative sex-role dress and behavior. One example of such gender-reversed homosexuality is the American Indian *berdache*. The third type identified by Herdt is *role-specialized homosexuality*, in which same-sex sexual activity is restricted to certain social roles and positions. This type occurs among some American Indian tribes that identify their shamans, who then cross-dress and engage in homosexual behavior, following dreams or visions that reveal their special status, and among certain working-class women in nineteenth-century China. Finally, Herdt describes the *modern gay movement*, consisting of egalitarian same-sex practices, as the fourth type of homosexual organization. While acknowledging that hierarchical relationships still exist in parallel with traditional forms of heterosexual relationships, he states that homosexuality in contemporary America has arisen as a new form of homosexual practice that comprises a sexual orientation, a social identity, and a political movement.

Findings from the cross-cultural study of sexuality and homosexuality highlight the limitations of any narrow explanation for the development and experience of homosexuality in a particular society. Variations in the organization and meaning of same-sex practices are enormous in their range across cultures, and changes within a given society over time have been amply demonstrated. The universality of the existence of same-sex sexual expression has been shown to be matched by the constancy of change and variation in its organization and meaning. Future cross-cultural studies can help to further explicate the social factors, such as industrialization, urbanization, religion, and class stratification, that influence the structural forms into which individual sexual desire and behavior are shaped within cultures. By challenging the culture-bound assumptions that are brought to scientific conceptualizations of homosexuality, cross-cultural approaches encourage a broader understanding of sexual development and behavior.

Psychosocial Studies of Development Classical theories of psychological development are based on linear pathways of development that progress sequentially from childhood to adulthood and posit the origins of adult personality and identity in childhood experience. Only in more recent years have the distinct processes of adult development been studied. An understanding of the psychological development of sexual orientation must be based on an examination of psychological and interpersonal events throughout the life cycle and must incorporate assumptions of both continuous and discontinuous patterns of development. Furthermore, when applied to sexuality and sexual orientation, models of development must be sensitive to the physical, cognitive, and emotional maturation that occurs across the lifespan and must not assume that childhood behaviors, awareness, and feelings are isomorphic with adult experiences. In addition, until recent years psychological studies of homosexuality have been based on the examination of very specific and unrepresentative populations, such as psychiatric patients, incarcerated individuals, and persons in the military. Most psychosocial studies continue to be plagued by problems of sampling and, although they may no longer be limited to these special populations, have tended to focus more on white, urban, openly identified, and community-affiliated gay men and lesbians, whose development and experience may not adequately reflect other groups.

The findings from psychosocial studies may also vary depending on what research methodology is followed. For example, findings from retrospective studies may demonstrate greater consistency with popular models of development as a result of social learning about those models that leads to their internalization as part of the life scripts of individuals. Studies of purported childhood precursors of adult homosexuality may focus too narrowly on selected characteristics, such as effeminacy in boys, that are associated with stereotyped notions of adult homosexuality, but ignore the enormous individual variability in patterns of development toward and characteristics associated with adult sexual identity.

Only recently has psychological research begun to examine potential childhood and adolescent antecedents of adult homosexuality. Even now, empirical studies of homoeroticism in American society before puberty are nonexistent, and only a few studies on same-sex desire during adolescence have been published. Inhibitions on acknowledging sexual attractions and behaviors, particularly same-sex desire and behavior, during childhood have fettered scientific inquiry and led to a profusion of models of development derived from the retrospective reconstruction of childhood experience. Virtually the only perspective that has been available to examine the psychosocial origins of homosexuality has been that of the clinician, whose vision is framed by a focus on dysfunction, pathology, and abnormality. As a result, children who are different in their gendered behavior and adults who are disturbed have continued to serve until recently as the primary source for the depiction of the psychological development of homosexuality. The potential psychosocial understanding that might derive from ethnographic and other social science approaches to studying sexuality in children has been applied only in other cultures and has thus not been utilized as a tool for the study of the development of sexual orientation in American society.

Current knowledge about the psychosocial origins of homosexuality has been acquired through studies of children who demonstrate early gender-role nonconformity, reconstruction of childhood histories within psychotherapy, and a small number of empirical reports about sexuality and homosexuality in adolescence. The origins of adult gay, lesbian, and bisexual identities in Western society have been described in theoretical models of identity acquisition and in the findings from a limited number of empirical studies of the specific behaviors and events associated with establishing these identities.

Origins of Homosexuality in Childhood and Adolescence Early attempts to describe the childhood psychosocial antecedents of adult homosexuality consisted primarily of psychoanalytic formulations derived from the histories of psychiatric patients that depicted trauma and disturbed family relationships during childhood as causal mechanisms. The conceptual and empirical inadequacies of these portrayals for explaining the multiple forms of same-sex desire and behavior in both psychologically healthy and disturbed individuals led gradually to the investigation of alternative explanations for the development of a variety of forms of normal sexual expression and identity. Current explorations into homosexuality in childhood continue to be guided primarily by essentialist views of sexual orientation, which assume that a particular personality characteristic or specific behavior is a reliable predictor of adult sexual orientation. It is unlikely, however, that a single set of characteristics or a unitary pathway leading to adult homosexuality will be identified, given the varied and fluid experiences associated with same-sex desire, behavior, and identity in American society.

The most common characteristics examined in studies of childhood factors associated with adult homosexuality are early gender nonconformity and the recollection of an awareness of being different. The appearance of early gender nonconformity—femininity in boys and masculinity in girls—appears to be correlated with the development of homosexuality in adulthood for some individuals. Similarly, many adult gay men and lesbians report a recollection of an awareness of “feeling different” during childhood. These characteristics seem to be more common among children who will become homosexual than in those who will become heterosexual.

Findings from large-scale surveys of sexual attraction during adolescence show that younger adolescents tend to be less aware of same-sex feelings and to identify themselves less often as lesbian, gay, or bisexual than older adolescents. Reports of same-sex attraction in teenage girls range from 7.5 to 18 percent and in boys from 7.7 to 21 percent, with an estimated 15 percent of youth overall experiencing some same-sex attraction. Fewer youth report same-sex sexual activity, and even fewer identify themselves as gay, lesbian, or bisexual, although this latter figure increases with age. Although exact figures are unavailable for comparison, more youth currently identify themselves as bisexual or uncertain about their sexual orientation than in previous generations as a reflection of the greater awareness of flexibility in sexual expression and of the diminishing social stigma associated with bisexual identity in contrast to lesbian and gay identities.

The study of homoeroticism and of the development of homosexual or bisexual identities in adolescence continues to be difficult because of the existence of strong peer pressures to conform to heterosexual norms, ongoing and significant societal stigmatization of same-sex desire and behavior, and institutional and familial repression and denial of the existence of same-sex sexual feelings and behaviors in youth. Recent studies have focused on the adjustment, health, and mental health of young people who self-identify as gay, lesbian, or bisexual and who present to community centers that provide services for these individuals. As a result of access to and concentration on this segment of the youth population, more may be known at this point about the problems experienced by youth with an emerging or solidified gay, lesbian, or bisexual identity than about the normative events associated with development.

Acquisition of Gay and Lesbian Identities Much of the contemporary discussion about the psychosocial development of homosexuality has taken place within the field of identity development, where it has flourished as a primary theme in the broader discourse of social constructionism and its analysis of the political and social meaning of identity in late–twentieth-century postindustrial Western society. Thus, it is important to understand not only the theoretical description of gay, lesbian, and bisexual identity development in an individual, but also to appreciate the increased importance of personal identities at a cultural level. From this perspective, the definition of lesbian, gay, and bisexual identities and the detailed description of their emergence and multifaceted expression within both society and the individual can be seen as an outcome both of personal growth and development for the individual and of the cultural evolution of the concept of the “homosexual person.” The appearance of fully developed gay, lesbian, and bisexual identities in individual men and women can thus be seen to be as much a reflection of the creation and acceptance of the late–nineteenth-century biomedical belief that sexual desire and behavior are core characteristics that define selfhood as an endpoint or process of

individual growth and maturation.

Viewing gay, lesbian, and bisexual identities as both personal narratives and cultural constructs should not detract from the recognition of their centrality in organizing the subjective experiences of individual women and men. Rather, the psychiatrist who works with persons who talk about their experiences of becoming gay or lesbian should view these personal stories as framed within the contemporary language that most accurately describes their experience. The language used to encapsulate these subjective experiences is helpful when understood and applied within the clinical setting, but models of development and categories of sexual orientation must not be used in a manner that objectifies or simplifies the enormous range of individual experiences associated with sexuality.

Although theoretical descriptions of lesbian, gay, and bisexual identity acquisition are inconsistent and sometimes fail to distinguish between such concepts as identity, self, and self-concept, the experience of these identities by lesbians, gay men, and bisexuals is widespread and subjectively meaningful. For this reason it is important for the psychiatrist to be familiar with the principles of identity development relevant for these men and women. Models of lesbian, gay, and bisexual identity acquisition describe an intrapsychic and interpersonal process whereby a subjective experience of oneself as lesbian, gay, or bisexual becomes increasingly congruent with the perception by others that one is lesbian, gay, or bisexual. This process is generally conceived of as occurring over time, in sequential stages, and in a manner that leads to an increasing integration of one's experience of being lesbian, gay, or bisexual into other aspects of one's sense of self. Gay, lesbian, and bisexual identity development has generally been conceived as consisting of a series of stages involving a period of growing awareness and confusion about the presence and meaning of same-sex erotic feelings; followed by a time during which these feelings are assumed to have relevance to the person's life; and ending with an extended phase of growing acceptance of and pride in the new identity.

The process of identity development leads to different outcomes for different individuals, is influenced by interpersonal effects and consequences and feedback from others, and may be interrupted or terminated at any point. Most models of gay, lesbian, and bisexual identity development incorporate the completion of several events or tasks: coming out, or becoming aware of same-sex attraction and disclosing it at some point to others; forming relationships with other gay and lesbian persons; engaging in same-sex sexual behaviors; becoming involved in gay and lesbian activities and communities; establishing primary relationships with persons of the same sex: and learning how to integrate one's sexual identity into other aspects of the self.

Models of gay and lesbian identity acquisition present an image of progressive elaboration and synthesis of sexual orientation with other aspects of the self, but the lives of individual men and women vary considerably in the degree to which they follow such models. Development may be truncated for some persons in response to a number of factors, including a particularly punitive or harsh internal or environmental response to aspects of their new identity and a redirection of focus on other developmental tasks, such as schooling or career development. Because of a greater potential fluidity in their sexual orientation, women in particular may not follow any ideal of lesbian identity development, tending rather to emphasize the nature of the relationship they are in regardless of the sex of their partner. Similarly, because models of gay, lesbian, or bisexual identities have been developed based on the experiences of urban white persons, individuals who live in situations that do not provide reinforcement for adopting these identities (e.g., individuals in rural areas and people from some communities of color) may participate in same-sex sexual activities without ever acquiring an identity associated with these behaviors.

Individual variations in the extent of development of gay, lesbian, and bisexual identity may result both from repressive factors that interfere with optimal personal growth and from normative psychosocial influences reflecting diverse individual experiences and different adaptational needs. The psychiatrist needs to appreciate the relevance of such identity development for each patient, to understand their particular psychological and social resources and needs in this area, and to appreciate the costs and benefits of different pathways of development. Ultimately it is the individual's responsibility to develop an identity; the clinician can only help to optimize the understanding of the meaning of various options and to establish opportunities for maximizing freedom in making choices about often-conflicting outcomes.

LIFE-CYCLE AND DEVELOPMENTAL ISSUES

In most respects the lives of lesbians and gay men are very similar to the lives of heterosexual persons; however, because of the experience of difference and the negative effects of antihomosexual attitudes, lesbians, bisexual persons, and gay men are presented with unique developmental tasks throughout the life cycle. For example, during childhood and adolescence, youth who feel they are different and who become aware of significant attractions to someone of the same sex will need to understand their difference and often begin to disclose their homosexuality to others through the process of coming out. In adulthood these men and women will confront the unique challenges associated with establishing close relationships and creating families in a society that fails to provide rituals for celebrating and laws for protecting their families. All men and women are faced at different ages with important tasks such as establishing a sense of trust in themselves and others, forming healthy personal identities, creating and maintaining intimate relationships, learning how to lead productive lives, and sustaining a sense of generativity and personal integrity in old age. Success in completing these tasks is dependent on many factors, including biological and environmental resources, the impact of larger social and historical events, personal opportunities and traumas, and individual personality characteristics that interact at different developmental stages to shape a unique life for each person. In navigating the life cycle, gay men and lesbians and bisexual men and women will also need to contend with the negative factors resulting from the stigmatization of their sexuality as well as the potentially positive aspects of being part of a minority community.

Antihomosexual Attitudes and Heterosexism The term *homophobia* was coined by George Weinberg in 1972 to refer to fear or hatred of homosexuality and of gay and lesbian persons. This term has had widespread popular currency and has been applied to a variety of antihomosexual attitudes, but it has also been criticized for implying that the occurrence of these attitudes in an individual suggests the presence of a formal psychiatric diagnosis. Although extensive research on homophobic attitudes has demonstrated that they are correlated with certain demographic and personality characteristics, including sex, area of residence, religion, and degree of authoritarianism, the presence of these attitudes does not represent a type of mental illness; in fact, they are considered normative among some groups and in many social and institutional settings, including many schools, the military, and some religious organizations. Currently, the broader phrase, *antigay and antilesbian attitudes*, is often used to refer to the wide range of negative beliefs and feelings about homosexuality and gay men and lesbians.

Heterosexism is a related term that is defined as “an ideological system that denies, denigrates, and stigmatizes any nonheterosexual form of behavior, identity, relationship, or community.” Heterosexism is similar to other forms of ideological oppression, like racism and sexism, and occurs at both individual or psychological and societal or institutional levels. Antihomosexual attitudes may be expressed by individuals through verbal abuse, prohibitions, and physical violence directed toward gay, lesbian, and bisexual persons. Institutions promulgate such attitudes by excluding gay men and lesbians and by maintaining discriminatory policies and practices. Antihomosexual attitudes are an expression of heterosexist beliefs and can serve to enforce the maintenance of a “compulsory heterosexuality” in society. Heterosexism and antihomosexual attitudes may not be viewed as negative in a society or among groups that devalue and wish to eliminate erotic feelings and behaviors between persons of the same sex. Indeed, these systems serve to restrict awareness and expression of such feelings. For example, many religious institutions, military groups, and school systems actively prohibit homosexuality and promote negative attitudes toward nonheterosexual forms of sexual and affectional relationships. Outdated psychiatric and psychological views of homosexuality as a form of mental illness and religious teachings that homosexuality and homosexual behavior are immoral may be used to reinforce such negative attitudes.

All lesbian, gay, and bisexual persons will to some extent contend with what has been called *internalized homophobia*, which occurs when the developing gay or lesbian person psychologically incorporates negative societal views of homosexuality and then experiences these feelings and beliefs in the form of a negative self-evaluation. Although the effects of internalized homophobia on the development of sexual orientation differ enormously at an individual level, these negative feelings can lead to the suppression of awareness of same-sex attraction, an interference with the acceptance of one's homosexuality, and the truncating of a healthy integration of sexual orientation into other aspects of identity. Many gay men and lesbians experience internalized homophobia as an oppressive sense of devaluation and limitation in relation to their homosexuality, and for some it can produce a variety of psychiatric and behavioral symptoms, including depression, anxiety, denial, and even suicide. Internalized homophobia interacts with individual life histories to produce a unique expression in each gay and lesbian person, but its common roots lie in experiences such as criticism and shaming because of gender-nonconforming behavior in childhood in adolescence, being systematically excluded from institutions like the military, and being discriminated against by prohibition of same-sex marriage and denial of equal health and other benefits to same-sex partners.

Antigay and antilesbian attitudes, heterosexism, and internalized homophobia serve to define important aspects of development and daily experience in the lives of lesbians and gay men. For some persons these negative forces impinge upon the successful completion of normative developmental tasks and may delay or prevent successful adaptation and achievement of a healthy sense of self. The psychiatrist can be helpful by recognizing the influence of these factors on the personalities and experiences of gay, lesbian, and bisexual persons and carefully differentiating the intrapsychic and interpersonal wounds that result from stigmatization, discrimination, and victimization associated with being lesbian, gay, or bisexual from other aspects of the self. The psychiatrist's tendency to perceive problems that arise because of a need to deny being gay or in response to negative societal reactions to homosexuality as problems with sexual orientation itself has historically put gay men and lesbians at risk for further injury when seeking psychiatric help.

Coming Out and Meaning of Disclosure *Coming out*, defined previously as the process of recognizing one's homosexuality and disclosing it to oneself and others,

is a concept that is essential for understanding the lives of lesbians, gay men, and bisexual persons. It is particularly useful because of its experiential relevance for these persons and because of its widespread application in the behavioral and social science as well as in the popular literature. Coming out is not synonymous with identity development. One way of understanding the difference between these two concepts is to view coming out as one part of the process whereby a lesbian or gay identity is formed as the outcome. Behaviors associated with coming out reflect underlying cognitive and affective transformations that occur as part of identity development. Thus, coming out to oneself—becoming aware that one is attracted to persons of the same sex—facilitates disclosure of these feelings to others, which in turn can lead to social reinforcement and support. Some gay men and lesbians may come out in certain spheres of their lives, for example, within friendship groups, but remain closeted in other areas, such as in the work setting or within families.

The extensive literature on coming out generally describes it at the most basic level as the state of being clearly and openly gay or lesbian, in contrast to remaining *in the closet* (hinding one's homosexuality from oneself or from others). Early gay liberation publications portrayed the political distinction between coming out and being closeted as a struggle between liberation and oppression. Subsequently, coming out has also been defined as a psychological and social process that can help the gay person to overcome self-hatred and other negative effects of internalized homophobia.

Coming out is an ongoing process because gay and lesbian persons must repeatedly inform others of their identity. In spite of the belief that stereotyped personalities and appearances are associated with homosexuality, gay men and lesbians cannot be identified without some intentional or unintentional disclosure of their identity. Persons are generally assumed to be heterosexual unless they declare themselves to be otherwise. Adoption of certain styles of dress or behavior, residing in areas where other gay men and lesbians live, participation in gay and lesbian communities, and being involved in relationships with persons of the same sex may serve to confirm the identity of the gay or lesbian person, but these acts are themselves signifiers of coming out that must be maintained in order to inform others that one is gay or lesbian. Thus, disclosure of one's homosexuality involves either telling other persons that one is gay or lesbian or showing them through the display of some commonly accepted signal of sexual orientation identity. Gender ambiguity resulting from deliberately playing with gender and sexual portrayals by many young people in a postmodern culture may also lead to confusion about or inaccurate assessment of the sexual orientation of these individuals on the part of persons who rely on traditional signifiers of gender.

Most empirical studies of coming out have described the ages at which gay men have reported events associated with coming out; fewer studies have reported on the process for lesbians. However, studies show that women tend in general to have their first sexual experiences and to come out later than men. Younger lesbians may experience stronger prohibitions on coming out because of intense expectations of heterosexual dating for women. More recent studies have also suggested that coming out, much like the age of the first sexual experience, is occurring at progressively earlier ages in adolescents and that there is significant variation in the process based on a variety of factors other than sex, such as socioeconomic status, education, and ethnicity. The study of various cultures also demonstrates variation in the coming-out process based on the degree of sexual restrictiveness of a society.

Coming out is a complicated process that involves both internal and external spheres, occurs over a lifetime, and may vary in different domains of a person's life. The clinician must be aware that even persons who appear to be gay or lesbian may have never verbally disclosed their sexual orientation, and that others who provide no stereotypical indications of being gay or lesbian may have widely disclosed their identity to family, friends, and co-workers. Some persons who are fully aware of their homosexuality may never disclose this fact to others, and the range of time that elapses between awareness of same-sex attraction and self-labeling as gay or lesbian may be from less than a year to decades. Each individual's coming-out process must be understood and appreciated as unique and multidimensional.

Effects of Diversity Homosexuality and its various forms of expression develop in relation to other aspects of the self, which are influenced by a variety of individual and group characteristics. Lesbians and gay men are members of the same subgroups of diverse individuals that exist in the general population, and their experiences are significantly shaped by membership in these groups, which are defined by such characteristics as sex, racial and ethnic background, age, and class. Thus, understanding the development and experiences of lesbians, gay men, and bisexual persons often requires appreciation for their multiple affiliations and identifications, including but not limited to those defined by sexual orientation. Membership in many of these groups may involve further experience of discrimination resulting both from the prejudice directed toward people because of their race, sex, religion, age, or other characteristics, and from particularly intense antihomosexual attitudes that exist within some of these populations, such as certain conservative religious and ethnic groups. For some lesbians and gay men, membership in such groups may be a far more important determinant of their identity than their sexual orientation, and it is helpful for the psychiatrist to understand the variations in meaning of sexual orientation within these groups. For example, an older woman of color who has had a long-term relationship with another woman generally has a completely different construction of identity than that of a young gay man.

Sex and Gender Undoubtedly the most important group characteristic affecting the expression of sexual orientation is biological sex; men and women have very different experiences in relation to homosexuality because sex and gender are profound determinants of their identity. *Sexism* the domination and exploitation of women by men, can operate in conjunction with homosexuality in parallel to its function in defining certain aspects of heterosexuality. Definitions of gender are used to categorize people based on their sex, whether they are gay or lesbian, bisexual, or heterosexual. Therefore, the belief that lesbians and gay men necessarily share common qualities and interests should be replaced with a recognition that lesbian psychology and development may relate far more fundamentally to the psychology of women than to the psychology of gay men. In addition, the existing body of research and theory about homosexuality has largely focused on homosexuality in men and may have much less relevance for lesbian women.

Growing up as a boy or girl influences the experience of sexuality and sexual orientation in two general ways: through the development of different gender characteristics associated with men and women and through the imposition of different expectations for men and women, which often take the form of limitation and even discrimination based on sex. Gender socialization of boys and girls is one of the most profound forces influencing the quality of social interactions, and as a result, men and women generally behave in different ways. Although a person's biological sex is ultimately not the determining factor in the development of gender characteristics, sex and gender are inextricably linked in our society at the experiential level. Consequently, a variety of features of same-sex relationships will be influenced by the gender characteristics of the partners. For example, men often are more sexually active and competitive, and resolve conflict differently than women, and women as a group may be more emotionally expressive and relationally oriented than men. Gay men and lesbians may also be less likely than heterosexual persons to conform to traditional gender stereotypes and therefore may be more variant in their manifestations of gender-related characteristics.

Associations of sex and gender with homosexuality have historically led to inaccurate views of gay men and lesbians that portray them as persons who have the gender characteristics of the other biological sex, or who form relationships based on the assumption of complementary gender roles by two men or two women. In fact, the range of gender attributes of gay men and lesbians is as large and their relationships are as varied as those of heterosexual men and women. The psychiatrist working with gay men, lesbians, and bisexuals should set aside any preconceived notions about their gender-role characteristics; appreciate the significant role of gender socialization in shaping the personalities of all men and women and, as a result, the effect of this socialization on gay men and lesbians and on the dynamics of same-sex relationships; and assess the specific gender-related issues that might be present for a particular individual or couple. Such an approach recognizes the important influence of sex and gender in the lives of lesbians, gay men, and bisexuals, as well as heterosexuals, and avoids introducing inaccurate and denigrating stereotypes into the clinical setting.

Age and Generation The age at which a gay man, lesbian, or bisexual came out, the era during which they grew up, and the length of time since they came out will significantly affect their experiences of being gay, lesbian, or bisexual. Comparing a 50-year-old man or woman who came out at age 20 with someone of the same age who came out at age 45 or with a young person coming out today will generally demonstrate vastly different perceptions of reactions by others to their homosexuality. Generally, older lesbians and gay men were confronted with a much more negative set of social responses to their homosexuality than young people are today, and people who remain closeted during their adolescence and much of their adulthood will generally feel a greater sense of deprivation and loss in relation to their homosexuality than people who come out and establish a gay or lesbian identity earlier.

The differences between people of similar ages who have come out relatively earlier and later is a function not only of the discrepancy in social reactions to homosexuality during different historical periods but also of the interaction between general developmental maturation and ages of coming out and acquiring a gay or lesbian identity. For example, the impact of coming out on someone who establishes an openly gay or lesbian identity before being involved in an intimate primary relationship will be very different than for someone who comes out after being involved with another person in a heterosexual relationship or who has avoided any expression of intimacy because of fear of being identified as gay or lesbian. In addition to such developmental factors, each decade has brought a very different set of responses to homosexuality in American society and has seen the creation of increasing numbers of social structures and organizations available to gay and lesbian persons. Access to these structures and organizations will vary considerably as a function of the historical period and the chronological age of the individual. Many settings and groups are age-specific and may not welcome persons who are older or struggling with their sexual identity.

The psychiatrist should carefully evaluate the influences of age and generation on the individual gay man, lesbian, or bisexual and appreciate the enormous potential effects of these factors on their experiences of their homosexuality. Most young people growing up gay or lesbian today have been exposed to a vastly different set of social depictions of homosexuality than older persons who grew up decades ago. The portrayals available today are not always more positive and may arise from

sources that are very negative toward homosexuality and gay and lesbian people, but there is greater discussion of the topic and more visibility of a wider range of possible role models for young people. The older person who is struggling with coming out today will often have more deeply ingrained internalized homophobia with which to contend than someone of the same age who came out earlier. The greater number of gay and lesbian venues and the increased visibility of gay and lesbian persons can, for some persons who come out at an older age, lead to increased frustration and lowered self-esteem as a result of problems in accessing these potential supports and self-recrimination about the inability to come out earlier. These variable responses must be carefully assessed in clinical work with lesbians and gay men.

Race and Ethnicity With respect to the race or ethnic background of the gay, lesbian, or bisexual individual, consideration must be given to two further issues: the attitudes within the specific group toward sexuality and homosexuality and the additional prejudice directed toward some racial and ethnic groups within society. These two factors may compound the experiences of stigma and discrimination with which gay men and lesbians of color and from some cultural groups will have to contend. One example occurs within communities of African Americans, which may have varying attitudes and beliefs about sexuality and homosexuality resulting from such factors as family structure, religion, and class. The interaction between the effects of racism in the gay community and homophobia in the African-American community may lead to inadequate coping techniques and poor self-concepts among African-American gay men. Finding validation within either the African-American or gay and lesbian communities may be difficult, and integration of potentially conflicting identities based on race and sexual orientation may be an important need for persons from these groups. Similar issues may arise for persons from other racial and ethnic groups. Hispanic individuals are often influenced by antigay and antilesbian religious attitudes and traditional gender role and family expectations. Native-American concepts of gender, sexuality, and sexual orientation often diverge considerably from non-Native notions of these constructs and may incorporate beliefs about spirituality as well. Because Asian-American gay men and lesbians come from a large number of different language and cultural groups that have diverse attitudes toward homosexuality and gay, lesbian, and bisexual persons, it is impossible to generalize about their experiences. Thus, although membership in a particular group may assist in predicting family, religious, and social reactions to homosexuality, the diversity of backgrounds within many legally designated minority groups requires careful assessment of each individual's experience, level of cultural identity, and degree of acculturation.

The expression of sexual attraction and identity may be strongly influenced by racial and ethnic identity. These identities may be experienced as conflictual, resulting in such strategies as maintaining complete secrecy about homoerotic feelings, adopting a bisexual instead of a gay or lesbian identity, or even feeling the need to choose between cultural and sexual orientation identities. For some persons the conflict between identities may lead to profound confusion and alienation from both groups. The helpful merging or compartmentalization of potentially oppositional personal identities into an integrated sense of self may be extremely difficult to achieve, and this struggle must be appreciated and understood by psychiatrists who work with multicultural gay and lesbian populations.

Religion The impact of religion on the lives of gay men and lesbians derives from the importance of religion both in individual history and in society. Individuals come from different religious backgrounds that may involve exposure to a wide range of attitudes toward homosexuality, and they may or may not maintain ties to the religions of their families of origin. Socially, religion influences gay men and lesbians who belong to particular religious groups that may present supportive, tolerant, or negative views of homosexuality as well as all gay and lesbian persons through shaping the larger cultural and political climate toward homosexuality. Many gay men and lesbians attempt to avoid negative religious teachings about homosexuality by eschewing any contact with religion; others work within their religious groups to try to change negative attitudes about homosexuality; and still others stay attached to, while feeling powerless to change, religions that reinforce their internalized homophobia. Many gay men and lesbians have actively sought a reconciliation between their sexual identity and their spirituality within existing religious groups, and others have moved to create new churches and spiritual settings that will affirm their sexual orientation and their relationships.

Increasingly, religious organizations within American society have been forced to deal with homosexuality both as a personal issue for their members and as a source of theological contention, and a growing number of religious groups have moved to positions that either tolerate or actively embrace gay men and lesbians. At the same time, in response to the rising social discourse about homosexuality some conservative religious organizations have reaffirmed their opposition to homosexuality and become more outspoken about the immorality of individuals who adopt gay, lesbian, and bisexual identities. Regardless of their personal relationship to religion or their involvement with a specific religious group, all gay men and lesbians have been profoundly affected by religious teachings about homosexuality.

Negative religious views about homosexuality often become internalized in lesbians and gay men and may seriously interfere with healthy psychosexual development, particularly involving sexual expression and relationships. Spiritual development itself may be impaired because of an inability to reconcile the conflicting internal and external messages concerning the erotic and spiritual aspects of the self. Until the gay or lesbian person is able to overcome such negative religiously based self-evaluations, it may be impossible for them to achieve a healthy identity. Some individuals may not be able or wish to disengage from their religions even when their homosexuality is judged harshly, and many others struggle to establish a connection to some other, more affirming spiritual community. The psychiatrist must understand the important need felt by some gay and lesbian persons to resolve these difficult situations without totally cutting themselves off from their religious groups or families. However, the pull to retain connections to such groups is sometimes very strong and it is essential to provide appropriate support for individuals who are unable to extricate themselves from this situation. Even when the separation is completely successful, however, serious psychological wounds may remain that continue to distort or truncate those dimensions of experience associated with spirituality and sexuality. These concerns may become an important focus in clinical work with lesbians and gay men.

Interaction of Sexual Orientation With Stage of Development Experiences associated with sexual orientation lead to a variety of tasks, challenges, and opportunities for gay men and lesbians at different points in their lives in relation both to levels of biological and psychosocial maturation and to the extent of coming out and of acquiring a gay or lesbian identity. In general the psychosocial and physical issues confronting gay men and lesbians during different developmental stages are similar to those for heterosexual persons, but there are also specific issues that occur as a result of being gay and lesbian during childhood, adolescence, young adulthood, midlife, and old age. Although the developmental tasks that occur across the life cycle do not occur at the same age for all persons, even when there are similar experiences related to awareness and expression of sexual orientation, most persons will have to confront certain tasks during each stage of development.

Childhood During childhood the issues for children who will grow up to be gay or lesbian derive primarily from the experiences on the part of some of them of being different and the related gender-role variations that some of these children demonstrate. Feeling different can lead to a sense of alienation that may result in reactions such as social isolation and denial. Boys who appear less masculine may have deficits in self-esteem, which may be reinforced by being shunned, humiliated, and derided by their peers in school and other social settings. Such children may also be criticized or otherwise devalued within the family, and some parents and mental health professionals may try to shape or enforce the formation of more traditional gender-role behaviors. Other parents may ignore or shun their children when they fail to conform to expectations of heterosexual development. These experiences usually lead to an internalization of the negative reactions of others and serve to pressure some children to reject the devalued aspects of self they associate with their sexuality and gender. If these effects are severe or are accompanied by incidents of overt discrimination or violence during childhood, the personality may be further damaged and lead to later impairment in the capacity for psychological, social, and work adaptation.

Adolescence Adolescence is a particularly vulnerable time for most youth, who need to begin during this period to establish a coherent identity, separate from their families of origin, and practice patterns of relating and working that will be further developed in early adulthood. Many gay and lesbian youth first become aware of their same-sex attraction during puberty when they begin to mature physically. Gay and lesbian adults often recall the development of a cognitive awareness of their sexual orientation during adolescence as well and many of them may also move through the early stages of establishing a gay or lesbian identity, begin to have affectional and sexual relationships with persons of the same sex, and develop connections with gay and lesbian communities. Successful accomplishment of these tasks can be inhibited or facilitated by the reactions of families and others to the emerging gay or lesbian identities and social interactions. Most gay and lesbian youth are also involved in heterosexual relationships during adolescence.

After telling his parents that he was gay, a 16-year-old high school student sought therapy from an openly gay psychiatrist. The parents insisted that the adolescent male enter therapy for his problem but the youth insisted that he would only see a lesbian or gay psychotherapist. During the evaluation the patient reported depression of several years standing, difficulty in his school work, and social isolation. The parents also were interviewed and stated their unhappiness with their son's declaration to them and their wish for him to become heterosexual.

The patient entered individual psychotherapy accompanied by some joint sessions with his parents. During the course of therapy he described his awareness of his sexual orientation prior to adolescence, his fear of being labeled gay in school, and his anger at his parents' refusal to accept him and his assertion about his sexual orientation. Over the course of two years in psychotherapy his long-standing symptoms of depression (including lethargy, withdrawal, lack of interest in school, and feelings of self-hatred) diminished and his mood improved considerably. He established better communication with his parents who were less openly critical of his sexual orientation. His grades improved and he developed a small network of close friends in high school who were aware that he was gay. Regular therapy ended when the patient moved to a large city to attend college. During a number of follow-up appointments over a period of several years when he visited his parents, the patient reported good adjustment at school and success in establishing satisfying relationships with other men. His parents were now supportive of him and seemed to accept his sexual orientation.

Most gay and lesbian adolescents either consciously or unconsciously delay some aspect of the development of their sexual orientation identity until they can obtain a greater degree of safety and support, which might be accomplished by going away to school, moving to an urban environment that allows more anonymity and acceptance, or creating a network of friends who will be accepting of the gay or lesbian identity. Some adolescents may suppress any awareness of same-sex attractions, others may defensively attempt to establish heterosexual relationships and identity, and others may consciously avoid any outward display of their sexual orientation. Less often but increasingly frequently in some urban settings, gay and lesbian youth may clearly identify their sexual orientation at an early age, disclose their feelings to others, and complete significant aspects of gay and lesbian identity formation during adolescence. Such youth may be able to avoid some of the problematic developmental decisions made by previous generations of gay men and lesbians, such as entering into unsatisfactory heterosexual relationships, believing that having and raising children could only occur within traditional heterosexual relationships, and forgoing any intimate relationships with persons of either sex because of the fear of disclosure of a gay or lesbian sexual orientation.

Because of the unavailability of adequate role models and resources for support, the ongoing stigma associated with being gay or lesbian, the frequent victimization of visible gay and lesbian youth in schools, and the absence of acknowledgment and affirmation from parents and other significant figures in their lives, most pregay and prelesbian adolescents undoubtedly continue to experience significant difficulty in forming and integrating a healthy gay or lesbian identity during adolescence. The psychiatrist should be aware of these negative influences on development for youth who may be gay or lesbian and be sensitive to the potential effects of these factors on their mental health.

Young Adulthood The period of transition from adolescence to adulthood is significant in the lives of many lesbians and gay men who often have their first opportunity to come out and to establish gay and lesbian identities independent of their families of origin during this time. Gay men and lesbians in their 20s and 30s confront the same developmental tasks as heterosexual men and women of the same age, including developing a career, establishing a social identity, achieving the capacity for intimate relationships, and perhaps childrearing, but these tasks may be accomplished in different ways and at different times because of the influence of being gay and lesbian. For example, as a result of negative external forces and internalized homophobia, some gay men and lesbians may experience a delay in the consolidation of their sexual identity and may compensate by investing relatively more energy in their careers during early adulthood, and because many young gay and lesbian adults have not been able to date others of the same sex during adolescence, they may engage in sexual and peer-group relationships that do not follow traditional heterosexual patterns of relating. The psychiatrist should not view these relational patterns as inadequate or abnormal but rather as adaptive for persons who have had to struggle to overcome societal disapproval of their identities and behaviors and to learn to create satisfying sexual and affectional bonds in the absence of visible social structures or role models for such relationships.

During early adulthood many heterosexual persons marry and have children. Gay men and lesbians are less likely to form long-term relationships at this age, but most of them will enter into primary relationships at some point. In previous generations a significant proportion of men and women with attractions to persons of the same sex adopted a heterosexual persona and entered into heterosexual marriages during early adulthood; many of these individuals also had children and raised families. Although currently there are a greater variety of options available to gay and lesbian people during this period, such as living in gay communities with supportive friendship networks, forming primary same-sex relationships, attempting in a self-aware manner to be in heterosexual relationships, and choosing to have or to adopt children, many gay and lesbian young adults continue to feel limitations in their choices as a result of discrimination and the effects of internalized homophobia. The threat of human immunodeficiency virus (HIV) infection and acquired immune deficiency syndrome (AIDS) has also had enormous impact on the sexuality and relationships of gay men by creating new barriers to establishing a healthy sense of well-being and to forming intimate relationships.

In the area of creativity and work, gay men and lesbians may in some instances choose careers during early adulthood that tend to ensure greater acceptance of their sexual identity. Although gay men and lesbians are represented in every type of occupation, they may tend to migrate in greater numbers to those fields that are not stereotyped as traditionally masculine or feminine. Some reports suggest that because gay men and lesbians have had to contend with and overcome negative reactions to them based on stereotypes of gender-nonconforming behaviors, they are better able to transcend gender limitations and to integrate masculine and feminine attributes more fully into their personalities. As a result, in the area of work some lesbians may be more able than many heterosexual women to achieve successful careers, and some gay men are able to be employed in fields historically associated with women, such as nursing and the fashion industry. Nonetheless, discrimination in hiring and promotion continues to be widespread for gay men and lesbians and the lack of legal protection creates considerable work-related stress for many of them.

Midlife The midlife decades of the 40s and 50s are marked for gay men and lesbians, as they are for heterosexual men and women, by consolidation of career identity, concerns about generativity, and emerging problems with health and aging. Gay men and lesbians currently in midlife represent the first generation to have openly identified themselves as gay and lesbian in significant numbers and as a result are forging new developmental patterns in relation to their sexual orientation. Many midlife lesbians and gay men appear to have been able to achieve a greater balance between their career and relationship than other groups, particularly when compared with heterosexual men.

Midlife lesbians are considerably more likely to be employed in professional or technical and managerial positions when compared with other women, although they do not always receive incomes commensurate with their level of employment. Lesbians and gay men may have to struggle with integrating their identities into the workplace and many are confronted with limitations on their advancement at work because of discrimination. Individuals who have invested more heavily in their careers in order to compensate for a lack of fulfillment in their relationships or in other areas of their lives resulting from unresolved issues about being gay or lesbian may be particularly vulnerable to such restrictions and rejections at work.

Many lesbians and gay men may have children to raise during midlife, as the result of previous marriage, adoption, or decisions to have and raise children outside of traditional heterosexual relationships. However, many of these parents do not receive the same support from their extended families as heterosexual parents do and thus may rely much more heavily on friendship networks for support of their families. During midlife and earlier, some gay and lesbian parents may be involved in extensive legal battles over custody and support of their children. Many gay men and lesbians who do not have children will seek outlets for their need to be generative in midlife in their friendship circles, through service as mentors or foster parents, or in other types of family and community involvement.

Gay men and lesbians have the same concerns about health during midlife as heterosexual men and women; however, in addition, they may suffer from a lack of access to adequate health care as a result of fear of disclosure of their sexual orientation and inadequate knowledge on the part of health care providers about their special needs. As a result of high rates of HIV infection, a large number of gay men are also confronted during midlife with issues of death and dying and increasingly with the need to live with long-term disease and uncertainty about health status.

Old Age Persons of any sexual orientation in their 60s and older have a wide range of experiences in relation to aging; some will develop serious illnesses and become incapacitated while others will live healthy lives for two or more decades. All older persons need to deal with the approach of death at some point, and older gay men and lesbians have additional factors to face. Stereotypes of older gay and lesbian persons are usually negative, portraying them as lonely and unhappy. However, they have been shown to be just as well adjusted as their heterosexual counterparts, and they may be better able than younger gay people to contend with the negative reactions to their sexual orientation because they may no longer be concerned about disclosure at work and they may have learned to accept their sexuality.

The best predictors of psychological adjustment in older gay men appear to be their commitment to their sexual identity and their integration into the gay community. Older gay men generally prefer to associate with their age peers, and many of them report that they are in relationships. A large majority of older gay men and older

lesbians report that they are happy, deny significant concerns about loneliness or fear of death, and describe good integration into social networks.

Problems for older gay men and lesbians exist because of the lack of adequate resources for older gay people, the widespread reluctance to disclose a nonheterosexual sexual orientation to health care and other providers, and the almost total absence of acknowledgment of gay and lesbian persons and their relationships and needs within institutions and agencies that provide care for older persons. The failure to acknowledge older gay and lesbian persons is a function both of the denial of sexuality in older people in general and of an unwillingness to recognize relationships that are not legally sanctioned. The resulting invisibility of gay men and lesbians in most health care and custodial settings that provide services to older persons perpetuates the stigmatization and discrimination that many of these men and women have experienced in relation to their sexual orientation throughout their lives and may reawaken old psychological wounds. The psychiatrist working with older persons should make every effort to acknowledge and affirm the sexual orientation and the intimate relationships and friendships of these patients. Same-sex partners and gay and lesbian friends may often be excluded within the health care setting, which may significantly compromise the quality of life and care for the older gay or lesbian patient.

Families and Relationships Gay, lesbian, and bisexual persons are born into the same families that produce heterosexual children; however, growing up in their families provides few of these children with the opportunity to have their emerging sexual orientation acknowledged and affirmed or to be exposed to positive adult gay and lesbian role models. The vicissitudes of being raised in families that often fail to support their sexual feelings and identity lead many gay men and lesbians to create what have been called *families of choice*, friendship networks that provide the interpersonal bonds and resources that were lacking in their families of origin or that generally occur outside of these families, such as in adult friendships. The majority of gay men and lesbians form their own nuclear family structures as well, in the form of steady romantic same-sex relationships, long-term cohabiting relationships, and single or co-parent households with children. The findings from a growing body of research have begun to describe these couples and families.

Families of Origin Versus Families of Choice Many gay men and lesbians have grown up in families that have either ignored or denigrated their sexual feelings and emerging identities; sometimes they report significant physical and emotional abuse from their families related to their sexual orientation. The reactions of parents and other family members to the disclosure by a young person of feelings of sexual attraction to persons of the same sex or of a gay or lesbian identity can significantly influence the self-esteem and self-acceptance of gay and lesbian youth and help shape expectations of acceptance or rejection by others in the world. Even in optimal situations, however, gay and lesbian youth may expect no more than tolerance of their sexual orientation within their families; rarely will they receive active acceptance or empathic support for the experiences and concerns that occur in relation to their emerging sexuality.

A 25-year-old woman sought treatment because of problems in her graduate degree program. Initially, she did not reveal her attraction to women but instead talked about the emotional abuse she felt from her conservative family who had never accepted her personal or educational choices. She gradually provided a history of unsatisfactory attempts to establish romantic relationships with men and her early recognition of her primary sexual and affectional preference for women.

The focus of the treatment was initially on her conflicts with her family and within her educational program. She described a longstanding pattern of disagreement with and ridicule by her parents and siblings because of her refusal to follow their conventional gender role expectations for her in terms of her physical appearance, dress, behavior, and career aspirations. Parallel conflicts had developed in her educational program, as evidenced particularly in her relationships with women instructors. Over the course of three years in weekly psychotherapy, she gradually began to discuss her reluctance to come out as a lesbian because of fear of her family's reaction to her and her own guilt about religious prohibitions. She tentatively began to explore the lesbian community in her town and eventually formed a relationship with a woman. Her conflicts within her graduate school program resolved as she developed a more secure lesbian identity and established satisfying relationships within the gay and lesbian community. She also came out to her parents and confronted what she experienced as their abusive treatment of her.

At the conclusion of therapy the patient moved in with the woman she had been dating. In subsequent follow-up appointments she reported improved relationships with her family and successful completion of her graduate degree program. She and her partner celebrated a religious commitment ceremony after living together for 1 year, and the patient appeared satisfied and quite happy.

Once gay and lesbian young people achieve appropriate separation from their families of origin, they often create networks of friends and acquaintances who provide them with the type of support and mirroring that was previously lacking. These families of choice may be extremely important in the lives of lesbians and gay men, serving the same functions as an extended family for many by helping them to pass through developmental crises, being present at celebrations and rituals, and providing them with a source of comfort and intimacy. In some cases these friendships may be more enduring than romantic relationships and more important than a lover or partner in the daily life of the gay man or lesbian. Families of choice often coexist with biological families, with each providing different types of nurturance. Holidays and social gatherings may involve combinations of individuals from biological and friendship relationships. The clinician who works with these individuals must understand and accept the importance of families of choice in the lives of lesbians and gay men.

Couples The majority of gay men and lesbians report being in a committed romantic relationship, with surveys indicating that 45 to 80 percent of lesbians and 40 to 60 percent of gay men are currently in such relationships. From 8 to 14 percent of lesbian couples and from 18 to 25 percent of gay male couples report that they have lived together for more than 10 years. In contrast to stereotypes of gay men and lesbians, they clearly form and maintain intimate same-sex relationships. While same-sex marriage is still legally prohibited, many same-sex couples live in relationships that are as enduring and emotionally significant as any heterosexual relationship, in spite of discrimination against these relationships, the absence of rituals and laws that support them, and the denial of equal protection and benefits to these couples.

Findings from the limited but growing research on gay and lesbian couples reveal that lesbian couples tend more frequently to be sexually exclusive than male couples. In addition, gay male and, particularly, lesbian couples, in comparison with heterosexual couples, generally have more equality in their relationships and do not differentiate household functions according to gender-based categories of work. Gay men and lesbians report the same degree of global satisfaction in their relationships as heterosexual men and women. However, undoubtedly as a result of gender socialization, women tend to appraise the value of and rewards from their relationships more highly than men, but gay and heterosexual men and lesbian and heterosexual women describe similar levels of valuing and rewards.

Empirical research by David McWhirter and Andrew Mattison led to the description of six stages in the development of male-male relationships: blending, nesting, maintaining, building, releasing, and renewing. Each stage is marked by specific characteristics and a time span although the stages may overlap and occur in a different sequence for some couples and the characteristics may appear in more than one stage. The relevance of this stage model for lesbians has not been determined, but some variation from the gay male experience should be expected. For example, lesbians may spend longer in the tasks associated with blending and the reappearance of the individual during the maintaining stage may not develop until later in lesbian relationships. Understanding the stages of gay and lesbian relationships can be helpful in identifying discrepancies between partners in progressing through the stages and in assessing stage-related problems in same-sex relationships.

Gay and Lesbian Parents and Their Children Many lesbians and gay men have had children, historically most often within heterosexual marriages and more recently through other avenues as well, including adoption, alternative insemination, and co-parenting arrangements outside of marriage. Numerous studies since the late 1970s have demonstrated the characteristics of gay and lesbian families and the impact of having a gay or lesbian parent on children. A significant change in recent years has been the greater visibility of families with gay and lesbian parents and the increased viability for gay men and lesbians of the choice to be involved in childrearing.

Research on gay and lesbian families was initially undertaken to disprove psychological and judicial assumptions about the harm that might be done to children raised by gay and lesbian parents. The findings resulting from such research have confirmed that lesbian and gay parents neither impact on their children in a negative way psychologically nor produce significantly different outcomes in the gender identity, gender role, or sexual orientation of their children when compared with the children of heterosexual parents. Children with gay and lesbian parents do have to struggle with their difference from heterosexual families and may have difficulty overcoming the stigma associated with this situation. The first era of research into the effects of gay and lesbian parents on their children has now yielded to a period of greater emphasis on understanding the dynamics of and determining the potential differences between families with heterosexual, gay, and lesbian parents. Future studies may involve greater methodological precision, focusing more on family process than on structure alone and allowing for improved understanding of differences between gay and lesbian families, derived from characteristics such as religion, age, class, race, and other characteristics, as well as sex and sexual orientation.

The emergence of families with openly gay, lesbian, and bisexual parents and children since the 1970s represents one of the most significant shifts in the structure of the family during the latter part of the twentieth century. The psychiatrist must recognize and validate the importance of this phenomenon in the lives of millions of

men, women, and children and not confound the clinical evaluation and approach to treatment of patients from these families with negative portrayals derived from political, religious, or psychological sources.

CLINICAL APPROACHES

For the most part the psychiatric concerns of lesbians, gay men, and bisexuals will be the same as those of the general population, and clinical work with them should involve approaches to assessment and treatment that are identical to those used with other patients. In addition, the psychiatrist must be aware of certain unique aspects of clinical work with this population.

General Considerations In spite of the fact that homosexuality and bisexuality are not considered to be mental disorders, many health care providers, including psychiatrists, continue to believe that homosexuality is associated with mental illness and dysfunction, report feelings of discomfort with gay and lesbian individuals, and admit to varying degrees of bias toward these men and women. Some even engage in attempts to change a person's sexual orientation when it is not heterosexual. As a result of the real risks of encountering disapproval, discrimination, insensitivity to their concerns, or abusive treatment within clinical settings, many gay, lesbian, and bisexual persons are reluctant to disclose their sexual orientation without a clear demonstration of a nonjudgmental and accepting attitude on the part of the clinician. Because of psychiatry's historical role in defining homosexuality as a type of mental illness and the persistence of negative views toward homosexuality on the part of some psychiatrists, clinicians must be particularly sensitive to the fear of mistreatment within psychiatric settings on the part of lesbians, gay men, and bisexuals. Optimal evaluation and treatment will therefore need to include a respectful and thorough assessment of all aspects of sexual orientation relevant to the care of a patient and careful monitoring of the reactions of patients to such inquiry and of the demeanor of the psychiatrist when discussing a potentially volatile and painful topic.

Inclusive and Special Clinical Settings Gay men and lesbians are for the most part treated in the same inpatient, outpatient, and residential clinical settings as other patients. In recent years a small number of special units have been developed for working with gay, lesbian, and bisexual persons—either community health centers intended to serve the needs of the local lesbian and gay communities or units geared to particular problems like HIV infection and substance abuse. Whether services are provided in general or specialized settings, staff need to be trained in how to deliver sensitive and unbiased care to gay men and lesbians and to be knowledgeable about the special concerns of this population. The clinical setting and staff with whom the patient comes into contact are important determinants of the climate of inclusiveness perceived by gay, lesbian, and bisexual patients. The explicit communication in these settings of awareness of and respect for diverse sexual feelings and identities is an essential component of successful psychiatric treatment.

The language and behavior of psychiatrists and other staff members should convey an awareness that not all individuals and families are heterosexual. For example, questions about relationships should be neutral with respect to the sex of partners. Clinicians should not assume that all married persons are heterosexual or sexually exclusive with their marriage partners. Questions about sexuality are most helpful when they inquire about desire, behavior, and identity as distinct entities. The availability of publications and forms indicating a recognition of diverse sexual orientations and family arrangements in the clinical setting and waiting area can help to reassure the gay, lesbian, or bisexual person as well as persons who are uncertain about their sexual orientation that they will be accepted in this setting and can talk about their concerns. Openly acknowledging that people have different types of sexual and emotional attractions and relationships can be a powerful tool for facilitating the honest presentation of a wide range of feelings and concerns about sexuality.

Another important strategy in clinical work with gay and lesbian patients is to routinely include appropriate references to significant friends and members of nontraditional families during evaluation and treatment. Same-sex partners and children in these families can be involved in the care of gay and lesbian patients to the same extent heterosexual partners and their children would be involved. For example, it may be important to obtain collaborating information from partners, to identify the potential source of a patient's problems in the context of the couple or family, or to include consideration of a partner's behavior in maintaining compliance. The same restrictions on confidentiality and decision making that apply to other families will also be relevant when working with gay and lesbian families.

Sexual Orientation of the Psychiatrist The effects of the psychiatrist's sexual orientation and of disclosing this orientation to the patient are complex. In general, the psychiatrist's sexual orientation will not be the most significant factor in determining clinical outcomes. Any therapist working with gay men and lesbians needs to maintain a conscious awareness of the potential for the development of antigay attitudes and heterosexist assumptions; possess a clear knowledge base about lesbian, gay, and bisexual issues; consistently apply gay-sensitive and gay-affirmative approaches to psychotherapy; and obtain adequate supervision when necessary.

When the lesbian or gay patient works with a psychiatrist who is openly gay or lesbian, there are several possible benefits and risks. Benefits of working with a psychiatrist of the same sexual orientation may include an easier rapport, greater efficiency resulting from shared knowledge about experiences associated with being lesbian or gay, and positive role-modeling effects of therapists who have established a healthy gay or lesbian identity. Possible risks for such pairs include the occurrence of unwarranted assumptions about shared experiences or personal characteristics based on sexual orientation alone, overidentification of the therapist or patient with each other, and a tendency to avoid discussion of certain events or affects associated with being gay or lesbian because of common knowledge about the pain associated with them.

It is also important to understand how the psychiatrist's sexual orientation is disclosed. For example, sometimes the patient has requested to work with an openly gay or lesbian therapist and has this knowledge before beginning treatment; in other cases this information becomes known after treatment has begun, either as the result of self-disclosure by the psychiatrist or from some other source. If self-disclosure is involved, the timing of the disclosure may have a significant impact on facilitating or inhibiting the work in therapy. It is important for the psychiatrist to be able to identify those gay and lesbian individuals and those situations for which working with an openly gay or lesbian therapist might be most helpful.

Sexual orientation may be far less significant than other personal characteristics in determining the effectiveness of a psychiatrist in working with gay, lesbian, and bisexual patients. A gay or lesbian therapist who has not fully come out or established a comfortable identity may have trouble working with patients struggling with similar concerns, and a therapist of any sexual orientation who is uncomfortable talking about sexual problems will have more trouble being helpful to gay and lesbian patients who have sexual concerns. Ultimately, the degree of empathy experienced and expressed by the therapist for the patient will in most cases be the most important factor in determining the effectiveness of treatment. Psychiatrists need to be vigilant about the dynamics of the ongoing interaction between their real or perceived personal characteristics, including but not limited to their sexual orientation, and the work of their patients.

Assessment of Sexual Orientation A careful and thorough assessment and description of sexual orientation is rarely completed in the clinical setting. When undertaken at all, an assessment usually does not go beyond designating a person as “homosexual,” or even less often, as “heterosexual” (heterosexuality usually being assumed). Sexual orientation is multifaceted and there are a variety of scales that can be useful in its assessment. These scales assess different components of sexual orientation—including desire, behavior, and identity—and evaluate the relative degree of sexual orientation for each component. Additional variables may also be included, such as changes over time in sexual orientation, social and emotional preference for one sex or the other, life-style choices, and gender-role identity. Sex research may involve psychophysiological quantification of sexual attraction through techniques like penile and vaginal plethysmography.

A 63-year-old man sought psychotherapy with complaints of depression and alcoholism, exacerbated since his father's death 2 years earlier. He did not present with concerns about his sexual orientation, and he described himself as “homosexual,” rather than as “gay.” He was employed in a very public setting, where he had always avoided questions about his private life. He reported that he did not feel comfortable with other homosexual people or in gay social settings. He had maintained a relationship for many years with another man who lived in a nearby city, spending one or two nights a week at this man's home and all holidays with him. When asked about various aspects of his sexuality, he stated that he had always only been attracted to men, had infrequent sexual interactions with other men in the past, but he did not consider himself to be gay. He described gay people as “flamboyant” and used derogatory terms to describe a “gay lifestyle.” Physically he was a large and attractive man who dressed impeccably and formally in a traditionally masculine manner.

During the course of psychotherapy, this man discussed his lifelong effort to hide his sexual orientation from others but he did not seek to change his attitudes about his homosexuality. He clearly had exclusively homosexual desire and behavior, but he denied any experience of a gay identity. His work in psychotherapy focused on his problematic relationships with his parents, his reactions to their deaths, his longstanding alcohol abuse, and his wish to retire and seek a new career. Although he discussed his views of his homosexuality extensively and attended an Alcoholics Anonymous (AA) retreat for gay men and lesbians while in therapy, he did not seek wider connections with other gay people and never saw himself as having a gay identity. At the end of psychotherapy, his depression resolved, he had no relapses of his alcoholism, and he successfully navigated his retirement. He was also less critical in his attitudes toward homosexuality in general, but his sexual orientation was not fully integrated into his self-identity.

The utility for the individual psychiatrist of the various approaches to assessment will depend on the extent to which information about sexual orientation is relevant to a particular patient's concerns. However, knowledge about the various scales and techniques informs the clinician about the complex and multidimensional nature of sexual orientation and helps prevent the tendency to attribute stereotyped global characteristics to individuals based on knowledge of one aspect of their sexuality. Assessment of sexual orientation on several dimensions can help to better understand the meaning and purpose of sexuality in an individual's life.

In evaluating sexual orientation the psychiatrist must balance the need to obtain all relevant information with the need to be sensitive when inquiring into an area about which a patient may feel very vulnerable. In addition, sexual orientation must not be approached solely as a sexual matter, as it also involves relational patterns, family structures, friendship and support networks, and community and cultural activities for many lesbians and gay men. Consideration of each of these psychosocial dimensions is important in developing approaches to treatment in work with lesbians and gay men.

Special Concerns Certain concerns are unique to lesbians, gay men, and bisexuals. The presentation of other concerns that do not directly relate to sexual orientation may also be shaped by the fact that a person is gay, lesbian, or bisexual, and for some persons being a member of a sexual minority group may interfere with and even prevent interactions with the health care system.

Societal and Domestic Violence The problem of hate-based violence directed against lesbians and gay men is widespread and well documented; it ranges from verbal abuse to violent homicide and is perpetrated by individuals, within families, by gangs, and by authorities such as the police. In addition, although studies have failed to show any causal connection between childhood sexual abuse and developing a gay, lesbian, or bisexual sexual orientation as an adult, sexual abuse of gay men and lesbians during childhood appears to occur at about the same rate as in the general population. Recent studies demonstrating the existence of domestic violence and abuse in lesbian and gay male relationships demonstrate that physical abuse occurs at about the same rate as in heterosexual relationships.

The effects of these various types of violence on gay men and lesbians are the same as they are on other victims of violence, including posttraumatic stress disorder, depressive disorder and a range of other psychological and emotional problems, but may also involve specific symptoms associated with being members of a stigmatized sexual minority group. The internalized homophobia of the victim of antigay or antilesbian violence may be triggered by the assault and lead to the belief that being gay or lesbian is the cause of the assault, and to feelings of inadequacy, embarrassment, or shame, or—depending on the severity of the attack and on the vulnerability of the victim—even to denial of one's sexuality and identity and avoidance of other gay and lesbian individuals. Gay and lesbian survivors of incidents of hate-based violence and of sexual or domestic abuse may encounter more difficulty reporting their experiences and seeking help than heterosexual persons because of fear of disclosure of their identity and of further harassment. The psychiatrist should be prepared to respond to the immediate crisis that may follow such an incident of abuse or violence, to the potential long-term effects of these events on the individual, and to the ongoing concerns about the various forms of violence directed against them on the part of all gay men and lesbians. Treatment and prevention can best occur in the clinical setting and in the community following the development of programs that will ensure adequate protection and safety for gay men and lesbians.

Increased Suicidality Determining the rate of suicide attempts and completed suicide among lesbian, gay, and bisexual persons is difficult because of such factors as the absence of information identifying sexual orientation on death certificates, the reluctance of many individuals who are too distressed about their emerging sexuality to discuss their feelings with mental health professionals, the general failure to assess sexual orientation adequately in most health care settings, and the inability to obtain representative samples. In spite of these problems in research, results from recent studies demonstrate that among youth being gay, lesbian, or bisexual increases the risk for attempting suicide. Among all youth, young women are more at risk for attempting suicide and young men are at greater risk for completing suicide. Suicide rates among gay, lesbian, and bisexual youth are also likely to vary based on the presence of other risk characteristics, such as mental illness, substance abuse, rejection by family, and degree of gender role nonconformity. In addition, increased risk of suicide may accompany struggles with internalized homophobia and problems with coming out and establishing a healthy gay, lesbian, or bisexual identity at any age.

Determining the exact numbers of persons who attempt or complete suicide who are gay, lesbian, bisexual, or struggling with their identity is ultimately less important than understanding the characteristics of these groups that contribute to risk for suicide. For gay youth, the invisibility of sexual-minority young people and the lack of adequate resources to address their health and mental health needs often prevent the necessary assessment of their concerns and the development of specialized programs for prevention and treatment. The politicization of funding for research to study suicidality among gay, lesbian, and bisexual young people has resulted from the equation of efforts to identify mental health concerns with attempts to promote minority sexual orientations, as though the need to obtain information about a medical problem is itself the source of the problem.

All youth in distress must be carefully evaluated for the presence of concerns about sexuality and sexual identity, and the psychiatrist can utilize approaches to assessment and treatment that do not place these persons at further risk following disclosure of their minority sexual orientation. Premature coming out can increase the potential for victimization of various kinds, including rejection by peers and family. The risk of suicide for persons of any age who are struggling with coming out and establishing a gay, lesbian, or bisexual identity must be recognized and clinical services appropriate for managing suicidality and for clarifying needs and providing support to these persons should be available when relevant.

Increased Rates of Alcohol and Substance Abuse Although findings from research into the problem vary considerably and controlled studies comparing comparable groups of heterosexuals with lesbians and gay men are absent, alcohol and other substance use and abuse appear to be increased among gay men and lesbians, with an incidence perhaps as much as two to three times higher than in the general population. Although lesbians and gay men consume more alcohol and are more likely to abuse substances at different points in their lives than the general population, they do not appear to have greater rates of drug or alcohol dependency. The causes of the problems with alcohol and other substance use are generally attributed to the psychosocial stressors associated with being lesbian, gay, and bisexual and to the tendency for gay and lesbian people to socialize in bars and clubs that encourage alcohol and drug use. Rates of substance abuse appear to be equally high among lesbians and gay men.

For some persons, links between substance use and abuse and problems with internalized homophobia are established when coming out and perpetuated during the stages of establishing a gay, lesbian, or bisexual identity, creating a profound and disturbing connection between sexual orientation and addiction. In addition, substances are often used to disinhibit prohibitions on sexual expression, and as a result many lesbians and gay men develop their sexual behaviors and patterns in relation to use of these substances. Identification of the possible comorbidity between substance abuse and problems with development of sexual orientation can be essential in defining adequate approaches to treatment of substance abuse among gay men, lesbians, and bisexuals. Specialized programs that simultaneously address problems with substance use and with establishing a healthy identity have been shown to be helpful for treating substance abuse in many gay, lesbian, and bisexual persons. Some 12-step and other self-help programs provide special settings in which gay men and lesbians can openly discuss their sexuality and identity as well as their use of substances.

The psychiatrist should be prepared to identify the overlap between problems with acceptance of one's sexual orientation and substance abuse. The signs of disturbance or delay in acquiring a healthy lesbian, gay, or bisexual identity and of addiction may be similar, including traits such as denial, fear, anger, guilt, helplessness, hopelessness, dishonesty, low self-esteem, self-hatred, and social isolation and alienation. Assessment of these problems and awareness of how each reinforces the other is essential if adequate treatment is to be accomplished. It is unlikely that recovery from substance abuse in gay, lesbian, and bisexual persons can occur without also establishing some degree of acceptance of sexual orientation; similarly, problems with sexual identity are very difficult to overcome while abusing substances that numb and interfere with self-awareness. As a result, programs designed for treatment of substance abuse must be both gay-sensitive and gay-affirming if they are to treat substance abuse disorders among gay men and lesbians successfully. Prevention of substance abuse among this population must involve efforts to address social and cultural factors that may predispose to use of substances, including the development of settings for socializing outside of bars.

Problems With Sexuality and Sexual Dysfunction The majority of problems concerning sexual functioning for gay men and lesbians are similar to those for the heterosexual population. Often, however, psychiatrists and other health professionals are uncomfortable talking about sexuality in general; dealing with the specific sexual concerns of gay men and lesbians may be particularly difficult because of unfamiliarity with or disapproval of same-sex sexual behaviors. The psychiatrist needs to be able to discuss the sexual concerns of gay and lesbian patients objectively and comprehensively and to be aware of special diagnostic issues and approaches to sex therapy with these men and women. Descriptions of existing diagnostic categories for sexual dysfunction and disorders have a heterosexist bias, which may lead to an avoidance of reference to concerns of same-sex couples, such as problems with anal intercourse and problems secondary to concerns about HIV infection for gay men and affectional and orgasmic difficulties for lesbians.

A variety of special problems may develop in the area of sexuality and sexual function for gay, lesbian, and bisexual persons. Gay men, for example, may struggle more with issues of sexual compulsivity, and bisexual men and women may also struggle with mastering safer-sex practices. Patterns of same-sex sexuality have been shown to be different from those in heterosexual couples, with female couples having decreased sexual interaction and male couples initially having increased amounts of sexual interaction in comparison with heterosexual couples. Typologies of male couples have sometimes described them in terms of their degree of sexual

exclusivity and openness, and issues related to sexual exclusivity may concern male couples. In contrast, female couples present more often with problems related to decreased sexual desire, which may be associated with a tendency for greater emotional and interpersonal intimacy and dependence among women.

The psychiatrist working with sexual problems in gay and lesbian individuals and couples will need to consider organic, developmental, interpersonal, and social causes. Assessment and treatment should adapt traditional heterosexually oriented paradigms of sexuality to include consideration of issues related to gay and lesbian development and to the dynamics of same-sex relationships. Special attention should be paid to cultural factors that may contribute to sexual problems among gay men and lesbians, including a failure to obtain accurate information about same-sex sexual behaviors resulting from prohibition on education about the topic and internalization of negative societal attitudes about same-sex sexuality.

Physical Problems Lesbians and gay men present with the same medical problems as the general population but also have particular problems in relation to their health and medical care that are associated with their sexual orientation; these include dealing with negative attitudes of health care providers; accessing providers who are sensitive and knowledgeable about their concerns; and dealing with an increased risk for some diseases. Knowledge of a person's current gay or lesbian sexual orientation and behaviors should not exclude careful inquiry about current or past heterosexual relationships and experiences that could also put them at risk for certain diseases.

There are no gynecological problems that are unique or occur more frequently among lesbians than among heterosexual women, although they may be at greater risk for undetected disease as the result of receiving fewer pelvic examinations and Pap smears. Sexually transmitted diseases are rare among women who are sexually active only with other women, and there are few cases of HIV infection in these women. The risk for some types of cancer in women may be affected by factors such as history of sexual intercourse with men, number of pregnancies, and breastfeeding. Historically lesbians have had a lower number of pregnancies than heterosexual women, but an increasing number of lesbians are choosing to have children through alternative insemination. It is important to consider the special needs of these women, a higher proportion of whom may seek care from nontraditional providers such as midwives.

In general, gay men have increased rates of sexually transmitted diseases, HIV infection, and use of certain substances such as inhaled nitrites (poppers). Since the 1980s the influence of HIV infection and AIDS on the individual lives and the communities of gay men has been enormous and has affected almost every aspect of the personal and public experience of being gay. As a result, HIV infection must be considered as a potential problem in the life of every gay man who enters the health care system, in relation to such issues as testing for HIV infection, ensuring early treatment intervention in infected individuals, preventing further HIV infection, responding to fears about contracting the disease, dealing with the chronic stress resulting from pervasive loss and illness, and taking care of gay men who are already infected. For many gay men HIV infection is negatively associated with aspects of their sexual identity and exacerbates pre-existing problems resulting from internalized homophobia. Recent advances in the treatment of HIV infection may diminish the importance of this disease in the lives of gay men, but current generations of these men have been profoundly affected by it. The psychiatrist can play an important role in differentiating functional and organic symptoms that occur in relation to HIV infection.

Physical illness of any type in gay men and lesbians may interact with experiences associated with their sexual identity. Life-style factors, family structures, and social networks can determine the extent and type of support available; the stress of being sick may evoke psychological reactions involving internalized homophobia; and the capacities for intimacy, affection, and sexuality, whether with the same or the other sex, may be significantly altered as the result of being sick. The psychiatrist should be sensitive to the unique issues that may arise for the gay man or lesbian when confronted with physical problems, including the lack of support from families who have rejected many of them because of their sexual orientation.

Psychotherapy The topic of psychotherapy with gay men and lesbians has been explored in a large number of publications that identify the special problems of these men and women and describe effective approaches to treatment. Treatment modalities include individual, couples, family, and group therapies. Since the 1970s most of these volumes have been written from the perspective of *gay and lesbian–affirmative psychotherapy*, described by Alan Malyon as a “theoretical disposition [that] regards homosexuality as a non-pathological human potential. The goals of gay-affirmative psychotherapy are similar to those of most traditional approaches to psychological treatment and include both conflict resolution and self-actualization.” Gay and lesbian–affirmative psychotherapy recognizes the centrality of sexual attraction, behaviors, and identity in a person's life but also appreciates that sexual orientation is only one aspect of personality and, depending on the patient's needs and goals, may or may not be a central focus of therapeutic work.

Antigay, Antilesbian, and Heterosexist Bias Within Psychotherapy In spite of the availability of helpful gay and lesbian affirmative approaches to psychotherapy, gay men, lesbians, and bisexuals are still at risk for encountering negative reactions to their sexuality and identities within psychotherapy. One study has identified 25 different ways in which bias can affect psychotherapy with gay men and lesbians in association with assessment, intervention, identity, intimate relationships, and therapist expertise and education. The psychiatrist should be informed about the detrimental effects of inappropriate and negative assumptions about patients based on their sexual orientation. Often these assumptions are a reflection of inaccurate information and outdated knowledge, but they may also result from personal prejudice. Regardless of their source, they may reinforce negative feelings in vulnerable persons seeking psychotherapy.

A limited number of authors continue to present homosexuality as a form of mental illness, to portray gay and lesbian identities as pathological adaptations, and to describe approaches to curing homosexuality. These views are inconsistent with current knowledge about sexual orientation and fail to follow contemporary diagnostic standards. These approaches generally seek to eliminate sexual attraction to persons of the same sex and to encourage the formation of heterosexual relationships. Careful review of reports of these so-called reparative therapies have failed to demonstrate their effectiveness in changing sexual orientation and have clarified the extent to which they confound an understanding of sexual orientation with gender identity and gender role. Behavioral approaches to eliminating same-sex desire and sexual behaviors developed from the 1950s through the 1970s were abandoned because of recognition of their lack of efficacy and of the harm they inflicted on persons struggling with their sexual feelings and identity. Currently these negative approaches are described almost exclusively by psychoanalytic and religiously affiliated writers.

Generally, persons who knowingly seek such treatment are experiencing reactions to internalized homophobia that are normative developmental events for gay and lesbian persons growing up in a heterosexist society with widespread antigay and antilesbian attitudes. The response to these reactions by a therapist who subtly or directly denigrates same-sex sexual feelings and expressions may interrupt or totally prevent development of a healthy gay or lesbian adaptation and can lead to acting out and other self-destructive behaviors. Temporary changes in behavior or relationships may result from a wish to please the therapist, particularly in persons who have already had heterosexual relationships, but long-term changes in sexual desire or expression resulting from psychotherapy have rarely been described or verified. Clinical reports of subsequent work in psychotherapy with patients who have been the subjects of such attempts to change their sexual orientation have demonstrated their negative effects in encouraging acting out, maintaining lack of self-acceptance, and prolonging struggles with identity acquisition.

A 52-year-old man entered psychotherapy with symptoms of depression and anxiety. He had been maintained on an antidepressant medication prescribed by his physician for the past year and reported a good response; however, recently he had experienced some return of his symptoms of tiredness, distraction, and self-doubt as well as concerns about his physical health. The patient reported a history of having been arrested three years previously after having sex with another man in a public setting. As a result of this incident, he lost his job and his marriage of twenty-five years had ended. After his arrest he was in psychotherapy with a psychiatrist for one year. The patient also reported that prior to his arrest he had seen two therapists, both of whom tried to help him stop his homosexual behavior and to restrict his sexual activity to his marriage. The patient reported that the new psychiatrist attempted to help him achieve a heterosexual adaptation and to suppress his homosexual feelings. At the end of this period the patient, who was also alcoholic, attempted suicide and was admitted to a residential substance abuse treatment program. While in this program, he stopped seeing the psychiatrist, entered an AA program, and began to work on accepting his homosexuality. The patient then became involved in local gay community activities and begun to date a man who was his own age. The were talking about living together.

During the course of once a week psychotherapy, this man talked about his lifelong sexual attraction to men and of his efforts to achieve heterosexual satisfaction with his wife to whom he had been deeply committed. He believed that he would have killed himself if he had not ended the therapy with the psychiatrist who wanted him to suppress his homosexual feeling and not begun a treatment program for his alcohol abuse. His symptoms of depression and anxiety decreased after examination of his fears about forming an intimate relationship with another man. He eventually purchased a home with the other man and reported satisfaction with his involvement in the gay community, becoming a leader in a number of political and social organizations. In follow-up appointments over a period of five years the patient reported episodic exacerbation of his symptoms of depression but no longer felt any conflict about his sexual orientation. He maintained sobriety, was satisfied in his gay relationship, and was successful in a new career.

Role of Gay and Lesbian Affirmative Psychotherapy Acceptance, acknowledgment, and affirmation of gay, lesbian, and bisexual persons are essential elements in work in psychotherapy with these men and women. These therapeutic stances reflect the therapist's regard and empathy for the patient's sexual feelings and for their

same-sex relationships, in contrast to the denial and derogation with which these aspects of the patient have often been met. Ultimately, as with any patient, the psychiatrist working with gay and lesbian patients should maintain a position of neutrality that will both help to contain the struggles of the patient and at the same time serve to convey a recognition of the ongoing negative impact of societal prejudice against gay and lesbian persons. Lack of awareness about and failure to explicitly acknowledge the effects of the negative interpersonal and social forces working against the expression of same-sex desire may suggest to the patient that the psychiatrist agrees with these attitudes, thereby representing a deviation from the appearance of neutrality. Explicit agreement with these negative attitudes—even when these views may be shared by some patients, as in the case of the therapist who utilizes so-called reparative approaches—constitutes therapeutic bias.

Being lesbian, gay, or bisexual represents a fundamental experience of feeling different and frequently alienated from mainstream culture. Often the sexual, romantic, and affectional expressions of gay and lesbian patients have been ridiculed and rejected. For many gay men and lesbians, speaking with a therapist may represent the first chance they have had to discuss their stigmatized sexuality with another person. The fundamental importance in therapy of having these feelings listened to without judgment, either positive or negative, having them acknowledged as real by a person in authority, and having them affirmed as commonly felt and normal cannot be emphasized enough. The tolerance and validation of such feelings by the therapist will allow the patient to express negative feelings as well, such as a fear of the reactions of others, negative feelings about being gay or lesbian, and regret about losses associated with being gay or lesbian. At these times the therapist should not reassure patients prematurely but rather should allow them to express and to come to terms with these experiences—which are often manifestations of internalized homophobia—at their own pace.

Special Issues Gay men and lesbians present to psychotherapy with the same concerns as other patients, seeking help with the full range of mental disorders and adjustment to interpersonal, work, and social situations. In many cases the sexual feelings, behaviors, or identity of the individual may be incidental to treatment; in other cases these issues may be central to the treatment. For example, some gay and lesbian patients who may have no problems with their sexual feelings or identity will present with symptoms of sexual dysfunction whereas others will seek help directly because of confusion about their attraction to someone of the same sex or of struggles with coming out or identity formation. As long as they are lesbian and gay affirming, practitioners of all schools of psychotherapy can be effective in working with lesbians and gay men; the same tools of evaluation, planning, and treatment used for other patients should be employed with these men and women.

It is helpful for the psychiatrist to be aware of several special treatment issues relevant to psychotherapy with lesbians and gay men. These issues can be clustered into general topics that have been discussed in other sections of this chapter: developmental experiences, including problems of youth, coming out, and acquiring a gay or lesbian identity; effects of heterosexism and antigay and antilesbian attitudes, including violence and internalized homophobia; families and relationships, including families of origin and families of choice, same-sex relationships, and having children; and physical and mental problems, such as alcohol and substance abuse, sexual dysfunction, and HIV infection. The experience of all these issues will be significantly influenced by the patient's biological sex, race, and other personal and social characteristics.

ETHICAL AND LEGAL ISSUES

Psychiatrists have an ethical responsibility to their patients to avoid harm and to attempt to ensure their well-being. In addition to this general responsibility several specific ethical and legal issues are relevant to psychiatric work with lesbians, gay men, and bisexuals. These involve confidentiality, medical records, the potential for abuse in military and other discriminatory settings, and maintenance of standards of care, including the avoidance of heterosexist and antigay and antilesbian bias. Confidentiality is important in relation to sexual orientation because of the risk of discrimination against lesbians, gay men, and bisexuals when their sexual orientation is known within the health care setting and by health insurers. Furthermore, because sexual relations between persons of the same sex are still illegal in more than 20 states, a medical record that states that someone has had such relationships could put the person at risk for being charged with a criminal act if this information were revealed. Although knowledge of the sexual identity of a patient may be essential in order to provide quality care, it is inappropriate to include this information in a medical record or to transmit it to others without the informed consent of the patient. In all instances the psychiatrist should discuss with the patient the intent to record this information before it is entered into the chart. When the gay or lesbian patient does not wish this information to be recorded and when the psychiatrist cannot agree to withhold this information, referral to another provider should be offered. Information about sexual feelings, behaviors, identity, and relationships should only be entered into the medical record when it is relevant to the evaluation and treatment of the patient and must always be treated in a confidential manner.

Psychiatrists working in the military, prisons, certain religious organizations, or other settings where knowledge about a person's sexual orientation could be used to harm the individual are faced with a difficult ethical dilemma. If the psychiatrist's knowledge that patients are gay or lesbian must be shared with authorities who will then use this knowledge to discriminate against them, for example, by discharging them from the military, then the psychiatrist may be torn between taking part in a discriminatory act that is prohibited by the code of professional ethics and violating the operating rules of the organization. Disclosure of the risk of harm that may come to patients who reveal their sexual orientation to providers who are then obligated to report this information to discriminatory organizations, like the military, is the minimal action required by psychiatrists in such circumstances. In the author's opinion, refusal to participate in the discriminatory process is the only behavior fully consistent with the professional code of ethics for psychiatrists.

Maintenance of appropriate standards of care in relation to sexual minority status requires the avoidance of heterosexist and antigay and antilesbian bias in providing assessment and treatment to gay men, lesbians, and bisexuals. Patients have suffered historically from psychiatric diagnosis of homosexuality as a type of mental illness; currently, a number of psychiatrists and other mental health practitioners continue to treat homosexuality as a form of mental illness even though it is no longer included in DSM and no empirical justification for this view exists. Diagnosis of sexual minority status as a mental illness or developmental problem and offering treatment for it represent overt expressions of bias on the part of the psychiatrist. Such pathologizing allies the authority of the mental health field with prejudicial attitudes and actions. These views not only place individual patients at risk but are also used to support the maintenance of institutionalized acts of legal and legislative discrimination, such as the denial of custody to gay and lesbian parents.

Other expressions of bias may be more subtle, including, for example, inappropriate recommendations and acting-out behavior on the part of gay and lesbian psychiatrists who are struggling with coming out themselves and dealing with feelings of internalized self-hatred, or the failure of psychiatrists to achieve competency in treating gay and lesbian patients by acquiring adequate knowledge about this group and recognizing the effects of discrimination on development. Gay and lesbian psychiatrists struggling with their own acceptance may need to refrain for a period of time from working with patients who have similar problems. Psychiatrists should undertake training to keep them informed about the concerns of gay and lesbian patients as well as of those from other minority groups. Problems in working with gay men and lesbians resulting from bias are often expressed indirectly and may be manifested as a tendency on the part of the therapist to marginalize or diminish the extent of problems such people experience. Psychiatrists should assume that they have learned heterosexist and antigay and antilesbian attitudes, and be alert to both direct and indirect forms of expressing such bias.

TRAINING AND RESEARCH NEEDS

Concepts of sexuality and sexual orientation have significantly shifted in the second half of the twentieth century. Psychiatric residents need to receive systematic training about the new body of knowledge concerning sexuality and the dimensions of sexual orientation and to develop attitudes and skills that will allow them to interact sensitively and competently with persons of all sexual orientations. Teaching about gay men, lesbians, and bisexual persons cannot be isolated to classes on sexuality but needs to be integrated into the general curriculum and should provide clinical examples of gay, lesbian, and bisexual persons with different forms of mental illness who are well adjusted to their same-sex relationships and identities. Many lesbian, gay, and bisexual residents have needs for special support during their training, and all residents can benefit from exposure to respected role models who are openly gay, lesbian, and bisexual. In the author's opinion, medical schools and professional organizations must increase the number of opportunities available for training about the clinical concerns of sexual minority individuals and encourage gay and lesbian faculty and other leaders to be visible and active in a wide range of professional activities.

Although much has been learned during the past several decades about sexual orientation and its development, a great deal more remains to be understood. Similarly, although attitudes toward gay, lesbian, and bisexual individuals have improved considerably during this period, antigay and antilesbian bias continues to be widespread and to have harmful effects on the development of gay and lesbian people. Since the 1800s the biomedical and social science research agenda in relation to sexual orientation has focused largely on finding a cause for homosexuality, whether in family dynamics, anatomical structures, or hormonal and gene variations. Cultural and psychological factors contributing to the development of sexual orientation have generally been of less interest. Until the 1970s virtually all this research on homosexuality attempted to locate a cause for a condition that was considered pathological. Since the removal of homosexuality from the list of mental disorders in 1973, researchers have been able to ask much more complex questions about the phenomena based on conceptualizations of sexual orientation that recognize its diverse forms and expressions over the lifespan.

As a result of the deepened understanding of sexual orientation, preliminary research has been undertaken to describe variations in sexual desire, behavior, and

identity associated with a range of demographic and personal characteristics, such as biological sex, age, race, class, geographical location, and religion. Although many studies continue to focus on white, urban, middle-class men, the need for further examination of variations of sexual orientation in other groups, such as women and persons of color, is now broadly recognized.

Research on the topic also needs to utilize longitudinal studies that will describe the development and experience of sexual orientation over time and across the life span. Retrospective methods alone are inadequate for describing the experiences of persons because of the inevitable subjective reconstruction involved when recalling history. Longitudinal studies will also expand understanding about those characteristics in childhood that contribute to the development of adult sexual orientation, as well as factors that shape individual expression of desire and behavior in adults.

Future research into sexual orientation will inevitably continue to evolve further beyond attempts to locate the cause for a single phenomenon representing some unitary factor or cluster of factors in all persons and developing consistently in a linear fashion across the life span. The development of a postmodern perspective has led to an appreciation for the wide range of cultural, familial, interpersonal, and individual elements that contribute to the construction of our sexual and relational selves and to an awareness of the profound and changing influence historical and social forces have on language and meaning, including the meaning of sexual orientation. Future research about sexual orientation and attitudes toward it must expand beyond the use of traditional biological and psychosocial approaches to utilize constructivist methodologies that also account for the role of fluctuating cultural and other historical forces in shaping individual lives and experience.

SUGGESTED CROSS-REFERENCES

Normal child development is discussed in Section 32.2, and normal adolescent development in Section 32.3. Normal human sexuality, other than homosexuality and homosexual behavior, and sexual dysfunctions are discussed in Section 19.1a. Gender identity disorders are discussed in Section 19.3 and the psychotherapies are discussed in Chapter 30.

19.2 PARAPHILIAS

STEPHEN B. LEVINE, M.D.

Sexual behaviors that deviate from intuitive notions of normality create uneasiness in large segments of the culture. Because psychiatry defines sexual abnormality and takes some responsibility for alleviating the suffering that abnormality generates, the profession's roles are complicated. A wide variety of sexual identity disorders and sexual dysfunctions exist. The paraphilias have almost forty different pathological manifestations. Also, it is easier to conceptually define an abnormality than to agree about where normality ceases and pathology begins. The paraphilias range from dangerous to relatively benign, from the bizarre to the almost ordinary, from the compulsively pursued to the incidentally noted. Even the dangerous, bizarre, and compulsive paraphilias blend uncertainly into ordinary sexual expression. Finally, the classic psychiatric approaches to any problem—definition, etiology, and treatment—are complicated for the paraphilias by the inherent tension between the conflicting social needs of sexual freedom and sexual regulation. Despite these formidable intellectual difficulties, the paraphilias bring mental health professionals to an awareness of the paradoxes, dilemmas, and enigmas of human sexual life—particularly male sexual life.

Society worries about the paraphilias because they can be detrimental to mental and physical well-being. Some of them, like rape and pedophilia, victimize others. Others can be ultimately self-destructive, as in autoerotic asphyxia, or chillingly self-destructive as when people pay to be injured. Still other paraphilias, such as shoe fetishism, seem harmless, unless the perspective of the partner is taken into account. Regardless of their patterns, persons who have a paraphilia cannot be easily identified objectively—some are socially unconventional and many others live rather ordinary nonsexual lives. Society identifies offenders only after victims have been created. Although the diagnosis of paraphilia is not well known, sexual victimization is. Some victims are created by individuals who are on a compulsive quest for sexual gratification through conventional sexual activities such as seduction. In seeking frequent relief, sexually compulsive persons victimize themselves and others. Psychiatry has not yet decided to classify these patterns as a variant form of paraphilia.

Three forces seem to keep sexual behaviors within acceptable social boundaries. The first is the presence of biological normality. This fortunate state of bodily health creates the substrate for personality development that is predisposed towards civilized sexual behavior. Continuing physical and mental health enables an adult to continue to uphold the requirements of nonvictimizing sexual expression. The second force consists of the socialization processes of family, educational, and religious life. These inculcate values about what is moral and immoral within relationships. The third is the legal system, which defines sexual crimes. Legal systems criminalize the egregious victimization of children, adolescents, and adults and reinforce moral standards through punishment. These general forces—health, education, and the law—are civilizing influences on every individual's development.

Psychiatry is now highly interested in the biological forces that may account for the paraphilias. For most of the twentieth century, however, individual psychological development was used to explain these disorders. Development meant the subtle private, conscious and unconscious, cognitive, emotional, and motivational processes that integrated all that occurred to and within a growing person. Whatever their ultimate causes, paraphiliac symptoms seem to be the result of (1) an abnormal sexual preoccupation—for example, “I am excited by the image of humiliating a person,”; (2) a deficiency of control over sexual attractions—for example, “I touched her on the escalator because she had nice thighs”; or (3) both—for example “the urge to exhibit my penis overcomes me and I cannot stop myself.” From these descriptions alone, it is clear that society expects a civilized person to be excited only by certain behaviors and to choose the context for sexual expression carefully.

A disorder such as a paraphilia is a pathological manifestation of something that more often exists in a different form. Paraphilia is an abnormal intention. *Intention* refers to what people want to do with their partners during sexual behavior and what they want their partners to do with them. Intention is the seldom-recognized third component of sexual identity. Like the widely recognized components of gender identity and orientation, intention has separate private and behavioral aspects. *Erotic intentions* are the mental aspects—they consist of attractions, fantasies, ideas, or scripts that generate intense arousals. *Sexual intentions* refer to the behavioral aspects—they consist of what one actually does with others or to oneself to become excited.

A person's sexual identity is largely developed in a private psychological manner. It is consciously derived from the individual's evolving self-observations on: (1) the erotic and behavioral aspects of his or her gender identity, orientation, and intention; (2) the labels the person eventually assigns to these components; and (3) the meanings that the components have to the person. Normal intentions, which are rarely even conceptualized by conventional people, involve desires to cooperate with a partner to create pleasure in a mutually acceptable, often mutually orgasmic fashion. Abnormal intentions, which are typically thought about a great deal by the paraphilic person, involve aggression, victimization, and extreme one-sidedness; that is, behaviors that are difficult to negotiate with others because of their bizarre or idiosyncratic nature.

The paraphilias are specific abnormalities of intention. Problems of gender identity or orientation phenomena are not paraphilias. Paraphilic behaviors occur among individuals with conventional and unconventional gender identities and among those of all orientations. A female who lives as a male and desires to be beaten during arousal is paraphiliac only on the basis of masochism, not because of her gender adaptation. A rapist is paraphiliac because his mental and behavioral intentions are aggressive; his masculinity and heterosexuality are irrelevant to the diagnosis.

DEFINITION

The fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) recognizes the paraphilias as consisting of recurrent, intensely sexually arousing fantasies, sexual urges, or sexual behaviors that involve either nonhuman objects, the suffering of the self or partner, children, or nonconsenting persons. To qualify as a DSM-IV diagnosis, however, these patterns must have existed for at least 6 months and they have to cause clinically significant distress or impairment in social, occupational, or some other important area of function, such as sexual function.

The DSM-IV specifies nine paraphiliac diagnoses: *exhibitionism* or genital exposure; *voyeurism* or clandestine observation of another person's undressing, toileting, or sexual behavior; *sadism* or causing suffering during sexual behavior; *masochism* or being humiliated during sexual behavior; *pedophilia* or sexual behavior with prepubescent or peripubertal children; *fetishism* or use of nonliving objects for sexual behavior; *frotteurism* or rubbing against or touching a nonconsenting person; *transvestic fetishism* or use of clothing of the opposite sex for arousal; and *paraphilia not otherwise specified* for the other 30 or so observed atypical sexual patterns such as dressing in diapers, requiring a partner who has an amputated limb, and others.

Other Diagnostic Distinctions

Criminalized Sexual Behavior Includes Paraphilia and Nonparaphilia While horrifying acts—rape, murder after or before sexual behavior, and penetration of children—have long been crimes, international awareness about the extent of sexual victimization has been growing since the 1970s. Now other sexual cruelties and childhood victimizations are routinely prosecuted. Date rape, incest, sexual behavior with children and young adolescents, sexual stalking, sexual harassment, professional sexual misconduct, and sexual violence against homosexual persons occupy the judicial system. Nonviolent offenses involving exhibitionism, voyeurism, frotteurism, and obscene phone calls are criminal acts as well, but prosecutors tend to view them as relatively harmless nuisance crimes even though they may not be. Nonviolent perpetrators are apt to be referred to mental health professionals as a condition of probation; more dangerous and destructive sexual cruelties are punished with incarceration.

The terms “sex offender” and “sexual perpetrator” refer to a person who has committed a sexual crime. However, all sexual criminals do not meet the criteria for a paraphilia—for instance, many incest offenders and rapists do not, and homosexual men arrested for public indecency during solicitation in public parks are usually not diagnosable as having exhibitionism. Sexual crimes are sometimes referred to as hands-on versus hands-off offenses. Typical hands-off crimes are exhibitionism, voyeurism, sexual harassment, and stealing underwear.

Parameters of Paraphiliac Severity

PERSONAL-RELATEDNESS Clinicians are often helped in their treatment planning by assessing the paraphilia patient's ability to relate to another person sexually. Four categories of relatedness can be observed among most of the paraphilia diagnoses.

Solitary Paraphiliac Expressions All paraphilia behaviors are rehearsed repeatedly in fantasy; often these unusual fantasies have been present since childhood or puberty. Some persons with paraphilias never experience any sexual behavior with partners. The shame of the paraphilia interest and the fear of negative consequences may contribute to a lifelong avoidance of intimate contact. Sexual behaviors consist entirely of masturbation, often with magazine or Internet pictures and bulletin boards, videotapes, reading material, clothing, or mechanical props. People in this category are the most psychologically unprepared for sexual expression within an ordinary relationship.

Paraphiliac Behaviors with Hired or Unmet Partners Female and male prostitutes have a long collective experience in dealing with paraphiliac men. Men pay to be urinated upon, spanked, observed masturbating, humiliated, beaten, cross-dressed, or told a paraphilial story. Many businesses sell the opportunity to watch others undress and dance in seminudity; they may provide private booths where men can masturbate in front of the dancer for an additional fee. Prior to the appearance of acquired immune deficiency syndrome (AIDS), some people used to belong to clubs for group sex activities. Men now pay for strangers to talk to them about sex over the telephone while they masturbate. For some computer-literate men, nude magazine collections have given way to the Internet's opportunities to download pictures and videos or to “talk” to others with similar interests in chat rooms. In each of these arenas, the man obtains sexual gratification with an illusion of an interpersonal relationship. Although many nonparaphiliac men partake in these activities, paraphilic customers are able to gratify their masochistic, exhibitionistic, and voyeuristic desires through public masturbation or with a prostitute. For some, this illusion of connection or relatedness is as far as their capacities have taken them.

Secret Paraphiliac Fantasies With Long-Term Partners Some paraphilia persons are able to have a more complex relationship with a partner that includes conventional sexual activity. Their paraphiliac fantasies occur during conventional sexual behavior with their partners. However, their partners are not told of the scenes that are occurring in their minds. Spanking fantasies, for instance, may occupy the thoughts of men and women during conventional sexual activities, but their partners may never know of the accompanying mental masochistic imagery.

Negotiated Paraphiliac Behaviors with Long-Term Partners Couples seen in clinical practice usually consist of a paraphilia patient and a nonparaphiliac partner. In order to sustain a paraphiliac script, the partners must negotiate about behaviors. Success at this process means that the partner understands the specific requirements of the paraphiliac lover; appreciates and accepts that people often have quirky means of attaining sexual gratification; and consents to cooperate. The partner with typical intentions has to learn to accommodate to her partner—for instance, to his wearing women's underwear or to his desire that she wear a shoe to bed. Consent is given because the partner realizes that cooperation is the best way to ensure a consistent opportunity for sexual intercourse; sometimes the partner consents in an attempt to preserve monogamy. Once given, consent may be withdrawn because partners cannot endure the narcissistic injury of not being desired for themselves, or because even with cooperation the paraphiliac partner is unable to have satisfactory sexual activities. Theoretically, the complementary paraphilias of sadism and masochism should sustain each other's script, particularly if each is willing and able to explore both sides of sadomasochism.

REQUIREMENT FOR AROUSAL While the usual functional significance of any paraphilia is that the person needs to use the paraphiliac fantasy or behavior in order to desire a partner, obtain arousal, and reach orgasm, the degree to which this occurs varies within most of the categories of paraphilia.

Absolutely Required In the most severe forms of paraphilia, the specific paraphiliac imagery or activity is absolutely necessary for any sexual function. Without it, the person is always sexually apathetic—there is no desire for sexual behavior with the partner, no sustainable arousal, or no orgasmic attainment. When embarrassment prevents the paraphiliac from sharing the secret, the relationship may never be consummated and the partner is either baffled or settles on a wrong explanation. If the paraphiliac is able to integrate the paraphiliac requirements into the lovemaking, either by engaging in the behavior or imagining it, sexual functioning may even be normal.

Usually Required in Some Manner In less severe forms, ordinary sexual behavior is possible. However, in many of these circumstances, sex only occurs if initiated by the partner, if a fetish is used, if the paraphiliac fantasy is sometimes spoken of, or if it is almost always privately imagined. Personal and relationship dynamics appear to affect the need for paraphiliac assistance, which sometimes is not present.

Not Required but Imagery Occasionally Appears In the least severe form, sexual behavior with a partner is normal but during times of stress, unhappiness, loneliness, or marital discord a longstanding paraphiliac intention appears in masturbation fantasy, during a daydream, or during sexual behavior with a partner. The paraphiliac imagery may be a source of shame, which only creates further distress. These erotic circumstances are sometimes referred to as deviant arousal coexisting with normal arousal.

Enhancements Heterosexual and homosexual couples may on occasion tie one another up, cross-dress, talk dirty, peek at other couples, or watch pornography to create novelty and alternate forms of excitement in their long-term relationship. These behaviors may either arouse, amuse, bore, or disgust the couple, but they do not become a requirement for sexual arousal; they are only experimental efforts to temporarily enhance excitement. Although this is not to be confused with paraphilia, it may be that the use of these paraphilia-like behaviors are only enhancements for one partner while the other partner is highly excited by them but unable to share their actual private significance.

COMPULSIVITY OR IMPULSIVITY The final parameter of severity is the degree of drivenness to masturbate or act out the fantasy with a partner.

Out of Control The most severe form of compulsivity is the loss of autonomy. The loss of autonomy has three characteristics: (1) the need for sexual behavior consumes so much money, time, concentration, and energy that the patient describes himself as out of control; (2) intrusive unwanted paraphiliac thoughts prevent concentration on other life demands and are the source of anxiety; and (3) orgasm does not produce satiety in the way it typically does for age mates. Thus, a man may masturbate six times a day, visit a prostitute twice in a day, or spend $200 on phone sex. Although such drivenness may exist for long periods of time and is presented to the clinician as uncontrollable, a careful history often reveals that both the thoughts and the behaviors can be interrupted by other life demands.

Autonomy Preserved The same paraphiliac desires—for instance, sadomasochism—may be present, distressing, and yet be contained to ordinary frequencies of masturbation and only occasional paraphiliac sexual behavior with another person. The imagery is present but the pressure to act upon it, although distressing, is manageable.

Impulsivity The lack of control of some individuals with paraphilia does not appear to be the result of a constant preoccupation with sexual thoughts; rather, it is because they suddenly perceive an opportunity to behave in a manner they have long fantasized about. For example, an exhibitionist sees two young girls are alone in the street and seizes the moment to expose himself. Often such impulsive behavior is explained as “something came over me.” This often-repeated pattern is not planned for; it occurs without much internal struggle or consideration of the consequences. The trigger for the behavior is the absence of external social control. For example, a pedophiliac grandfather who had not touched a child inappropriately since age 22 and “pretty much forgot about it,” began periodically licking the genitals of his first infant granddaughter because he had the urge and his recently too-busy wife was preoccupied upstairs. Paraphiliac impulsivity often is seen in those with brain pathologies, but organicity is certainly not required.

Internal Compulsivity and External Impulsivity Although there are paraphiliac behaviors that clinicians might agree are either compulsive or impulsive, the distinction between the two concepts often quickly blurs. Clinicians need to be mindful of two circumstances. The first is when the clinician cannot decide whether the person is compulsive or impulsive; he seems to be both. Compulsivity and impulsivity seem to trigger one another. Intrusive sexually arousing thoughts culminate in one episode of sudden acting out or one impulsive act leads to intense preoccupation, masturbatory activity, and a binge of planned paraphiliac acts. The second circumstance is patient deceit. Most pedophiles and incest offenders, for example, scheme to arrange for sexual behavior with a child, and they groom a victim. The perpetrator falsely claims impulsivity. The opportunity that he had been visualizing and organizing his social behavior toward for years finally presents itself, but he hides behind the excuse of being overcome by an irresistible impulse. Grooming is not usually admitted unless clinicians carefully question the patient about the

antecedents to the impulsive act.

Nonparaphiliac Compulsivity and Addiction Clinicians have a diagnostic problem when they evaluate patients with major social and vocational impairments due to sexual compulsivity if the urges are for ordinary sexual behaviors with adults. This is a common circumstance. Devotion to seduction of strangers, frequent uses of prostitutes, relentless requests for intercourse or fellatio within an established relationship, or masturbatory preoccupation with pictures of naked women can erode the autonomy of heterosexual men. Similarly, cruising for sex can occupy days at a time to the detriment of homosexual men's jobs, relationships, safety, and physical health. Women often describe themselves as compulsively seeking love through sexual behaviors with strangers. These patients often say, “I am driven.” Are such cases to be classified as paraphilia not otherwise specified or as sexual preference disorder unspecified?

The answer seems to depend upon the clinician's ideological framework. Psychopharmacologists tend to view these cases as equivalent to paraphilias because of similar consequences, comorbidities, and responses to medication; they are now labeled paraphilia-related disorders. Psychoanalysts use the term near-perversions and assume that the paraphiliac fantasies are unconscious and will emerge in intensive treatment. Other terms used are *sexual addictions* because the patients' destructive loss of autonomy directly parallels consequences of substance abuse or simply *compulsive sexual behavior* because that is what it seems to be. Seven or more orgasms per week in an adult is generally considered a reasonable definition of *sexual compulsivity*. The point of agreement in all of this is that people with “normal” desires can be quite destructive to themselves and their partners.

The term *sexual addiction* arose from Alcoholics Anonymous treatment programs to describe, explain, and treat sexual compulsivity. The term does not distinguish paraphiliac from nonparaphiliac compulsivity and does not have a specific definition. It does convey, however, the person's sense of being unable to control the incessant desire for some sexual behavior. Men and women of all orientations describe themselves as sexually addicted. Many use this term to denote the relentless use of anything sexual: masturbation, pornography, prostitutes, strip bars, cruising, telephone sex, school-age children, or a partner. Some professionals use *addiction* only when the conscious intentions are conventional because paraphilia adequately describes bizarre intentions.

HISTORY

Inversion, Perversion, and Deviance Throughout the late-nineteenth and twentieth century, these three terms were used by mental health professionals to denote the paraphilias. They are officially out of favor now because they no longer connote acceptable standards of objectivity and they have been generically applied to any unconventional aspect of sexual identity—cross-dressing, homosexual orientation, or sexual sadism.

Character Pathology and Sociopathy Early editions of DSM assumed that the paraphilias were manifestations of a severe defect in character formation due to various preoedipal developmental difficulties. As nosologies embraced a more observational basis for classification, the paraphilias came to be recognized as worthy of a distinct category under the sexual diagnoses. Character problems are now carefully defined on Axis II and causes are recognized to be hypotheses.

COMPARATIVE NOSOLOGY

ICD-10 The 10th revision of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) describes the paraphilias as nine categories of disorders of sexual preference (Table 19.2-1). Each of these disorders must meet three criteria: (1) The individual experiences recurrent intense sexual urges and fantasies involving unusual sexual objects or activities; (2) the individual either acts on the urges or is markedly distressed by them; and (3) the preference has been present for at least 6 months. The term *fetishism* is applied to those who rely on use of nonliving objects—for example, footwear, leather, rubber—as a stimulus for sexual arousal and gratification *Fetishistic transvestism* is applied to those who wear articles of clothing of the opposite sex in order to create the appearance and feeling of being a member of that sex. Cross-dressing is associated with sexual arousal and once orgasm occurs and sexual arousal declines, there is a strong desire to remove the clothing. *Exhibitionism* is used for those who have a recurrent or persistent tendency to expose their genitals to unsuspecting strangers, usually of the opposite sex. The act is associated with sexual arousal and masturbation but there is no intention to have sexual intercourse with the witness of the exhibition. *Voyeurism* is the term applied to those who have a recurrent or persistent tendency to look at people engaging in sexual or intimate behavior such as undressing. The act is associated with sexual arousal and masturbation but there is no intention to be sexually involved with the person observed. *Pedophilia* is the diagnosis of those who have a persistent or predominant preference for sexual activity with a prepubescent or early pubertal child or children. The individual must be at least 16 years of age and at least 5 years older than the child victim. *Sadomasochism* is a preference for sexual activity as a recipient or provider or both of pain, humiliation, or bondage. The activity is the most important source of stimulation or is necessary for sexual gratification. *Multiple disorders of sexual preference* is used for those whose sexual preferences include more than one of the above and none has a first-rank position; the most common combination is fetishism, transvestism, and sadomasochism. Other disorders of sexual preference is used for those with any one of a variety of patterns including obscene phone calling, rubbing up against people in crowded places for sexual stimulation, sexual activity with animals, use of strangulation for intensifying sexual excitement, sex with a dead person, preference for partners with a specific anatomical abnormality such as amputated limbs, and other such preferences. *Disorder of sexual preference unspecified* is applied to those whose patterns do not fit any of the preceding categories.

Table 19.2-1 ICD-10 Diagnostic Criteria for Disorders of Sexual Preference

While there are some differences in the labels used for the nine categories of the DSM-IV and the ICD-10, the basic concepts are identical. Both these classifications separate issues of gender identity and orientation from those of intention or preference.

EPIDEMIOLOGY

The sophisticated epidemiological studies of the prevalence of mental disorders published since the late 1980s did not investigate the sexual psychopathologies. Had this been undertaken for the paraphilias and sexual compulsivities, researchers would have faced formidable methodological obstacles such as asking the right questions to delineate cases of the major paraphiliac forms in a relaxed and nonjudgmental fashion; overcoming the political problem of gaining funding for the project from the government or a foundation source; and ascertaining the extent of subject lying about illegal behaviors. There are no large-scale sophisticated community-based studies on the topic. However, studies on sexual criminals, many of whom are paraphiliac, do exist.

Sex Crimes Most adult perpetrators of sex crimes experience multiple paraphilias over time. In a study of 561 nonincarcerated sex criminal volunteers, the average number of paraphilias per person was 2.02. When paraphilias evolve, the behaviors tend to get more destructive to victims over time. Within any particular paraphiliac category, the number of offenses committed by the perpetrators ranged widely. Rape had consistently lower offense rates (7.2 times) than others, such as exhibitionism (500 times). Compared with pedophiles, exhibitionists, frotteurs, and voyeurs were high-frequency offenders. Nonincestuous pedophiles who targeted boys had far more victims than those who targeted girls. Incest offenders had fewer sexual victims than nonincestuous pedophiles, but they had far greater numbers of sexual encounters with their victims than nonincestuous offenders.

Data from 1616 perpetrators between 5 and 21 years of age, most of whom were between 10 and 18 years old, demonstrate that the backgrounds of youthful sexual criminals typically involve emotional neglect and physical and sexual abuse. Nonsexual psychopathic features are common. Perpetrators often recognize their paraphiliac interests by puberty and begin offending early in their lives. These data estimated that 15 percent of forcible rapes are committed by boys under age 18

and 20 percent of all sex offenses are committed by adolescents. At intake 42 percent reported a history of physical abuse, 39 percent of sexual abuse, 26 percent of neglect, and 63 percent of witnessing severe domestic violence. The majority of youngsters had a history of engaging in other antisocial activities. Ninety-one percent of their victims were between the ages of 3 and 16 years; 63 percent were less than 9 years of age. The majority of the sexual assaults involved orifice penetration; most of the perpetrators showed no empathy for the victims; only 19 percent accepted full responsibility for the assaults. Another study estimated that between 30 and 50 percent of child molestations are committed by juvenile offenders.

Reporting of pedophiliac offenses increased at least 300 percent in the United States during the 1980s and is still thought to underestimate the sexual exploitation of children and young adolescents. The number of treatment centers for adolescent sex offenders has increased more than thirty fold. Estimates of the percentage of American children who are sexually abused vary considerably. A conservative estimate is that 15 percent of girls and 8 percent of boys are victimized. Sexual abuse of children is a rampant public health problem.

Paraphiliac Eroticism In a questionnaire study of patients seeking care from family practitioners, 4 percent of 230 patients acknowledged paraphiliac erotic imagery; none admitted to acting upon their fantasies.

Comorbidity Significant psychiatric and physical comorbidities are common among men and women diagnosed with paraphilias, compulsive sexual behavior syndromes, and sex-offending behaviors. Substance abuse, anxiety disorders, and dysthymic and other mood disorders, conduct disorders, or character pathology, for example, are to be expected in the majority of patients who are seen. In a study of volunteers who claimed to be sexually compulsive, for example, the lifetime histories of substance abuse was 64 percent, phobic disorder was 42 percent, mood disorder was 39 percent, and personality disorder was 44 percent. Among 60 consecutive paraphiliac and nonparaphiliac sexually impulsive men seeking treatment, the lifetime presence of comorbid Axis I disorders were: mood—77 percent; dysthymic disorder—53 percent; substance abuse—47 percent; anxiety disorders—47 percent; and social phobias—32 percent. In general psychiatric settings these comorbidities are what are first perceived.

ETIOLOGY

Like most behavioral disorders, paraphilia is multifactorial and eludes a simple explanation. Three broad approximations of causality can be seen among paraphiliac persons: an abnormal brain, gross psychological adversity, and idiosyncratic development. Each of these categories contains many variations and the categories are not mutually exclusive. Paraphiliac phenomena are usually broader than any clinician's experience; what the physician encounters depends to a large extent on the setting. A forensic clinic, adolescent residential treatment center, adult alcohol treatment center, and a private outpatient practice generate different impressions about the forces that commonly shape abnormal intentions.

Brain Abnormalities The association of paraphilia with abnormalities of brain structure or function may be explained as follows: (1) the sexual disorder is a direct result of the abnormal neural organization; (2) the brain abnormality places the person at a social disadvantage, which leads to abnormal intentions; (3) the brain abnormality impairs the person's social judgment; and (4) the brain abnormality decreases the person's control over antisocial impulses. Seizure disorders, mental retardation, attention-deficit/hyperactivity disorder, cerebral palsy, dementia of the Alzheimer's type, multiple cortical infarcts, and postconcussional disorder are occasionally important Axis III diagnoses.

A mentally retarded 22-year-old ruined his first community job as a grocery clerk when on his second work day he spotted a 7-year-old girl wearing MaryJane shoes. He stopped what he was doing, followed the girl for a few minutes and asked her excitedly if he could caress her shoes. The girl's mother almost immediately stopped him and complained to the manager. He could not explain why he has been interested in little girl's shoes since he was young, but he acknowledged masturbating to images of stroking little girl's shoes throughout adolescence. MaryJanes were his favorite since he first saw them in a magazine.

Egregious Developmental Adversity Parental abandonment; recurrent physical, psychological, and sexual abuse; exposure to parental violence; prostitution; or chronic intoxication are often part of the backgrounds of persons with paraphilia and sex offenders. To the extent that a dependable, stable loving relationship with a parent is required for normal sexual development, the opportunities of some individuals with paraphilia have been severely limited from early childhood.

A 15-year-old was brought for assessment to a residential setting by his third foster mother who could no longer tolerate his stealing of her underwear and his sexually provocative behavior with the two other foster children in the home. In the residential treatment center he constantly masturbated and repeatedly initiated sexual behaviors with staff and boy and girl residents. His developmental history was rife with early physical abuse, substance-abusing parents, paternal then maternal abandonment, and cross-dressing since age 6.

A 29-year-old bank loan officer sought help for his addiction to prostitutes, hostile sexual preoccupations, and lack of sexual interest in his wife. His father is a practicing sadomasochist. As his father was leaving his wife and children, he gave the 11-year-old patient his collection of pornographic magazines, the use of which triggered the beginning of more than daily masturbation. The father arranged that his new wife and her live-in best friend separately have intercourse with his son, who was then 16 years old. After this, the patient's incessant seeking of sexual experiences with classmates and prostitutes began. Throughout his adolescence the patient was frequently berated by his mother for being “just like his father—a bum.” The patient always calls the prostitutes some demeaning name before intercourse and thinks of this as getting even with his mother.

Less Extreme Developmental Adversity Often the cause of paraphiliac problems seems to consist of sexual trauma at various stages of life, less than ideal relationships with parents, or idiosyncratic responses to seemingly ordinary events.

A 28-year-old single man on a golf outing thought that he had successfully seduced a woman he met in a bar. As they were having intercourse, the woman's husband appeared. The patient's panic quickly subsided when the couple explained that the husband was a friendly voyeur who just wanted to watch and masturbate. Their negotiations led to 3 days of drunken sexual experimentation for the young man, which culminated in him being dressed in women's clothes by the couple and then having intercourse in front of the voyeur who also was cross-dressed. Never having cross-dressed or ever having indulged in any unconventional sexual behavior, the man sought help 2 years later because of his inability to stop thinking about the weekend with excitement and his continuing experimentation with wearing women's clothing to masturbate.

A substance-abusing professional was finally able to attain sobriety at age 33 years. With this accomplishment, he met a woman and got married, began to work steadily for the first time in his life, and was able to impregnate his new wife. His preferred sexual activity had been masturbation in semi-public places. The patient had a strong sense that his mother had always thought him to be inadequate, did not like to spend time with him, and constantly made negative comparisons between him and his “all-boy” younger brother. He recalled several times when his father had tried to explain his mother's antipathy: “It is just one of those things, son; your mother does not seem to like you.” Without substance abuse, he gave up his exhibitionism, but he quickly developed sexual incapacity with his wife and became “addicted” to phone sex.

A 38-year-old thin, stylish mother of three with lifelong inability to attain an orgasm with a partner sought help for dysthymic disorder with recurrent suicidal ideation, sedative abuse, and aversion to sexual experience with her highly valued husband. She had masturbated almost every day of her life to orgasm to thoughts of being painfully penetrated with medical instruments, burned, or given painful enemas. The medical instrumentation fantasies began at age 19 when she worked in a urologist's office. She thought of her fantasies as “sick, uncontrollable, but necessary to relieve my tensions.” A painfully shy child with school and social phobias until adult life, she was unable to recall any childhood medical procedure, burn experience, or physical or sexual abuse that might explain why her erotic life has been dominated by masochism. She was extremely close to her grossly obese mother, rarely saw her hard-working idealized father, and was reluctant to discuss the possibility that she had experienced any pain and suffering in her home.

Psychodynamic Features Many new ideas have been offered to explain the paraphilias. Some simply ignore psychodynamic considerations. They pass over the fact that intentions are part of sexual identity development and bear important relationships to masculinity and femininity, attachment to others, self-esteem, the intrapsychic balance of warmth and aggressiveness, and the ability to cope with difficult realities. This results in the paraphilias being referred to as variants of other nosological categories: obsessive-compulsive disorder, posttraumatic stress disorder, mood disorders, impulse-control disorders, or addiction, with which they are frequently comorbid. The evidence given for paraphilias being variants is that paraphilia patients seeking help may respond to selective serotonin reuptake inhibitors (SSRI) tricyclic drugs, anxiolytics, or 12-step programs. Comorbidity and response to therapy are not infallible evidence of pathogenesis, however. Even the lives of

patients with classic psychiatric entities have been shaped by psychodynamic forces.

Earlier in the twentieth century psychodynamic explanations were focused almost entirely on intrapsychic developmental considerations. Explanations such as preoedipal helplessness with a frightening mother, castration anxiety, passive-into-active erotization of hated persons or of humiliating events placed little importance on developmental processes that follow the preoedipal and oedipal stages. All psychodynamic hypotheses are moored by two anchors: (1) that the vital intrapsychic developmental steps that are required for the development of normal intentions are not known and (2) that mental life and its erotic aspects continuously develop, recombine, and dynamically fluctuate. Trauma, deprivation, abuse, neglect, and idiosyncratic developmental explanations focus on the original organizing forces for the abnormal intention but they do not necessarily explain their persistence.

Once established, paraphiliac intentions are impressive in their ability to provide an escape from various unpleasant emotional states and life situations. Thus, paraphiliac preoccupations and behavior function as a defense against dysphoria or a frightening life challenge. “Rather than looking for a job and risking being told ‘no' once again, my husband just spends all day looking at pornography, drinking, and masturbating. Life has become too much for him.” Psychodynamic hypotheses that emphasize what paraphilias have in common include denial of the differences between the sexes, fear of castration, fear of the woman's genitalia, and a symbolic act that preserves the gender identity of the individual with a paraphilia.

DIAGNOSIS AND CLINICAL FEATURES

The diagnosis of a paraphilia or compulsive sexual behavior is easy to make once the patterns of private and behavioral arousal are ascertained and a sexual developmental history is obtained. However, before this, several conditions must be met. The patient has to perceive a good reason to discuss this subject with the clinician. The patient needs to know whether confidentiality exists. The clinician has to know enough about this subject to ask relevant questions about it in calm, nonjudgmental manner that indicates an understanding of the subject. When there is suspicion of paraphilia and patient denial, it is important to obtain descriptions of sexual crimes from police reports or victim statements to help confront the denial.

Transvestic Fetishism This pattern usually begins with private childhood or pubertal use of female undergarments. In the peripubertal period the clothing becomes a stimulus to masturbatory arousal. Years of experimentation with lingerie may give way to the use of outer garments and the imagining of the self as a woman. Cross-dressing and its attendant imagery captures erotic life, retards heterosexual development, and generates shame about this habit. As the young man learns that his pattern is called transvestism and that others like him exist, he may begin to experiment with dressing as a woman in public. “Passing” typically begins with walks around the block at night, drives in a car, or brief appearances at a mall. Eventually, sexual arousal to lingerie weakens. Although masturbation may still occur after cross-dressing, his mental life becomes captured by his dual roles: masculine-in-the-world and feminine-in-solitude.

In adulthood, fetishistic transvestism may take several subsequent paths: private cross-dressing with occasional passing as a woman; part-time living as a woman (these two paths are sometimes referred to as transgenderism); introducing the spouse to his secret and integrating the cross-dressing into sex play (adult form of transvestitic fetishism); and the total abandonment of the male gender role (*transsexualism*).

Most fetishistic transvestites are perceived by others as inconspicuously masculine-enough during grade school children and adolescence. As adults, however, their memories of these times involve feeling uncomfortable as a boy or not being like other boys. Female clothing must have powerful symbolic meanings to these boys because the texture of the underwear or the underwear itself generates sexual arousal. Some young adolescents who are easily excited by female undergarments use them as a prop to their imagining being with a girl who is wearing the garments whereas these boys use the garments to imagine themselves as girls. This experience may contain three aspects: (1) the boy's inadequate sense of his masculinity; (2) his envy of girls for their nurturant abilities; and (3) his hopelessness in becoming an aggressive and popular boy. The cross-dressing adolescent or adult often cannot explain dynamics because the cross-dressing enables him to be excited without thinking or feeling these issues. Such adolescents can, however, recognize them when pointed out. They tend to think of themselves as literally having separate male and female selves, with the female self being far more interesting. They fail to integrate male and female elements into a singular self and often spend their lives in unhappy masculine compartments where they may marry and father children. Married transvestites' sexual desire for their partners is enhanced if they are allowed to wear female garments, but this often impairs their wives' capacities to sustain personal sexual interest in them. Most women are uneasy with or insulted by their husband's cross-dressing; many try to eroticize it but fail. Mere accommodation is the more typical outcome.

Not all fetishistic transvestites are heterosexuals. Some transvestitic males are bisexual, uncertain about their orientation, autogynephilic—that is, only attracted to the image of themselves as females, or homoerotic homosexuals. Homosexual cross-dressers tend not to be as strongly fetishistic at puberty. Gay communities provide far greater acceptance for cross-dressing than does the dominant culture for heterosexual transvestites.

Several psychological hypotheses exist for understanding cross-dressing. The first is that the child, feeling deprived of adequate maternal nurturance and embarrassed about his continued longings for closeness to an unavailable person, invents a feminine self to provide for himself through his imagination and play activities. The second is that the child simply has subthreshold form of gender identity disorder manifested by subjective unmasculinity rather than behaviorly expressed wishes to be girl. The third is that he has concluded that girls have a better chance of being loved and he envies their opportunities to grow up to be helpful like mothers rather than frightening like fathers. The fourth is that the child has identified with his transvestitic father.

Socially, dual-role transvestites, transgenderists, and transsexuals come together in organizations that are formed to provide environments that enable these men to appear as women. These cross-dressers network, build relationships, and learn more about their life possibilities at regional and national meetings. Participants have occasionally been the object of questionnaire studies and are the source of information from nonpatient transvestites. These samples raise the possibility that there are some transvestites who are not paraphiliac because they sense no occupational, relationship, or other social impairment. Such studies also point to the fact that the gratifying aspects of networking and displaying the self as a female represent a good adaptation to this proclivity. It contrasts to those socially isolated ashamed men who cross-dress in private and who remain mortified at the possibility of anyone knowing about their situation. Table 19.2-2 lists the DSM-IV diagnostic criteria for tranvestic fetishism.

A. Over a period of at least 6 months, in a heterosexual male, recurrent, intense sexually arousing fantasies, sexual urges, or behaviors involving cross-dressing.
B. The fantasies, sexual urges, or behaviors cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

Specify if:
With gender dysphoria: if the person has persistent discomfort with gender role or identity.

Reprinted with permission from American Psychiatric Association: *Diagnostic and Statistical Manual of Mental Disorders*, ed 4. © American Psychiatric Association, Washington, DC, 1994.

Table 19.2-2 DSM-IV Diagnostic Criteria for Transvestic Fetishism

Fetishism Unlike transvestic fetishism where the man imagines himself as a woman, simpler forms of fetishism focus on an item of clothing (e.g., shoes, gloves, stockings). The fetish is linked to someone closely involved with a patient during childhood and has a quality associated with this loved, needed, or even traumatizing person. Usually, the disorder begins by adolescence, although the fetish may have been established in childhood.

Sexual activity may be directed toward the fetish itself (for example, masturbation with or into a shoe), or the fetish may be incorporated into sexual intercourse (e.g., the demand that high-heeled shoes be worn).

Table 19.2-3 presents the DSM-IV diagnostic criteria for fetishism.

A. Over a period of at least 6 months, recurrent, intense sexually arousing fantasies, sexual urges, or behaviors involving the use of nonliving objects (e.g., female undergarments).
B. The fantasies, sexual urges, or behaviors cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
C. The fetish objects are not articles of female clothing used in cross-dressing (as in transvestic fetishism) or devices designed for the purpose of tactile genital stimulation (e.g., vibrator).

Table 19.2-3 DSM-IV Diagnostic Criteria for Fetishism

The questionnaire responses of 262 of 1000 gay and bisexual men who belonged to a national organization, the Foot Fraternity, provides a nonclinical view of this pattern of arousal to clean feet, boots, shoes, and smelly socks. About half of the respondents were also aroused by clothes. About 75 percent were particular about the type of footwear—wingtips versus penny loafers, for example—but their preferences changed over time. Over half wanted the footwear to have been worn by someone so that they could fantasize about the man whose feet had been in the shoes. One fifth of the respondents had no idea why feet or shoes aroused them; 50 percent pointed to the sensual qualities of feet—smell, taste, sight, and touch and fondly remembered being tickled as children or teenagers on the foot; 30 percent emphasized that the shoe symbolized the essence of masculinity—power, strength, success, and youth. Partner play was much less frequent than masturbation. Seventy-seven percent had foot play with a partner in the past year and 66 percent had sex with a partner without foot play. For 75 percent, foot play with a partner was an important part of sex with partners. About 66 percent of the foot play activities were part of a larger interest in sadomasochistic relationships—dominance and submission games—but for the rest, massaging, caressing, kissing, and licking without any role playing enhanced arousal.

Seventy percent of the respondents were not socially isolated from friends within the gay subculture. The Foot Fraternity helped fetishists to meet one another socially and for foot play, to learn more about how to enjoy feet, and to increase self-acceptance. The authors concluded that most of the respondents would not meet DSM-IV criteria for paraphilia.

Sexual Masochism Table 19.2-4 lists the DSM-IV diagnostic criteria for sexual masochism. Masochism occurs in both sexes, but has been thought to be more common among men. In questionnaire studies of masochistic women, about one fourth had been prostitutes; the majority of others had had large numbers of sexual partners. Respondents of both sexes can be subgrouped into those who simply prefer submissiveness, those who prefer the dominant role in sadomasochistic behavior, and those who enjoy playing both roles. Masochism's mild behaviors, such as the desire to be spanked, and its more dangerous forms, such as whipping or urethral insertions, are known to exist in individuals of every orientation. The persistence of masochistic behaviors throughout the life cycle, although possibly frequent, should not be presumed. Masochism tends to coexist with various forms of fetishism in both sexes and is part of the evolution of paraphiliac forms. Some masochists advertise, join clubs, frequent particular bars, or purchase sexual services to find the right partner. Whereas the sadist is actually dominating, humiliating, or causing physical pain, the masochist typically thinks that he or she is actually controlling the abusive episode. During sexual games, some sadomasochists are aware that while dominating they are identifying with someone who hurt them as a child. “I sometimes know that I am beating her like my mother beat me. After hurting her for a while, I identify with her. I feel love for her because she knows how I felt as a child. I then asked to be beaten. In the delicious experience of pain, I feel loved and loving... Most of the time I don't feel that good about myself or her.” Although studies of nonpatient devotees of masochism suggest that many do not consider that their sexual patterns impair their nonsexual lives, clinicians may see those who have been impaired.

A. Over a period of at least 6 months, recurrent, intense sexually arousing fantasies, sexual urges, or behaviors involving the act (real, not simulated) of being humiliated, beaten, bound, or otherwise made to suffer.
B. The fantasies, sexual urges, or behaviors cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

Table 19.2-4 DSM-IV Diagnostic Criteria for Sexual Masochism

A 53-year-old, house-bound man with agoraphobia who had been married four times sought help for a recent loss of control over his usual need for foot fetishism and fantasies of humiliation and domination. He claimed that his masochistic hunger dominated all his waking moments. He recalls being sexually aroused by women's feet since age 4. When his mother sat in a chair and placed her sole on his face, he developed an erection. He spent many of his childhood hours orchestrating games in which babysitters and neighbors placed their feet on his face. As an adult, he says he likes to be degraded, humiliated, and owned by a woman who leaves him with no decision-making capacities. He is excited by leather and the smell of a foot—particularly by being forced to endure the disgusting odor from a foot. His new wife's insistence that he seek help came after he sought total domination from her and told her that “I want to be broken, with no way out, then be used as a slave for sex and to cook and clean. I even want to watch you have sex with another man.” She threatened to leave with their 4-year-old daughter and insisted that he seek professional help. When his first wife refused such behavior, he had an affair with a woman who whipped him. He and his second wife were “into bondage” until he became so obsessed that she became uncomfortable. His third marriage at age 50 was to a very aggressive thief who sexually dominated him but did not care about him outside their bedroom dramas. In order to conduct intercourse during the last decade, he has had to fantasize about being dominated. He has masturbated at least daily since age 17 and continues to attempt to regulate his frequent sexual tensions 3 to 4 times per day via masturbation or intercourse with his wife.

A 36-year old man with a lifelong gender identity disorder was sexually abused for several years by his stepfather beginning at age 12. Ever since he has been erotically excited by being ordered to do the sexual bidding of men. Such passivity increased his sense of his femininity. For several years in his late 20s, he and his wife ran a sex business that used a photoadvertisement that depicted him as a boy who dresses as a woman who is interested in submission. His preferred sexual activity with clients was intracrural intercourse because that is what his stepfather did before he hugged him, held him, and told him that he loved him. His masochism, however, did not seem to be restricted to his sexual life. Now in prison for armed robbery and being a fugitive from the criminal justice system, his life story seemed to contain repeated episodes of dramatically bad judgment. He might someday be described as having a self-defeating personality disorder.

Autoerotic Asphyxia This form of masochism is characterized by the use of self-strangulation up to the point of loss of consciousness in order to enhance sexual arousal. Oxygen deprivation is brought about by the use of a noose, ligature, a plastic bag, mask, a volatile nitrite, or chest compression. Death may occur because of equipment failures, planning errors, or suicide. Most of the 250 to 1000 deaths per year in the United States are thought to be accidental. Experiments that have shown that as little as 7 pounds of pressure on the carotid arteries can cause unconsciousness in 7 seconds. Males die of asphyxia 25 times more often than females. Deceased men are often found cross-dressed, with dildos in the anus or objects that cause pain to the nipples or genitals, or surrounded by pornography. Adolescent victims are thought to be more often accidental; older persons are more often thought to be suicides. Some couples practice asphyxia (hypoxyphilia) in pairs. Sexual asphyxia has been known for centuries in both the eastern and western worlds. A study of five adolescent practitioners of this elaborate masturbatory ritual found that each had an early history of being choked by parents and other episodes of physical or sexual abuse. Their developmental histories were abject.

Sexual Sadism Table 19.2-5 lists the DSM-IV diagnostic criteria for sexual sadism. Sexual sadists are most commonly encountered by forensic mental health professionals after the person's sexual cruelties have become known. Rape or sexual assault of a nonconsenting adult is the usual issue. Women are by far the most

common victims. Coerced vaginal, oral, or anal penetration may be brought about by various degrees of verbal, physical, and psychological threats and humiliation. The rapist may be a stranger, an acquaintance, a separated or exspouse, or a spouse batterer. The mental health professional may be called upon to distinguish between paraphilic and power-aggression rape. This judgment is typically made by considering three questions: (1) Does the man fulfill the 6-months duration criterion for paraphilia? (2) Has the man had other paraphiliac manifestations such as pedophilia, exhibitionism, voyeurism, or frotteurism? (3) If physiological testing is done, does he show a maximum arousal to violent sexual stimuli? Rapists are a heterogeneous group. Estimates of the frequency of paraphilia among rapists vary widely, beginning at only 5 percent.

A. Over a period of at least 6 months, recurrent, intense sexually arousing fantasies, sexual urges, or behaviors involving acts (real, not simulated) in which the psychological or physical suffering (including humiliation) of the victim is sexually exciting to the person.

B. The fantasies, sexual urges, or behaviors cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

Table 19.2-5 DSM-IV Diagnostic Criteria for Sexual Sadism

Sexual sadism is not restricted to rape, however. A large minority of college-aged men in numerous studies admit to being aroused by and fantasizing about coercive sex with strangers, including rape. The fantasies often end with the woman's enjoyment. A smaller but sizable minority of women admit to being aroused by fantasies of being coerced into sex until they enjoy the sexual activity.

Occasionally sexual sadism other than rape becomes obvious in a general psychiatric setting.

A massively obese 28-year-old rarely employed man with a high school education sought help for a chronic depressive disorder and revealed that he spent most of his days masturbating to the image of hurting prostitutes. He claimed to reach as many as 12 orgasms per day as he thought about torturing, cutting, and killing these women. Also having a stocking fetish, the sight of women's legs often mesmerized him. While he claimed that his childhood was deeply unhappy, he generally refused to discuss it preferring never to remember his critical family members.

A controlling, narcissistic physician, raised alone by his widowed mother since age 2, has been preoccupied with spanking's erotic charge for him since age 6. Socially awkward during adolescence and his 20s, he married the first woman he dated and gradually introduced her to his secret arousal pattern of imagining himself spanking women. Although horrified, she episodically agreed to indulge him on an infrequent schedule to supplement their frequent ordinary sexual behavior. He ejaculated only when imagining spanking. Following her sixth episode of anxious, sullen, depression in 20 years of marriage, her psychologist instructed her to tell him, “No more.” He fell into despair, was diagnosed with a major depressive disorder, and wrote a long letter to her about why he was entitled to spank her. He claimed to have had little idea that her participation in this humiliation was negatively affecting her mental health (“She even had orgasm sometimes after I spanked her!”). He became suicidal as a solution to the dilemma of choosing between his or her happiness and that what he was asking was evil. He was shocked to discover that she had long considered suicide as a solution to her marital trap of loving an otherwise good husband and father who had an unexplained sick sexual need.

Pedophilia Of the terms used to describe those who have genital contacts with young adolescents and children who are at least 5 years their junior— *child molester, incest offender, sex offender, child rapist, statutory rapist, sexual abuser, sexual deviant, serial child molester, ephebophile*, and *pedophile*—only the latter is a formal diagnosis. Its criteria, however, do not cover all those who are arrested for child molestation. The term “pedophile” has two meanings: (1) a person who fulfills the DSM-IV criteria (Table 19.2-6) for the diagnosis and (2) a person with a lifelong erotic preference for children.

A. Over a period of at least 6 months, recurrent, intense sexually arousing fantasies, sexual urges, or behaviors involving sexual activity with a prepubescent child or children (generally age 13 years or younger).

B. The fantasies, sexual urges, or behaviors cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

C. The person is at least 16 years and at least 5 years older than the child or children in criterion A.
Note: Do not include an individual in late adolescence involved in an ongoing sexual relationship with a 12- or 13-year-old.

Specify if:
Sexually attracted to males
Sexually attracted to females
Sexually attracted to both

Specify if:
Limited to incest

Specify type:
Exclusive type (attracted only to children)
Nonexclusive type

Table 19.2-6 DSM-IV Diagnostic Criteria for Pedophilia

Child molesters are subdivided in four ways. First, by age of the perpetrators: (1) A large minority of molestations are committed by adolescents seemingly in their attempt to learn about sex with naive and accessible children; (2) young and middle-aged adults who molest their own children, stepchildren, or friends' children; and (3) elderly men who may be organically impaired, isolated, or lonely. Second, by sex of the offender: Females are found to molest children far less frequently than males. When they are discovered, they are often deteriorated by substance abuse, major mental illness, major organic illness, or thought to be coerced into the behavior by a dominant man. However, many adolescent sex offenders claim to have been abused by women in their prepubertal period. Third, by orientation: Men who have been sexually aroused by children all their lives have the largest numbers of child victims. The most destructive of these individuals find work or recreational opportunities to be in the company of children and young adolescents. They are synonymously labeled as having an anomalous orientation or a preference for children or as fixated pedophiles. Pedophiliac orientation is often seen in pure form. When it coexists with an adult heterosexual or homosexual orientation, the person may be called a regressed pedophile who under extenuating circumstances has sex with children. Fourth, by victim characteristics: (1) boys versus girls (androphilic versus gynephilic); (2) infants and toddlers, preschoolers, grade schoolers, or adolescents; and (3) indiscriminant. Although these four categories are not mutually exclusive, they suggest that children are molested under such a wide array of circumstances that clinicians should not seek a single explanation for pedophiliac offenses.

Within each of these categories, however, child molesters display a startling set of rationalizations for their behavior. These include: (1) “I was educating the child about sex to learn the right way”; (2) the child initiated the behavior; (3) the child readily consented to it; (4) it was merely a caring act to provide pleasure; (5) it caused no harm whatsoever; and (6) it was less problematic than having an affair with an adult. These notions are referred to as cognitive distortions that demonstrate the molesters' lack of empathy for their victims. While children of many ages are subjectively attractive to many adults who never behave sexually with children, the compelling question about child molesters is what accounts for their behavior. Since the answer seems to vary significantly from case to case, the clinician should formulate a sophisticated answer with each perpetrator.

A 67-year-old man with a doctorate degree whose aspiration for entrepreneurial success remained undaunted despite his lifetime of failures touched his 9-year-old granddaughter's genitals under the guise of teaching her what others should never do to her. The visibly disturbed child told her mother who quickly called a family meeting to expose a previous secret she and her father had maintained: between the ages of 13 and 16 her father had sexual intimacies with her and told her it would not be good for her depressed mother to know this. Her younger sister too had been approached when she was pubescent, but she had strongly rebuffed the father. The man described that he and his beloved granddaughter were having their usual warm affectionate time reading a story together when for “no good reason” he began educating her. He had not been erotically preoccupied with her; he was just in his ordinary state of sexual and financial frustration. Although potent, he had no interest in sex with his unemployable dysthymic wife who could not stop complaining about her husband's vocational failures and their serious financial problems.

A 62-year-old married janitor had worked as a fourth-grade school teacher for 26 years before he transferred school districts and finally several years later mysteriously lost his second job. He was referred for help after his family discovered that he had repeatedly fondled the genitals of his 4- and 6-year-old granddaughters. A father of five who had not had sex with his wife for 30 years after strenuously objecting to her cigarette smoking, he was generous, helpful, and cooperative with his children and grandchildren. Intellectually slow, he preferred comic books and had a charming manner of playing with young children “like he was one himself.” By his estimate he had touched the buttocks and genitals of at least 300 girl students, thinking only of how they did not know what he was doing because he was being affectionate and they were too young to realize what was happening. He loved the anticipation and excitement of this behavior. His teaching career ended when parents complained to a principal. The principal discovered that the new teacher had been transferred, not fired, from his longstanding teaching job for the same reason. The patient had tried to touch his 12-year-old daughter who angrily warned him to stay away from her, but he had also managed to touch her girlfriends and his best friend's daughters as they neared puberty.

An ebullient 60-year-old rural clergyman was arrested after parental complaints of his inappropriate behaviors within a youth program. He recently had confessed his love for a 14-year-old boy in his parish. Limited by an osteoarthritic hip, widowed for 10 years from a woman with multiple sclerosis whom he married when he was 35 years old he learned to deal with his social isolation and loneliness by creating programs for seventh-grade boys. In the last decade he made friends with adult homosexual men and occasionally had sexual relationships with them. These typically ended when he changed churches. Between these more satisfying adult relationships, he provided fellatio to at least 30 teenagers in three different church settings. He offered them these services “when your girlfriend was not being friendly to you.” He admired the boys' masculinity, which contrasted with his own sense of effeminacy. “They were normal guys and I was just a momma's boy who loved to perform musical theater.” “But I did not count on falling in love with him. I guess I did because he was just like I would like to have been.”

Studies have suggested a correspondence between the victimizers' personality characteristics and the age of their victims. Pedophiles are described as immature with poor social skills, low self-esteem, insufficient self-assertiveness, and more signs of psychotic thinking whereas those who offend against adolescents are intermediate between the immaturity of pedophiles and the psychopathology of those who rape adults. Such findings, however, may be encompassed by other observations such as many pedophiles are males of low social status.

Exhibitionism Table 19.2-7 lists the DSM-IV diagnostic criteria for exhibitionism. The desire to display one's penis, erection, or naked body to a girl or woman who is a stranger is usually motivated by the hope of shocking or exciting the witness. This idea is so exciting that the behavior culminates in masturbation at the site of the exhibition or soon after fleeing to safety. When men exhibit themselves exclusively to girls, clinicians wonder whether this pattern is a form of pedophilia. Although exhibitionists account for approximately one third of arrests for all sexual crimes, the vast majority of indecent exposures are not reported to the police. Exhibitionists often seem socially unskilled, shy, and unable to negotiate a psychologically intimate relationship with an adult woman that includes regular sexual intercourse. They are commonly regarded as harmless hands-off offenders, but some are involved in aggressive sexual and nonsexual assaults. A large minority of exhibitionists report cross-dressing; a smaller percentage also are voyeurs.

A. Over a period of at least 6 months, recurrent, intense sexually arousing fantasies, sexual urges, or behaviors involving the exposure of one's genitals to an unsuspecting stranger.
B. The fantasies, sexual urges, or behaviors cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

Reprinted with permission from American Psychiatric Association: *Diagnostic and Statistical Manual of Mental Disorders*, ed 4. © American Psychiatric Association, Washington, DC, 1994.

Table 19.2-7 DSM-IV Diagnostic Criteria for Exhibitionism

A divorced 62-year-old schizoid, chronically depressed radiologist who had overcome an opiate addiction was asked to retire after being arrested in his community for walking naked in a public place at night. Since early adolescence, he has had a fantasy of walking naked in public. The fantasy only occasionally was acted out except that he did often walk naked on his property after dark and masturbated in the woods to the image of being seen exhibiting himself. Considered to be competent in his field, he never could explain to himself what “comes over me and causes me to want to do that,” but “it is just the way I am.”

Voyeurism Table 19.2-8 lists the DSM-IV diagnostic criteria for voyeurism. Voyeurism is a pathological manifestation of the widespread arousal responses that men and women have at the sight of other people having sex. Voyeurs' erotic lives are dominated by surreptitious watching, their sexual behavior is masturbatory, and is not used to enhance a sexual relationship with a socially appropriate partner. Secretly watching another undressing, showering, masturbating, or having sex tends to consume the person, undermine other sexual behaviors, and eventually get the person into marital, familial, or legal difficulty. Most incidents of voyeurism are undetected because victims do not realize that they have been spied upon. When voyeurs are detected, however, they are only rarely found to be purely voyeuristic; about three quarters of voyeurs exhibit themselves and a minority cross-dress.

A. Over a period of at least 6 months, recurrent, intense sexually arousing fantasies, sexual urges, or behaviors involving the act of observing an unsuspecting person who is naked, in the process of disrobing, or engaging in sexual activity.
B. The fantasies, sexual urges, or behaviors cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

Reprinted with permission from American Psychiatric Association: *Diagnostic and Statistical Manual of Mental Disorders*, ed 4. © American Psychiatric Association, Washington, DC, 1994.

Table 19.2-8 DSM-IV Diagnostic Criteria for Voyeurism

A 52-year-old married sociopathic chronic alcoholic nearly illiterate contractor had been hospitalized 12 times for binge drinking before he revealed his pattern of exhibitionism. A more careful history revealed a 30-year history of 2 to 5 exposures per week, repeated searches for windows into which to peek, frequent date rape and coercive sex with women he met in bars, and episodes of cross-dressing. Most recently he felt he was losing control of his temptations to touch his daughters' girl friends. Arrested only once for a sexual crime, his voyeuristic preoccupations and his genital exposures to young teenage girls make him fear that he will jeopardize his marriage, family, and business because of greater risk taking in recent years. “I feel like I am a boy in a man's body.”

Paraphilia Not Otherwise Specified The classification of paraphilia not otherwise specified includes varied paraphilias that do not meet the criteria for any of the aforementioned categories (Table 19.2-9).

This category is included for coding paraphilias that do not meet the criteria for any of the specific categories. Examples include, but are not limited to, telephone scatologia (obscene phone calls), necrophilia (corpses), partialism (exclusive focus on part of body), zoophilia (animals), coprophilia (feces), klismaphilia (enemas), and urophilia (urine).

Table 19.2-9 DSM-IV Diagnostic Criteria for Paraphilia not Otherwise Specified

Telephone and Computer Scatologia Telephone scatologia is characterized by obscene phone calling and involves an unsuspecting partner. Tension and arousal begin in anticipation of phoning; the recipient of the call listens while the telephoner (usually male) verbally exposes his preoccupations or induces her to talk about her sexual activity. The conversation is accompanied by masturbation, which is often completed after the contact is interrupted.

People also use interactive computer networks, sometimes compulsively, to send obscene messages by electronic mail and to transmit sexually explicit messages and video images. Because of the anonymity of the users in chat rooms who use aliases, on-line sex (cybersex) allows some people to play the role of the opposite sex (“genderbending”), which represents an alternative method of expressing transvestite or transsexual fantasies. A danger of on-line cybersex is that pedophiles often make contact with children or adolescents who are hired into meeting and then molested. Many on-line contacts develop into off-line liaisons. While some people report that the off-line encounters develop into meaningful relationships, most such meetings usually are characterized by disappointment and disillusionment. In other situations, when adults meet, rape or even homicide may occur.

Necrophilia Necrophilia is an obsession with obtaining sexual gratification from cadavers. Most people with this disorder find corpses in morgues, but some have been known to rob graves or even to murder to satisfy their sexual urges. In the few cases studied, those with necrophilia believed that they were inflicting the greatest conceivable humiliation on their lifeless victims.

Partialism People with this paraphilia concentrate their sexual activity on one part of the body to the exclusion of all others. Mouth-genital contact—such as cunnilingus, fellatio, and anilingus—is normally associated with foreplay. But when a person uses these activities as the sole source of sexual gratification and cannot have or refuses to have coitus, a paraphilia exists.

Zoophilia In zoophilia, animals—which may be trained to participate—are preferentially incorporated into arousal fantasies or sexual activities, including intercourse, masturbation, and oral-genital contact. Zoophilia as an organized paraphilia is rare. For many people, animals are the major source of relatedness, so it is not surprising that a broad variety of domestic animals are sensually or sexually used.

Sexual relations with animals may occasionally be an outgrowth of availability or convenience, especially in parts of the world where rigid convention precludes premarital sexuality and in situations of enforced isolation. Because masturbation is also available in such situations, however, a predilection for animal contact is probably present in opportunistic zoophilia.

Coprophilia and Klismaphilia Coprophilia is attraction to sexual pleasure associated with the desire to defecate on a partner, to be defecated on, or to eat feces (coprophagia). A variant is the compulsive utterance of obscene words (coprolalia). These paraphilias are associated with fixation at the anal stage of psychosexual development. Similarly, klismaphilia, the use of enemas as part of sexual stimulation, is related to anal fixation.

Urophilia Urophilia, is interest in sexual pleasure associated with the desire to urinate on a partner or to be urinated on. In both men and women, the disorder may be associated with masturbatory techniques involving the insertion of foreign objects into the urethra for sexual stimulation.

PATHOLOGY AND LABORATORY EXAMINATION

Newer diagnostic probes of brain function have not yet been applied to paraphiliac problems. However, using the clinical history and neurological examination, several investigators have suggested a higher-than-expected frequency of soft neurological signs and learning disabilities among sex offenders. Technology for assessing paraphilia has largely focused on pedophilic offenders, rapists, and juvenile offenders. Penile plethysmography measures penile circumference while subjects are exposed to audiotapes, slides, or videotapes of paraphiliac and nonparaphiliac stimuli. Penile enlargement data provides the clinician with objective evidence of arousal to a specific stimuli—for instance, children—to counter the person's denial that he is not sexually interested in children. Plethysmography is limited by the ability of some perpetrators to enhance their arousal to nonparaphiliac stimuli, to suppress their arousal to children, and by the fact that arousal to images of children does not mean that the person behaves sexually with children. Some men demonstrate limited or no arousal in the laboratory setting. A proprietary system with scientifically definable and acceptable limits, Abel Screening, can detect pedophiliac interest without measuring penile circumference changes. Some centers use the polygraph for initial and subsequent assessments. None of these approaches, however helpful at times, can alone resolve the issue of a person's guilt or innocence. Pedophiliac arousal in the laboratory can be highly useful in confronting a person who denies any interest in children and may trigger a more truthful process between the clinician and the accused. Laboratory assessments are generally not considered admissible evidence in courts.

DIFFERENTIAL DIAGNOSIS

Commonly made mistakes in the evaluation of the paraphilias stem from failure to take a comprehensive sexual developmental and psychiatric history. This is prevented by taking enough time for evaluation, tracing the person's sexual behavior and fantasies from childhood to the present, asking about unmentioned categories, and thoroughly investigating comorbid conditions. A large percentage of patients will not be entirely truthful about their sexual behaviors at first. Since paraphilias are frequently comorbid with a wide variety of psychopathologies, hypomanic episodes, substance intoxication, and dementia or organic brain disease should be given serious consideration. However, it is safer to think about them as releasing factors than to ignore the Axis I diagnosis of paraphilia. Some brain diseases may release behaviors that at first glance seem paraphiliac, for instance, postictal undressing, but are not part of a longstanding pattern of arousal.

COURSE AND PROGNOSIS

When paraphiliac behaviors appear to be released during new pathology, for example, tumor, epilepsy, intoxication, or social or psychological deterioration due to schizophrenia or chronic substance abuse, it is useful to recall that abnormal intentions are developmentally constructed, usually manifested in childhood or shortly after puberty and managed by internal mental and social control mechanisms. What is so dangerous about the chronic problem of paraphilias, particularly paraphilias that victimize others, is that the mental homeostasis that keeps the impulses unconscious or behaviorally suppressed may fail under conditions that are idiosyncratic

to the patient or that are generally understood as stressful. Thus, clinicians need to be wary whenever they find themselves thinking that the “problem is resolved”—unless they add, “for now.”

While the diagnosis of a paraphilia carries a pessimistic prognosis when the person remains untreated, a more realistic view of its natural history may be approximated by returning to the parameters of severity and the etiological concepts. Many paraphiliacs are highly damaged persons, others seem to have more psychological capacities to use what therapists have to offer. Thus, each case must be comprehensively assessed beyond what is necessary to make a formal diagnosis.

TREATMENT

Five types of psychiatric interventions are used to assist the paraphilia patient to rebalance internal control mechanisms, cease victimization of others, and enhance the capacities to relate to others: external control, reduction of sexual drives, treatment of comorbid conditions, cognitive behavioral therapy, and dynamic psychotherapy. The art of therapy is to select and modify these various elements for the individual patient.

Provision of External Controls When sexual victimization of others has occurred, new external controls should be instituted. All relevant persons in the environment need to know what the person has done and is capable of doing again under opportune conditions. For intrafamilial abuse of children, for instance, the adults and other children in the family are informed of the abuse. The children in the family are not permitted to be alone with the offender again as long as they are unable to adequately protect themselves. With such controls implemented, those who victimize girls in their own home have recidivism rates of less than 5 percent. The more socially, economically, and psychologically disruptive alternative is to remove the offender from the home. When professionals who have sexually offended return to their work settings, external controls take the form of restricting access to potential victims and monitoring by administration, co-workers, and sometimes by patients with the use of exit questionnaires. Perpetrators and their professional colleagues can be educated about boundary crossings. When a therapist agrees to keep the knowledge of the patient's victimizing sexual patterns from family members, administrators, or colleagues on the basis of confidentiality, the single most effective psychiatric intervention is removed from the treatment plan. The therapist will probably be the last to know of the resumption of victimizing behaviors.

Prison is an external control mechanism for sexual crimes, but it is not part of rehabilitation; it is designed for public safety and punishment. Many states are considering instituting laws “Megan's Law” that would inform relevant persons in the community when a person who has served time for extrafamilial child abuse was about to be released from prison. The tension between the constitutional rights of privacy for the sex offender and rights of the community to protect itself has yet to be resolved in a legally satisfactory manner.

Reduction of Sexual Drives Several medications can be used to reduce sexual drive for those assessed to have lost their self-control or autonomy. Each medication is relatively safe in physically healthy men and is effective and reversible. The administration of medroxyprogesterone (Provera) to males in dosages ranging from 20 to 120 mg by mouth daily or 400 to 600 mg intramuscularly a week (intramuscular treatment has considerably more adverse effects) may within 96 hours begin to reduce the drive to behave sexually. The reduction is reflected in lower rates of masturbation and partner sex, less intense erotic preoccupations, a greater ability to concentrate on nonsexual matters, and an increase in calmness. Medroxyprogesterone typically reduces serum testosterone to subnormal concentrations of 100 to 250 µg/dL, which is usually sufficient to bring about the desired effect. Medroxyprogesterone decreases sperm production, which may require 10 months for total recovery. Outside the United States cyproterone is used for this purpose. The pretreatment serum testosterone concentrations of male paraphilia patients are normal not supranormal. These compounds empirically assist men who feel out of control sexually to gain more autonomy. They may exert their beneficial effects by decreasing testosterone synthesis, increasing testosterone reductase activity, displacing testosterone from its plasma binding protein, and blocking cellular membrane receptors and intracellular metabolism. The SSRIs are more commonly used to reduce the craving for sexual expression and in one open-label trial helped 70 percent of men with paraphilia or paraphilia-related conditions. No large-scale double-blind conditions studies of the SSRIs have been done, however, and no comparative studies of testosterone-lowering drugs and the SSRIs have been published. Other more expensive drugs, such as a once-monthly dosage of leuprolide (Lupron), may achieve the same testosterone-lowering effect, but generally are unnecessary.

Treatment of Comorbid Conditions Psychiatrists need to consider the role of inadequately treated comorbid states when planning to treat sexual compulsivity or impulsivity. Alcohol and substance abuse, major depressive disorder, grief, psychotic disorder, attention-deficit/hyperactivity disorder, bipolar II disorder, and others each may be the co-factor that enables a compensated sexual pattern to deteriorate and come to clinical attention.

Cognitive-Behavioral Therapy It is frequently observed that sex offenders lack the social skills necessary to live effectively and create nonproblematic sexual relationships. Correcting some of these deficits is a goal of most cognitive-behavioral treatment programs for sexually offending paraphiliac men. Each intervention is an aspect of a therapy approach that assumes that a paraphiliac lifestyle is learned and can be significantly modified. The specific techniques can be done in individual or group settings. They include: role playing how to initiate and maintain conversations *(social skills training)*; role playing for acceptable methods of self-assertion *(assertiveness training); sex education*; confrontation about the rationalizations used to support victimization of others *(cognitive restructuring)*; learning about the feelings and adverse consequences experienced by victims *(victim empathy)*. Other more complex overlapping techniques deal directly with deviant arousal: *imaginal desensitization* teaches the patient to use progressive muscular relaxation when feeling anxious from resisting the paraphiliac impulse; *relapse prevention* by identifying the triggers to paraphiliac urges and teaching new social and psychological coping strategies; *modified aversive behavioral rehearsal*, the most ambitious technique, in which the offender demonstrates his problematic sexual pattern—cross-dressing, exhibitionism, or pedophilia with a mannequin—while being videotaped and in the presence of a therapist and other offenders. The audience asks questions about the perpetrator's feelings, thoughts, and motives and repeatedly confronts the cognitive distortions and lack of victim empathy. Work on victim empathy is predicated on the assumption that a large minority of perpetrators have been victims of childhood sexual trauma. The cognitive-behavioral approach is an integrated treatment approach that can be tailored for the individual patient; it readily incorporates 12-step programs for alcoholism or sex addictions into the treatment plan.

Dynamic Psychotherapy The nonviolent paraphilias and the paraphilia-related disorders are often treated with traditional individual or group therapies using a combination of supportive, growth-promoting tactics. Such therapies aim at creating an evolving hypothesis about the unique developmental origin of the patient's eroticism. The defensive function of the impulse to act out (the anxiety reduction function) is defined so that the person can deal directly with the unpleasant feelings that trigger the impulses. Hypotheses get more complex as more developmental details emerge. The vast majority of patients need many therapeutic opportunities to work through the paraphiliac defense so that they can simply feel and cope with their particular life issue. Dynamic psychotherapy approaches emphasize the importance of the trusting relationship to the therapist to enable the work to occur. Therapists often face a delicate situation because most paraphilia embodies the capacity to transform the pain of childhood misery—for instance, “Mother didn't love me” into the pleasure of sexual arousal—“I'll exhibit myself to a teenager.” Although the patient may no longer want to act out sexually, his desire to not re-experience his painful past may be greater. When the therapist decides to assist the patient in working through some of his painful memories, a great deal of support may be needed. Generally speaking the more globally impaired the paraphiliac is, the less likely it is that he or she can be treated in a dynamic psychotherapy.

Negative Countertransference Therapist hostility, disgust, and fear are important obstacles to providing care for paraphilia patients. Their presence is often manifested by resistance to initially seeing a patient, treating the comorbid symptoms and ignoring the paraphilia in the hope that disorder of intention will spontaneously remit, or quickly referring the patient. Many therapists tell their patients that they do not know anything about this subject. The patient's attempts to get help are further frustrated by the fact that many insurance contracts will not cover a paraphilia diagnosis. Negative countertransference reactions should be defined, discussed, and thoughtfully considered so that the therapist can be objective and discover the patient's developmental issues and attempt to ameliorate them. The problem is that many therapists are so offended by the victimization of others that they refuse to learn about the patient's life experiences and avoid abandoning their assumption that perpetrators are “simply evil through and through.”

Ideological Synthesis As experience with paraphiliac persons has accumulated since the 1970s the behavioral, psychodynamic, and nosological camps have come together in agreement about the profound deficits observed, the formidable therapeutic tasks, and the social problems that these disorders create.

Treatment Results The results of various interventions have profound methodological limitations that rest upon the many distinctions developed in this chapter. For sex offenders, the parameter of success that is of greatest interest is the lack of recurrence of violence towards others, not the disappearance of paraphiliac eroticism in itself. Behavior therapist define outcomes and constantly evolve new treatment approaches for offenders. With selected groups of rapists treated with cognitive restructuring and procedures to enhance victim empathy, for example, the recividism rates in some hands are less than 10 percent. Despite periodic reports of therapy success, however, the impression exists that good results are most often attained when a single paraphilia is present, a successful adult attachment has been made that supports nonparaphiliac behaviors, an intelligence quotient (I.Q.) above 70; nonsexual antisocial personality traits are absent; alcohol and drug problems are absent; rationalizations of the crimes are not tenacious; and the degree of paraphiliac arousal on physiological testing is not great. When incest offenders are

considered, the prognosis is better if intercourse with the child has not occurred and there is no evidence of an exclusive attraction to children.

Centers that provide comprehensive evaluation tend to use multiple modalities of therapy. Psychodynamically oriented clinicians do not generate outcome data, but are anecdotally known to assist people in various ways: (1) to act out less frequently and to deal with life stresses more competently; (2) to enhance their capacity to relate nonsexually and sexually to a life partner; and (3) to accept their eroticism with more comfort and seek the company of others with similar erotic interests to enhance general adjustment—for example, joining a support group for cross-dressers. Regardless of the therapy methods used, the data available from intense research efforts, or the ideological preferences of the therapist, paraphiliac problems are recognized to be serious chronic maladaptive attempts to relate to others.

SUGGESTED CROSS-REFERENCES

Gender identity disorder is discussed in Section 19.3, personality disorders in Chapter 24, and sexual dysfunctions in Section 19.1b. The discussions of pervasive developmental disorders in Chapter 38 and separation anxiety disorders in children in Section 46.3 are also relevant. Child abuse is covered in Section 49.4.

19.3 GENDER IDENTITY DISORDERS

RICHARD GREEN, M.D., J.D., AND RAY BLANCHARD, PH.D.

Cross-gender identity (gender identity contradicted by anatomical sex characteristics) in adulthood virtually always causes distress to the individual, and cross-gender identity in childhood represents a distinct risk of cross-gender identity in adulthood. Cross-gender identity at any age, therefore, is appropriately regarded as a disorder and a possible reason for clinical intervention. Many persons with gender identity problems—particularly those functioning well in other areas of life—dislike the classification of such problems as psychiatric disorders because they regard all psychiatric diagnoses as stigmatizing. For this reason, activists in the transsexual community have proposed alternative conceptualizations. These include the argument, intended to eliminate the perceived stigma of psychiatric disorder while preserving the possibility of third-party payment for sex-reassignment surgery, that transsexualism is a somatic rather than a psychiatric condition. This position cannot at present be justified on medical or scientific grounds. Therefore, the best solution to the problem of psychiatric nosology is to retain the classification of severe gender identity problems as psychiatric disorders while emphasizing, in clinical teaching, clinical care, and research writings, that gender identity disorders can be quite circumscribed in their effects, leaving the individual free to function in other areas of life at a satisfactory or even outstanding level.

DEFINITIONS

The fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) defines gender identity disorders as a heterogeneous group of disorders whose common feature is a strong and persistent preference for the status and role of the opposite sex. These disorders may be manifested verbally, in assertions that one properly belongs to the opposite sex, or nonverbally, in cross-sex behavior. The affective component of gender identity disorders is commonly referred to as *gender dysphoria*, which may be defined as discontent with one's biological sex, the desire to possess the body of the opposite sex, and the wish to be regarded as a member of the opposite sex. The extreme forms of gender identity disorders, collectively referred to as *transsexualism* in the third edition of DSM (DSM-III) and revised third edition (DSM-III-R), commonly involve attempts to pass as a member of the opposite sex in society and to obtain hormonal and surgical treatment to simulate the phenotype of the opposite biological sex.

HISTORY

Transsexualism became popularly known with the sex change of George Jorgensen into Christine Jorgensen in 1952. The 1966 professional book by Harry Benjamin, the pioneer who evaluated or treated hundreds of patients, and the introduction of sex-reassignment surgery at the Johns Hopkins Hospital in 1966 legitimized its treatment.

In 1960 a paper described behaviors in children that were consistent with the later-described gender identity disorder of childhood, and in 1974 a text was published that described several dozen boys with sexual identity conflict. Drawing on this and related work, the psychosexual disorders advisory committee for DSM-III introduced the diagnostic entity gender identity disorder of childhood in 1980.

COMPARATIVE NOSOLOGY

DSM Gender identity disorders first entered the American Psychiatric Association's official nomenclature in DSM-III, reflecting the growth of that area of human sexuality in psychiatry since the second edition of DSM (DSM-II).

Nosological Position of Gender Identity Disorders In DSM-III gender identity disorders were included in the category of psychosexual disorders along with the paraphilias and sexual dysfunctions. In DSM-III-R the gender identity disorders were placed in the section on disorders usually first evident in infancy, childhood, or adolescence.

In the fourth edition of DSM (DSM-IV) gender identity disorders was placed in a separate section called sexual and gender identity disorders. The heading has the same status as mood disorder, anxiety disorders, and other major classifications.

Number of Major Categories In DSM-III two specific categories of gender identity disorders were coded, each with its own diagnostic criteria: transsexualism and gender identity disorder of childhood. DSM-III-R added a third category, gender identity disorder of adolescence or adulthood, nontranssexual *type*, which appears to apply to persons with mild or fluctuating gender dysphoria.

DSM-IV reversed the trend toward greater differentiation by reducing the number of major diagnostic categories to just one, gender identity disorders. The main objective of the change was to unify the diagnostic criteria for children, adolescents, and adults. However, inspection of the DSM-IV diagnostic criteria shows that that goal was only partially realized; the diagnostic criteria for children do not fully parallel those for adults.

Subtypes Following a long tradition of classifying cross-gender syndromes according to the patient's sexual orientation, DSM-III and DSM-III-R listed three subtypes of gender identity disorder. The heterosexual subtype is attracted to members of the opposite genetic sex, the homosexual subtype to members of their own genetic sex, and the asexual subtype to neither. DSM-IV continues the tradition while avoiding the customary labels for those orientations. It also added a fourth subtype, bisexual, based on evidence that among gender dysphoric men the bisexual subtype is at least as common as the heterosexual or asexual subtypes. DSM-IV subtypes are (1) sexually attracted to males, (2) sexually attracted to females, (3) sexually attracted to both, and (4) sexually attracted to neither.

The current diagnostic criteria for both children and adults are organized under two main headings, cross-gender identification and *discomfort* with the assigned sex. A potential problem is that the arrangement promotes a questionable distinction between the two categories of symptoms. Criterion A for children, for example, includes the intense desire to participate in the games and activities of the other sex whereas criterion B includes rejection of sex-conventional toys.

DSM-IV requires the diagnosis of gender identity disorder not to be concurrent with a physical intersex condition (e.g., hermaphroditism). This criterion assumes, not always correctly, that when the symptoms of gender identity disorder are manifested by a child with some intersex status, the behaviors are due to that status. It also assumes that children without obvious intersex status have no physiological basis for their disorder, which also may ultimately be proved false.

In the ninth revision of *International Statistical Classification of Diseases* (ICD-9), gender identity disorders, without diagnostic criteria, were placed in the section on sexual deviations and disorders. As in DSM-III, ICD-9 had two major categories of gender identity disorders: transsexualism and disorders of psychosexual identity. The latter corresponded to DSM-III's gender identity disorder of childhood.

In ICD-10, gender identity disorders are placed in the section on disorders of adult personality and behavior. Three main categories are included: transsexualism, dual role transvestism, and—strangely, given the section heading—gender identity disorder of childhood.

The diagnosis of dual-role transvestism the 10th revision of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) corresponds

roughly to the DSM-III-R diagnosis of gender identity disorder of adolescence or adulthood, nontranssexual type, a diagnosis eliminated in DSM-IV. The diagnosis of dual-role transvestism applies to individuals who cross-dress episodically without any sexual excitement or those who desire surgical sex reassignment. It could be applied equally well to homosexual “drag queens” or to transvestic fetishists in their later years, who often continue to cross-dress even though this activity is no longer accompanied by penile erection or masturbation.

EPIDEMIOLOGY

Prevalence in Children The prevalence of the gender identity disorder of childhood can only be estimated because no epidemiological studies have been published. A rough estimate can be obtained from two items on Thomas Achenbach's Child Behavior Checklist that are consistent with components of the diagnosis: behaves like opposite sex and wishes to be of opposite sex. Among a sample of 4- to 5-year-old boys referred for a range of clinical problems, the reported desire to be of the opposite sex was 15 percent. Among 4- to 5-year-old boys not referred for behavioral problems, it was only 1 percent. For ages 6 to 7, the rates were 2.7 and 0 percent; for ages 8 to 9, 5.1 and 0 percent; and for ages 10 to 11, 1.1 and 2.3 percent. For clinically referred girls, there was more uniformity across the ages, with the highest being 8 percent at age 9, and the low 4 percent. For nonreferred girls, the highest rate was 5 percent at ages 4 to 5, and then less than 3 percent for other ages.

Parents reported cross-gender behavior for 16 percent of the clinically referred boys at ages 4 to 5, and for about 10 percent with the other age groups. Among the nonreferred boys the rates were about 5 percent. With clinically referred girls, nearly 19 percent reportedly showed cross-gender behaviors at ages 4 to 5, as did between 9 and 14 percent of girls in the other age groups. The rate was about 11 percent for all ages of nonreferred girls. These data offer only an approximation for gender identity disorder in children because they do not assess the longitudinal persistence of the reported behavior and do not elucidate what constitutes “behaves like opposite sex.”

Another way to estimate the prevalence of gender identity disorders in children is to use the percentage of adults with a predominant or exclusive homosexual orientation. The adult rates can then be compared with the percentage of homosexual men and women in various studies who report childhood cross-gender behavior. Predominant or exclusive homosexuality is estimated at 3 to 4 percent for men and 1½ to 2 percent for women. Estimates for homosexual men recalling childhood cross-gender behavior are between 50 and 65 percent, and for homosexual women perhaps 50 percent. A methodological problem is that the behaviors in those retrospective reports are contaminated by time and are different from study to study. Further, they rarely address the key item of wanting to be the opposite sex as a young child. Based on these imprecise assumptions, a high estimate of about 3 percent is reached for boys and of 1 percent for girls.

Sex Ratio in Children As many as five boys are referred for each girl referred, for which several explanations are possible. First, there is greater parental concern with sissiness than with tomboyishness, and greater peer group stigma attaches to substantial cross-gender behavior in boys. Thus, there may be an equal prevalence of gender identity disorder in boys and girls but a differential referral rate. Another possibility is that a genuine disparity results from the male's more perilous developmental course. The fundamental mammalian state is female. No sex hormones are required for prenatal female anatomical development (XO children with gonadal dysgenesis [Turner's syndrome] appear female at birth). Sex hormones are required at critical developmental times for male anatomical differentiation. If the mechanisms of behavioral development track anatomical development, the masculine behavioral system requires adequate levels of hormone at the appropriate time for normative expression. Finally, the psychodynamic developmental model explaining the disparate referral rates views both boys and girls as initially identifying with the female parent, with only boys needing to make the developmental shift for later normative identification.

Age of Onset in Children Most children with a gender identity disorder are referred for clinical evaluation in early grade school. Parents typically report that cross-gender behaviors were apparent before age 3.

Prevalence in Adults There is no basis for estimating the proportion of adults who would qualify for a DSM-IV diagnosis of gender identity disorder. The only relevant data are for transsexuals, who comprise only a subgroup of gender-dysphoric adults, and even those figures may be underestimates. The available data (from the United Kingdom, the Netherlands, Sweden, and Australia) place the prevalence rate of transsexualism at about 1 case per 10,000 males and 1 in 30,000 females.

Sex Ratio in Adults Recent data suggest that the sex ratio of adults with sufficient gender dysphoria to present at a gender identity center is about four males for each female. Many factors undoubtedly influence sex ratios at inception of treatment, including the greater publicity given to male-to-female transsexuals and the greater cosmetic and functional success of vaginoplasty compared with phalloplasty. Another factor is that gender-dysphoric females nearly all belong to the homosexual subtype whereas gender-dysphoric males include an equal number of homosexuals and a large contingent, which has no comparable counterpart among the females, of nonhomosexual (heterosexual, bisexual, and asexual) individuals.

Age of Onset in Adults Most gender-dysphoric adults of the homosexual subtype would have qualified for a DSM-IV diagnosis of gender identity disorder in childhood, with their adult behavior simply being a continuation of their childhood disorder. Both males and females of that subtype tend to present for clinical attention for the first time in their mid-20s.

Nonhomosexual gender-dysphoric adults (virtually all of whom are males) typically seek help for their disorder in their mid-30s—a striking difference from the homosexual subtype. If the age of onset is considered to be the point at which they first qualify for a DSM-IV diagnosis of gender identity disorder, they generally have an adolescent or adult onset. However, in most cases prodromes of the disorder were present before puberty.

ETIOLOGY

Much empirical evidence suggests that the three main types of nonhomosexual gender identity disorder in males (heterosexual, bisexual, and asexual) are superficially variant forms of the same condition; that nonhomosexual and homosexual gender identity disorder are etiologically different conditions; that nonhomosexual gender identity disorder is etiologically related to transvestic fetishism; and that homosexual gender identity disorder is etiologically related to typical homosexuality.

The conclusion that heterosexual, bisexual, and asexual gender identity disorders are superficially variant forms of the same condition is based on a wide variety of evidence. Similar majorities of men with heterosexual, bisexual, and asexual gender identity disorder acknowledge some history of transvestic fetishism; such self-reports are rare in men with homosexual gender identity disorder. Men with heterosexual, bisexual, and asexual gender identity disorder are also similar to each other, and dissimilar to men with homosexual gender identity disorder with regard to their degree of recalled childhood femininity, age at clinical presentation, extent of interpersonal heterosexual experience, and a history of erotic arousal in association with thoughts of being a woman.

It is possible that the common denominator linking transvestic fetishism and heterosexual, bisexual, and asexual gender identity disorder is *autogynephilia*, a male's tendency to be sexually aroused by the thought or image of himself as a woman. Autogynephilia is highly variable in its manifestations. It may be expressed in fantasies of dressing as a woman (transvestic fetishism); in (masturbatory) fantasies of engaging in stereotypically feminine behavior like knitting; in fantasies of gestating, lactating, or menstruating; in fantasies of being treated by other people as a woman; or in fantasies of possessing a woman's body. When an autogynephilic man's favorite sexual fantasy is that of possessing a vagina, he is very likely to develop cross-gender wishes that persist even when he is not sexually aroused, along with a desire for surgical sex reassignment.

Autogynephilia may be conceived as a modified form of heterosexuality, in which a man's sexual approaches are directed not at external women but at a feminized version of himself. It seems to involve some developmental anomaly in the learning of sexual behavior, because the man's principal erotic object in many cases—for example, the thought or image of himself wearing pantyhose, applying make-up, or knitting—cannot be innate but must have been assembled from experiences. It remains to be discovered whether some men are relatively prone to such developmental anomalies for neurological reasons.

The conclusion that homosexual gender identity disorder and typical homsexuality (i.e., homosexuality without gender identity disorder) have etiological commonalities is based on two lines of evidence. The first is that the early manifestations of homosexuality and homosexual gender identity disorder appear rather similar. Research has consistently shown that at least 50 percent of adult homosexual men with no gender identity problems nonetheless recall significant amounts of cross-gender behavior in childhood. Similar although somewhat less striking findings obtain for homosexual women. These observations suggest that the difference between ordinary homosexuality and homosexual gender identity disorder may begin as a difference in degree, which develops during adolescence into a difference in kind, when the less severely affected children shed their cross-gender traits and the more severely affected children elaborate them into a full-blown cross-gender identity.

The second line of evidence is epidemiological in nature and pertains only to males. Research on homosexual men without gender identity disorders has established that homosexual men are on average born later in the sibling order than comparable heterosexual men. Recent studies have established that this difference in birth order is caused by homosexual males having a greater number of older brothers; they do not have a greater number of older sisters, once their number of older brothers has been taken into account. Studies of Dutch, Canadian, and British male patients with gender identity disorder have produced the similar finding that homosexual patients are on average born later than nonhomosexual patients. These observations suggest that whatever etiological factor is reflected by high birth order contributes to the development both of homosexuality and of homosexual gender identity disorder.

The foregoing discussion illustrates that theories developed to explain homosexuality or transvestic fetishism may also apply to homosexual or nonhomosexual gender identity disorder, respectively. Furthermore, theories developed to explain gender identity disorder without further qualification may apply to only one of the two main types.

Biological Factors Theories of homosexual development, notably in males, have taken on an increasingly biological basis as opposed to an experiential one.

Genetic Factors The Franz Kallmann twin study of the 1950s found a 100 percent concordance for homosexuality between presumably monozygotic male twins. Further research identified discordant pairs, and methodological critiques of the Kallmann study resulted in a general decline of interest in the genetic basis. However, in recent years twin studies and other family studies of sexual orientation have promoted new interest.

A 1991 study of 56 male monozygotic pairs of twins raised together found a 52 percent concordance for homosexuality compared with 22 percent for 54 dizygotic pairs. A 1992 study found that of 71 female monozygotic twin pairs, 48 percent were concordant for homosexuality or bisexuality compared with 16 percent for 37 dizygotic pairs.

Monozygotic twins separated at birth, although rare, provide a better model for testing the relative influences of environment and genetics than do twins reared together, where the two factors are confounded. A report of two pairs of males separated at birth argues for an inherited influence on homosexual orientation. In one pair, both men were homosexually oriented. In the second pair, one twin was homosexual, and the other, while heterosexually married, had had a 3-year homosexual relationship in adolescence. By contrast, in four pairs of separated female-female twins where one twin in each pair was lesbian, none of the cotwins was lesbian.

Family studies of nontwin siblings of homosexual men and women also lend support to a genetic basis, although the confound of a similar environment is considerable. Two studies found higher rates of homosexuality in brothers than is expected in the general male population. No corresponding increase in the number of lesbian siblings was reported.

Two gene linkage studies add further weight to a genetic basis of male homosexuality. When families are selected for having male homosexuals on the mother's side of the family tree, and two of the mother's sons are homosexual, there is an increased probability of a marker for a shared gene on the sons' X chromosome (contributed by the mother). The marker is less often shared between a homosexual and heterosexual brother.

Hormonal Factors Evidence for a hormonal influence on gender identity disorder derives from several research sources. One possible source is congenital virilizing adrenal hyperplasia. Girls with this condition overproduce adrenal androgen from before birth. They are more rough-and-tumble, less interested in doll play, and more likely to be considered tomboys than girls without the condition. Conversely, there is limited evidence that prenatal exposure of males to estrogenic or progestational agents may reduce the expression of conventional boy-type behaviors. Atypical levels of sex-typed hormones before birth and the attendant effects on specific sex-typed behaviors can substantially modify the child's early social experiences. Boys who are disinclined to rough-and-tumble play or who play with dolls have different father-son and mother-son relationships and a different peer group experience from more conventionally masculine boys. Similarly, girls who prefer rough-and-tumble activity and sports to doll play have a different early socialization experience with parents and peers from girls who are conventionally feminine. Thus, hormonal influences may act through a pathway of affecting sex-typed behaviours that interact with socialization experiences.

Reported neuroendocrine and neuroanatomical differences also suggest an inborn contribution to sexual orientation, particularly in men. One phenomenon tested is the feedback response on luteinizing hormone (LH) after an intravenous pulse of estradiol. In women there is a marked rebound after an initial drop (the hormonal basis of ovulation). The original research found an attenuated female-like response in homosexual men, which theoretically reflected a deficiency in prenatal androgenization of the central nervous system (CNS). In another study using the same methodology, more than half of a sample of homosexual men showed a response more like that of the heterosexual women than of the heterosexual men in the study. However, a subsequent study, which used a different approach to elicit the luteinizing hormone feedback phenomenon, found no significant group difference, and another study with a methodology similar to that used in the original research also failed to confirm a difference.

A related phenomenon that suggests that a deficiency in male hormone in utero leads to a homosexual orientation in men derives from the prenatal stress theory.

Stressing pregnant rodents results in feminized behavior in male offspring, owing either to the competition between adrenal stress steroids and testicular androgens or to the mistiming of testicular androgen secretion as a result of stress. In one study a higher-than-average rate of homosexuality was found in men who were born in Germany between 1941 and 1946, the stressful years of World War II. However, an environmental explanation is also possible, because fathers were more likely to be away from their sons during the war. A second study, based on retrospective reports by homosexual, bisexual, and heterosexual men describing stress in their mothers, found more stress during the pregnancies of the mothers of homosexual men.

Other research has been less supportive of an association between stress and homosexuality. Some research found no connection. One American study found a marginally significant relationship, based on the reports of mothers of college students. Another found a low correlation between reported pregnancy stress and lesbianism, but not with male homosexuality. No prospective studies are reported.

Although medical histories given by parents of children with gender identity disorder do not provide a basis for grossly abnormal hormone levels before birth, a neuroendocrine base may still be posited at a more subtle level. If the range of prenatal androgen levels is as wide as that in adult life, the fetus may also be exposed to a wide range of androgen. Another factor could be the androgen surge that occurs in boys between about 3 weeks and 3 months of age.

Immunological Theories Two immunological theories have been advanced to explain the finding that homosexual men (including those with gender dysphoria of the homosexual subtype) have a greater average number of older brothers than do heterosexual men. Both theories propose that male homosexuality may result from a maternal immune reaction, which is provoked only by male fetuses and which becomes stronger after each pregnancy with a male fetus. The earlier theory proposed that antibodies to testosterone, produced by a woman pregnant with a male fetus and passed through the placenta from the mother to the fetus, could reduce the hormone's biological activity and thus compromise the sexual differentiation of the fetal brain. This seems unlikely because steroid hormones are not ordinarily antigenic. An alternative theory is that the relevant fetal antigen might be one of the male-specific, Y-linked, minor histocompatibility antigens, often referred to collectively as H-Y antigen. Although there is no direct evidence for this theory, it is consistent with a variety of observations, including the finding that male mice whose mothers were immunized to H-Y prior to pregnancy are much less likely to mate successfully with receptive females.

Brain and CNS Involvement A difference in a nucleus of the anterior hypothalamus may represent a CNS difference related to sexual orientation. The area known as interstitial nucleus of the anterior hypothalamus-3 (INAH-3) was compared in autopsy between homosexual men, heterosexual men, and heterosexual women. Although there was some overlap between the size of the nucleus between the groups, it was smaller on average in the homosexual men and women compared with the heterosexual men. All the homosexual men and some of the heterosexual men and women had died of acquired immune deficiency syndrome (AIDS), but death from AIDS was not a factor. No homosexual women were studied to determine whether the size of their nucleus was similar to that of the heterosexual men. INAH-3 is embedded in the hypothalamic area that appears to be related to some aspects of sexual behavior in male nonhuman primates. This study has neither been confirmed nor refuted by subsequent research. Another finding, of a larger suprachiasmatic nucleus in a sample of homosexual men, may be less relevant because that area is not known to be associated with sexual behavior. However, it may be related to endocrine function. A more recent finding points to a difference in the brain of male-to-female transsexuals. In a postmortem sample of 6, the bed nucleus corresponded in size to that of typical females rather than to that of typical males; it was not relevant whether the male transsexual was heterosexual or homosexual.

Psychosocial Theories Psychodynamic and behavioral influences may lead to extensive cross-gender identification. In an early study boys with an excessive mother-son symbiosis in the early years, replete with extensive mother-son skin-to-skin contact, appeared later to manifest significant feminine behavior. This is attributed to the inability to differentiate psychologically from the mother. Male-identified females have been reported to have mothers who were removed in affect

from their children, frequently by depression, and fathers who did not support their daughters' femininity. The girl becomes a substitute husband to treat the mother. Other reports describe traumatic psychological losses to boys and girls in the earliest years that appear related to the onset of cross-gender behavior.

Research on a sample of 66 boys with gender identity disorder found a positive correlation between the extent to which parents supported cross-gender behaviors in their sons and the extent of that cross-gender behavior. In most of the families at least initially there was no discouragement of cross-gender behaviors. In more limited work with girls with gender identity disorder, initial parental reactions were similar. A study of cross-gendered boys found the extent of father-son involvement in the early years to be related to later sexual orientation. The association emerged not only between the two groups of boys studied (gender identity disorder and control) but within the subgroup of boys with gender identity disorder. Less father-son involvement was associated with a more homosexual orientation.

Social Learning Theories Social learning theories typically focus on the differential reinforcement by parents of sex-typed behaviors, starting shortly after birth. This reinforcement shapes conduct into conventional masculinity or femininity. Cause and effect are hard to distinguish here. On the one hand, sex differences are reported early in life, probably before any major differential impact of parental reinforcement; on the other hand, mothers and fathers apparently treat male and female newborns differently.

In Baby X experiments adults are told, sometimes incorrectly, the sex of a clothed child and asked to describe the child's attributes or to provide it with toys. Perceived boys are encouraged more to physical action and are given more whole-body stimulation than perceived girls.

When 6-month-old children were similarly clothed, toy choice by adults was related to perceived gender of the child. Boys were presented with footballs, girls with dolls. Strong bald babies were seen as male, soft fragile ones as female.

At 1 year, boys may be more exploratory and active and toy preferences may differ. Girls were found to prefer soft toys and dolls whereas boys preferred transportation toys and robots. A preference for same-sex playmates emerges early. When 3½- to 4½-year-olds were shown photographs of boys and girls and asked to select those with whom they would like to play, boys preferred boys and girls preferred girls. By age 2 to 3 years, boys appear to be more aggressive toward peers and to show more rough-and-tumble play. Fathers are as likely to give a 1-year-old daughter a truck as a doll but more likely to give the son a truck. However, when children are given dolls, boys play with them less than girls. Fathers more than mothers give negative responses to boys playing with dolls. Boys receive more positive responses for playing with blocks and girls receive more positive responses for playing with dolls.

Imitative and vicarious learning pervade general theories of social learning of sex typing. In imitative learning, behaviors are adopted that simulate those of a significant other person, the model. In vicarious learning, if something happens to a model the viewer's behavior is modified to resemble the model because the child perceives the model as possessing desirable attributes or obtaining desirable goals. The cognitive developmental theory, by contrast, sees the child first labeling itself as male or female and then finding the behaviors associated with that label rewarding.

Nature Versus Nurture The classic research on intersexed or hermaphroditic children pointed to the early-life emergence of gender identity as being influenced primarily by environment and as irreversible. In the studies by John Money, Joan Hampson, and John Hampson, a range of anatomical features discordant with the gender of rearing were found to be less relevant to the adoption of a male or female gender identity than the gender of rearing.

Studies of matched pairs, for example, demonstrate that with the syndrome of congenital virilizing adrenal hyperplasia, the newborn female, if considered to be male and designated male, matures with a male identity in spite of having the XX female chromosomal pattern, ovaries, and a uterus. If considered female the child matures with a female identity. However, questions have been raised about the generalizability of those findings to nonintersexed children because of the atypical prenatal endocrine environment and other atypical genetic or anatomical influences of intersexed children.

Studies of children born with normal sex characteristics who undergo gender reassignment early in life may be a more relevant test of nature versus nurture. The tragedy of penile amputation, usually through negligent circumcision, has provided such a model. In one celebrated case a reassigned male monozygotic twin who was reportedly being raised successfully as a girl failed to incorporate a female identity and now lives as a heterosexual male. Reassignment in that case was at 22 months, which may have been after core identity as a male was in place. A somewhat more complicated outcome was revealed in the very recent psychosexual follow-up of another biologically normal male whose penis was accidentally ablated during circumcision at the age of 2 months. The decision to reassign the infant as a female occurred sometime between 2 and 7 months, at which point surgical castration occurred. At age 26 years, clinical interviews and self-report questionnaires were used to obtain information on the patient's gender identity, gender role, sexual orientation, and sexual identity. In adulthood the patient lived socially as a woman and her gender identity was unequivocally female, with no evidence of gender dysphoria. However, the patient's childhood gender role behavior had been predominantly masculine, and her current occupation was male-dominated. Moreover, she fantasized sexually about women more often than about men. On the other hand, her objective sexual history included roughly equal amounts of sexual experience with women and men. At the last follow-up, the patient was living with a new female partner, in a lesbian relationship.

Psychoanalytic Theories As in other areas of psychopathology, psychoanalytic theories about gender identity disorders constitute a tradition distinct from biological and other nonbiological approaches. One influential theory is that of Ethel Person and Lionel Ovesey, who advanced the hypothesis that transsexualism in males originates from unresolved separation anxiety during the separation-individuation phase of infantile development. To cope with this anxiety, the child resorts to a reparative fantasy of symbiotic fusion with his mother. Adult transsexualism may be understood as an attempt to master that anxiety through sex reassignment surgery, through which the transsexual acts out his unconscious fantasy and symbolically becomes his mother.

According to this hypothesis, male transsexuals vary in the directness with which they proceed to the transsexual resolution. Some individuals never develop any other psychosexual phenomena as defenses against separation anxiety, and they proceed to the transsexual outcome in a straightforward manner. Others develop transvestism or effeminate homosexuality as initial defenses. When those defenses fail in the face of various stressors, the individual regresses to the primitive fantasy of symbiotic fusion with his mother and begins to experience transsexual impulses.

The other major psychoanalytic theory was developed by Robert Stoller to explain the etiology of transsexualism in a specific group of biological males, who would fall within the DSM-IV category of gender identity disorder, sexually attracted to males. Stoller called those males true transsexuals.

The theory begins with the grandmother of the future transsexual who treats her daughter coldly and neither encourages nor models femininity for her. The grandfather has a closer relationship with the daughter, but he encourages masculinity in her. In consequence the mother of the future transsexual develops a mild gender identity disorder of her own. In adolescence, however, she abandons her conscious transsexual wishes of someday being male and adopts a heterosexual façade. At the unconscious level she nevertheless retains a strong penis envy.

The transsexual's mother eventually enters an empty marriage with a passive and withdrawn husband who is psychologically if not physically absent from the household. The final pathogenic process becomes operative when the mother gives birth to an infant son whom she perceives as particularly beautiful and graceful. The boy, who represents her feminized phallus, fulfills her lifelong wish for a penis. The mother-son interaction, described by Stoller as a blissful symbiosis, includes excessively close and prolonged body contact, sometimes with the infant's nude body cradled against the mother's nude body. The mother's behavior expresses her need to treat her son as an extension of her own body.

The transsexual's early experiences, especially the continuous skin-to-skin contact, produce an overidentification with his mother, a blurring of ego boundaries, and eventually a feminine gender identity. The transsexual boy never develops a “heterosexual” relationship with his mother and therefore never develops an oedipal conflict. His femininity is produced nonconflictually and remains a nonconflictual, autonomous form of behavior. This theory does not account for “secondary” transsexuals, notably those who evolve through a transvestite, heterosexual pattern.

DIAGNOSIS AND CLINICAL FEATURES

The DSM-IV diagnostic criteria for gender identity disorder are listed in Table 19.3-1. The ICD-10 diagnostic criteria are presented in Table 19.3-2.

Table 19.3-1 DSM-IV Diagnostic Criteria for Gender Identity Disorder

Table 19.3-2 ICD-10 Diagnostic Criteria for Gender Identity Disorders

Children A longitudinal study of 66 boys provides a picture of gender identity disorder in children. The age range at the initial evaluation was 4 to 12 years. One third of the boys frequently stated their wish to be girls and three fifths did so occasionally; three quarters cross-dressed frequently. The age of onset of cross-dressing was before the fifth birthday with 90 percent. A female-type doll, such as Barbie, was the favorite toy for one fifth of the boys and a frequently played with toy for another two fifths. Three-fifths of the boys took a female role when playing house; over four-fifths had a primarily female peer group; and three fifths of the boys were rejected by other children or were voluntary loners.

The full prepubertal age range for evaluating gender identity disorders in children yields a variety of presenting behaviors. Younger children aged 3 to 5 may believe that they are of the other sex or that they can easily become the other sex. Between the ages of 6 to 9 years the children's gestures and mannerisms may be cross-sex stereotypes. Older children have often been subjected to increased peer teasing and so may have gone underground with their cross-gender behaviors, particularly cross-dressing.

A 5-year-old boy, referred by his general practitioner, was brought for evaluation by both parents. He had been saying either he was a girl or had wanted to be one since age 3. His preferred clothing was that of his sister. He wanted to wear makeup and his mother's jewelry. His favorite toys were dress-up dolls, especially those with long hair. He refused to stand to urinate. In make-believe games he was usually the mommy or a female character. Most of his friends were girls. He showed no interest in sports. All the pictures he draws are of women. The cross-gender behavior was recalled by both parents since the boy was age 2. Neither attempted to interrupt it or redirect his interests until recently, when their efforts were met by the boy with resistance. They had been advised by a preschool teacher and a regular babysitter to ignore the behavior as it would go away. Neither parent expressed concern that their son would become homosexual but they are concerned that he may be transsexual.

A 7-year-old girl referred through the school had been insisting to other children that she was a boy. Since the age of 2 years she has said that she was a boy and that she did not want to be a girl. Her clothing style preference is that of boys and attempts to make her wear a dress are met with refusal. She watches her father shave and ignores her mother applying makeup. Her friends are boys and her favorite activity is sport. She has no interest in doll play but loves action and soldier toys and guns. She frequently attempts to urinate while standing.

Associated Features Boys with gender identity disorder have been shown in some reports to evidence greater general psychopathology than nonclinical control boys. Using the Child Behavioral Checklist, a study found that boys with gender identity disorder had indices of psychopathology similar to a clinic-referred group used in the instrument's standardization. However, another report by the same investigator did not find more behavioral problems on the checklist than among concurrently assessed, demographically comparable clinical controls.

Some clinical experience argues that much of the behavioral problem seen in gender-atypical boys is secondary to discomfort over gender and the consequent social ostracism and teasing. That social ostracism is the basis of psychopathology in cross-gendered boys is supported by the finding that checklist symptom scores increase with the age of the child (when stigma increases).

Some clinicians have found separation anxiety disorder in boys with gender identity disorder. They claim that separation anxiety disorder precedes feminine behavior, with cross-gender behavior emerging to restore the emotional tie with a mother who is perceived as unavailable. A recent study using liberal criteria for diagnosing separation anxiety disorder found a correlation between that disorder and gender identity disorder. In the absence of convincing data demonstrating that separation anxiety disorder precedes gender identity disorder and because most children with separation anxiety disorder do not have a gender identity problem, the connection is still unclear.

Psychological Tests No psychological test is diagnostic of gender identity disorder in children. However, two tests, the It-Scale for Children and the Draw-A-Person Test, discriminate boys with gender identity disorder from gender-typical boys.

The It-Scale presents a child with a neuter stick figure (It). “It” then selects from a series of cards depicting gender-typed accessories and activities. Cross-gendered boys more often select feminine or girl-type cards. The Draw-A-Person Test in its basic format requires a child to draw a person. Most gender-typical children draw a person of their sex. By contrast, the majority of cross-gendered boys draw a female first. Conversely, with a sample of nonclinical tomboys, the majority drew a male first, in contrast to a matched sample of nontomboys. These tests can be used as ancillary evaluation procedures. The Draw-A-Person Test, in particular, is a good technique for making a child comfortable during the initial interview.

Adults Virtually all adults who present complaining of gender dysphoria are self-referred. In most cases the relevant diagnostic question is not whether the patient is gender dysphoric but how severe the condition is.

Central features of gender identity disorders in adults are the persistent sense that one was born into the wrong sex, the belief that one would have been happier as the opposite sex, and the conviction that one has the typical feelings and reactions of the opposite sex. The discontent extends to the social, interpersonal, and somatic realms of the person's existence although the relative emphases differ from case to case.

Social Realm At the social level there is a consistent indifference to or distaste for roles and activities traditionally associated with the original sex, together with recurrent desires to live in society as a part-time or full-time member of the opposite sex. In response to these longings, the gender-dysphoric person begins cross-dressing in isolation, in the company of friends, or attempts to pass as a member of the opposite sex in public. These behaviors may stabilize as intermittent

activities or expand to permanent adoption of the cross-gender role, depending in part on the intensity of the gender dysphoria and the person's success in simulating the appearance and manner of the opposite sex.

Interpersonal Factors The enjoyment of relationships, especially romantic ones, is significantly diminished by the conflict between the person's subjective feelings of masculinity or femininity and the discrepant perceptions of others. A female-to-male transsexual, for example, may reject an otherwise acceptable female partner if that partner clearly regarded the transsexual as essentially female and the relationship as a lesbian one. Efforts to find sexual or romantic partners who perceive the gender-dysphoric person as a member of the opposite sex may lead the person into dangerous circumstances. For example, adolescent gender-dysphoric females sometimes pass themselves off as males when first dating or courting potential girlfriends. Male-to-female transexuals sometimes complete entire sexual encounters with unsuspecting men, discouraging interest in coitus with the excuse of menstruation and offering fellatio instead.

Somatic Factors The gender-dysphoric person often fails to value the primary and secondary sexual characteristics of his or her body, in many cases developing an aversion to those characteristics. A male-to-female transsexual, for example, may describe his penis as an “ugly growth” and avoid touching it as much as possible. Somatic dysphoria is usually accompanied by the desire for some or all of the physical characteristics of the opposite sex. Gender-dysphoric persons use various means to simulate the desired phenotype. Women, for example, commonly flatten their breasts with elastic binding to produce a masculine chest contour, men wear prosthetic breasts. Transsexuals of both sexes seek hormonal and surgical treatment to complete the transformation.

A 37-year-old man presented with a request for sex reassignment surgery. He was dressed as a man, and he was masculine in his physical appearance and mannerisms.

The patient had not been observably effeminate in boyhood. He had, however, been attracted to and fascinated by feminine activities from an early age. He particularly recalled having liked to watch women apply makeup. He began cross-dressing around puberty. During adolescence he sometimes stole women's underwear from clotheslines. At that stage he preferred women's clothes that had been worn because he felt that they were somehow infused with femininity. Cross-dressing was sexually arousing from puberty until his early 30s, when sexual excitement yielded to feelings of comfort and naturalness.

The patient married at 25. He initially hoped that marriage would cure his cross-dressing but that hope soon proved false. The couple's sex life was poor and the marriage dissolved after 8 years. The patient began another heterosexual relationship a few years after his divorce, but that relationship also failed in the face of his growing gender dysphoria.

Following clinical assessment, the patient began making systematic plans to move into the female role and commenced living and going to work as a woman full-time at 39. The attempt to live as a woman proved successful, and the patient underwent surgical sex reassignment at 41.

After moving into the female role, the patient went on a few dates with men but found that she could not really develop an interest in them. After surgery she began moving in lesbian social circles and having sexual relationships with women. She was content with her life in general and had no regrets about her decision to undergo sex reassignment.

A case of classic transsexualism, corresponding to the popular notion of a “woman trapped in a man's body,” is illustrated by this homosexual male gender-dysphoric patient, who presented at a university-affiliated gender identity clinic at the age of 22, requesting sex reassignment surgery. The patient presented in the female role, wearing a dress; well-applied make-up; clean, long, curly hair with bangs; and pink nail polish. The patient's voice and mannerisms were convincingly feminine, and the overall impression was that of an attractive young woman.

The patient was the second of three children, having one older brother and one younger sister. The patient reported that from earliest childhood he preferred girls' games, dolls, and female playmates. His obviously feminine behavior continued after he entered school, and he was teased and ridiculed by his classmates, sometimes being asked if he was a boy or a girl. The patient's mother, who was also interviewed as part of his assessment, reported that she had noted the teasing by his classmates when he was in school but claimed that she had not attributed this to his feminine behavior and had not known what was causing it. The mother stated that she never tried to feminize the patient in any way, but she did allow him to dress up as a pretty young witch on Halloween.

The patient began cross-dressing secretly in Grade 8, in his mother's nylons, brassieres, and dresses. However, he wore his own underwear because he did not want to soil his mother's clothing. He avoided detection by being very careful about how he returned his mother's clothes to her drawers. These sessions were never accompanied by sexual arousal.

The patient reacted negatively to his physical changes at puberty, especially the appearance of facial hair. At age 15, he began to hide this with makeup, which he wore outside the home and even to school.

He never made any real friends at school and he did not participate in any school activities. He was very lonely and unhappy during these years, and he made a suicidal gesture in Grade 10 with pills belonging to his mother. The only effect of this was that he awoke the next morning with a bad headache, and he did not seek medical or psychiatric attention. Despite his psychological and social problems, he maintained average grades and graduated high school at the normal age.

After graduating high school, the patient remained at home. His father died in a construction accident around this same time. The patient was still living at home with his mother and younger sister at the time he presented at the gender identity clinic. He was unemployed and had never held a job.

He informed his mother and sister about his cross-gender feelings shortly after his father's death. The mother's initial reaction was: “I hate to see it this way. I pray every night it will change, but I know it won't.” During this period the patient began cross-dressing at home, but he usually waited for his mother and sister to go out, for fear of making them uncomfortable. The patient began going out in public as a female in the year prior to his presentation at the gender identity clinic.

At the time of clinical intake, the patient's sexual history was virtually nil. He reported that he had masturbated only once, around the age of 18. He found the experience “horrible and disgusting.” He had had no sexual experience with either men or women. He reported that he was romantically interested in men but that he would not feel comfortable attempting sexual intercourse at the present time. He explained his reluctance as follows: “I guess I'm just an old-fashioned girl—I don't believe in sex before surgery.”

Following the intake assessment, the patient (now “she”) adopted the female role full-time. She changed most of her identifying documents so that they showed her as a female, and she obtained a job as a secretary. She also obtained her driver's license—something she had thought she could never achieve. Her morale improved substantially, and with it, the degree of acceptance from her family. The patient's mother commented that “living with John was a living hell,” but that Joanna was a completely different person. She cited, as an example, the fact that the patient had a conversation with her brother for the first time that the mother could remember.

The patient eventually acquired a boyfriend who had no idea that she was biologically male. She avoided sexual intercourse and his proposal of marriage with the excuse that she had “intersex problems” and required surgery to make her a more complete woman. She underwent surgery at the age of 28 and married her boyfriend a year later. The couple were still happily married at our last contact with the patient, 4 years later. The patient was at this time managing her husband's trucking business. He still did not know the nature of her “intersex” problems and was aware only that she could not have children.

A 21-year-old woman complained that she felt uncomfortable with her body, that she should have been a male, and that she wanted to be a male. She presented in the female role, but all of her clothes (jeans, shoes, shirt, vest) were men's style. Her mannerisms and her voice were convincingly masculine.

The patient recounted a childhood history typical of gender identity disorder in girls. Her dissatisfaction with her sex intensified at puberty. She hated menses and her developing breasts, which she began hiding with jackets and sweatshirts. The last time she wore a dress was at her eighth-grade graduation.

The patient had no sexual experience with men. Her first homosexual relationship occurred in high school and lasted about 2 years. Her second was with her current partner, a divorcee 10 years older than she. She was cohabiting with her partner and her two young children. Their sexual relationship was reported by both partners to be satisfactory although it was one-sided; the patient brought her partner to orgasm but would not allow her own breasts or vulva to be touched because that reminded her of her anatomical sex.

The patient regarded herself as gay in high school but eventually came to realize that she was transsexual. Her goals at clinical presentation were to undergo sex reassignment, to marry her partner, and to be a father to her partner's children.

Associated Features Gender identity disorders may be associated with character pathology. Clinical authors sometimes assert that gender identity disorder patients tend to have narcissistic or borderline personality disorders, perhaps because a significant minority of patients seem self-absorbed, demanding, unempathic, selfish, inconsiderate, or interpersonally shallow. It is likely that only a fraction of these, however, would meet DSM-IV criteria for a formal diagnosis of narcissistic personality disorder or borderline personality disorder. It is possible that, in some cases, the labels “narcissistic” and “borderline” are simply used as the closest available description for personality patterns that in fact may be specifically associated with gender identity disorders.

Associated features vary markedly for different subtypes. Gender-dysphoric women exhibit the least associated psychopathology, and what they do exhibit appears to fall into no particular category. The sexually attracted to male subtype of males includes a proportion of persons with histories of drug abuse, property offenses, and prostitution. Prostitution is usually carried out in the female role, or, more precisely, in women's attire; the customers are frequently men specifically seeking transsexual prostitutes in preference to biologically female prostitutes.

The majority of men with nonhomosexual subtypes of gender identity disorder report past histories of erotic arousal in association with cross-dressing, and some qualify for a concurrent diagnosis of transvestic fetishism. Careful questioning usually reveals that they are more aroused by the thought or image of themselves as women (autogynephilia) than by items of clothing per se. Therefore, the label “fetishism” applied to their sexual behavior, may be somewhat misleading.

One feature that is occasionally found among nonhomosexual gender-dysphoric men is sexual interest in (other) feminized males. It has been previously argued that persistent and recurrent sexual interest in such males represents a distinct paraphilia, *gynandromorphophilia*. The feminized males of interest to gynandromorphophiles include men wearing women's attire and men—known in the vernacular as “she-males”—who have surgically or hormonally feminized bodily contours but intact male genitalia. In some cases the key feature that makes a feminized male attractive to a gynandromorphophile is simply the thought or knowledge that this individual had been transformed from male to female; thus, postoperative male-to-female transsexuals are of interest to some gynandromorphophiles, even though the reassigned transsexual lacks male genitals.

The clinical impression that gynandromorphophilia is sometimes associated with gender dysphoria, transvestism, or both was supported by a statistical study of male subscribers to a voice mail system devoted to personal advertisements for sexual or romantic partners. About 40 percent of the men who sought to meet cross-dressers, transvestites, transsexuals, or she-males for sexual or romantic purposes were cross-dressers themselves.

This 39-year-old lawyer was referred to a gender identity clinic because of various related complaints involving gender identity. He was unremarkably masculine in manner and demeanor, wearing a full beard and appropriate male attire. The patient reported that he had been thinking about sex reassignment; however, he appeared to have no real desire for women's genitals and actually said that he might prefer to live as a woman with a penis.

The patient's earliest recollection of anything that presaged his later gender identity problems was a vague memory involving his mother's petticoat. His second memory, at about the age of 6, was that of encountering a woman's shoe with a stiletto heel lying in the gutter. He remembered this because it made such an impression on him. He cross-dressed for the first time at about the age of 8, in a slip that he found outside. He began cross-dressing in earnest at about the age of 12 or 13, using both his mother's and his sister's clothes. Cross-dressing was usually accompanied by masturbation. In his late 20s he lived by himself during one period, during which time he cross-dressed very frequently. He had never gone out in public in women's attire, however, and he had ceased cross-dressing at the time he presented clinically.

The patient had his first heterosexual experience at about age 20. This was a casual encounter with a woman he met at a party or in some similar situation; he could not fully recall the details of this first intercourse. He had no long-term sexual relationships until he met his future wife, at age 29. They were married about 2 years later; the marriage lasted 5 years. There were no children, because neither partner desired them. Although his wife knew about his cross-dressing early in their relationship, she became progressively less accepting over time. The patient and his wife were divorced 4 years before he presented at the gender identity clinic.

When he was having heterosexual intercourse, he had difficulty ejaculating unless he engaged in private fantasies. He mentioned three fantasies that could excite him enough to ejaculate: the first was that he was cross-dressed, the second was that some other male was cross-dressed, and the third was that his partner was really a postoperative male-to-female transsexual (rather than a biological female). The patient had no sexual interest at all in (untransformed) men. He had had only one homosexual experience in his life, at age 12 or 13, with another boy about the same age. He did not really understand what was happening at the time, and this was a meaningless experience for him.

The patient's erotic fascination with feminized males appeared to center on the thought of a male being (or having been) transformed into a female. The erotic potential of this thought did not depend on concrete evidence of maleness, such as intact male genitals. On the contrary, the presence of male genitals on an otherwise attractive feminized male would kill any possible sexual interest on his part. The only type of feminized male with whom he could contemplate actual intercourse was a postoperative male-to-female transsexual who simulated a biological female perfectly, and whom he simply knew previously to have been male. On the one occasion when he attempted sexual intercourse with a real postoperative transsexual, the experience was not successful because he was turned off by the transsexual's residual male anatomical features, such as beard stubble.

The patient's first recollection of being stimulated by the idea of another feminized male was at about age 15 or 16, when he first heard of or saw female impersonators. He was excited by this idea as soon as he was exposed to it. At the time he presented, he was occasionally going to bars where she-males or transsexuals congregated. He did not attempt to pick any up because he was afraid of contracting HIV. He did, however, talk to them and appeared to derive some erotic pleasure simply from being in that milieu. Although his gynandromorphophilic interests were longstanding, recurrent, and well differentiated, they do not appear to have been his strongest sexual interests. He reported that his main masturbatory fantasy was that of being cross-dressed in the presence of a woman.

Other gender-dysphoric patients with gynandromorphophilia illustrate similarities to the patient in the foregoing vignette as well as differences. In the next vignette, a striking similarity is the patient's self-report—accurate or otherwise—that his very first exposure to the image of another cross-dressed male produced an immediate and powerful emotional reaction. A striking difference is the patient's absolute requirement that the male genitals be present rather than absent for a feminized male to be sexually arousing.

A heterosexual male gender-dysphoric patient recalled that when he was 4 or 5 years old he watched a Bugs Bunny cartoon in which Elmer Fudd, for reasons relevant to the plot, cross-dresses as a female. The patient wrote that he could still remember the impact of seeing Elmer Fudd dressed as a female: “The moment my young mind saw Fudd changed into a woman something hit me like a fist in the chest, releasing in me a desire to become a woman myself—a desire that has pursued me my entire life.” When he reached puberty, his favorite masturbatory fantasy was that some imagined male—not himself—was being transformed into a female. In adulthood, he spent considerable sums of money on she-male pornography. It was essential to him that the male genitals be exposed in the photograph or videotape. He reported that the sight of the genitals confirmed the person's biological sex and that this was what produced sexual excitement. The sight of the penis and scrotum was not arousing in and of itself.

DIFFERENTIAL DIAGNOSIS

Children Gender atypical children without a gender identity disorder must be distinguished from those with a diagnosable disorder. Tomboys without gender identity disorder prefer functional and casual clothing or gender-neutral clothing. By contrast, gender identity disorder girls refuse to wear girl's clothes and usually reject gender-neutral clothes. Many girls prefer shirts and pants to dresses, enjoy rough-and-tumble play or sports, and show little interest in doll play. They may say it is better to be a boy because of perceived social advantages, but such girls do not necessarily have a gender identity disorder. What distinguishes girls who do is their repeated statements of being or wanting to be a boy and wanting to grow up to be a man, along with repeated cross-sex fantasy play.

With boys the differential diagnosis must distinguish those who do not conform to traditional masculine sex-typed expectations but who do not show extensive cross-gender identification, and who are not discontented with their anatomical sex. It is not uncommon for boys to reject rough-and-tumble play or sports, to prefer sedentary or aesthetic activities, or occasionally to role-play as a girl, to play with a doll, or to dress up in a girl's or woman's costume. Such boys do not necessarily have a gender identity disorder. This fact must be stressed to parents, especially to fathers who may have vigorous athletic expectations for their sons. What distinguishes boys who do have a gender identity disorder is the stated preference for being a girl and for growing up to become a woman, along with repeated cross-sex fantasy play, a strong preference for traditionally female-type activities, including cross-dressing, and a female peer group.

The clinician may sometimes see boys with repetitive cross-dressing but no other observable evidence of cross-gender identification. Those boys are often brought by parents when they discover their son cross-dressed, usually in his mother's underclothes. Such children would not satisfy the diagnostic criteria for gender identity disorder in children, although it is possible that some of them will warrant a diagnosis of gender identity disorder by the time they are grown. Monosymptomatic cross-dressing of this nature is sometimes recalled by adults with transvestic fetishism, but no studies are available predicting the sexual outcome of early isolated cross-dressing.

Because the diagnosis of gender identity disorder excludes children with anatomical intersex, a careful family medical history needs to be taken, with a focus on any suggestion of hermaphroditism in the child, such as an unusual appearance of the genitalia. When there is doubt, referral to a pediatric endocrinologist is indicated for appropriate hormonal and cytological examinations.

Adults Psychotic persons rarely develop the delusion that their sex is changing. A male patient, for example, may claim that he can feel his breasts growing or his penis shrinking. Such beliefs are never expressed by adult patients with gender identity disorder, who understand that sex reversal does not occur spontaneously. In any event there are other signs (e.g., hallucinations, ideas of reference) to aid in the differential diagnosis.

A more difficult diagnostic problem is posed by some late-adolescent patients who report that they were extreme sissies (or tomboys) as children, that they have always felt like members of the opposite sex, and that they are uncomfortable with their bodies, but who go on to say that they feel guilty about being attracted to members of their own sex, that they believe homosexuality to be worse than transsexualism, and that they want sex reassignment so that they can lead normal heterosexual lives. It can be difficult at initial assessment to determine how much of the patient's behavior is driven by true gender dysphoria and how much by internalized homophobia. Fortunately, the diagnosis becomes clearer when such patients are followed into young adulthood.

COURSE AND PROGNOSIS IN CHILDREN

In a 15-year prospective study, 44 of 66 cross-gendered boys, most of whom would be diagnosed today with gender identity disorder, were followed to adolescence or young adulthood. Sexual orientation was determined by interviews tapping erotic fantasies and erotic behaviors. Fantasies were determined from questioning about masturbation content, erotic nocturnal dreams, and experiences of arousal when seeing pornography or attractive persons. Behaviors were assessed by reports of interpersonal genital sexuality.

On the dimension of erotic fantasy, 33 of 44 (75 percent) previously gender-atypical boys were bisexual to homosexual (rated 2 to 6 on the Kinsey 7-point scale of sexual orientation, where 0 is exclusive heterosexuality and 6 is exclusive homosexuality). With behavior, 24 of 30 (80 percent) were bisexual to homosexual. One boy at 18 years was transsexual. None of the boys was sexually aroused by cross-dressing.

Behavioral changes were evident in the boys during the years prior to the determination of sexual orientation. There was a general lessening of specific cross-gender behaviors and a denial by all but one of the continued desire to be female.

There are several possible reasons for the considerable behavioral change from the time of initial evaluation to adolescence, with or without formal treatment. When deciding to seek professional counsel, parents have usually concluded, or may conclude after consultation, that their child's extensive cross-gender behaviors should be limited or eliminated. The child is also receiving negative reactions from age-mates for obviously cross-gendered activities. The developmental course of activity preferences in typical children also dictates change. Because even typical girls play less with dress-up dolls as they get older, cross-gendered boys can also be expected to show less interest.

There have been no large studies of atypical females evolving into adolescence. A community-based sample of 50 tomboys found that the girls shared some (but not all) features with girls with gender identity disorder. Because federal research funding was not forthcoming, no follow-up data are available for this unique sample. Confusion and controversy have resulted from the inclusion of gender identity disorder as a childhood mental disorder and the finding from longitudinal research that most such children (especially boys) become homosexual or bisexual adults and on that basis do not meet the criteria for mental disorder. Notice must be given to the cardinal complaint of gender identity disorder, which is gender dysphoria or discontent with one's birth sex. When such children grow out of their dysphoria they no longer meet the criteria for gender identity disorder because erotic attraction to same-sex partners is not a disorder. However, if dysphoria endures, it can be diagnosed as gender identity disorder or transsexualism.

COURSE AND PROGNOSIS IN ADULTS

Biological Males Sexually Attracted to Males and Biological Females Sexually Attracted to Females Biological males sexually attracted to males and biological females sexually attracted to females are similar in course and prognosis. In many regards the characteristics of the one group are mirror images of the characteristics of the other.

Course Adult homosexual gender-dysphoric persons primarily represent that fraction of gender identity disorder children who did not normalize in gender identity by the end of adolescence. The course of the disorder is continuous, although certain manifestations of it may be driven underground in late childhood or the early teens. A feminine boy, for example, may cross-dress frequently in connection with fantasy play; cease cross-dressing entirely from junior high school to early adulthood as he attempts to fit into society or at least to minimize conflicts with family and peers; and then resume cross-dressing in his 20s with the intention of pursuing sex-assignment surgery.

Homoerotic feelings begin in puberty. Some adolescents label themselves initially as homosexual and seek companionship in a gay crowd. They find they do not really fit in there either, although some adolescent male transsexuals continue to socialize in the homosexual drag circuit simply because it offers the only available supportive environment. Eventually, homosexual gender-dysphoric persons of both sexes begin to label their erotic attractions in terms of their subjective gender identity. Thus, for example, a female-to-male transsexual will assert that her romantic interest in another woman is heterosexual not lesbian because inside she is really a man.

In young adulthood there is often an increase in cross-dressing and in attempts to pass as the opposite sex. Some patients have already moved into the cross-gender role full-time by the time they present for clinical attention. These developments reflect freedom from parental controls and increased opportunities for self-expression more than intensification of the gender dysphoria. The homosexual type (biological male sexually attracted to males and biological female sexually attracted to females) of gender identity disorder does not have the character of a progressive disorder. In young males, adoption of the female role is sometimes accompanied by withdrawal from society at large into a subculture consisting mostly of other male-to-female transsexuals.

At initial presentation female patients more often than males are involved in love relationships with same-sex partners. The female partner typically concurs with the patient's self-evaluation that she is really a man and reports that she perceives her lover as a man without a penis. Such partners are often anxious to be part of the

transsexual's evaluation.

Prognosis Young adults who are still living in the original gender role when they first present sometimes relinquish the desire for sex reassignment and make a satisfactory adjustment to a homosexual lifestyle. In most cases, however, the disorder is chronic.

Impairment and Complications Peer ostracism often makes school attendance so difficult for biological males with gender identity disorder, sexually attracted to males, that they drop out of high school without graduating. Lack of education and job skills contribute to chronic unemployment and further marginalization of the individual in society. Societal rejection and its sequelae may lead to prostitution or to drug and alcohol abuse. Gender identity disorder has fewer such outcomes for women, possibly because of society's greater tolerance of cross-gender behavior in girls and women.

Biological Males Sexually Attracted to Females, Both Sexes, or Neither Sex There are marked and probably qualitative differences between the type of gender identity disorder that may occur in homosexual males and females (biological males sexually attracted to males and biological females sexually attracted to females) and the types that occur in nonhomosexual males (biological males sexually attracted to females, sexually attracted to both, and sexually attracted to neither). The differences in their natural histories suggest that homosexual and nonhomosexual gender identity disorders are etiologically different conditions.

Course In terms of observable symptoms, nonhomosexual gender identity disorders may be characterized as progressive disorders with an insidious onset. The course is fairly continuous in some cases; in others, the intensity of symptoms fluctuates to the point that the course might be called episodic. The subjective experience is of a lifelong struggle with feminine longings that change their focus from time to time and may temporarily recede in the face of conflicting desires, but which have always been present in one form or another from the early years.

In most cases the first outward manifestation of the disorder is surreptitious cross-dressing in childhood (e.g., in mother's or sister's clothing). Many men also report that they first began wishing they were female during that period. The boyhood behavior does not, however, exhibit the pervasive pattern of effeminacy required for a childhood diagnosis of gender identity disorder. At puberty, cross-dressing begins to elicit penile erection, and for the next few years or decades, the individual may qualify for a diagnosis of transvestic fetishism. In his 20s or 30s, the person's penile response to cross-dressing begins to wane while at the same time his desire to have a woman's body grows stronger and more insistent. In general, the cross-gender wishes attain the highest intensity by the mid-30s and remain about the same thereafter. It must be emphasized, however, that the course is highly variable.

Most men with gender identity disorder, sexually attracted to females, sexually attracted to both, or sexually attracted to neither establish relationships with women at some point in their lives and many marry and father children. Those who fall in love with a woman often report that, during the early days of the romance, they lose their interest in cross-dressing or surgical sex reassignment. When the relationship becomes routine and the initial excitement subsides, however, the desire to dress or live as a woman reasserts itself.

The course of nonhomosexual gender identity disorders may also be punctuated by periods of increased symptomatology. Men of that type occasionally present during an episode of intensified gender dysphoria, with anguished longings to be female accompanied by frustration and despair at their male state.

Prognosis The disorder tends to be chronic. Its tendency towards cyclical variation in many cases may mislead the patient or his therapist into thinking that the patient has been cured when he would be better regarded as in remission. As a group, nonhomosexual gender-dysphoric patients are less likely than homosexual gender-dysphoric patients to pursue surgical sex reassignment to completion. Many simply learn to live with their feelings. Acute episodes of intensified gender dysphoria usually resolve to the preepisode level after a few months, and patients should be discouraged from taking steps toward establishing themselves as females during such periods.

Impairment and Complications Nonhomosexual gender identity disorders tend to interfere with heterosexual relationships. Feelings of sexual interest aroused by the sight of a beautiful woman may turn, in the next instant, into feelings of envy. Heterosexual intercourse may require the person to fantasize that he is the woman and his partner is the man or that he and his partner are two women having lesbian relations; even with the help of such autogynephilic fantasies, erectile problems are common.

Gender identity disorders commonly result in marital breakdown, either because the husband wishes to be free to pursue sex reassignment or because the wife can no longer tolerate her husband's cross-dressing or other cross-gender behaviors. Men contemplating or undergoing divorce often feel considerable guilt about the effect of their behavior on their children and anxiety about their prospects for continued access to them. These concerns are often part of the clinical picture in patients of the nonhomosexual type first presenting for assessment.

TREATMENT

Children Evaluating the effects of intervention is difficult. Whereas short-term behavioral changes toward more conventional gender-typed activities are described, few data are available about adult sexuality. In a prospective study, a subsample of boys with gender identity disorder was treated by several therapists with a variety of approaches, including psychoanalysis, family therapy, individual psychotherapy, and behavior modification. With each intervention the boys showed lessening of cross-gender behaviors. At follow-up none expressed the desire to be female. However, the rates of homosexual or bisexual orientation did not differ from those boys who had no formal treatment, who also showed a lessening of cross-gender behaviors.

At present there is no convincing evidence from any controlled research that psychiatric or psychological intervention with children with gender identity disorder affects the direction of subsequent sexual orientation. Transsexualism, however, may be affected. Transsexuals are unable to cope socially as persons of their anatomical sex. The treatment of gender identity disorder in children is directed largely at developing social skills and comfort in the sex role dictated at birth. To the extent that treatment is successful, transsexual development is interrupted. Clinicians experienced in the treatment of gender dysphoria in adulthood can attest to the extraordinary difficulties faced by such patients. It is the rare transsexual who does not acknowledge that life would have been better if the overwhelming discontent over birth sex could have been overcome in childhood. The low prevalence of transsexualism in the general population, however, even in the special population of cross-gendered children, thwarts the testing of this.

The most systematic attack on specific cross-gender behaviors is the behaviorist approach. Specific cross-gender behaviors in boys have been substantially reduced by the use of a token economy or differential social reinforcement. To the extent that such changes reduce stigma and enhance the boy's self-image, the results could be considered positive. However, one goal of George Rekers, the principal proponent of that type of intervention, appears not to be realized. Rekers wished to prevent the boy from yielding to “homosexual temptation” with homosexuality having “been sold to the unwary public as a right between consenting adults.” At least two graduates of that program are bisexual. Systematic follow-up of adult sexual orientation on the others in that series has not been reported, although it is over two decades since many were treated. One current treatment approach is eclectic in that it addresses the child's interaction with each parent, the child's perception of sex roles, and the child's relations with peers.

In a typical case it has been a year or more during which parents have observed behaviors in their child that constitute gender identity disorder. During that time, one parent may have taken a firmer stand against some of the behaviors, but for the most part the children have not been interrupted in these activities. Parents have typically been uncertain or ambivalent about its meaning, and until recently, if at all, the child has not been aware that his or her parents object to the atypical behavior. A child may interpret a parent's neutral stance to atypical behaviors as positive. Some parents may have begun to be concerned, but they have been advised by preschool teachers that the behaviors are normal and should not be discouraged. A parent who is concerned about the excessive nature of the child's cross-gender behaviors may have difficulty convincing the school of that child's special needs, notwithstanding any ideal of androgyny. The family doctor may dismiss the behavior as a “passing phase.” A grandparent or housekeeper may be supportive of the child's cross-gender activities or at least may not discourage them, again undermining efforts at behavioral change at least toward gender-neutral activities. Initial limit-setting by parents usually meets with resistance and testing by the child. It may result in behaviors continuing in secret. Some children will relabel the cross-gender behaviors as gender-appropriate. For example, a long, flowing robe that was previously a princess gown is now a Superman cape.

One strategy of therapy looks to the child's level of cognitive development. Young children paint the world in black and white. In the area of gender, there are no grays. A child who does not like the activities he or she associates exclusively with that child's sex concludes that being the other sex is the only solution. A girl will say that only boys play sports or a boy will say boys play too rough. Grays must be introduced. Boys need to know that they can participate in sedentary play with other children, both boys and girls. Girls needs to know that girls play sports and can be as good as or better than many boys. Parents should find children who

demonstrate those behaviors to play with their own child.

Goals with parents should be set early. Many parents are motivated to the initial evaluation by fears that their children will become transsexual or homosexual. Parents should be redirected from hypothetical concerns of decades ahead to the immediacy of the child's life. At present, the child is unhappy being a boy or a girl, and the focus should be on making the child content with who he or she is. In the immediate term, the child is experiencing social stigma. The child should be integrated more effectively into the peer group.

It has been demonstrated that by ages 4 to 5 boys and girls differ in their manners of walking, running, throwing a ball, and narrating a story. Cross-gender gestures and mannerisms should be pointed out to the child. The reason given to the child and parents for intervention is that otherwise the child will be teased. Children are often unaware of cross-gender mannerisms, but alerting them can help bring them into consciousness and under control.

A boy with gender identity disorder typically has a strained relationship with his father. Identifying cause and effect in the distant father-son relationship is difficult. Some fathers were not available to their sons in the earliest years, and the boy gravitated toward his mother's activities. Then the father found that the boy did not respond to his belated attempts to engage him in sports or other activities. Alternatively, a father may have been available from the outset, but the child was temperamentally attuned to his mother's activities. The father became discouraged and his attention focused elsewhere, perhaps to another sibling with whom he shared interests. The need for a positive father-son experience must be emphasized to fathers. Nonathletic activities can be mutually enjoyable. Taking the son to work provides a better image of who father is. Board games, video games, and a shared father-son activity, such as Indian Guides, a program sponsored by the YMCA that emphasizes crafts and camping, can be helpful. The father's busy work schedule must be compromised lest the best years of their relationship be sacrificed. Whatever the outcome of the boy's sexuality, a more positive father-son relationship is to be sought; it is good for both father and son.

The child may believe that the parents wanted a child of the other sex. Sometimes parents did and conveyed the wish to the child. Parents must convey the message to the child that this is not so (if it ever was) and that they are happy with the sex of their child.

Young children should be taught that sex is irreversible. Not yet having achieved gender constancy at ages 4 to 6, they may think that by cross-dressing or changing hair length they change their sex. They should know the anatomical differences between the sexes and that superficial changes will not achieve their goal. Older children who are aware of genital differences and are cognitively more advanced may also be sophisticated about sex-change surgery. The parade of transsexuals on television has educated older children so that the clinician's statement of irreversibility of sex can be challenged.

The same treatment strategies used for boys with gender identity disorder are applicable to girls. Parental responses that have been supportive of behaviors causing the girl to be stigmatized can be interrupted. Same-sex peer group experiences are to be encouraged. Where a swagger has evolved and teasing results, it should be modified as are the extensive feminine mannerisms in a boy.

No hormonal or psychopharmacological treatments for gender identity disorders in childhood have been identified.

In recent years controversy over treatment of gender identity disorders has increased. The Human Rights Commission in the City and County of San Francisco in September 1996 issued a resolution condemning the use of a gender identity disorder diagnosis against children and young people. It contends that the diagnosis of gender identity disorder in children and young people was established to identify “pre-homosexual” and “pre-transsexual” children to prevent them from growing up to be gay or transsexual. The resolution also asserted that gender identity disorder of childhood and adolescence is used to stigmatize children and young people who have been discriminated against because of gender nonconformity. The diagnosis of gender identity disorder of childhood and adolescence was seen as reinforcing bias against gender-atypical young people.

From this perspective, the Commission called on the American Psychiatric Association and Psychological Association to oppose treatment designed to “manipulate a young person's sexual or gender identity” and for a ban on funding for treatment. On the other hand, a transgendered child psychiatrist sees this perspective as myopic and as ignoring the extreme distress continuing for decades in the untreated or unchanged gender-dysphoric child.

Although critics of treatment for childhood gender identity disorder currently point to the high association between this disorder and later homosexual orientation (itself not a disorder), the “corollary” that gender identity disorder was introduced as a substitute for homosexuality in DSM-III is factually wrong. The psychiatrists who were the strongest advocates for omitting homosexuality from DSM and who were very concerned with the stigma of pathologizing homosexual behavior also agreed with the new diagnosis of gender identity disorder. The reason that gender identity disorder was included is that it was consistent with the new DSM criteria for mental disorder, namely subjective distress and social limitations. Children with gender identity disorder are unhappy with their gender and are socially stigmatized.

Whether or not someone else agrees, parents have the legal right to bring a child for therapy to modify behavior they disapprove of and with the goal of preventing a later behavior of which they disapprove. Under American law a parent, for example, may withdraw a child from a state mainstream school in the child's early teens to further education only in Amish ways. A parent may require a child to observe religious dietary laws or attend religious services on a regular basis and not to participate in a sex education program. Therefore, parents may also engage a psychotherapist to treat what is diagnosed as gender identity disorder or attempt to change their child's behavior without professional intervention.

Adolescents Young persons whose previous gender identity disorder has normalized (with or without treatment) by the end of puberty may experience new conflicts when homosexual feelings emerge in adolescence. Although homosexuality is not a psychiatric disorder, it may be a source of anxiety to the adolescent and cause intrafamily conflict. Teenagers should be reassured about the prevalence and the nonpathological aspects of a same-sex partner preference. They should understand that sexual experimentation in adolescence need not reflect their final orientation. Parents must also be informed of the nonpathological nature of a same-sex orientation. They must be dissuaded from obsessing over (or even asking the question) “Where did I go wrong?” The goal of family intervention is to keep the family stable and to provide a supportive environment for the adolescent.

Adolescents whose gender identity disorders have persisted beyond puberty present different treatment problems. One problem in treating adolescent transsexuals is how to manage the rapid emergence of unwanted secondary sex characteristics. Legal issues may confront the clinician who would prescribe hormone-inhibiting substances or later contrasex hormones to thwart that development, even with parental approval. Social cross-gender living is a possible alternative. Some schools have permitted teenagers to enroll as opposite-sex students.

Adults Adult patients with gender identity disorders present with various agendas. Some are seeking help in suppressing their cross-gender feelings, some are gathering information about gender identity disorders and treatment options, and still others come with straightforward requests for surgical sex reassignment. For all the patients seeking a cure or information, and many of those seeking surgery, the first consideration should be to help the patient reconcile to the original gender role or at least learn to function reasonably well in it.

Psychotherapy At present, only psychological therapies are available to help patients accept their biological sex. No drug treatment has been shown to be effective in reducing cross-gender desires per se.

There are no general guidelines for individual psychotherapy with gender-dysphoric patients. Some authorities recommend that when treating patients with unrealistic hopes of sex reassignment surgery, it is best not to confront the patient on that point directly. Patients may be more open to critical examination of their goals and alternatives if they perceive the therapist as open-minded about the surgical option. There are exceptions: Some patients are relieved to be told frankly by an experienced professional that they are not suitable—or ready—for sex reassignment surgery, and they drop the idea without resistance.

Psychotherapy may be appropriate either when the patient requests it or when the patient willingly accepts a recommendation for psychotherapy from the attending clinician. Some gender identity clinics go further than this and require all patients to undergo psychotherapy as a condition for approving them for sex-reassignment surgery. There is, however, variability on this point and other reputable clinics do not have such a requirement.

Gender identity disorder patients are often amenable to group therapy, especially if the group is homogeneous. Mixing patients who are attempting to become reconciled to their original gender roles with patients who are pursuing sex reassignment may make it more difficult to promote group cohesion.

Medical Treatment When the patient's gender dysphoria is severe and intractable, sex reassignment may be the best solution. The first medical intervention in this process is hormone therapy. Dosage should be set with endocrinological consultation. Biological males are usually treated with daily doses of oral estrogens. These

produce breast enlargement, which continues for about 2 years at any given dose. The final amount of gynecomastia varies greatly among patients. The other major effects of estrogen treatment are testicular atrophy, decreased libido, and diminished erectile capacity. There may be a slight decrease in the growth of facial and body hair together with arrest of male-pattern baldness.

Biological females are treated with biweekly or monthly intramuscular injections of testosterone. Because the effects of exogenous testosterone are more profound than those of estrogen, clinicians should be more conservative about commencing females on hormone treatment. The pitch of the voice drops permanently into the male range as the vocal cords thicken. The clitoris enlarges to about three times its pretreatment length, with a growth plateau of 1 year; that is often accompanied by increased libido. A full, thick beard often develops. Male pattern baldness may develop, and acne may appear. Ovarian function is suppressed, with the menses ceasing within 3 months of the start of treatment. When treatment of adolescents is contemplated a pediatric endocrinologist should be consulted.

The second major stage in the medical treatment of transsexualism is sex reassignment surgery. All major gender identity clinics in North America and western Europe require their patients to live full-time in the cross-gender role for some time—usually 1 to 2 years—prior to surgery. Most gender identity clinics further require that patients either maintain gainful employment, attend school, or perform bona fide charity work in the cross-gender role during the probationary period. It is a good idea to require patients to provide documentation verifying such activities; these documents may take various forms, including pay receipts, school transcripts, or letters on known institutional letterheads.

The requirement of work, school, or charity in the cross-gender role is intended to demonstrate that the patient is capable of interacting successfully with members of the general public in the cross-gender role. Without this requirement, it would be possible for patients who claim to be cross-living to be in fact leading completely reclusive lives, restricting their activities to the privacy of their home, to the company of a few sympathetic friends or relatives, or to contacts with members of the helping professions. A reclusive life-style does not demonstrate to the clinician that the patient has the ability to function normally in society as a member of the other sex. It also does not ensure that the patient has the genuine experience of what it is like to live in society as the other sex or test the patient's expectations and fantasies against the reality of everyday living. Because of the importance of documented evidence that the patient can function successfully in society at large as a member of the other sex—which includes functioning successfully in public and among strangers—it is not sufficient for male-to-female patients to be full-time housewives during the presurgical probationary period or for female-to-male patients to be full-time househusbands.

Sex reassignment surgery for biological males consists principally of vaginoplasty. Operative techniques vary, mainly in the method of obtaining material to line the neovagina. One technique uses a section of the rectosigmoid colon. The standard methods involve lining the neovagina with penile skin flaps, scrotal skin flaps, and free grafts from the thigh, in various combinations. Occasional postoperative complications include urethral strictures, caused by retraction of the urethra, and rectovaginal fistulas. Vaginal stenosis sometimes occurs; this is usually caused by inadequate postoperative care of the neovagina by the patient. Inadequate vaginal width or depth may make penile penetration difficult.

Surgical reassignment procedures for females are more variable. Construction of a male chest contour is virtually always performed. Panhysterectomy and bilateral salpingo-oophorectomy are usually carried out, although some patients, satisfied with the menstrual suppression produced by testosterone therapy, do not request those procedures. Phalloplasty is the least commonly performed, partly because it is relatively expensive and partly because it is not as successful, cosmetically or functionally, as vaginoplasty. Surgical techniques for phalloplasty have recently improved, however, so that picture may be changing.

An alternative to phalloplasty is a procedure most commonly known as metoidioplasty. The administration of testosterone medication to female-to-male transsexual stimulates growth of the clitoris. In some patients the degree of enlargement is sufficient for the hypertrophied clitoris to be used as a penis. Metoidioplasty capitalizes on this phenomenon to construct a neophallus from the clitoris, using techniques similar to those used for correction of severe hypospadias in biological males with transposition of the scrotum and penis. In this procedure the clitoris is moved anteriorly to the penis position, the labia majora are moved posteriorly and fused together into a scrotal configuration, and the chordee is released and excised according to the principles of hypospadias surgery. The urethra is formed from a vaginal flap and the inner part of the labia minora. Testicular prostheses are inserted into the neoscrotum, and the feminine mons veneris is reduced with liposuction or direct excision of fat.

The best technique for constructing a male chest contour varies according to the size of the patient's breasts. For small-breasted females, the surgeon may perform a subcutaneous mastectomy through a keyhole incision without disturbing the nipple-areola complex. Large-breasted patients require breast amputation and replacement of the nipple as a free graft. Postoperative complications of the latter procedure include obvious chest scars and widening of the nipple-areola grafts.

Additional plastic surgery is commonly sought by biological males, rarely or never by biological females. Male patients most often undergo thyroid cartilage shave (Adam's apple reduction), rhinoplasty (to create a more feminine nose), and breast implants. They require facial hair electrolysis and may need vocal pitch surgery.

Clinical management of transsexuals incarcerated in the prison system—in particular, prescribing hormones for the inmate or recommending sex reassignment surgery—poses special problems. Many jurisdictions follow a formal or informal policy of “freeze-framing” the inmate at the hormonal and surgical status at the time of incarceration. The rationale would appear to be that the prison environment is not representative of society at large, so there can be no adequate evaluation of an individual's ability and motivation to function successfully in the cross-gender role as normally assessed during the presurgical probationary period.

Treatment Outcome Numerous studies have investigated the postoperative adjustment of reassigned transsexuals, primarily among patients assessed and approved for surgery by established gender identity clinics. The findings are generalizable only to properly screened patients. The most reliable conclusion is that the overwhelming majority of postoperative transsexuals are content with their decision to undergo sex reassignment.

Outcome studies as a whole suggest that surgical sex reassignment produces additional improvements in psychosocial adjustment. The main areas of benefit are interpersonal relationships and psychological symptomatology, especially morale and mood. It should be noted that only one outcome study has included random assignment to surgically treated and (waiting list) control groups. Its findings bolster the conclusion that postoperative improvements in social integration, sexual adjustment, and psychological symptomatology can be attributed to the surgical intervention.

The available evidence for socioeconomic improvement is weaker, perhaps because most studies fail to look at outcome variables for males and females separately. Studies that have examined socioeconomic change separately for male and female transsexuals have found that the socioeconomic status of biological females improves when they move into the male role whereas the socioeconomic status of males worsens when they adopt the female role.

It has been shown that in male-to-female transsexuals the cosmetic and functional adequacy of surgical interventions affects the self-image of transsexuals and the degree to which they and their partners are reminded of the sex-reassigned status. Thus, the better the surgical result—other things being equal—the better the postoperative adjustment.

Finally, that sex reassignment surgery has little or no effect on major mental illness or serious character pathology. Patients with preoperative histories of psychiatric hospitalization for depression or multiple suicide attempts are liable to be at risk for further episodes after surgery.

Intersex Disorders Patients who present with uncertainty or confusion about their correct gender or are discontented with the gender in which they have been living may have an intersexed physiological status. Differences between gender identity patients with and without physical intersexuality suggest distinct causes of gender identity complaints in the two groups. There are, on the other hand, occasional patients (e.g., adult men with Klinefelter's syndrome) who appear similar in their clinical presentations to otherwise comparable men with normal karyotypes. For this reason, there is continuing discussion among specialists about whether the presence of intersexuality should preclude the diagnosis of gender identity disorder. For research purposes, intersexed patients should be excluded from gender-dysphoric samples. According to DSM-IV, intersex conditions are an example of a gender identity disorder not otherwise specified (Table 19.3-3).

This category is included for coding disorders in gender identity that are not classifiable as a specific gender identity disorder. Examples include 1. Intersex conditions (e.g., androgen insensitivity syndrome or congenital adrenal hyperplasia) and accompanying gender dysphoria. 2. Transient, stress-related cross-dressing behavior. 3. Persistent preoccupation with castration or penectomy without a desire to acquire the sex characteristics of the other sex.

Table 19.3-3 DSM-IV Diagnostic Criteria for Gender Identity Disorder Not Otherwise Specified

Congenital Virilizing Adrenal Hyperplasia Formerly called *adrenogenital syndrome*, this disorder is characterized by an enzymatic defect in the production of cortisol by the adrenal gland. As a result, excessive androgenic adrenal hormone production begins prenatally. At birth, affected females show varying degrees of genital virilization; after birth, excessive androgen production can be largely controlled by cortisone.

With diagnosis of congenital virilizing adrenal hyperplasia neonatally, male or female children appear to develop a gender identity consistent with their chromosomal and gonadal sex and sex of rearing. Girls may show more than typical boy-type play behaviors. In earlier cases before the diagnosis was made neonatally and when the diagnosis for a woman was not made in childhood and socialization was as a man, a male identity typically evolved. There may be higher rates of homosexual behavior in affected women, whether or not treated with cortisone in childhood.

Turner's Syndrome One sex chromosome is missing in Turner's syndrome, so that the sexual karyotype is simply X (designated XO). Affected children have poorly developed ovaries and possibly other anomalies, including an unusual appearance of the chest and neck. Their genitalia are female at birth. They develop into short women who require replacement estrogen for female secondary sex characteristics. Identity is usually female and gender identity conflict is rare, but they may experience psychosexual conflict over infertility.

Klinefelter's Syndrome An additional X chromosome is present in this condition along with the typical XY male pattern. At birth affected infants appear to be normal males. There may be excessive gynecomastia in adolescence, and the testes are small, usually without spermatogenesis. Testosterone levels are low and the body habitus is eunichoid. A higher rate of gender identity disorder has been suggested in affected persons, but unrepresentative sampling clouds the issue.

5-a-Reductase Deficiency An enzymatic defect here prevents the conversion of testosterone to dihydrotestosterone, which is required for prenatal virilization of the genitalia. Thus, the XY-affected individual is born with female-appearing genitalia, although there is some evidence of abnormality. At puberty extensive virilization occurs from testosterone and some dihydrotestosterone; there is phallic growth and a male chest pattern.

Gender identity development is the subject of controversy. Many of the earliest described cases were raised as girls who with virilization during adolescence evolved a male identity. They were later heterosexually active as men. This transition was variously interpreted from neuroendocrine and social learning perspectives. It was posited that testosterone organized the prenatal central nervous system to mediate a later male identity, although that hormone was inadequate to virilize the genitalia in utero. Alternatively, it was posited that social pressures on these male-appearing adolescents to act like men and avoid the stigma of homosexuality forced them into their masculine heterosexual status. Subsequent generations born with the disorder are recognized as those who will virilize at puberty and so are raised with that hermaphroditic identity. When raised as men, perhaps with androgen supplementation, they function as relatively normal men, although their phallus is not entirely normal. When castrated in infancy and raised as girls, they may be markedly tomboyish in childhood. Insufficient numbers of cases are available for predicting their adult psychosexual status, but some appear to be feminine heterosexual women, without menses.

Androgen Insensitivity Syndrome Formerly called testicular feminization, androgen insensitivity syndrome is a disorder of metabolism in the XY individual where tissue cells are unable to use testosterone or other androgens; consequently, the person appears to be a normal female at birth. Testes are undescended and no internal female reproductive structures are present. Puberty brings female-type breast development (from the conversion of testosterone to estradiol). A vagina needs to be constructed. Gender identity usually evolves as female, with a sexual interest in males. There may be psychosexual conflict over the absence of menses and infertility.

CHAPTER 20. EATING DISORDERS

KATHERINE A. HALMI, M.D.

The eating disorders anorexia nervosa, bulimia nervosa, and variants thereof have been identified in the history of western civilization for the past 15 centuries. The eating disorders are syndromes and are classified on the basis of the clusters of symptoms with which they present. The prevalence of anorexia nervosa and bulimia nervosa has increased since the late 1960s to the extent that they are now commonly encountered in clinical practice. Over a long-term course such as 30 years, 15 to 20 percent of anorexia nervosa patients will die as a result of the disorder. Another 25 percent remain chronically ill, either maintaining a low body weight or developing bulimia with wide fluctuations in weight. About 40 percent will eventually recover and the others will function well with mild eating disorder symptomatology. There is a high prevalence of mood, anxiety, and substance use disorders with the eating disorders. These comorbidities further impair the quality of life of the patient. The diverse nature of the eating disorders has stimulated the development of a variety of treatments.

DEFINITIONS

Anorexia nervosa is characterized by willful and purposeful behavior directed towards losing weight, weight loss, preoccupation with body weight and food, peculiar patterns of handling food, intense fear of gaining weight, disturbance of body image, and amenorrhea. About half of these persons will lose weight by drastically reducing their total food intake and some will also develop rigorous exercising programs. The other half of these patients will also rigorously diet but will lose control and regularly engage in binge eating followed by purging behaviors. Some patients routinely purge after eating small amounts of food.

Bulimia is merely a term that means binge eating, which is defined as eating more food than most people in similar circumstances and in a similar period of time, accompanied by a strong sense of losing control. When binge eating occurs in relatively normal weight or overweight persons who are also excessively concerned with their body shape and weight, and who regularly engage in behaviors to counteract the calorie gain in binges, the binge eating is in the context of the disorder known as *bulimia nervosa.*

HISTORY

Willful dieting leading to irreversible self-starvation was carefully documented in the fasting female saints of the middle ages. Princess Margaret of Hungary, who lived from 1242 through 1271, could be an example of anorexia nervosa—restricting type. She excelled in all her studies, in the chores of the monastery, and in the austerities of fasting and was never idle. She died with a clear alert mind and a poor wasted body at the age of 28. Catherine of Sienna could well be diagnosed with anorexia nervosa—binge eating purging type. She inserted and then withdrew a specific reed from her throat to self-induce vomiting. Whether dieting for sainthood or for thinness produces the same disorder remains a matter of controversy. The psychobiological vulnerability factors that induce the development of the anorectic symptom cluster are probably similar across the ages.

In the second half of the seventeenth century case descriptions of self-starvation appeared. One of these was of an 18-year old English girl named Martha Taylor who had lost her menses, stopped taking all solid food, and became emaciated. She was examined by John Reynolds who wrote, “most of these damsels fall into this abstinence between the age of 14 and 20 years.” Twenty-two years later Richard Morton described two cases of typical anorexia nervosa symptomatology and distinguished them from consumption.

In the nineteenth century Dr. Louis-Victor Marce of Paris described several cases of “young girls, who at the period of puberty, and after a precocious development, became subject to inappetance carried to the utmost limits.” He conceptualized a gastric nervous disorder becoming cerebro-nervous. In 1873 Sir William Gull of London and Ernest Charles Laseque almost simultaneously published papers on the description and treatment of “hysterical anorexia.” Gull recommended a treatment that to some extent is still followed: “the patient should be fed at regular intervals, and surrounded by persons who would have moral control over them; relations and friends being generally the worse attendance.” During this period very little attention was paid to these cases of fasting women in the United States. However, two neurologists, William Alexander Hammond and Silas Weir Mitchell described cases of great self-starvation. The term *anorexia nervosa* was commonly used after Gull's publications.

In the early twentieth century there was confusion between pituitary insufficiency and the disorder of anorexia nervosa. This was definitively clarified in a book by E.L. Bliss and C.H. Branch in which the current endocrine studies as well as the history and psychological descriptions of anorexia nervosa were summarized. Later in the 1950s Hilda Bruch described a core psychological facet of anorexia nervosa; “a paralyzing sense of ineffectiveness which pervades all thinking and activities.” She also laid the foundation for cognitive therapy by describing methods for treating the disturbed cognitions of such patients.

Bulimia nervosa was first described as a distinct syndrome in 1979 by Gerald Russell. Subsequent extensive studies of this disorder have continued to define it more precisely.

COMPARATIVE NOSOLOGY

The 10th revision of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) criteria for anorexia nervosa (Table 20-1) are very similar to those of the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) in that they acknowledge the weight loss, the fear of becoming fat, and the amenorrhea. The criterion concerning body image disturbance is limited to the perception of being too fat. The ICD-10 criteria for bulimia nervosa do not clearly separate bulimia nervosa from anorexia nervosa—binge eating/purging type. There is also a lack of clear distinction between bulimia nervosa as defined in ICD-10 and another condition in this classification system labeled *hyperorexia nervosa.* The ambiguous and overlapping definitions of various bulimia subtypes listed in ICD-10 pose problems for research studies in this area; reliability and validity studies are needed to justify these classifications.

Table 20-1 ICD-10 Diagnostic Criteria for Eating Disorders

EPIDEMIOLOGY

Incidence rates are commonly expressed with eating disorders as the rate per 100,000 of a population per year. One of the major problems in studying the epidemiology of eating disorders over time is the change in criteria for these syndromes since the late 1960s. Despite this problem, studies suggest that the overall incidence of both anorexia nervosa and bulimia nervosa have increased in the past 50 years. There was a consistent increase in the registered incidence of anorexia nervosa over a period from 1931 to 1986 in cases presenting to the health care system in several industrialized countries. For example, a study in northeastern Scotland showed that between 1965 and 1991 there was almost a sixfold increase in the incidence of anorexia nervosa—from 3/100,000 to 17/100,000. A study conducted in southwest London between the period of July 1991 and June 1992 showed an incidence of anorexia nervosa to be 2.7 cases per 100,000 total population. In females aged 15 to 29 years the incidence was 19.2 cases per 100,000. In Rochester, Minnesota a recent study found an overall adjusted incidence for females of 14.6 per 100,000 per year; for men the corresponding figure was 1.8. When estimates are based on the population at large, the incidence rate of anorexia nervosa in industrialized countries is estimated at 8.1 per 100,000 population per year. A recent prevalence study of anorexia nervosa was found to be 20.2 cases per 100,000 population (0.02 percent total population) in the United Kingdom. In a recent study conducted in the United States, lifetime prevalence rates for anorexia nervosa were found to be 0.51 percent (narrowly defined) and 3.7 percent (broadly defined). A summary of numerous prevalence studies across European countries reported an average prevalence of anorexia nervosa using strict diagnostic criteria of 0.28 percent of young females.

There are very few studies of the incidence of bulimia nervosa. A large representative sample of the Dutch population in Holland showed an incidence of bulimia nervosa at 11.4 per 100,000 population per year during the period from 1985 through 1989.

A review of over 50 prevalence studies of bulimia nervosa conducted from 1981 through 1989 in Europe and the United States showed a remarkable consistency in finding that bulimia nervosa had a prevalence rate of about 1 percent in adolescent and young adult women. Partial eating disorders occur at a far greater frequency in the general community—in about 5 to 10 percent of young women. In a recent Canadian study the lifetime prevalence rate for bulimia nervosa was 1.1 percent for females and 0.1 percent for males. In industrialized countries the prevalence is about 1 percent for bulimia nervosa.

All studies show that eating disorders are rare among males. In clinical samples the male-to-female ratio for eating disorders lies consistently between 1:10 and 1:20. Studies conducted in the early 1970s and 1980s found a higher prevalence of eating disorders among the middle and upper classes; however, eight studies from the 1980s to the present failed to demonstrate this relationship. This is true of both anorexia nervosa and bulimia nervosa.

Transcultural studies show that anorexia nervosa is rare in non-Western developing countries. When non-Westerners are exposed to Western ideals of thinness, they are significantly affected. For example, a study of the prevalence of eating disorders among Greek and Turkish girls who remained in their homeland and those who were living in Germany showed twice the prevalence in the latter compared to the former group. A recent review of eating disturbances among American minority groups found that compared to Caucasian females, eating disturbances were equally common among Hispanic females, more frequent among Native Americans, and less frequent among black and Asian females. These studies also indicated that minority females who are younger, better educated, and more identified with white, middle-class values are at greater risk for developing an eating disorder.

ETIOLOGY

A specific cause and pathogenesis for the eating disorders anorexia nervosa and bulimia nervosa is unknown. The current concepts of the development of these disorders are best represented by a multidimensional model that emphasizes that dieting behavior is the instigating and common stimulus that leads to the development of the serious eating disorders. Behaviors and influences antecedent to the dieting experience can be categorized into problems of biological vulnerability, psychological predispositions, and societal influences. Disturbances in these categories propel the dieting behavior so that starvation effects, weight loss and nutrition effects, as well as psychological changes occur. Psychological and physiological reinforcement of the maladaptive eating behavior continues a sustaining cycle of core dysfunctional eating disorder behaviors.

Sociocultural Factors Slenderness as an expression of attractiveness is prominently emphasized in Western culture. Much willful dieting occurs for the purpose of being more attractive. Other willful dieting occurs for the purpose of being more professionally competent; for example, ballet dancers, gymnasts, jockeys, and wrestlers—all of whom have a high risk for developing an eating disorder. It has been hypothesized but not proven by systematic studies that some women diet strenuously in response to the conflict of professional and social demands and nurturing expectations.

Psychological Factors Earlier psychological theories on the etiology of anorexia nervosa centered mostly on phobic mechanisms and psychodynamic formulations. It has been postulated that anorexia nervosa constitutes a phobic avoidance response to food, resulting from the sexual and social tension generated by the physical changes associated with puberty. Psychodynamic theories have focused on fantasies of oral impregnation and dependent, seductive relationships with warm, passive fathers and guilt over aggression toward ambivalently regarded mothers. A cognitive and perceptual developmental defect has been theorized to be the cause of anorexia nervosa, with the disturbances of body image (denial of emaciation), disturbances in perception (lack of recognition or denial of fatigue, weakness, hunger), and a sense of ineffectiveness being caused by untoward learning experiences.

Comprehensive studies assessing personality traits before the onset of anorexia or bulimia nervosa are extremely difficult to conduct, thus, most studies assess these patients after recovery as well as during the illness. Recovered patients often continue to have obessional and inflexible thinking, social introversion, greater interpersonal insecurity and minimization of affect, excessive conformance, and more regimentation of behavior. An obsessional, perfectionistic personality is considered a risk factor for the restricting type of anorexia nervosa. These patients have often had a lack of childhood experiences that foster personal independence.

Although personality development can be strongly influenced by family interactions, studies that have sound methodology and specificity are difficult to conduct. Studies of family interactions during the acute stages of these disorders can give some idea of what factors may be contributing to the maintenance of the eating disorder. One carefully controlled study showed that families of bulimia patients had greater hostility, chaos, feelings of isolation, and substantial deficits in nurturing and empathy compared with control families. This same study showed that parents of daughters who had anorexia nervosa communicated mixed messages with antithetical meanings. These parents were often very affectionate as they controlled their daughter and suffocated her separateness.

The expression of personality is also influenced by comorbid psychiatric illnesses. Anorexia nervosa patients had a high rate of major depression (68 percent), anxiety disorders (65 percent), obsessive-compulsive disorder (26 percent), and social phobia (34 percent) in one large study. About one fourth of patients with the restricting type of anorexia nervosa have a Cluster C anxious personality disorders. About 40 percent of patients with the binge eating/purging type of anorexia nervosa have a cluster B, the impulsive cluster personality disorder diagnosis. They also have a high prevalence (32 percent of the anxious cluster of personality disorders. Bulimia nervosa patients have considerable comorbidity with major depressive disorder varying from 36 to 70 percent, substance abuse from 18 percent to 32 percent, and Axis II personality disorders from 28 percent to 77 percent, with a predominance of Cluster B (impulsive) personality disorders.

Biological Factors

Familial Genetic Factors Family studies of anorexia nervosa have shown a tendency to familial occurrence of this disorder. Female siblings of anorexia nervosa patients in one study had 6.6 percent risk of developing anorexia nervosa. Another study showed that the concordance for restricting anorexia nervosa was markedly higher for monozygotic twins (66 percent) than for dyzygotic twins (0 percent). In a large population-based twin registry study, the concordance for bulimia nervosa was significantly higher in monozygotic than in dyzygotic twin pairs. Several studies have found a familial aggregation of anorexia nervosa, bulimia nervosa, and variants of these disorders in the first-degree relatives of both anorexia nervosa and bulimia nervosa probands. Some authors have proposed that anorexia nervosa has a genetic predisposition that could become manifest under adverse conditions, such as inappropriate dieting or emotional stress. This genetic vulnerability might implicate a particular personality type, a general susceptibility to psychiatric instability (in particular, mood disorder), or may directly involve a hypothalamic dysfunction. Family studies of anorexia nervosa and bulimia nervosa have shown an increased frequency of mood disorder in the first-degree relatives of the eating disorder probands compared with the first-degree relatives of normal control subjects. Another study showed an increased prevalence of obsessive-compulsive disorder in the mothers of anorexia nervosa patients compared with the mothers of control persons. Thus, it is likely that a family history of mood disorders and perhaps of anxiety disorders or more specifically of obsessive-compulsive disorder places a person at risk for developing an eating disorder.

Hypothalamic-Neuromediator Factors A primary hypothalamic dysfunction in anorexia nervosa has received some support from the fact that many persons develop amenorrhea before weight loss has occurred, and the return of the normal menstrual cycles often lags behind the return to a normal body weight. The resumption of

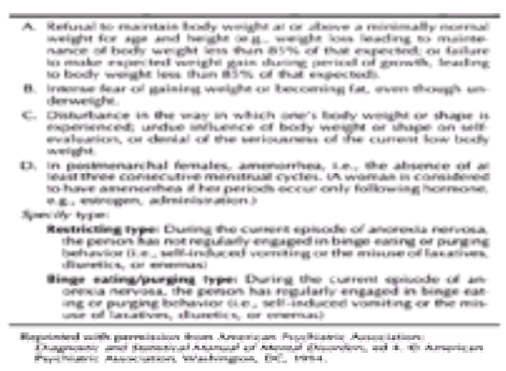
menses in anorexia nervosa is associated with marked psychological improvement after weight gain. In the area of the paraventricular nucleus in the hypothalmus, neurotransmitters have complex interactions in regulating eating behavior. Norepinephrine can have an appetite-stimulating effect; serotonin increases satiation, decreases food intake, and modulates aggressive, impulsive, and obsessive-compulsive behaviors. Underactivation or overactivation of dopamine systems can produce eating deficits. Drugs and hormones are in vivo environmental stresses that interfere with dopamine transmission and can cause disinhibition of eating. Current studies have shown there is evidence for dysfunction in all three neurotransmitters in anorexia nervosa. Because of the prohibitive cost of investigating large numbers of people before they develop anorexia or bulimia nervosa, the only possible strategy is to compare the acutely ill patient with the recovered patient and controls. Recently more focus has been placed on serotonin because of its widespread influences on behaviors that are disturbed in anorexia nervosa. Long-term weight-restored anorexia nervosa patients in one study had an elevated cerebral spinal fluid (CSF) 5-hydroxyindoleacetic acid (5-HIAA) concentration compared with controls. This finding is compatible with the hypothesis that obsessional traits in anorexia patients are associated with a hyperfunctioning of this serotonergic neurotransmitter system. Corticotrophin-releasing factor (CRF) is a potent inhibitor of feeding. Emaciated patients with anorexia nervosa have increased concentrations of CSF CRF, which return to normal range with weight gain. The increased CRF may be one of the physiological mechanisms that maintains the anorexia and abnormal eating behavior in patients with anorexia nervosa. Neuropeptide Y, which stimulates feeding behavior, was found to be elevated in the CSF of underweight and recently weight-restored anorexia nervosa patients. However, in long-term weight-restored anorexia nervosa patients these concentrations return to normal. A reduction of food intake may produce a homeostatic increase in neuropeptide secretion that should serve to stimulate feeding, but this mechanism seems to be ineffective in the anorectic patient. Decreased secretion of gonadotrophin-releasing hormone (GnRH) is the cause of amenorrhea in anorexia nervosa. The secretion of GnRH is highly influenced by the neurotransmitters norepinephrine and serotonin, which help to regulate eating behavior and to influence mood. The relation of these neurotransmitters to GnRH, neuropeptide Y, and CRF secretion in anorexia nervosa is an area of ongoing research and may help to reveal biological risk factors. Starvation-induced changes such as reduced norepinephrine turnover, hyperactivity of the hypothalamic-pituitary-adrenal axis, diminished thyroid-stimulating hormone (TSH) response to thyrotrophin-releasing hormone (TRH), low plasma triiodothyronine (T_3) concentrations, and increased basal growth hormone concentrations revert to within the normal range with nutritional rehabilitation.

Because of the role of serotonin in producing satiety or fullness and in regulating impulsive behaviors, a dysfunction of the serotonergic neurotransmitter system was suspected in bulimia. Normal-weight bulimia patients have decreased prolactin response to the pharmacological challenge test of fenfluramine and methchlorophenylpiperazine (mCPP) compared with controls. High binge frequency in bulimia patients is significantly related to lower CSF5 HIAA than is present in controls. This is some evidence for a cerebral-CNS serotonergic deficiency in bulimia nervosa patients. Table 20-2 presents neuroendocrine changes caused by anorexia nervosa.

Table 20-2 Neuroendocrine Changes in Anorexia Nervosa and Experimental Starvation

DIAGNOSIS

Anorexia Nervosa The three criteria for anorexia nervosa proposed by G.F.M. Russell over 20 years ago are still embedded in the latest DSM-IV criteria (Table 20-3). Russell's criteria are: (1) behavior that is designed to produce marked weight loss, (2) a morbid fear of becoming fat, and (3) evidence of an endocrine disorder that in the postpubertal girl causes the cessation of menstruation. Because there is no specific amount of weight loss associated with other symptoms of anorexia nervosa, the current DSM-IV first criterion simply states, “refusal to maintain body at/or above a minimally normal weight for age and height.” The second criterion, “intense fear of gaining weight,” has remained unchanged through the decades. Patients with anorexia nervosa fear gaining weight even when they are emaciated.



A. Refusal to maintain body weight at or above a minimally normal weight for age and height (e.g., weight loss leading to maintenance of body weight less than 85% of that expected; or failure to make expected weight gain during period of growth, leading to body weight less than 85% of that expected).
B. Intense fear of gaining weight or becoming fat, even though underweight.
C. Disturbance in the way in which one's body weight or shape is experienced; undue influence of body weight or shape on self-evaluation, or denial of the seriousness of the current low body weight.
D. In postmenarchal females, amenorrhea, i.e., the absence of at least three consecutive menstrual cycles. (A woman is considered to have amenorrhea if her periods occur only following hormone, e.g., estrogen, administration.)

Specify type:

Restricting type: During the current episode of anorexia nervosa, the person has not regularly engaged in binge eating or purging behavior (i.e., self-induced vomiting or the misuse of laxatives, diuretics, or enemas).

Binge eating/purging type: During the current episode of anorexia nervosa, the person has regularly engaged in binge eating or purging behavior (i.e., self-induced vomiting or the misuse of laxatives, diuretics, or enemas).

Table 20-3 DSM-IV Diagnostic Criteria for Anorexia Nervosa

The third criterion in DSM-IV for anorexia nervosa pertains to body image disturbance and has evolved since the late 1970s into a more complex concept. In the third edition of DSM (DSM-III) body image disturbance was narrowly defined as body image related to visual self-perception. Because studies have shown that many anorexia patients do not visually overestimate their sizes, and that overestimation is not unique to those with anorexia nervosa, the criterion was then reworded in the revised third edition of DSM-III-R to focus on attitudinal and affective dimensions of body image. This newly worded criterion of “overconcern with body size and shape” has significant overlap between anorexia nervosa patients and the general female population. In order to articulate the core cognitive distortions of the anorexia nervosa patient more precisely, this criterion was again revised in DSM-IV and has three components. “Disturbance in the way in which one's body weight or shape is experienced” reflects the person's claiming to feel fat or believing that one area of the body such as thighs are too fat even when obviously underweight. “Undue influence of body weight or shape on self-evaluation” reflects the dominating importance of the latter to the person. Losing weight and dieting are skills these persons can perform competently and from which they receive strong positive reinforcements. The security of being thin and of dieting compensates for vast insecurities in other areas of life such as interpersonal relationships and adult role expectations. “Denial of the seriousness of the current low body weight” reflects the person's unwillingness to acknowledge that her emaciated body is not healthy or attractive. DSM-IV divides anorexia nervosa into two subtypes: the restricting type and the binge-eating/purging type. There are significant differences between anorexia nervosa patients who engage in bulimic or purging behaviors compared with those who consistently restrict their dietary intake. Impulsive behaviors such as stealing, drug abuse, suicide attempts, and self-mutilations are significantly more prevalent in the binge-eating/purging type compared with the restricting type. The bulimic group of anorexia nervosa patients also has a higher prevalence of premorbid obesity, familial obesity, mood ability, and debilitating personality characteristics; the latter are often in the context of a Cluster B or the impulsive personality disorder cluster. The binge-eating/purging type of patients are actually similar to persons with bulimia nervosa in all of these behaviors and characteristics. They are not classified as having bulimia nervosa because they have lost large amounts of weight and meet the criteria for anorexia nervosa. The specific mechanisms by which the binge-eating/purging type patients are able to obtain and maintain large weight losses are still unknown and are being investigated.

The fourth criterion for the diagnosis of anorexia nervosa in the DSM-IV is amenorrhea, which can occur before noticeable weight loss has occurred and may be caused by a primary disturbance of hypothalamic function. A common hypothesis is that psychological stress can bring about the full expression of this vulnerable risk factor, which then expresses itself in the form of amenorrhea. Malnutrition can perpetuate the amenorrhea but is not primarily responsible for the endocrine disorder.

Specific mechanisms of hypothalamic dysfunction in anorexia nervosa are still under investigation.

Bulimia Nervosa The DSM-III-R criteria for bulimia nervosa are more arbitrary and more ambiguous compared with the criteria for anorexia nervosa. When G.F.M. Russell defined bulimia nervosa in 1979 he proposed three criteria: a powerful and intractable urge to overeat, resulting in episodes of overeating; avoidance of the "fattening" effects of food by inducing vomiting or abusing purgatives or both; and a morbid fear of becoming fat. These criteria do not distinguish bulimia nervosa patients from anorexia nervosa patients of the binge-purge subtype. Because there are physiological differences between bulimic people who lose large amounts of weight and have anorexia nervosa and those who never lose weight, it became necessary to define bulimia nervosa more precisely. Although binge eating is a necessary diagnostic criterion for bulimia nervosa, there is no consensus on what constitutes a binge and what is acceptable as the minimum binge frequency for this disorder. In the first criterion for bulimia nervosa (Table 20-4) binge eating is defined as eating more food than most people would in similar circumstances in a similar period of time. The sense of losing control is a significant subjective aspect that occurs in binge eating and is present as a second part of this criterion. The emphasis on a discrete time period is to differentiate binge eating from continual snacking throughout the day.

A. Recurrent episodes of binge eating. An episode of binge eating is characterized by both of the following:
   (1) eating, in a discrete period of time (e.g., within any 2-hour period), an amount of food that is definitely larger than most people would eat in a similar period of time under similar circumstances
   (2) a sense of lack of control over eating during the episode (e.g., a feeling that one cannot stop eating or control what or how much one is eating)
B. Recurrent inappropriate compensatory behavior in order to prevent weight gain, such as self-induced vomiting; misuse of laxatives, diuretics, enemas, or other medications; fasting; or excessive exercise.
C. The binge eating and inappropriate compensatory behaviors both occur, on average, at least twice a week for 3 months.
D. Self-evaluation is unduly influenced by body shape and weight.
E. The disturbance does not occur exclusively during episodes of anorexia nervosa.

Specify type:

Purging type: during the current episode of bulimia nervosa, the person has regularly engaged in self-induced vomiting or the misuse of laxatives, diuretics, or enemas

Nonpurging type: during the current episode of bulimia nervosa, the person has used other inappropriate compensatory behaviors, such as fasting or excessive exercise, but has not regularly engaged in self-induced vomiting or the misuse of laxatives, diuretics, or enemas

Table 20-4 DSM-IV Diagnostic Criteria for Bulimia Nervosa

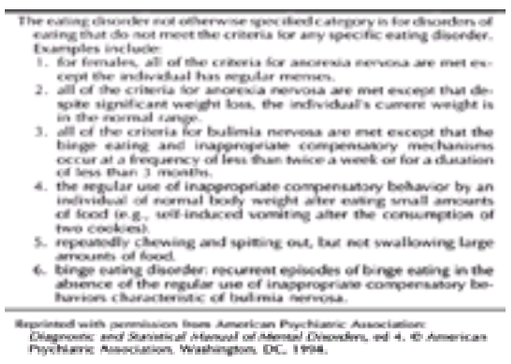
The second criterion in the diagnosis of bulimia nervosa is the recurrent use of inappropriate compensatory behaviors to avoid weight gain. These behaviors can be purging, such as self-induced vomiting or laxative abuse, or very restrictive dieting. There is evidence that bulimic persons who purge differ from binge eaters who do not purge in that the latter tend to have less body-image disturbance and less anxiety concerning eating. Bulimia nervosa patients who do not purge tend to be obese. There are also distinct physiological differences between bulimia patients who purge and those who do not. Because of all these differences the diagnosis of bulimia nervosa is subtyped into a purging type, for those who regularly engage in self-induced vomiting or the use of laxatives or diuretics, and a nonpurging type for those who use strict dieting, fasting, or vigorous exercise but do not regularly engage in purging.

The third chronicity and frequency criterion is arbitrary because there was no specific research to support that a minimum average of two episodes of binge eating and two inappropriate compensatory behaviors a week for at least 3 months was associated with impaired behavior and other symptoms of bulimia nervosa. However, when earlier definitions of bulimia nervosa excluded the chronicity and frequency criterion, the prevalence of this disorder seemed unusually high and not always associated with an impairment of function. Ongoing research should eventually provide data to define this criterion more specifically.

The fourth criterion states that self-evaluation is unduly influenced by body shape and weight and more accurately describes the preoccupation of bulimia nervosa patients with their physical appearance than Russell's previous "morbid fear of becoming fat." Further data are needed to define this criterion more specifically.

The fifth and final criterion for bulimia nervosa is that the disturbance does not occur exclusively during episodes of anorexia nervosa. This clearly separates bulimia nervosa from the binge-eating/purging type of anorexia nervosa.

Eating Disorder Not Otherwise Specified This category is for patients who display most of the core clinical features of anorexia nervosa and bulimia nervosa but do not meet criteria for the full syndrome (Table 20-5).



The eating disorder not otherwise specified category is for disorders of eating that do not meet the criteria for any specific eating disorder. Examples include:
1. for females, all of the criteria for anorexia nervosa are met except the individual has regular menses.
2. all of the criteria for anorexia nervosa are met except that despite significant weight loss, the individual's current weight is in the normal range.
3. all of the criteria for bulimia nervosa are met except that the binge eating and inappropriate compensatory mechanisms occur at a frequency of less than twice a week or for a duration of less than 3 months.
4. the regular use of inappropriate compensatory behavior by an individual of normal body weight after eating small amounts of food (e.g., self-induced vomiting after the consumption of two cookies).
5. repeatedly chewing and spitting out, but not swallowing large amounts of food.
6. binge eating disorder: recurrent episodes of binge eating in the absence of the regular use of inappropriate compensatory behaviors characteristic of bulimia nervosa.

Table 20-5 DSM-IV Diagnostic Criteria for Eating Disorder Not Otherwise Specified

Based on clinical work and a survey of the literature researchers came to the conclusion that a significant number of people had serious problems with binge eating but did not meet criteria for bulimia nervosa. These people lacked the compensatory weight-control behaviors and the overconcern with body weight and shape. This proposed disorder was labeled "binge eating disorder" (Table 20-6) and is classified as an eating disorder not otherwise specified in DSM-IV. It is distinguished from bulimia nervosa, nonpurging type by the lack of any compensatory behavior to avoid weight gain and the necessity of binge eating twice a week for a 6-month period (Table 20-4); additional field trials are needed to provide sufficient evidence that this is indeed a specific diagnostic entity.

A. Recurrent episodes of binge eating. An episode of binge eating is characterized by both of the following:
   (1) eating, in a discrete period of time (e.g., within any 2-hour period), an amount of food that is definitely larger than most people would eat in a similar period of time under similar circumstances
   (2) a sense of lack of control over eating during the episode (e.g., a feeling that one cannot stop eating or control what or how much one is eating)
B. The binge eating episodes are associated with three (or more) of the following:
   (1) eating much more rapidly than normal
   (2) eating until feeling uncomfortably full
   (3) eating large amounts of food when not feeling physically hungry
   (4) eating alone because of being embarrassed by how much one is eating
   (5) feeling disgusted with oneself, depressed, or very guilty after overeating
C. Marked distress regarding binge eating is present.
D. The binge eating occurs, on average, at least 2 days a week for 6 months.
   Note: The method of determining frequency differs from that used for bulimia nervosa; future research should address whether the preferred method of setting a frequency threshold is counting the number of days on which binges occur or counting the number of episodes of binge eating.
E. The binge eating is not associated with the regular use of inappropriate compensatory behaviors (e.g., purging, fasting, excessive exercise) and does not occur exclusively during the course of anorexia nervosa or bulimia nervosa.

Table 20-6 DSM-IV Research Criteria for Binge Eating Disorder

CLINICAL FEATURES

Anorexia Nervosa Anorexia nervosa patients (Fig. 20-1) continually engage in behaviors to maintain or increase their marked weight loss. They try to get rid of food surreptitiously to avoid eating it. They drastically reduce their total food intake and disproportionately decrease the intake of high carbohydrate and fatty foods. Some anorexia patients will follow rigorous exercising programs and others will simply be as active as possible at all times. The binge-eating/purging type of patients will self-induce vomiting and use laxatives and diuretics to lose weight. Many anorexia nervosa patients are preoccupied with food, often collecting recipes and preparing elaborate meals for their families. They may hide carbohydrate-rich foods and horde large quantities of candies, carrying them in their pockets and purses.

FIGURE 20-1 Patient with anorexia nervosa. Note the normal amount of pubic hair. (From Novak ER, Jones GS, Jones HW: *Novak's Textbook of Gynecology*, ed 8. Williams & Wilkins, Baltimore, 1970.)

Anorexia nervosa patients typically express an intense fear of gaining weight; they stare in the mirror frequently to reassure themselves that they are not gaining weight.

The significance of body weight and shape are greatly distorted in anorexia nervosa patients. Some feel globally overweight and others realize they are thin but think certain parts of their body, particularly the abdomen, buttock, and thighs, are too fat. They fail to recognize that they are dangerously emaciated. They often feel very ineffective and for them losing weight is an impressive achievement that boosts their self-esteem and sense of control. The denial of the seriousness of the medical implications of their malnourished state allows them to believe that thinness can solely define their self-worth. Obsessive-compulsive behavior often develops after the onset of anorexia nervosa. An obsession with cleanliness is often apparent as an increase in housecleaning activities occurs. In students compulsive studying may develop, although difficulty concentrating often forces students to spend many more hours at their studies.

Amenorrhea is due to diminished secretion of GnRH, which in turn diminishes the pituitary secretion of follicle-stimulating hormone (FSH) and luteinizing hormone (LH); this in turn is responsible for abnormally low levels of estrogen.

The obsessions concerning food and weight are egosyntonic in these patients. Patients have characteristic cognitive distortions such as dichotomous thinking (all-or-none reasoning). Persons with anorexia nervosa have little or no motivation for treatment because the illness serves a strong positive function in their life by allowing them to escape uncomfortable interpersonal problems or developmental issues. Poor sexual adjustment is frequent in anorectic patients. Many anorectic adolescents have delayed psychosocial sexual development, and adults often have a markedly decreased interest in sex with the onset of anorexia nervosa.

Medical Complications Most of the physiological and metabolic changes in anorexia nervosa are secondary to the starvation state or purging behaviors (Table 20-7 and Table 20-8). These changes revert to normal with nutritional rehabilitation or cessation of the purging behavior. Abnormalities in hematopoiesis include leukopenia and a relative lymphocytosis. Patients who engage in self-induced vomiting (Fig. 20-2) or abuse laxatives and diuretics may develop hypokalemic alkalosis. This is diagnosed by elevated serum bicarbonate, hypochloremia, and hypokalemia. Patients with electrolyte disturbances may have physical symptoms of weakness, lethargy, and cardiac arrhythmia. The latter condition may result in a sudden cardiac arrest, which is a cause of death in patients who purge. Elevation of serum enzymes reflects fatty degeneration of the liver and is present both in the emaciated anorectic phase and during refeeding. Elevated serum cholesterol levels tend to occur more frequently in younger patients. Carotenemia is often observed in malnourished anorectic patients.

Table 20-8 Medical Complications of Eating Disorders

FIGURE 20-2 Dental erosion of upper front teeth of a patient with longstanding bulimia nervosa, binge eating/purging type. (Reprinted with permission from Walsh BT: Eating disorders. In *Psychiatry*, vol 2, A Tasman, J Kay, JA Lieberman, editors. Saunders, Philadelphia, 1997.)

Sue, a 19-year-old single white female, has just completed 6 months in an eating disorder specialty unit for the treatment of anorexia nervosa and obsessive-compulsive disorder. She arrived weighing 30 kg (66 lbs) and was 162 cm (5'1") tall.

Sue recalls that as early as age 4 she had to do everything “perfectly” and had rituals for putting things away and cleaning things thoroughly. These behaviors continued throughout grade school. In school she was extremely competitive and always obtained straight As. She began gymnastics when she was 8 years old and continued with this until the onset of her anorexia nervosa at age 12, when she began eating foods slowly and gradually eating less food. She denies any reason for doing this or any stress at the time. The following summer she was hospitalized because of weight loss at a time when she should have been growing and gaining weight. It was then she was diagnosed as having anorexia nervosa. Her obsessions and compulsions became more severe as her anorexia worsened. She developed rituals around cleaning, straightening and arranging objects, counting, and exercising. She felt and continues to feel that she must be constantly industrious, moving and accomplishing things because she fears becoming “lazy.” She was often unable to leave her home in the morning for hours because she had to touch objects and perform a number of rituals, which caused her to frequently be late for school. The following year her weight dropped to 50 lbs and she was hospitalized again. This was the beginning of a series of repeated hospitalizations and weight losses up to the time she graduated from high school as valedictorian despite her almost continued absence from school. After graduation she worked as a cashier in a grocery store for 1 year while living with her parents and was able to stay out of the hospital for 18 months. She then had a series of several hospitalizations and short-term jobs working as a copy center associate and as an aide in a nursing home.

Sue denies any binge-eating; purging; illegal drug use, or use of alcohol, cigarettes, or caffeine. She only restricts her intake and vigorously exercises. She is very distressed about her obsessions and compulsions but not about her eating behavior. She has never shown the signs and symptoms of depression. She has primary amenorrhea.

Sue stated she always had girlfriends throughout high school.

She has never dated or had a boyfriend and has never been sexually active. She is extremely angry with her father and has an openly antagonistic relationship with him. She states she has always wanted attention and approval from him but has never received it. She is the youngest of three children; her two older sisters have done well academically and professionally. She has a close and enmeshed relationship with her mother.

On admission to the specialized eating disorder program, Sue was placed on a liquid diet. She had enormous difficulty adhering to unit rules and procedures. She was perpetually in motion. She was very upset and angry when confronted by staff and was extremely sensitive to criticism. She was exceedingly harsh, critical, and self-punishing. After 6 months of hospitalization, she was able to successfully maintain her weight within a normal range. Her confidence was greatly improved in her ability to eat three meals and maintain her weight. She stated she actually enjoyed eating because she was allowed to be a vegetarian. She was much more sociable, interacting with peers and vocal in community meetings and groups. Her rituals had gradually decreased and she was actually able to get through several days with no rituals. She found it more difficult to abstain from rituals in the evening and she still felt very concerned about “being lazy.” She was also more comfortable and open in talking with her father.

During her fifth month of hospitalization when she had reached her target weight, Sue was placed on 225 mg a day of clomipramine (Anafranil), which was helpful in reducing her obsessions and compulsions. Throughout her hospitalization Sue was treated with a cognitive-behavioral therapy program and family counseling. She was discharged to a specialized eating disorder outpatient program with cognitive psychotherapy, family counseling, and group therapy.

Discussion Sue had perfectionistic traits, a feature of obsessive-compulsive personality disorder, as a young child. There is growing evidence that this type of personality trait puts a young woman at risk for developing anorexia nervosa—restricting type, which is Sue's diagnosis. After several years in addition to having an obsession-compulsive personality disorder, Sue actually met diagnostic criteria for Axis I obsessive-compulsive disorder. These behaviors were not severe until she developed anorexia nervosa. There is a distinct difference between obsessions and compulsions such as counting and checking compared with eating disorder rituals and preoccupations. Sue was distressed by the former, which were egodystonic, but was not bothered by the latter eating disorder rituals, which were egosyntonic. Because she failed to respond to fluoxetine (Prozac) in her previous hospitalizations she was placed on clomipramine and responded well to this drug, as evidenced by a decrease in obsessions and compulsions.

Bulimia Nervosa Bulimia nervosa usually begins from a period of a few weeks to a year or longer after dieting. The dieting may or may not be successful in achieving weight loss but the weight loss is never enough to qualify for a diagnosis of anorexia nervosa. Restrained eating gives way in these persons to binge-eating episodes, which are usually terminated by abdominal pain or discomfort, self-induced vomiting, or social interruption. The bulimic episode is often followed by feelings of guilt, depression, or self-disparagement. Some bulimia nervosa patients will use laxatives for weight control and have a pattern of alternating binges and fasting. A minority of bulimic patients use diuretics for weight control. Patients with bulimia nervosa have a fear of not being able to stop eating voluntarily and thus develop a pattern of severe dieting, interrupted by binge-eating episodes. The food consumed during a binge usually has a high dense calorie content and a texture that facilitates rapid eating. Frequent weight fluctuations can occur in bulimia nervosa patients.

The average length of a bingeing episode is about 1 hour. Some patients with the disorder have abrasions and scars on the backs of their hands from sticking their fingers down their throat to induce vomiting. Bulimia nervosa patients will abuse amphetamines to reduce their appetite and to lose weight; they will also use ipecac to induce vomiting. Most bulimia nervosa patients do not eat regular meals and have difficulty feeling satiety at the end of a normal meal. They usually prefer to eat alone and in their homes. Although many have been at the upper end of a normal weight range or slightly overweight they will often choose a weight at the lower end of a normal weight range as their ideal body weight. About 10 percent of bulimia nervosa patients have been markedly overweight. They can be very concerned about their body shape and image but are not driven to lose weight like anorexia nervosa patients are. For many bulimia nervosa patients the actual binge-eating episode often gives them a relief of tension and anxiety and thus can become a rewarding behavior.

Patients with bulimia nervosa have a wide range of psychological and behavior problems. Their lives are often chaotic with troublesome interpersonal relationships, impulsive behaviors, and high levels of anxiety and compulsivity. They have poor self-concepts and a high prevalence of mood disorders. Substance abuse is not unusual in patients with this disorder, with alcohol abuse being the most common. About one fourth of bulimic patients have problems of impulsively stealing, with food, clothing, and jewelry being most commonly stolen.

Medical Complications Bulimia nervosa patients who engage in self-induced vomiting and abuse purgative or diuretic medications are susceptible to the same complications as anorexia nervosa patients involved in this behavior. Exposure to gastric juices through vomiting can cause severe erosion of the teeth, pathological pulp exposures, diminished masticatory ability, and an unaesthetic appearance. Parotid gland enlargement is associated with elevated serum amylase concentrations and is commonly observed in patients who binge and vomit. Acute dilatation of the stomach is a rare emergency condition for patients who binge eat, and esophageal tears can occur in the process of self-induced vomiting. Severe abdominal pain in the bulimia nervosa patient should alert the physician to a diagnosis of gastric dilatation and the need for nasal gastric suction, X-rays, and surgical consultation. Cardiac failure caused by cardiomyopathy from ipecac toxication is a medical emergency that usually results in death. Symptoms of pericardial pain, dyspnea, and generalized muscle weakness associated with hypotension, tachycardia, and

electrocardiogram (EEG) abnormalities should alert medical personnel to possible ipecac intoxication.

Alice was 21 years old and had been binge-eating and vomiting for 8 years before she was referred to an eating disorder treatment program. She had achieved her greatest weight of 59 kg when she was a sophomore in high school and 15 years old. She had several stresses during that year—she did not make the cheerleading team; her grandfather, with whom she was very close, died; and some close friends moved away. She developed a general feeling of unhappiness, loneliness, and loss. During that year, her pets had been given away by her parents because they were too much trouble. It was during this time that Alice decided she wanted to lose weight and soon developed the habit of self-induced vomiting. She gradually increased the amount of vomiting until her senior year of high school, when she was vomiting four times a week. When Alice began to lose weight, she resorted to a series of fad diets. She refused to eat meals with her family and after about 6 months of dieting she began to get up at night for binge-eating episodes followed by self-induced vomiting, which she had perfected for the past several months.

After graduating from high school, Alice went to college for 1 year and majored in animal science. She did not like this curriculum and dropped out after a year. However, during that time her symptomatology increased and she actually wallpapered one of her walls with M&M wrappers. She then went back to live at home and had a series of jobs in food stores, such as a donut shop and a deli, as well as a clothing store. Finally, she was unable to hold a job for more than a few months because of her binge-eating and vomiting behavior. Her most stable relationship was with her boyfriend, with whom she was living a year before hospitalization. During that time, at her boyfriend's insistence she saw a social worker weekly for several months but then stopped treatment abruptly. Her binge-eating and vomiting got out of control, so her boyfriend took her to a local hospital. She was there for 3 months and then transferred directly to another program in a different hospital. During her initial hospitalization she was allowed to come and go as she pleased and she continued her binge-eating and vomiting behavior. At the time of admission to the special eating disorder treatment program, Alice admitted to feeling depressed and having frequent crying spells. She also had difficulty falling asleep at night. She was totally preoccupied with thoughts of binge-eating and of food. The significant findings on her physical examination were a slight scoliosis and marked deterioration of her teeth.

Alice began her menses at age 14. At about the age of 16 she began to have irregular menses; however, she continued to menstruate. Her lowest weight was 50.9 kg and that was just a few months before her admission to an eating disorder specialty unit.

She was placed on a multifaceted treatment program with twice-weekly individual psychotherapy sessions, daily group therapies, and biweekly family sessions. Initially she expressed considerable denial and anger and was later able to describe feelings of emptiness, loneliness, and a sense of inadequacy. Response prevention techniques were used to stop the vomiting and binge-eating behavior and she responded very well in a structured setting. She also received 60 mg of fluoxetine daily. Alice gradually gained control over the eating behavior and developed considerable insight into her problems and insecurities. During her 4 months in a special eating disorder treatment program, she responded well to the gradual introduction of responsibility for her eating behavior and other aspects of her life. After discharge from the hospital, she continued her treatment in an outpatient setting and received individual and family therapy. She returned to live with her parents and brother, where she stayed for 6 months until she moved into a supportive apartment. Several months later she began attending a community college. Her binge-eating and vomiting had stopped entirely and she was eating normally and maintaining her weight within a normal range. Her prognosis, however, is guarded because of her long history of dysfunctional eating behavior.

Discussion Alice's dieting began when she had a series of stresses that challenged her feelings of competency and effectiveness. She was mildly overweight when she began dieting and was not very effective at it until she started self-induced vomiting. Even with this behavior, as is typical in bulimia nervosa patients, she was not able to become emaciated. She was able to maintain a sexual relationship with her boyfriend, which is in contrast to the more typical asexual nature of the anorexia nervosa patient. The rest of her life, however, was chaotic in that she could not keep a job for longer than a few months and was unable to have stable relationships with most people. She suffered from depression, which responded to fluoxetine. Over the course of a year of cognitive psychotherapy, she ceased bingeing and vomiting. Although most bulimia nervosa patients have an immediate reduction in their bingeing and vomiting as a response to cognitive therapy, complete cessation of this behavior often occurs 1 or 2 years after the intensive therapy has occurred.

PATHOLOGY AND LABORATORY EXAMINATION

Anorexia Nervosa There are no laboratory tests that can provide a diagnosis of anorexia nervosa. The medical phenomena present in this disorder result from the starvation or purging behaviors. There are several relevant laboratory tests that should be obtained in these patients. A complete blood count will often reveal a leukopenia with a relative lymphocytosis in emaciated anorexia nervosa patients. If binge-eating and purging are present, serum electrolytes will reveal a hypokalemic alkalosis. Fasting serum glucose concentrations are often low during the emaciated phase, and serum salivary amylase concentrations are often elevated if the patient is vomiting. An electrocardiogram may show S-T segment and T-wave changes, which are usually secondary to electrolyte disturbances; emaciated patients will have hypotension and bradycardia. Young girls may have an elevated serum cholesterol level. All these values revert to normal with nutritional rehabilitation and cessation of purging behaviors. Endocrine changes that occur, such as amenorrhea, mild hypothyroidism, and hypersecretion of corticotrophin-releasing hormone are due to the underweight condition and revert to normal with weight gain.

Bulimia Nervosa The predominant laboratory abnormalities in bulimia nervosa patients occur in those who purge and are seen as changes in serum electrolyte values. The purging behavior can produce hypokalemia and a metabolic alkalosis. Patients who vomit frequently may have an elevated salivary serum amylase. On rare occasions the bulimia nervosa patient will have to be hospitalized because of severe electrolyte disturbances or depression with suicidal ideation.

DIFFERENTIAL DIAGNOSIS

Anorexia Nervosa Because anorexia nervosa patients are usually in the physician's office at the insistence of family, friends, or employers and have a strong denial of their illness, obtaining an accurate history is often difficult. It is important to ascertain that the patient has no medical illness that can account for the weight loss. In rare circumstances a patient can have both anorexia nervosa and a medical illness that contributes to the weight loss. In such a situation the diagnosis of anorexia nervosa is made by the positive criteria for anorexia nervosa and both the underlying medical condition and the anorexia nervosa have to be treated.

Weight loss, peculiar eating behavior, and vomiting can occur in several psychiatric disorders. Weight loss frequently occurs in depressive disorders, which have several features in common with anorexia nervosa; for example, depressed moods, crying spells, sleep disturbances, obsessive ruminations, and occasional suicidal thoughts. There are, however, several distinguishing features between the disorders. Generally, a patient with a depressive disorder has a decreased appetite whereas an anorexia nervosa patient denies the existence of an appetite. It is only in the severe stages of anorexia nervosa that the patient actually has a decreased appetite. The hyperactivity seen in anorexia nervosa patients differs from the agitative activity seen in patients with depressive disorders in that much of the activity of the patient with anorexia nervosa is planned and ritualistic—exercising, jogging, and cycling programs. The preoccupation with the calorie content of food, collecting recipes, and preparing gourmet feasts, which is typical of the anorectic patient, is not present in the patient with a depressive disorder. Patients with depression do not fear becoming fat nor do they have a disturbance of their body image, as anorexia nervosa patients do.

Weight fluctuations, vomiting, and peculiar food handling may occur in somatization disorder. The weight loss in somatization disorder is usually not as severe as in anorexia nervosa, nor does the patient in the former disorder express a morbid fear of becoming overweight. Also, amenorrhea that lasts for 3 months or longer is unusual in a patient with somatization disorder.

Delusions about food in schizophrenia are seldom concerned with the calorie content of food. A patient with schizophrenia is not preoccupied with a fear of becoming obese and does not have the hyperactivity seen in an anorectic patient. Chronic medical illnesses frequently associated with weight loss are Crohn's disease, hyperthyroidism, Addison's disease, and diabetes mellitus.

Bulimia Nervosa If bingeing and purging behaviors are occurring in a person who meets diagnostic criteria for anorexia nervosa, bulimia nervosa cannot be the diagnosis. Severe weight loss and amenorrhea are the two features distinguishing these eating disorders.

On rare occasions a central nervous system tumor may be associated with bulimic behaviors. Overeating episodes also occur in the Kluver-Bucy syndrome, which consists of visual agnosia, compulsive licking and biting, inability to ignore any stimulus, and hypersexuality. Another uncommon syndrome associated with hyperphagia is the Kleine-Levin syndrome, which is characterized by periodic hypersomnia lasting for several weeks.

COURSE AND PROGNOSIS

The only long-term studies of eating disorders are based on patient samples. There are no data available on people who have eating disorders but do not get treatment. Large–sample-size long-term studies have occurred predominantly in anorexia nervosa patients because bulimia nervosa was defined as a separate entity and has been studied as such only since in the 1980s.

Anorexia Nervosa Anorexia nervosa has a bimodal peak of onset either between the ages of 14 and 15 or at age 18. Although infrequent, cases are reported in girls as young as 9 years and some first episodes have occurred in postmenopausal women. The course of anorexia nervosa can vary from one episode with full recovery, commonly occurring partial recovery with relapses, to a chronic severe course that results in death.

Ten-year outcome studies in the United States have shown that about one fourth of the patients recover completely and another one half are markedly improved and functioning fairly well. The other one fourth includes an overall 7 percent mortality rate and those who are functioning poorly with a chronic underweight condition. Swedish and English studies over a 20- and 30-year period have a mortality rate of 18 percent. Good prognostic indicators across studies include an earlier age of onset (under age 18), no previous hospitalization for the illness, and no purging behaviors. Some factors such as parental conflict, degree of denial, immaturity, and self-esteem have been related to outcome in some studies but not others. About half of anorexia nervosa patients will eventually have the symptoms of bulimia, usually within the first year after the onset of anorexia nervosa.

Bulimia Nervosa Course of illness and prognostic studies of bulimia nervosa are now appearing in the literature. Of these, the majority have a relatively short-term follow-up of between 6 months and 2 years posttreatment. A recent review of 88 articles on the naturalistic and treatment follow-up of bulimia nervosa with periods ranging from 6 months to 10 years reached the following conclusions: the typical age of onset for bulimia nervosa is between 18 and 19 years and mortality rates can be estimated between 0 and 3 percent. After between 5 and 10 years about 50 percent of bulimic patients will be fully recovered, 20 percent will continue to meet diagnostic criteria for bulimia nervosa. About one third of recovered bulimic patients will relapse within 4 years of presentation. Patients with personality disorders marked by problems with impulse control generally had a worse prognosis, compared with bulimia nervosa patients with no personality disorder problems.

TREATMENT

Anorexia Nervosa The severity of illness will determine the intensity of treatment required for the anorexia nervosa patient. Treatment levels can range from an inpatient specialized eating disorder unit to a partial ospitalization or day program to outpatient care depending on the weight, medical status, and other psychiatric comorbidity of the patient. Decisions about the particular treatment modalities and strategies must be based on the needs of the patient as well as the capabilities of the treatment setting. Understandably it has been extremely difficult to subject severely medically ill patients with anorexia nervosa to controlled treatment studies in the emaciated state of the illness. Since patients with anorexia nervosa are resistant to and disinterested in treatment there are very few outpatient controlled treatment studies. Open studies have indicated that a multifaceted treatment approach is the most effective, which includes medical management, psychoeducation, and individual therapy utilizing cognitive and behavior therapy principles. Controlled studies have shown that children under the age of 18 do better if they have family therapy. Nutritional counseling and pharmacological intervention can also be useful components to the treatment plan. Guidelines for admission to a hospitalized or day treatment program for anorexia nervosa are presented in Table 20-9. To obtain the patient's cooperation for treatment it is helpful to emphasize the benefits of treatment and reassure the patient that treatment can bring about relief of distressing symptoms related to anorexia such as insomnia, depression, and obsessive thoughts about food and body weight that interfere with the ability to concentrate on other matters, and can result in increased physical well-being, energy, and improved peer relationships.

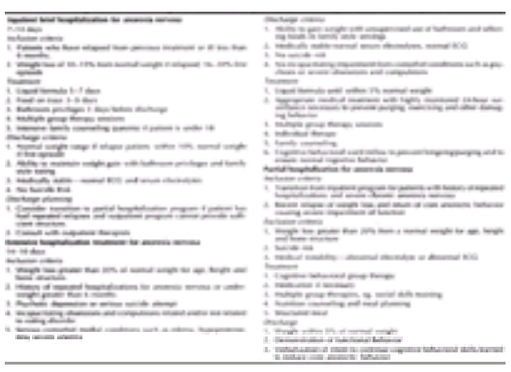

Table 20-9 Guidelines for Hospitalizations and Day Treatment for Anorexia Nervosa

The severely ill anorexia nervosa patient can present an extremely difficult medical-behavioral management challenge. These patients should be hospitalized in a specialized inpatient eating disorder treatment setting that has a team of individuals highly skilled in the multidisciplinary treatment of anorexia nervosa. Outpatient therapy has the best chance for success in anorectic patients who: (1) have had the illness for less than 6 months, (2) are not bingeing and vomiting, and (3) have parents who are likely to cooperate and participate effectively in family therapy.

Medical Management Medical management requires weight restoration, nutritional rehabilitation, rehydration, and correction of serum electrolytes. Inpatient hospitalization should include daily monitoring of weight, food, calorie intake, and urine output. Patients should be monitored closely for attempts to vomit. Outpatients should be weighed weekly in the physician's office with periodic physical examinations and measurement of serum electrolytes if the patient is purging.

Cognitive-Behavioral Therapy Cognitive and behavior therapy principles can be applied in both inpatient and outpatient settings. Behavior therapy has been found to be effective for inducing weight gain. There are no large–sample-size controlled studies of cognitive therapy with behavior therapy in anorexia nervosa patients. Monitoring is an essential component of cognitive-behavioral therapy. Patients are taught to monitor their food intake, their feelings and emotions, their bingeing and purging behaviors, and their problems in interpersonal relationships. Cognitive restructuring is a method that patients are taught in order to identify autonomic thoughts and to challenge their core beliefs. Problem solving is a specific method whereby patients learn how to think through and devise strategies to cope with their food-related and interpersonal problems. Patients' vulnerability to rely on anorexic behaviors as a means of coping can be reduced if they can learn to use these techniques effectively.

Family Therapy A family analysis should be done on all anorexia nervosa patients who are living with their families. On the basis of this analysis a clinical judgment can be made as to what type of family therapy or counseling is advisable. In some cases family therapy is not possible. However, in those cases issues of family relationships can be addressed in individual therapy. In some cases brief counseling sessions with immediate family members may be the extent of family therapy required. In one controlled family therapy study in London, anorectic patients under the age of 18 benefited from family therapy whereas patients over the age of 18 did worse in family therapy compared with the control therapy. There are no controlled studies of the combination of individual and family therapy. However, in actual practice most clinicians provide individual therapy and some form of family counseling in managing anorexia nervosa patients.

Pharmacotherapy Medications can be useful adjuncts in the treatment of anorexia nervosa. The first drug used in treating anorectic patients was chlorpromazine. This medication is particularly helpful for severely ill patients who are overwhelmed with constant thoughts of losing weight and behavioral rituals for losing weight. Surprisingly there are no double-blind controlled studies to definitively prove this drug's effectiveness for calming these patients and inducing weight gain. It may be necessary to start at a low dosage of the liquid form such as 10 mg 3 times a day and to gradually increase the dosage. Cyproheptadine (Periactin) in high dosages (up to 28 mg a day) can facilitate weight gain in anorectic restrictors and also has an antidepressant effect. Some recent small–sample-size open studies indicate that fluoxetine may be effective in preventing relapse in patients with anorexia nervosa.

Bulimia Nervosa In contrast to the relatively few outpatient treatment studies of anorexia nervosa, treatment outcome studies of bulimia nervosa have proliferated since the late 1980s.

Cognitive-Behavioral Therapy Cognitive-behavioral therapy should be considered the benchmark, first-line treatment for bulimia nervosa. It has been found to be the most effective treatment in over 35 controlled psychosocial studies. About 40 to 50 percent of patients are abstinent from both binge eating and purging at the end of treatment (16 to 20 weeks). Altogether, improvement by a reduction in binge-eating and purging occurred in a range from 70 to 95 percent of patients. Additionally, another 30 percent of those who did not show improvement immediately posttreatment showed improvement to full recovery 1 year after treatment. In patients with a depressive disorder and bulimia nervosa, cognitive-behavioral therapy was also found to decrease depression.

The data supporting the efficacy of cognitive-behavioral therapy is based upon strict adherence to rigorously implemented, highly detailed, manual-guided treatments that include about 18 to 20 sessions over 5 to 6 months. It should be noted that all controlled studies have been conducted by therapists specifically trained in these manual-guided treatments written for bulimia nervosa. Cognitive-behavioral therapy implements a number of cognitive and behavioral procedures to: (1) interrupt this self-maintaining behavioral cycle of bingeing and dieting, and (2) alter the individual's dysfunctional cognitions and beliefs about food, weight, body image, and overall self-concept.

Family Therapy Family therapy is not widely used in the treatment of bulimia nervosa as it is for anorexia nervosa because most patients with bulimia nervosa are in their 20s and live away from their family of origin. There is a consensus that families of younger patients should be involved with their treatment; however, controlled studies are needed to prove this.

Interpersonal Therapy Interpersonal therapy has been applied as a treatment for bulimia nervosa because interpersonal problems frequently accompany this disorder. This therapy, which focuses on interpersonal functioning and does not target eating behaviors, has shown promising results. In one controlled study interpersonal therapy was not as effective as cognitive behavioral therapy at the end of treatment but at 1 and 6 years following treatment it had produced equally significant changes. These findings suggest that interpersonal therapy has a delayed but powerful effect.

Pharmacotherapy Since the late 1980s over a dozen double-blind, placebo-controlled trials of antidepressant medications, such as desipramine (Norpramin), imipramine (Tofranil), amitriptyline (Elavil), nortriptyline (Pamelor), phenelzine (Nardil), and fluoxetine, have been conducted in normal-weight outpatients with bulimia nervosa. The dosage of antidepressant medication used was similar to that used for the treatment of depression. In all trials the drugs were significantly more effective than placebo in reducing binge eating. In addition, the medication improved mood and reduced eating disorder symptoms such as preoccupation with shape and weight. However, the average abstinence rate from binge eating and purging in these studies was 22 percent, indicating that the majority of patients were still symptomatic at the end of treatment. The few long-term studies to evaluate maintenance of change showed disappointing results, with over 80 percent of patients relapsing. There is some indication that if medications are used the treatment should be continued for 6 months to prevent relapse. However, studies are needed to assess the adequate length of time for pharmacotherapy. One large multicenter collaborative study showed fluoxetine in doses of 60 mg a day to be effective in reducing episodes of binge eating and purging. Controlled double-blind placebo trials are needed for other selective serotonin reuptake inhibitors (SSRI).

Three studies have examined the combined effects of cognitive behavioral therapy and antidepressant medication in treating bulimia nervosa. One study found that group cognitive-behavioral therapy was superior to imipramine in decreasing binge eating and purging, but the combined treatment demonstrated no additive effects over those of the cognitive-behavioral therapy group alone. Another study compared individual cognitive-behavioral therapy, desipramine, or both and found that all groups were similar at 16 weeks. At 32 weeks, only the combined treatment given for 24 weeks was superior to medication given for 16 weeks. In the third study cognitive-behavioral therapy plus medication (desipramine, followed by fluoxetine in nonresponders) was superior to medication alone, but supportive psychotherapy plus medication was not. Cognitive-behavioral therapy plus medication was superior to cognitive-behavioral therapy alone. Cognitive-behavioral group therapy is especially cost-effective for patients as well as for treatment centers. Group therapy is also appealing because patients with bulimia nervosa often keep their eating disorder a secret and feel isolated, ashamed, and embarassed about their symptoms. They have difficulty asking for help and frequently have interpersonal problems. Although widely practiced using cognitive-behavioral therapy techniques, group therapy for bulimia has not been studied in a controlled assessment that compares it with individual cognitive-behavioral therapy.

Guided Self-Help Guided self-help is a new approach to the treatment of bulimia nervosa. Two self-help programs based on the cognitive behavioral therapy approach have been published in which the patient follows a self-help program with some support and guidance from a therapist; the therapist's involvement is minimal. Methodologically sound controlled studies are needed to establish evidence for the effectiveness of these self-help groups.

SUGGESTED CROSS-REFERENCES

Some of the specific syndromes that can be associated with eating disorders are found in Chapter 14 on mood disorders, in Chapter 15 on anxiety disorders, in Chapter 16 on somatoform disorders, in Chapter 11 on substance-related disorders, Chapter 22 on impulse-control disorders not elsewhere classified, in Section 25.6 on endocrine and metabolic disorders, and in Section 7.3 on typical signs and symptoms of psychiatric illness. Personality disorders are discussed in Chapter 24, and the relationship between eating disorders and feeding in childhood, rumination, and pica are discussed in Chapter 41. Other areas that relate to this chapter include consultation-liaison psychiatry (Section 25.12), relational problems (Chapter 26), psychodynamic therapy (Section 30.1), and psychiatric treatment of infant, child, and adolescent (Chapter 48). Sections on genetics and psychiatry (Section 1.18), psychopharmacology (Chapter 31), and family therapy (Section 30.5) provide more detailed background to understanding eating disorders.

CHAPTER 21. SLEEP DISORDERS

CONSTANCE A. MOORE, M.D., ROBERT L. WILLIAMS, M.D. AND MAX HIRSHKOWITZ, PH.D.

Sleep is a process the brain requires for proper functioning. The seriousness of sleep disorders is poorly recognized by the general public and the clinical community. Although individuals afflicted with sleep problems desperately seek help, they are often met with indifference on the part of health care providers. Whether this comes from lack of knowledge or a jaded attitude resulting from the sleepless-overworked "rite of passage" during internship, residency, or graduate study is not known; however, the old saying "no one ever died from a sleep problem" is incorrect. Many sleep disorders are life threatening, either directly (e.g., fatal familial insomnia and obstructive sleep apnea) or indirectly as a result of sleep-related accidents. Investigations link many major industrial catastrophes to sleepiness. The indirect costs of sleep-related accidents total approximately 100 billion dollars per year in the United States. Thus, sleepiness is a serious, potentially life-threatening condition that affects not only the individual but also the family, coworkers, and society in general.

The 1959–1960 American Cancer Society survey of more than one million Americans included several questions related to sleep habits. Results showed increased mortality among individuals who habitually slept significantly more or less than normal. Specifically, men 30 years old or older sleeping less than 4 hours per night were 2.8 times more likely to die within 6 years than those who slept 7 to 8 hours per night. Adult men sleeping more than 10 hours per night had higher death rates (1.8) than normal sleepers. Follow-up studies, controlling for comorbidity factors, confirmed these results.

Sleep disorders medicine is a rapidly evolving subspecialty. Interest in sleep disorders was initially dominated by psychiatry, psychology, and neurology. The past two decades have witnessed discoveries that now make sleep medicine truly multidisciplinary. Recognizing the consequences of sleep-disordered breathing has attracted many pulmonary and internal medicine specialists. Sleep-wake cycle–related endocrinologic and circadian rhythm research has migrated from the laboratory to the clinical arena. Finally, maturation of the Clinical Sleep Society into the American Sleep Disorders Association (ASDA), provides an intellectual home for practitioners interested in sleep disorders.

The ASDA sponsored the development of the International Classification of Sleep Disorders (ICSD). ICSD is the most comprehensive classification of sleep disorders and is referred to frequently (Table 21-1). The fourth edition of *Diagnostic and Statistical Manual of Mental Disorders*, (DSM-IV) includes many ICSD diagnostic classifications. However, the organizational scheme differs, and DSM-IV frequently lumps several ICSD nosological entities into a single diagnostic classification. Nonetheless, because this is a textbook of psychiatry, this chapter organizationally follows the DSM-IV classification (Table 21-2). Overall, DSM-IV differentiates between primary sleep disorders, sleep disorders related to another mental disorder, sleep disorder due to a general medical condition, and substance-induced sleep disorder. In addition to DSM-IV and ICSD, the 10th revision of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) has its own classification of sleep disorders (Table 21-3).

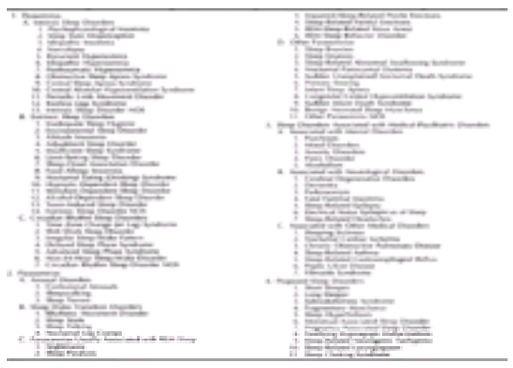

Table 21-1 International Classification of Sleep Disorders

Table 21-2 DSM-IV Classification of Sleep Disorders

Table 21-3 ICD-10 Diagnostic Criteria for Nonorganic Sleep Disorders

PRIMARY SLEEP DISORDERS

Primary sleep disorders are dichotomized into dyssomnias and parasomnias. Dyssomnias include insomnias and hypersomnias. DSM-IV defines insomnia as difficulty initiating sleep or maintaining sleep. Many sleep specialists also would include nonrestful or poor-quality sleep. Hypersomnia is excessive sleepiness. Dyssomnias can be characterized by disturbance in amount, quality, or timing of sleep. By contrast, parasomnias are characterized by abnormal behaviors or physiological events associated with sleep. These events can occur during specific sleep states, during any stage of sleep, or at the transition between sleep and wakefulness.

Dyssomnias are thought of as disturbances involving sleep-wake generating or timing mechanisms. Parasomnias, however, involve inappropriately timed activation of (or failure to suppress) behavioral or physiological systems or both during sleep and sleep-wake transitions.

Dyssomnias DSM-IV lists five specified classifications for primary dyssomnias: primary insomnia, primary hypersomnia, narcolepsy, breathing-related sleep disorders, and circadian rhythm sleep disorder as well as a “not otherwise specified” category. Table 21-4 cross-references DSM-IV primary dyssomnias to the ICSD classification. The table shows ICSD classification differentiates diagnostic categories more fully than DSM-IV. Because in most cases this affects the treatment plan, it is of more than passing academic interest.

Table 21-4 Cross-References Between DSM-IV Primary Sleep Disorders and ICSD Classifications

For example, a patient with psychophysiological insomnia may have a prolonged latency to sleep as a classically conditioned arousal response to getting in bed; treatment would focus on deconditioning. By contrast, if a clinical interview reveals that the patient is engaging in behaviors counterproductive to being able to sleep, inadequate sleep hygiene may be diagnosed. In this case, intervention would focus on improving sleep habits by decreasing or eliminating the sleep-defeating behaviors. However, both cases would be diagnosed as primary insomnia.

Primary Insomnia Primary insomnia is diagnosed only after a patient complains of sleeplessness or poor quality sleep for 1 month or more. The insomnia, or consequent sleepiness, must produce significant distress or impair activities of daily life. Recognizing that insomnia occurs as a symptom of many different underlying conditions, DSM-IV lists various exclusionary criteria for diagnosing insomnia as primary. The clinician must not be able to account for the insomnia as a feature of another primary sleep disorder or secondary to another mental disorder, medical disorder, or substance use. DSM-IV diagnostic criteria are shown on Table 21-5. ICSD defines four distinct nosological entities that would be included in, and further differentiate, primary insomnia: (1) inadequate sleep hygiene, (2) psychophysiological insomnia, (3) sleep state misperception, and (4) idiopathic insomnia.

A. The predominant complaint is difficulty initiating or maintaining sleep, or nonrestorative sleep, for at least one month.

B. The sleep disturbance (or associated daytime fatigue) causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.

C. The sleep disturbance does not occur exclusively during the course of narcolepsy, breathing-related sleep disorder, circadian rhythm sleep disorder, or a parasomnia.

D. The disturbance does not occur exclusively during the course of another mental disorder (e.g., major depressive disorder, generalized anxiety disorder, a delirium).

E. The disturbance is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition.

Table 21-5 DSM-IV Diagnostic Criteria for Primary Insomnia

Ms. W. was a 41-year-old, divorced, white female who presented with a 2 ½ year complaint of sleeplessness. She had some difficulty falling asleep (30- to 45-minute sleep-onset latency) and awakened every hour or two after sleep onset. These awakenings might last 15 minutes to several hours, and she estimated having approximately 4.5 hours of sleep on an average night. She rarely takes daytime naps notwithstanding feeling tired and edgy. The patient described her sleep problem with the following words. “It seems like I never get into a deep sleep. I have never been a heavy sleeper, but now the slightest noise wakes me up. Sometimes I have a hard time getting my mind to shut down.” She viewed the bedroom as an unpleasant place of sleeplessness and stated: “I tried staying at a friend's house where it is quiet, but then I couldn't sleep because of the silence.”

At times, Ms. W. was unsure whether she was asleep or awake. She had a history of clock watching (to time her wakefulness) but stopped doing this when she realized it was contributing to the problem. Reportedly the insomnia is unrelated to seasonal changes, menstrual cycle, or time-zone translocation. Her basic sleep hygiene was good. Appetite and libido were unchanged. She denied mood disturbance, except for being quite frustrated and concerned about sleeplessness and its effect on her work. Her work involved sitting at a microscope 6 hours of a 9-hour working day and meticulously documenting her findings. Her final output hadn't suffered, but she had to “double check” for accuracy.

She described herself as a worrier and a type-A personality. The patient did not know how to relax. For example, on vacation she continually worried about things that could go wrong and would not even begin to unwind until she had arrived at the destination, checked in, and unpacked. Even then, she was unable to relax.

Medical history was unremarkable except for tonsillectomy (age 16 years), migraine headaches (current), and diet-controlled hypercholesterolemia. She took naproxen (Naprosyn) as needed for headache. She did not currently drink caffeinated beverages, smoke tobacco, or drink alcoholic beverages. She did not use recreational drugs.

The problem with insomnia began after relocation to a new city and place of employment. She attributed her insomnia to the noisy neighborhood in which she lived. She first sought treatment 18 months earlier. Her family-practice physician diagnosed depression and fluoxetine therapy was started. This made her “climb the walls.” Antihistamines were tried next with similar results. She was then switched to low-dose trazodone (Desyrel) (for sleep) and developed nausea. After these medical interventions, she sought medical care elsewhere. Zolpidem (Ambien), 5 mg was prescribed, but it made her feel drugged, and upon discontinuation she had withdrawal effects. Another family-practice physician diagnosed “nonspecific anxiety disorder” and began treating her with buspirone (BuSpar); an experience she described as “having an alien try to climb out of my skin.” Buspirone treatment was discontinued. Paroxetine (Paxil) was tried for 8 weeks with no effect. Finally, a psychiatrist was consulted, who diagnosed adult attention-deficit disorder (without hyperactivity) and suggested treatment with methylphenidate. At this point, the patient was convinced that a stimulant would not help her insomnia and demanded referral to a sleep disorders center.

Discussion Ms W.'s symptoms fell into the broad category of an insomnia, and the symptoms began after having moved from one city to another. Environmental sleep disorder (noise) and adjustment sleep disorder (new job, city, apartment) were likely initial diagnoses. However, a more-chronic, endogenous problem became operative. What was it? Ms. W. was a “worrier” and meticulous but did not meet diagnostic criteria for personality or anxiety disorders. Dyssomnia associated with mood disorder should be considered in any patient with sleep maintenance problems and early morning awakening insomnia. However, this patient did not have other significant signs of depression. Unfortunately, many patients are misdiagnosed with depression or “masked depression” on the sole basis of an insomnia complaint and are unsuccessfully treated with antidepressant medication. Ms. W.'s job demands long hours with focused concentration. Her job performance had been superior for many years notwithstanding insomnia. Thus, a diagnosis of attention-deficit disorder is unlikely. Idiopathic insomnia implies a childhood complaint, which Ms. W. denied.

The likely working diagnosis was psychophysiological insomnia. She may have some sleep state misperception (sometimes unclear whether she was awake or asleep), but this cannot adequately account for the constellation of symptoms. An initial treatment plan should include further documentation of the sleep pattern using a sleep log. Behavioral treatments would likely benefit this patient. Medications with sedative effects are sometimes useful during initial treatment of psychophysiological insomnia. However, thus far in this patient they have done more harm than good. She is likely to be a challenging patient to treat.

INADEQUATE SLEEP HYGIENE DSM-IV indicates that inadequate sleep hygiene sometimes falls within the primary insomnia classification, depending on the specific sleep hygiene factor involved. ICSD defines inadequate sleep hygiene as “a sleep disorder due to the performance of daily living activities that are inconsistent with the maintenance of good quality sleep and full daytime alertness.” Many behaviors can interfere with sleep and may do so by increasing nervous system arousal proximal to bedtime or by altering circadian rhythms. Treatment should focus on only two or three problem areas at a time. Overwhelming the patient with too many lifestyle changes or a complex regimen seldom succeeds. Some general dos and don'ts are instructive.

PSYCHOPHYSIOLOGICAL INSOMNIA The patient with psychophysiological insomnia has developed a conditioned arousal associated with attempts to sleep. Objects associated with sleep (e.g., the bed, the bedroom) likewise become conditioned stimuli that evoke insomnia. Thus, psychophysiological insomnia is sometimes called conditioned insomnia. Psychophysiological insomnia often occurs in combination with other causes of insomnia, including episodes of stress and anxiety disorders, delayed sleep phase syndrome, and hypnotic drug use and withdrawal. In contrast to the insomnia in patients with psychiatric disorders, daytime adaptation is generally good. Work and relationships are satisfying; however, extreme tiredness can exist. Other features include (1) excessive worry about not being able to sleep; (2) trying too hard to sleep; (3) rumination, inability to clear one's mind while trying to sleep; (4) increased muscle tension when attempting to sleep; (5) other somatic manifestations of anxiety; (6) being able to sleep better away from one's own bedroom; and (7) being able to fall asleep when not trying (e.g., watching TV). The sleep complaint becomes fixed over time. Interestingly, many patients with psychophysiological insomnia sleep well in the laboratory.

Treatment can be difficult. Sleeping pills should be used only sparingly and at the lowest effective dose. Sleeplessness during withdrawal from long-term sleeping pill use typically exacerbates the problem. Stimulus control therapy is recommended to break the conditioning and improve the association between going to bed and being able to fall asleep. Because many patients with psychophysiological insomnia have developed poor sleep habits, improving sleep hygiene is usually beneficial. If muscle tension and rumination at bedtime are prominent features, relaxation therapy is a useful ancillary treatment.

SLEEP STATE MISPERCEPTION For most persons, loss of awareness is a cognitive marker for sleep-onset; however, under some circumstances mental and biological processes become discoordinated. Sleep state misperception is diagnosed when a patient complains of difficulty initiating or maintaining sleep and no objective evidence of sleep disruption is found. For example, a patient sleeping in the laboratory reports taking more than an hour to fall asleep, awakening more than 30 times, and sleeping less than 2 hours the entire night. By contrast, the polysomnogram shows sleep onset occurring within 15 minutes, few awakenings, a 90 percent sleep efficiency, and total sleep time exceeding 7 hours. Sleep state misperception can occur in individuals who are apparently free from psychopathology or represent a somatic delusion or hypochondriasis. Some patients with sleep state misperception have obsessional features concerning somatic functions. Short-term sleep state misperception can occur during periods of stress, and some clinicians believe it can result from latent or ineffectively treated anxiety or depressive disorders. Cognitive relabeling, diffusing the worry about being unable to sleep, or both can help. Interestingly, anxiolytics can profoundly reduce the perception of sleeplessness without remarkably changing sleep physiologically.

IDIOPATHIC INSOMNIA Idiopathic insomnia typically starts early in life, sometimes at birth, and continues throughout life. As the name implies, its cause is unknown; suspected causes include neurochemical imbalance in the brainstem reticular formation, impaired regulation of brainstem sleep generators (e.g., raphe nuclei, locus coeruleus), or basal forebrain dysfunction. Treatment is difficult, but improved sleep hygiene, relaxation therapy, and judicious use of hypnotic medicines are reportedly helpful.

PHARMACOLOGICAL TREATMENTS FOR INSOMNIA For many years, benzodiazepines were far and away the most commonly prescribed sedative-hypnotic medications for treating insomnia. Chloral hydrate (Noctec) is sometimes useful because adverse effects limit its abuse potential. The imidazopyridine-derivative zolbidem (Ambien) has rapidly replaced benzodiazepines. Also, a variety of over-the-counter sleep aids are available. Nonprescription formulas include sedating antihistamines, protein precursors, and other substances. L-Tryptophan was popular and readily available at health food stores until an outbreak of eosinophilia several years ago. Melatonin is now the leader in self-administered food additives believed by some to alleviate sleeplessness.

Regardless of their pharmacology, long-term use of sleeping pills is not generally recommended. Since prescription medicines are rigorously tested in clinical trials, they hold an advantage over the virtually untested over-the-counter remedies. Nonetheless, most premarket study of prescription hypnotics involves short-, not long-term, use. Issues surrounding safety and efficacy of self-administered sedating drugs should not be underestimated. Most sleep-promoting substances work best with time-limited use to overcome short-term insomnia. When properly used, sedative-hypnotics can provide immediate and adequate relief from sleeplessness. One

should prescribe the lowest possible dose for the shortest period of time. As a rule the authors recommend that patients take the medication for two or three nights consecutively and repeat this sequence no more than two or three times. If this does not suffice, a review of the diagnostic possibilities is in order, and other treatments should be considered. Continued long-term dosing can perpetuate the sleep problem. The clinician should realize that these medicines can mask underlying disorders that need to be addressed.

NONPHARMACOLOGICAL TREATMENTS FOR INSOMNIA Some dyssomnias result directly from extrinsic factors. Often problems arise from environmental conditions or maladaptive habits. *Sleep hygiene* refers to basic rules designed to provide circumstances and conditions conducive to sleep. They include a list of things to incorporate into a good sleep ritual and things to avoid.

Universal Sleep Hygiene Sleep-enhancing directives include maintaining a regular sleep-wake schedule; keeping a steady program of daily exercise; insulating the bedroom against excessive noise, light, cold, and heat; eating a light snack before retiring if hungry; and setting time aside to relax before getting into bed. The final item on this list is especially important. It attempts to keep a person from developing conditioned arousal associated with the bed and bedroom. Developing a pattern of emotional arousal upon getting into bed can lay the foundation for psychophysiological insomnia.

Sleep hygiene don'ts are designed to prevent behaviors or relieve conditions incompatible with restful sleep. They include avoiding strenuous exercise immediately before bedtime; abstaining from alcohol, tobacco, and caffeinated beverages in the evening (or early in the day if one is especially sensitive); not watching television in bed; and not chronically taking sleeping pills. Finally, the bed must not become an emotional or sexual battlefield on which couples work through or act out their anger.

Often a few simple alterations in a patient's habits or sleep environment can be effective. The clinician, however, needs to spend time during the interview to review both the patient's routine and its irregularity. In some respects, the essence of insomnia is its variability. The day-to-day changes in behavior and the changing severity of sleeplessness can obscure the factors responsible for the problem. A carefully explained program of sleep hygiene, with follow-up, represents a fairly inexpensive but effective intervention. Furthermore, improving sleep habits can enhance sleep even when the major cause of insomnia is physical.

Stimulus Control Therapy Stimulus control therapy aims to break the cycle of problems commonly associated with difficulty initiating sleep. By attempting to undo conditioning that undermines sleep, stimulus control therapy helps reduce both primary and reactive factors involved in insomnia. The rules attempt to enhance stimulus cues for sleeping and diminish associations with sleeplessness. The instructions are simple, but they must be followed consistently.

The first rule is to go to bed only when sleepy, to maximize success. Second, use the bed only for sleeping. While in bed do not watch television, do not read, do not eat, and do not talk on the telephone. Rule three instructs the patient not to lie in bed and become frustrated if unable to sleep. After a few minutes (do not watch the clock), get up, go to another room, and do something nonarousing until sleepiness returns. The goal is to associate the bed with rapid sleep onset. Rule three should be repeated as often as needed. The last two instructions, four and five, attempt to enhance the mechanisms underlying the circadian and sleep-wake cycles. Rule four is to awaken at the same time every morning, regardless of bedtime, total sleep time, or day of week. The final rule is to totally avoid napping. Stimulus control therapy does work; results may not appear during the first few weeks or month. If rules are continually practiced, the bouts of insomnia lessen in both frequency and severity.

Sleep Restriction Therapy Restricting time in bed can help consolidate sleep for patients who find themselves lying awake in bed unable to sleep. If the patient reports sleeping only 5 hours of a scheduled 8 hours in bed, reduce the time in bed. It is advised, however, not to reduce bedtime to less than 4 hours per night and to warn the patient about the hazards of daytime sleepiness. Sleep at other times during the day must be avoided, except that elderly adults may take a 30-minute nap. The clinician then monitors sleep efficiency (time asleep as a percentage of the time in bed). When patient-estimated sleep efficiency reaches 85 percent (averaged over five nights), time in bed is increased by 15 minutes. Sleep restriction therapy produces a gradual and steady decline in nocturnal wakefulness.

Relaxation Therapy and Biofeedback The most important aspect of relaxation therapy is that it be performed properly and overlearned. Self-hypnosis, progressive relaxation, and deep breathing exercises are all effective if they produce relaxation. Patients require careful and adequate training, simply giving them an instruction tape is not especially helpful. Biofeedback, to provide stimulus cues for physiological markers of relaxation can increase self-awareness. Techniques should be mastered during the day for several weeks before application to the sleep problem. Relaxation techniques readily lend themselves to being combined with sleep hygiene and stimulus control therapies.

Primary Hypersomnia Primary hypersomnia is diagnosed when a patient complains of excessive sleepiness that cannot be accounted for by another primary sleep disorder, mental disorder, medical disorder, or substance use. Unless the hypersomnia is a recurrent type, symptoms must persist for at least 1 month. The most common causes of debilitating sleepiness to exclude are sleep-disordered breathing, insufficient sleep, depression-related sleepiness, and narcolepsy. DSM-IV diagnostic criteria are shown in Table 21-6. ICSD diagnostic entities are well matched to DSM-IV primary hypersomnia, with minor differences in nomenclature; that is, primary hypersomnia is called idiopathic hypersomnia and recurrent type primary hypersomnia is called recurrent hypersomnia. ICSD divides these into distinct nosological classifications because presentation, afflicted group, and presumed etiology differ considerably.

A. The predominant complaint is excessive sleepiness for at least one month (or less if recurrent) as evidenced by either prolonged sleep episodes or daytime sleep episodes that occur almost daily.
B. The excessive sleepiness causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
C. The excessive sleepiness is not better accounted for by insomnia and does not occur exclusively during the course of another sleep disorder (e.g., narcolepsy, breathing-related sleep disorder, circadian rhythm sleep disorder, or a parasomnia) and cannot be accounted for by an inadequate amount of sleep.
D. The disturbance does not occur exclusively during the course of another mental disorder.
E. The disturbance is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition.

Specify if:
Recurrent: if there are periods of excessive sleepiness that last at least three days occurring several times a year for at least two years.

Table 21-6 DSM-IV Diagnostic Criteria for Primary Hypersomnia

Mr. J. was a 28-year-old, single, African-American male with an approximately 10-year history of fatigue and sleepiness in the daytime. He began to recognize the daytime sleepiness as a problem in his freshman year of college, when he would fall asleep in class or in the dormitory. He admitted that his sleep-wake schedule was disrupted during college due to taking long naps and then having to stay up until 1:00 or 2:00 AM to complete his studies. His grades and social life suffered and he described himself as depressed, isolated, and hopeless about his planned future as a certified public accountant (CPA).

As a child, Mr. J. said he slept “normally.” In high school he felt best with 10 hours of sleep per night and was able to function well in the daytime. Mr. J. denied abuse of alcohol or drugs. He did not use tobacco and drank about 8 to 10 cups of coffee per day. Family history was negative for known sleep or psychiatric disorders. Physical examination findings were noncontributory except for a body mass index of 0.29. Routine laboratory test results were normal, including thyroid-stimulating hormone (TSH).

Mr. J.'s excessive sleepiness continued, notwithstanding some improved sleep hygiene. Improvements included more-consistent bedtime, trying not to nap, and a torturous month-long trial without caffeine. He remained dysphoric and discouraged about his future, blaming his chronic sleepiness as the continuing impediment to his life plans. “I'm just tired of being tired,” he said.

When last seen his bedtime was between 10:00 and 10:30 PM; his wake-up alarm was set for 6:30 AM. He oversleeps at least once a week on work days and sleeps from 10:30 PM until 10:00 AM on weekends in an attempt to “catch up.” He has difficulty awakening and feels unrefreshed or mildly refreshed. By drinking six to eight cups of coffee in the morning, he can usually avoid dozing during the morning. Luckily, he is an independent CPA and can schedule client appointments during this relatively alert time. After lunch he routinely falls asleep at the computer while working. He sleeps for 20 to 60 minutes and is usually awakened by his secretary. He then drinks another two cups of coffee and continues with his work. Unexpected napping can also occur later in the afternoon or evening, and he has “nodded off” while driving. He sleeps alone; however, he has been told that he snores loudly. He does not awaken gasping or choking. He denied hypnagogic hallucinations and sleep paralysis but thought he might feel weak after the rare occasions when he participated in a heated argument.

Discussion Mr. J. had one of the hypersomnias. Most consistent with his history are obstructive sleep apnea syndrome, idiopathic hypersomnia, sleep deprivation in a long sleeper, dyssomnia associated with mood disorder, and narcolepsy. The ancillary symptoms of narcolepsy are absent, with the possible exception of cataplexy. When cataplexy occurs clearly, the diagnosis of narcolepsy is strongly indicated. However, Mr. J.'s possible infrequent weakness during heated arguments is equivocal for cataplexy. His persistent desire for a 10-hour sleep period would be unusual for a patient with narcolepsy.

A long sleeper (ICSD proposed sleep disorder) or an individual with idiopathic hypersomnia requires prolonged sleep periods and may awaken groggy as does Mr. J. The main differentiating feature is that whenever consistently given a chance to have a full nightly sleep period (usually 10 to 12 hours), the long sleeper does not experience excessive daytime sleepiness. Furthermore, patients with idiopathic hypersomnia may display associated autonomic nervous system dysfunction or polysomnographic evidence of elevated slow wave sleep percentage.

Sleepiness associated with a low-grade chronic depression may be difficult to differentiate from other causes of hypersomnia. Polysomnography, psychiatric interview, and psychometric testing can be helpful. Mr. J. related his dysphoria to sleepiness and not vice versa; nonetheless, dyssomnia associated with mood disorder should be considered.

Obstructive sleep apnea syndrome is a strong possibly. Mr. J. is overweight (BMI = 0.29) and snores loudly. Many patients are unaware of gasping or choking for breath. Often, family members witness cessation of breathing during sleep and urge patients to seek treatment. However, Mr. J. lives and sleeps alone.

Polysomnography is recommended for patients suspected of obstructive sleep apnea syndrome, narcolepsy, or idiopathic hypersomnia. These disorders usually require lifelong treatment and have significant morbidity and mortality if untreated.

IDIOPATHIC HYPERSOMNIA Patients with idiopathic hypersomnia have prolonged periods of well-consolidated but nonrestorative sleep. They may sleep more than 10 to 14 hours and awaken unrefreshed. Long naps (1 to 2 hours) are common and likewise not refreshing. Patients may awaken disoriented and groggy (sleep drunkeness). Electroencephalographic studies confirm long sleep periods and sometimes reveal increased slow wave sleep. Otherwise, the sleep pattern is essentially normal (Fig. 21-1). Notwithstanding prolonged nocturnal sleep, patients with idiopathic hypersomnia usually fall asleep rapidly if allowed to nap. Typical age of onset is 15 to 30 years, and once established, it is a lifelong problem.

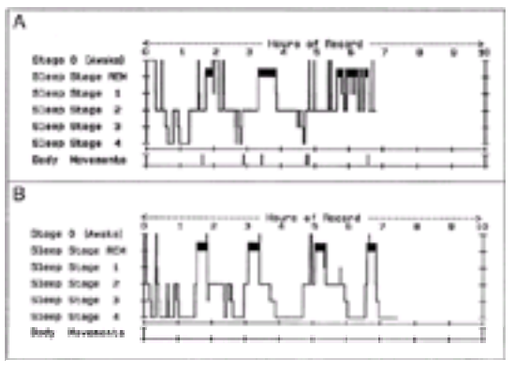

FIGURE 21-1 Sleep stage histograms comparing a normal sleep profile with that of a patient with idiopathic hypersomnia. **A** illustrates the sleep pattern recorded in a healthy young adult. His sleep was interrupted several times by awakening associated with other concurrent laboratory procedures; however, all parameters were within normal limits. **B** depicts the sleep pattern of a patient with severe daytime sleepiness. The patient did not have narcolepsy or apnea. In the laboratory, sleep onset was rapid, sleep continued virtually without interruption, and he was extremely difficult to arouse. This recording was terminated after 7.5 hours to begin daytime testing; however, the patient's sleep revealed little indication of progressing toward a lighter state. In contrast to the normal sleep pattern, slow wave sleep duration was elevated and it continued to be alternated with REM sleep throughout the night.

Although unproved, this dyssomnia is presumed to be of central nervous system origin. Three subgroupings have been proposed. Subgroup 1 includes individuals who have other affected family members, are HLA Cw2 positive, and often have autonomic nervous system dysfunctions. Subgroup 2 is composed of patients with a history of viral infection such as Guillain-Barré syndrome, mononucleosis, and atypical viral pneumonia. The final subgroup are those in whom the dyssomnia is neither postviral or familial.

Response to treatment is usually poor. Psychostimulants are used palliatively to alleviate sleepiness. Pemoline (Cylert), mazindol (Sanonex), methylphenidate (Ritalin), and dextroamphetamine (Dexedrine) are used. Cardiovascular complications must be monitored when using stimulants. Behavioral approaches are recommended but usually provide limited benefit.

RECURRENT HYPERSOMNIA Recurrent hypersomnia, sometimes called periodic hypersomnia, involves episodic bouts of extreme sleepiness that can occur weeks or months apart. Underlying hypothalamic or limbic dysregulation is the suspected cause. Kleine-Levin syndrome, the best-recognized recurrent hypersomnia, predominantly afflicts males in early adolescence, but can occur later in life and in females. In its classic form, the recurrent episodes are associated with extreme sleepiness (18-to-20–hour sleep periods), voracious eating, hypersexuality, and disinhibition (e.g., aggression). A monosymptomatic hypersomnolent form can occur.

Narcolepsy

DIAGNOSIS Narcolepsy is a syndrome of unknown origin characterized by irresistible urges to sleep. These sleep attacks typically occur two to six times a day and last 10 to 20 minutes. They may occur at inappropriate times (e.g., while eating, talking, or driving, and during sex). Narcolepsy may occur in as many as 10 to 60

individuals per 10,000, making it nearly as common as multiple sclerosis. Symptoms typically appear in the second decade of life, but narcolepsy may remain undiagnosed for many years. It is usually associated with one or more of the following symptoms: cataplexy, sleep paralysis, and hypnagogic hallucinations. DSM-IV and ICSD agree on terminology and classification of narcolepsy. Table 21-7 lists DSM-IV diagnostic criteria.

A. Irresistible attacks of refreshing sleep that occur daily over at least three months.

B. The presence of one or both of the following:
   (1) cataplexy (i.e., brief episodes of sudden bilateral loss of muscle tone, most often in association with intense emotion)
   (2) recurrent intrusions of elements of rapid eye movement (REM) sleep into the transition between sleep and wakefulness, as manifested by either hypnopompic or hypnagogic hallucinations or sleep paralysis at the beginning or end of sleep episodes

C. The disturbance is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or another general medical condition.

Reprinted with permission from *DSM-IV: Diagnostic and Statistical Manual of Mental Disorders*, ed 4. © American Psychiatric Association, Washington, DC, 1994.

Table 21-7 DSM-IV Diagnostic Criteria for Narcolepsy

Patients with narcolepsy frequently have sleep-onset rapid eye movement (REM) sleep both at night and during daytime naps (Fig. 21-2). The multiple sleep latency test (MSLT) takes advantage of this phenomenon and is used diagnostically. MSLT provides a patient four to six nap opportunities at 2-hour intervals throughout the day. The latency to sleep on each nap opportunity is used to quantify sleepiness and the presence of sleep-onset REM sleep on two or more naps helps confirm narcolepsy.

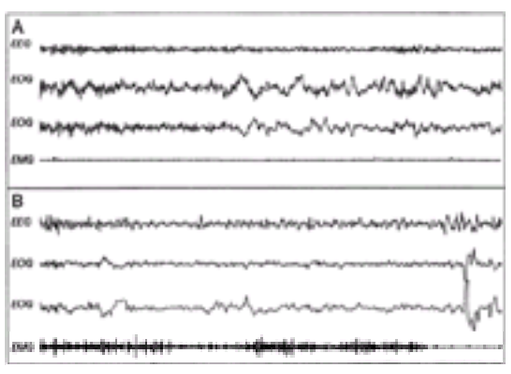

FIGURE 21-2 Polygraphic tracing comparing normal sleep onset with that of a patient with narcolepsy. Each panel illustrates approximately 30 seconds of polysomnographic recording beginning with relaxed wakefulness. **A** (normal sleep progression) shows reduced EEG alpha activity and development of slow rolling eye movements. **B** shows the normally expected abatement of EEG alpha activity associated with increased theta activity and the appearance of a few slow eye movements. However, within 25 seconds (*far right of figure*) a swift loss of muscle tone occurs accompanied by rapid eye movements. This appearance of sleep-onset REM sleep characterizes narcolepsy and is part of the diagnostic criteria.

Cataplexy ranges from transient weakness in the knees to total loss of skeletal tone during full consciousness. It is triggered by emotion (e.g., anger, laughter) and usually lasts for several seconds to several minutes. The patient may fall to the floor and be unable to speak. *Sleep paralysis* is similar to the muscle atonia that normally occurs during REM sleep; however, the patient is awake and unable to move. It also lasts seconds to minutes and can be extremely frightening to the patient. Reportedly, attacks may be terminated by patients vigorously moving their eyes or by someone touching or speaking to them. *Hypnagogic hallucinations* are vivid dreams that occur while the patient is still conscious; they are associated with sleep-onset REM sleep periods.

TREATMENT There is no cure for narcolepsy, but symptom management is possible. Psychostimulants are commonly used to manage sleepiness. REM sleep–suppressing drugs (e.g., many antidepressants) are used to treat cataplexy. Although drug therapy is the treatment of choice, the overall therapeutic approach should include scheduled naps, lifestyle adjustment, psychological counseling, drug holidays to reduce tolerance, and careful monitoring of drug refills, general health, and cardiac status.

Stimulants are used to treat hypersomnolence associated with some sleep disorders. Stimulants are appropriate for certain intrinsic dyssomnias (e.g., narcolepsy, idiopathic hypersomnia, and recurrent hypersomnia) and for some dyssomnias associated with sleep-related medical conditions (e.g., sleep-related asthma). However, they should not be used to treat the sleepiness associated with other intrinsic dyssomnias (e.g., obstructive sleep apnea) or most of the extrinsic dyssomnias. Taking stimulants to overcome daytime sleepiness caused by inadequate sleep hygiene or hypnotic-dependent sleep disorder constitutes drug abuse.

Sleepiness associated with narcolepsy can usually be managed with pemoline or methylphenidate. Sometimes however, amphetamines are needed to combat sleepiness. There is also a newly approved drug called modafinil (Provigil) that is somnolytic without some of the adverse side effects of traditional psychostimulants. Nonetheless, the clinician must monitor usage and be sensitive to developing tolerance. Drug-free holidays may help forestall loss of efficacy. Scheduled naps, as stimulant dose replacements, are also thought to help.

Sleep specialists often prescribe tricyclic drugs or selective serotonin reuptake inhibitors (SSRIs) to reduce cataplexy. This approach capitalizes on the REM sleep–suppressant properties of these drugs. Since cataplexy is presumably an intrusion of REM sleep phenomena into the awake state, the rationale is clear. Many reports indicate that imipramine (Tofranil), protriptyline (Vivactil), and flouxetine (Prozac) are quite effective in reducing or eliminating cataplexy.

Breathing-Related Sleep Disorders

DIAGNOSIS The DSM-IV classification breathing-related sleep disorders includes three ICSD nosological entities: obstructive sleep apnea, (OSA), central sleep apnea, and central alveolar hypoventilation. Sleep apnea is the cessation of breathing during sleep for 10 seconds or more. Episodes of apneas can be associated with oxygen desaturation and cardiac arrhythmias. An apnea episode may be obstructive, central, or mixed. In *obstructive apnea*, breathing stops because of airway blockage; however, respiratory effort continues (Fig. 21-3). *Central apnea* is an absence of breathing due to lack of respiratory effort. In *mixed apnea*, the episode usually starts as a central apnea and then progresses to an obstructive apnea. OSA is most common. In the past few years, upper airway resistance syndrome has gained wide recognition as another form of sleep-disordered breathing. This syndrome is marked by snoring, hypersomnia, and other symptoms associated with OSA; however, cessations of breathing are minimal. A patient with loud disruptive snoring, no apneic events, and neither daytime sleepiness nor insomnia is classified as having the parasomnia primary snoring (Fig. 21-4). Table 21-8 lists DSM-IV criteria for breathing-related sleep disorders.

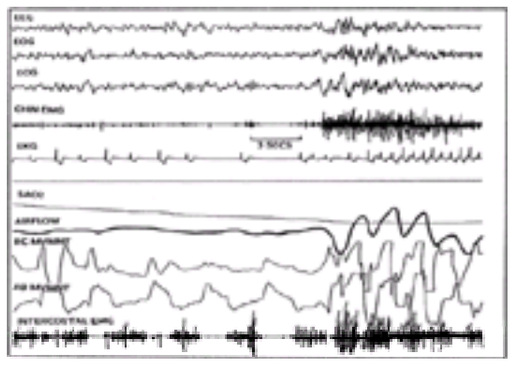

FIGURE 21-3 Obstructive sleep apnea. The airflow tracing shows cessation of breathing while the ribcage (*RC*) and abdominal (*AB*) movement (*MVMNT*) tracings clearly reveal respiratory effort. *Intercostal EMG* also confirms attempt to breathe. As blood oxygen saturation (*SAO2*) plummets, electrocardiographic abnormalities appear. Sinus pauses of more than 3 second's duration occurred. When the patient finally aroused (note *EEG-EOG–Chin EMG*), breathing resumed and was associated with a rebound tachycardia. This patient, whose chief complaint was excessive daytime sleepiness, had more than 200 similar events during a single night of sleep.

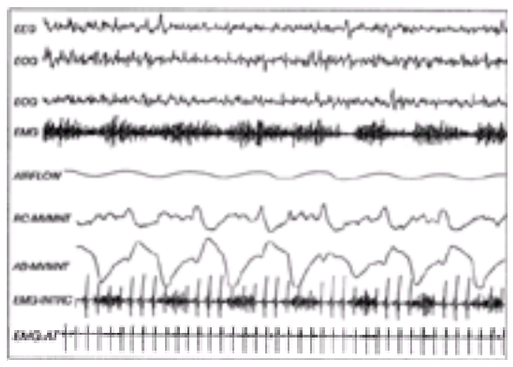

FIGURE 21-4 Polygraphic tracing of snoring. For comparison with obstructive sleep apnea, this tracing shows continual reduction in, but no cessation of, airflow. The movement (*MVMNT*) pattern of the ribcage (*RC*) and abdomen (*AB*), as well as the firing pattern of intercostal muscles (*EMG-INTRC*) indicates considerable respiratory effort, presumably caused by increased airway resistance. Vibration artifact of submental *EMG (fourth tracing from top)* in cadence with breathing reflects the patient's loud, disruptive snoring.

A. Sleep disruption, leading to excessive sleepiness or insomnia, that is judged to be due to a sleep-related breathing condition (e.g., obstructive or central sleep apnea syndrome or central alveolar hypoventilation syndrome).

B. The disturbance is not better accounted for by another mental disorder and is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or another general medical condition (other than a breathing-related disorder).

Coding note: Also code sleep-related breathing disorder on Axis II.

Table 21-8 DSM-IV Diagnostic Criteria for Breathing-Related Sleep Disorder

Predisposing factors for OSA include being male, reaching middle-age, obesity, micrognathia, retrognathia, nasopharyngeal abnormalities, hypothyroidism, and acromegaly. Clinical features associated with obstructive sleep apnea include profound hypersomnolence, snoring, obesity, restless sleep, nocturnal awakenings with choking or gasping for breath, morning dry mouth, morning headaches, and heavy nocturnal sweating. Patients may also have hypertension, erectile dysfunction, depression, nocturia, polycythemia, and memory impairment as a result of OSA.

TREATMENT A wide assortment of treatments are available for OSA. Weight loss helps many patients. However, because losing weight and keeping it off is difficult and unreliably achieved, the prudent clinician should recommend weight loss but rely on other therapies. Because OSA has pathophysiological and potentially life-threatening consequences, aggressive treatments evolved soon after its recognition. The earliest surgical intervention was designed to create a patent airway; thus, in the late 1970s tracheostomies were performed on individuals with severe apnea. There is little doubt that tracheostomy succeeds in creating an airway. Although no longer the preferred treatment, it remains a standard against which newer, more refined therapies are judged.

Second-generation surgical approaches to treating OSA attempt to correct airway obstructions and malformations. Early studies of uvuolopalatopharyngoplasty (UPPP) suggested that soft palate modification effectively relieved most sleep apnea. More-recent follow-up results are less impressive. Approximately 30 to 50 percent of patients with sleep apnea benefit from UPPP. These patients are those with oropharyngeal obstruction; thus, careful attention to selection criteria undoubtedly improves outcome. However, if obstruction occurs in the posterior airway space, maxillomandibular surgery may be appropriate. In retrognathic patients or in patients with cephalometrics revealing compromised posterior airway space moving the jaw forward can achieve impressive normalization of breathing during sleep.

Currently, nasal continuous positive airway pressure is the preferred treatment for sleep-disordered breathing. The continuous positive airway pressure apparatus consists of a fan-driven blower, a nasal mask, and tubing connecting the two. It provides constant pressure through the nasal mask to offset oropharyngeal collapse produced by inspiratory negative thoracic pressure. In this manner it acts as a pneumatic splint, thereby maintaining the airway. When the pressure is properly titrated, even the most severe sleep apnea can be alleviated (Fig. 21-5). Results are usually dramatic. Continuous positive airway pressure therapy is the standard treatment for patients with sleep apnea who can tolerate sleeping with the machine. Its success has made surgical intervention a secondary option, unless patient acceptance issues arise. Sometimes a patient has difficulty exhaling against the constant column of air. In these cases, a variant that allows differential setting of inspiratory and expiratory pressures can be used.

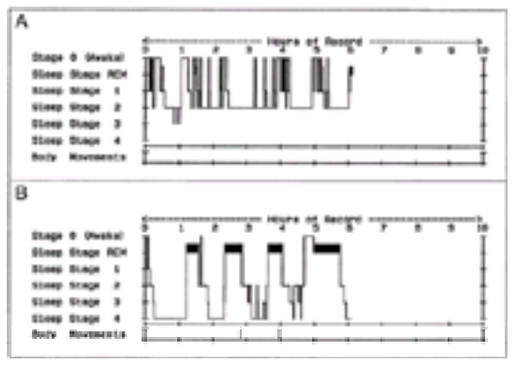

FIGURE 21-5 Sleep stage histogram illustrating the immediate, dramatic improvement in sleep architecture produced by treating obstructive sleep apnea with continuous positive airway pressure (CPAP) therapy. **A** illustrates the abnormal sleep pattern on a night when the patient had more than 200 episodes of obstructive sleep apnea. Sleep is disturbed by frequent awakenings while REM and slow wave (stages 3 and 4) sleep are nearly absent. **B** shows data from the same patient being treated with CPAP on the next night. Normalization of sleep continuity with a massive rebound in REM and slow wave sleep is evident.

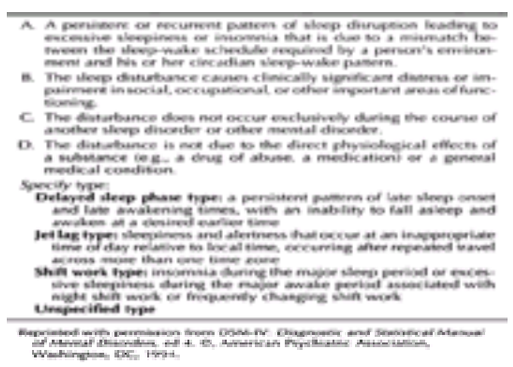
A variety of oral appliances have also been used to treat snoring and, in some cases, sleep apnea. The general approach is to either manipulate the position of the mandible or retain the tongue or both. In some cases, these devices may improve airway patency and reduce soft palate vibration. Improved sleep-related breathing does not always reach satisfactory levels; therefore, follow-up sleep studies are needed.

In some patients, sleep-disordered breathing occurs only in the supine position. In such situations, preventing patients from sleeping on their backs may produce beneficial results. Tennis balls sewn onto or placed into pockets on the back of the nightshirt may accomplish this goal.

Finally, several drug therapies have been tried for sleep-disordered breathing. Methoxyprogesterone acetate was originally thought to be helpful but is seldom used now. Likewise, tricyclic drugs sometimes decrease apnea severity by reducing REM sleep, the stage of sleep in which obstructive apnea is usually more frequent. Recently, theophylline (Theo-Dur) was reported to reduce apnea, but further study is needed.

Circadian Rhythm Sleep Disorder Circadian rhythm sleep disorders share the same basic underlying cause, that is, a desynchrony between an individual's internal circadian biological clock and the desired sleep-wake cycle. The circadian [*circa* + *di*(*em*), approximately 1 day] pacemaker usually cycles once every 24 to 26 hours. It is located in the suprachiasmatic nucleus, whose firing patterns oscillate with a pronounced daily rhythm that correlates with the core body temperature cycle. Suprachiasmatic nucleus firing patterns persists even in isole preparations. Mismatched circadian clock and desired schedules can arise from improper phase relationships between the two, travel across time zones, or dysfunctions in the basic biological rhythm. DSM-IV diagnostic criteria (Table 21-9) provide coding-specific subtype coding for three of six ICSD circadian rhythm sleep disorders. The additional three specific ICSD entities can be coded as circadian rhythm sleep disorder unspecified type.



A. A persistent or recurrent pattern of sleep disruption leading to excessive sleepiness or insomnia that is due to a mismatch between the sleep-wake schedule required by a person's environment and his or her circadian sleep-wake pattern.
B. The sleep disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
C. The disturbance does not occur exclusively during the course of another sleep disorder or other mental disorder.
D. The disturbance is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition.

Specify type:

Delayed sleep phase type: a persistent pattern of late sleep onset and late awakening times, with an inability to fall asleep and awaken at a desired earlier time

Jet lag type: sleepiness and alertness that occur at an inappropriate time of day relative to local time, occurring after repeated travel across more than one time zone

Shift work type: insomnia during the major sleep period or excessive sleepiness during the major awake period associated with night shift work or frequently changing shift work

Unspecified type

Table 21-9 DSM-IV Diagnostic Criteria for Circadian Rhythm Sleep Disorder

DELAYED SLEEP PHASE SYNDROME In an optimal schedule, hours in bed must coincide with the sleepy phase of the circadian cycle. When the circadian sleep-wake cycle lags behind the desired schedule, mismatch is called *phase delay*. Individuals with a delayed sleep phase are more alert in the evening and early nighttime, stay up later, and are more tired in the morning. These individuals are characterized as “owls.” When this desynchrony is severe enough to interfere with daily living, delayed sleep phase syndrome is diagnosed.

ADVANCE SLEEP PHASE SYNDROME In contrast to delayed sleep phase, individuals with *advanced sleep phase* are drowsy in the evening, want to retire to bed earlier, awaken earlier, and are more alert in the early morning. Individuals with this pattern of advanced sleep phase are sometimes called “larks.” When severity impairs routine daily function, the diagnosis is made.

TIME ZONE CHANGE (JET LAG) SYNDROME With the advent of high-speed air travel, an induced desynchrony between circadian and environmental clocks became possible. Thus, the term *jet lag* came into use. Individuals who rapidly cross many time zones induce either a circadian phase advance or a phase delay, depending upon the direction of travel. Typically, a one or two time zone translocation does not produce a sustained problem; however, overseas travel can be marked by great difficulty in adjusting one's sleep-wake routine. Individuals who frequently travel for business can find themselves quite impaired at the time they need to make important decisions. Owls experience greater difficulty adjusting to eastward travel because resynchronization requires phase advance. Similarly, larks theoretically have more difficulty with westward travel. The number of time zones crossed is a critical factor. Normally, healthy individuals can easily adapt to one to two time zone changes per day; therefore, natural adjustment to an 8-hour translocation may take 4 or more days.

SHIFT WORK SLEEP DISORDER Many service industries require 24-hour operation (e.g., transportation, health care). Similarly, as our cultures became more capital intensive, mining and manufacturing became around-the-clock enterprises. The number of individuals doing shift work has been increasing steadily for decades. Shiftworkers commonly suffer from insomnia, excessive sleepiness, or both.

Some individuals require only a short time to adjust to a shift change while others have great difficulty. Frequent shift rotation adds to the problems. Also, to meet social demands, shiftworkers often adopt a nonshifted sleep-wake schedule on weekends and holidays. The result can be severe sleep deprivation and a circadian rhythm poorly entrained to the sleep-wake schedule. The natural low point in the normal sleep-wake rhythm occurs at approximately 3:00 to 5:00 AM, precisely the time frame during which transportation and industrial accidents commonly occur as a direct consequence of sleepiness.

NON-24-HOUR SLEEP-WAKE DISORDER As the name implies, the non-24-hour sleep-wake disorder occurs when the circadian sleep-wake pacemaker has a cycle length longer or shorter than 24 hours and does not reset each morning. The normal cycle length is 24 to 26 hours; however, resynchronization occurs daily. Problems occur incrementally when internal and environmental clocks become more and more out of phase. If the circadian clock's period exceeds 24 hours and does not reset each day, the patient experiences progressively worsening sleep-onset insomnia and daytime sleepiness. Sleep problems peak when circadian and environmental clocks are 12 hours out of phase and then begin to lessen, emulating progressively resolving advanced sleep phase. Eventually the clocks correlate and sleep-wake cycle is normal for a few days, after which the insomnia-hypersomnia cycle begins again. For this reason, non-24-hour sleep-wake disorder has been called periodic insomnia and periodic excessive sleepiness.

IRREGULAR SLEEP-WAKE PATTERN In contrast to the non-24-hour sleep-wake disorder, the irregular sleep-wake pattern occurs when the circadian sleep-wake rhythm is absent or pathologically diminished. The sleep-wake pattern is temporally disorganized, and the timing of sleep and wakefulness is unpredictable. Individuals with this condition have a normal amount of sleep during a 24-hour period; however, it is fragmented into three or more episodes that occur irregularly. Long daytime naps and inappropriate nocturnal wakefulness occur. Except in unusual circumstances, activities of daily life are significantly impaired.

TREATING CIRCADIAN RHYTHM SLEEP DISORDERS Under normal circumstances the internal circadian pacemaker is reset each day by bright light, social cues, stimulants, and activity. When these factors fail to reentrain the circadian rhythm, circadian sleep disorders occur.

Chronotherapy is one technique used to reset the biological clock. It involves progressive phase delays until the circadian oscillator is synchronized with the desired sleep-wake schedule. When individuals are deprived of environmental time cues and told to sleep when they feel sleepy, the typical “day” lasts 25 to 26 hours. This “free running” rhythm suggests that most young and middle-aged adults naturally phase delay. Thus, phase delaying each night by 2 or 3 hours is thought to be easier than phase advancing because it capitalizes on a natural tendency. Halting the phase delay at the appropriate moment and maintaining the desired synchrony can be

a challenge. The patient also has to cope with an odd sleep-wake schedule for the better part of a week during therapy (which can interfere with school or work). For these reasons, light therapy has overshadowed chronotherapy in the past few years.

Recent advances in sleep disorders research indicate that exposing an individual to bright lights (more than 10,000 lux) can alter the endogenous biological rhythm. With precise timing of bright light exposure, the biological clock can be reset. Exposure to light modifies the setpoint of the biological clock. Using core body temperature as a physiological marker, bright lights presented before the temperature nadir produce sleep phase delay. By contrast, light exposure after temperature nadir evokes phase advance. The closer one presents light to the point of inflection (temperature nadir), the more robust the response in altering the cycle. Thus, early morning bright light therapy can be used to phase advance individuals with delayed sleep phase syndrome. Similarly, exposure to bright light in the evening can help patients with advanced sleep phase syndrome.

Light therapy is now being used to reset the circadian rhythm of shift workers, astronauts, and individuals experiencing jet lag. Results are encouraging. However, additional outcome studies are needed to assess the efficacy of this mode of therapy properly. Using bright light exposure to overcome circadian desynchrony represents an exciting frontier in sleep research.

Recent experimental use of melatonin to treat circadian rhythm disorders in the blind has proved successful. Researchers posit that melatonin secretion acts as the biological substrate for the internal circadian oscillator; thus its use may generalize beyond treatment of the blind. Its efficacy in managing sighted patients with disturbed sleep-wake cycles is controversial and currently under investigation.

Dyssomnia Not Otherwise Specified Nine ICSD diagnostic classifications fall within DSM-IV's dyssomia not otherwise specified (Table 21-10) grouping: insufficient sleep syndrome, restless legs syndrome, periodic limb movement disorder, altitude insomnia, environmental sleep disorder, adjustment sleep disorder, limit-setting sleep disorder, sleep-onset association disorder, and nocturnal eating (or drinking) syndrome.

The dyssomnia not otherwise specified category is for insomnias, hypersomnias, or circadian rhythm disturbances that do not meet criteria for any specific dyssomnia. Examples include:

1. Complaints of clinically significant insomnia or hypersomnia that are attributable to environmental factors (e.g., noise, light, frequent interruptions).
2. Excessive sleepiness that is attributable to ongoing sleep deprivation.
3. Idiopathic "restless legs syndrome": uncomfortable sensations (e.g., discomfort, crawling sensations, or restlessness) that lead to an intense urge to move the legs. Typically, the sensations begin in the evening before sleep onset and are temporarily relieved by moving the legs or walking, only to begin again when the legs are immobile. The sensations can delay sleep onset or awaken the individual from sleep.
4. Idiopathic periodic limb movements ("nocturnal myoclonus"): repeated low-amplitude brief limb jerks, particularly in the lower extremities. These movements begin near sleep onset and decrease during stage 3 or 4 non-rapid eye movement (NREM) and rapid eye movement (REM) sleep. Movements usually occur rhythmically every 20–60 seconds, leading to repeated, brief arousals. Individuals are typically unaware of the actual movements, but may complain of insomnia, frequent awakenings, or daytime sleepiness if the number of movements is very large.
5. Situations in which the clinician has concluded that a dyssomnia is present but is unable to determine whether it is primary, due to a general medical condition, or substance induced.

Table 21-10 DSM-IV Diagnostic Criteria for Dyssomnia Not Otherwise Specified

INSUFFICIENT SLEEP SYNDROME Insufficient sleep syndrome results from an individual's disregard for the sleep-wake schedule. It is usually subclinical and occurs in much of the population. Medical help is generally not sought because individuals are aware of the cause of their sleepiness. Insufficient sleep, however, is an insidious killer and is related to many vehicular and industrial accidents (Fig. 21-6). When an individual becomes progressively more and more sleep deprived, eventual payment for the sleep debt will be exacted. Excessive sleepiness associated with insufficient sleep can be unmasked by a heavy meal, low-dose alcohol ingestion, a warm room, or sedentary activity. Although caffeinated beverages are commonly self-administered, sleep extension is the appropriate intervention for insufficient sleep syndrome.

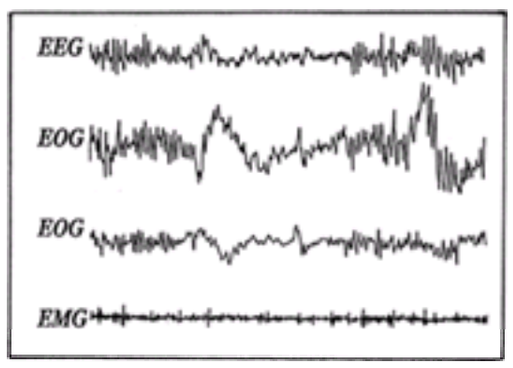

FIGURE 21-6 Microsleep. Figure illustrating one of the most dangerous consequences of excessive daytime sleepiness, regardless of its origin. This patient lapses into a 3-second episode of microsleep (*center one third of figure*) during performance of a vigilance test. Note the transient disappearance of EEG alpha activity and the appearance of slow rolling eye movements. Awakening occurs spontaneously, thereby aborting the microsleep's progression into frank sleep. At normal highway speed, an individual lapsing into microsleep of this duration, would travel almost the length of a football field.

RESTLESS LEGS SYNDROME Restless legs syndrome, once known as Ekbom's syndrome, is characterized by the irresistible urge to move one's legs while trying to fall asleep. Patients often report crawling feelings in their lower legs. A patient may describe the sensation as feeling as if worms or ants are crawling inside the legs (Fig. 21-7). The legs may feel tired or heavy. Moving the legs or walking around are often the only ways to alleviate the discomfort. Patients may feel compelled to pace, swing their legs from the side of the bed, or march in place. Restless legs can be caused by pregnancy, anemia, renal failure and other metabolic disorders. Various drug treatments have been used in restless legs syndrome including benzodiazepines, opiates, and dopaminergic medications (levodopa [Larodopa], bromocryptine [Parlodel], pergolide [Permax], pramipexole [Mirapex], and ropinirole).

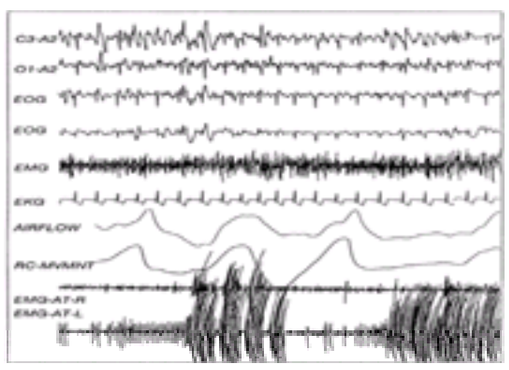

FIGURE 21-7 Restless legs syndrome. This patient presented with complaints of uncomfortable, crawling sensations in the legs when trying to fall asleep. Patients commonly report an urge to move the leg to dispel the sensation. This figure shows a bilateral pattern of leg EMG activity; however, the discharge is more pronounced in the left anterior tibialis (*EMG-AT-L*) than the right (*EMG-AT-R*). This pattern continued for more than an hour as the patient attempted to fall asleep; note that the sharp activity in central and occipital EEG (*C3-A2* and *O1-A2*, respectively) and *EOG* is an EKG artifact and not an EEG abnormality.

PERIODIC LIMB MOVEMENT DISORDER Periodic limb movement disorder (formerly called nocturnal myoclonus) involves brief, stereotypic, repetitive, nonepileptiform movements of the limbs, usually the legs. It occurs primarily in non-REM (NREM) sleep and involves an extension of the big toe. Partial flexion of the ankle, knee, and hip may also occur. These movements range from 0.5 to 5 seconds in duration and occur every 20 to 40 seconds (Fig. 21-8). The leg movements are frequently associated with brief arousals from sleep and as a result can (but do not always) disturb sleep architecture. The prevalence of periodic limb movement disorder increases with aging. It can occur in association with folate deficiency, renal disease, anemia, and the use of antidepressant drugs. Patients with periodic limb movement disorder often complain of nonrefreshing sleep.

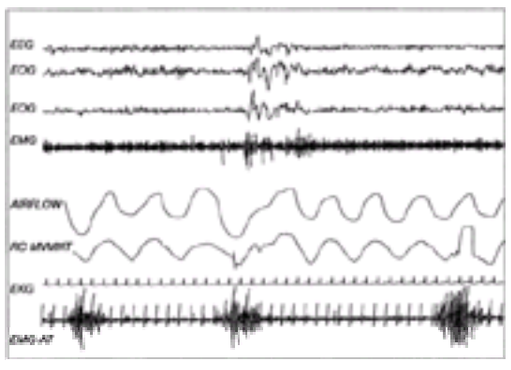

FIGURE 21-8 Periodic leg movements during sleep. This figure of approximately 33 seconds of recording clearly shows a pattern of muscle activity in anterior tibialis (*EMG-AT*). The activity pattern repeats at regular intervals and sometimes produces transient arousals (note *EEG-EOG-EMG*) after movement at center of figure. This patient, whose chief complaint was nonrefreshing sleep with sleep maintenance insomnia, had more than 250 such leg movements during each night he slept in the laboratory.

Benzodiazepines are commonly used to treat periodic limb movement disorder. Clonazepam (Klonopin) and other benzodiazepine hypnotics may not eliminate the leg movements; however, they blunt arousal. Thus, the patient sleeps through the muscle activity, and sleep does not become fragmented by repeated, brief arousals. However, the development of tolerance to the medication remains problematic. Many sleep medicine practitioners now prescribe a low dose L-dopa for periodic limb movement disorder. Unlike sedative-hypnotics, L-dopa suppresses the leg or limb muscle activity rather than merely preventing arousals and awakenings. While the drug is sometimes effective, some clinicians are hesitant to use L-dopa. Potential hazards include unbalancing the dopamine system (risking emergence of Parkinson-like movement disorders) and the chance of dopamine-induced psychosis. However, 5-year follow-up data indicate that these problems are minimal.

ALTITUDE INSOMNIA Altitude insomnia, also known as acute mountain sickness, results from breathing problems associated with sleep-onset ventilatory drive setpoint change. Because oxygen concentration declines as altitude increases, insomnia worsens with increasing elevation. The patient may awaken realizing the apneic event. A person who experiences symptoms usually does so after having been at an altitude of 4000 meters for 72 hours or more. Acetazolamide (Diamox) can increase ventilatory drive via medullary pH receptors and thereby decrease hypoxemia.

ENVIRONMENTAL SLEEP DISORDER Noise, heat, cold, light, bedpartner activity, or perceived danger can induce an environmental sleep disorder. The insomnia or hypersomnia is directly caused by the disturbing environmental factor. Onset, course, and termination of the problem are correlated with introduction, presence, and removal of the specific factor or factors. Thus, treatment involves identifying and removing the environmental irritant.

ADJUSTMENT SLEEP DISORDER Adjustment sleep disorder is a transient insomnia caused by acute stress, conflict, or change. Course is usually brief, lasting a week to several months. The problem quickly resolves when the stressor is removed. The first day of school, an impending examination, a divorce or separation, sudden financial crisis, a change in employment, or the death of a loved one may briefly disturb the normal sleep-wake pattern.

LIMIT-SETTING SLEEP DISORDER Limit-setting sleep disorder occurs when a child takes advantage of an inadequately enforced bedtime schedule. *Childhood insomnia*, as it is sometimes called, involves a child refusing to, or delaying, going to bed when the caregiver stipulates. If unresolved when children reach adolescence and can set their own schedule, inadequate sleep hygiene, insufficient sleep syndrome, or irregular sleep-wake pattern may become the problem. Delay strategies used by children include getting up to use the bathroom, requests for another drink, wanting another bedtime story, or complaints of hunger. Sometimes children claim that they are afraid of the dark, monsters under the bed, or some other factitious creation. The well-intentioned parent may be manipulated out of emotional concern. The problem often begins when the child can climb out of the crib or has been moved to a bed. The caregivers' knowledge and ability to properly set limits is critical; therefore, psychoeducational therapy leads to effective treatment.

SLEEP-ONSET ASSOCIATION DISORDER The sleep-onset association disorder is another dyssomnia characteristic of childhood; however, adult cases have been reported. The classic example involves insomnia when children do not have their pillow, blanket, or teddy bear. Children may become conditioned to fall asleep only while being nursed, rocked, or held. When the sleep-onset associated objects, conditions, or both are not met, sleep is disturbed. It is a problem for the caregiver who is the conditioned sleep-onset queue. In adults, sleep may be disturbed if the television, radio, or night light is not on. Between ages 6 months and 3 years, an estimated 15 to 20 percent of children have this disorder; however, prevalence declines precipitously thereafter.

NOCTURNAL EATING SYNDROME Nocturnal eating (or drinking) syndrome involves an inability to get back to sleep after awakening unless the individual has something to eat or drink. After eating or drinking, return to sleep is normal. Nocturnal eating (drinking) syndrome predominantly affects infants and children; however, adult cases have been reported. The problem is believed to be mainly associated with breast nursing, bottle feeding, or both. An infant will drink 4 to 8 ounces or more at each awakening. Wetting is also excessive. Infants should be able to sleep through the night without feeding after age 6 months; however, afflicted individuals cannot. The syndrome invariably leads to the caregiver becoming sleep deprived. In adults, eating may become obsessional, and patients may be unaware of their behavior. As with sleepwalking, complex behaviors are possible; however, they are not always executed properly. Weight gain may become a problem.

Parasomnias The parasomnias are behavioral or physiological phenomena that occur during, or are potentiated by, sleep. The frequency of occurrence of the different parasomnias vary from nightly to a few times per year. This can make it difficult to document the disorder in a sleep laboratory. When a patient with a parasomnia complaint (e.g., nightmares) is studied polysomnographically and no evidence is found, one should not necessarily conclude that the patient is not afflicted by the suspected sleep disorder.

Ms. R. was a 20-year-old white woman who was referred with symptoms of talking, mumbling, and crying out during sleep. At least twice per week she screamed in her sleep. She was bothered by excessive sleepiness and falling asleep inappropriately (e.g., during a conversation). When inactive, she was tired and sleepy, even after a full 8-hour night of sleep. However, she had energy when motivated and led a vigorous life. Once, she awakened outside of her apartment and her roommate had to let her back in because she had locked herself out. She did not recall the sleepwalking episode or other nocturnal wanderings but remembered yelling sometimes. From the history, crying seemed to occur in light sleep but she rarely recalled any sleep-related thoughts or dreams. She had a history of occasional nightmares and bruxism. The patient used an oral appliance to protect her teeth. Leg kicking and mild snoring without gasping or choking were noted. The patient also complained of leg kicking during sleep. Her sleep-wake schedule was irregular and she averaged between 5 and 7 hours of sleep per night. She occasionally awakened with a headache in the morning.

Previous health history included a hospitalization for febrile convulsions during infancy, ophthamological surgery for strabismus during childhood, and tonsillectomy as a teenager. Health was otherwise excellent. The patient did not smoke tobacco or drink alcohol.

Discussion By history Ms. R. had one or more of the parasomnias. Sleep talking alone does not require a sleep study, but this patient had nocturnal wanderings. Polysomnography, with clinical EEG were indicated to rule out unrecognized nocturnal seizure disorder or other organic factors inducing sleep walking. Sleepwalking is common and not necessarily considered abnormal in young children; however, in the adult it is rare and merits careful evaluation. Ms. R.'s excessive daytime sleepiness was likely due to insufficient sleep (5 to 7 hours per night) and possibly parasomnia-related disruption. Interestingly, many parasomnias are exacerbated by sleep deprivation as is nocturnal seizure disorder.

Sleep studies were performed using comprehensive, attended, laboratory polysomnography. Prior to the overnight study, a clinical EEG was performed, which did not reveal any significant abnormal EEG activity during baseline, photic stimulation, or hyperventilation. An extended EEG montage was used during the sleep study. Overall sleep quality was within the normal range. Sleep efficiency was 96 percent, and latency to sleep was 1 minute. REM sleep percentage was elevated (31 percent), and latency to REM sleep was below normal (57 minutes). Slow wave sleep was normal in percentage, but EEG delta activity was of very high amplitude. The overall macroarchitectural sleep pattern suggested rebound from sleep deprivation.

By contrast, sleep microarchitecture contained many abnormal features. We observed high amplitude paroxysmal EEG bursts. Excessively prolonged sleep spindles were noted and rhythmic K complexes were observed. There was one arousal out of slow wave sleep with rhythmic EEG discharges alternating with sharp waves. Sharps and spikes occurred several times; however the focus was difficult to localize (possibly right temporal lobe). She exhibited frequent body movements and full body jerks, most of which occurred during NREM sleep. Episodes of moaning during slow wave sleep and laughing during stage 2 sleep were followed by high-amplitude theta bursts and REM sleep. Frequent movements and arousals from REM sleep were observed but no REM-related spikes or sharp waves. Seizurelike EEG activity was noted during the night and occurred predominantly during slow wave sleep. However, the patient did not attempt to sleepwalk. Sharp wave and spike activity increased during the final 45 minutes of the sleep study.

The patient did not have any sleep-related breathing impairment and SaO_2 nadir was 90 percent. She had no periodic limb movements during sleep and polygraphic features associated with restless legs syndrome were absent.

Nightmare Disorder Nightmares are anxiety-provoking dreams that occur during REM sleep. Nightmares are typically complex dreams that become increasingly frightening toward the end, culminating in an awakening. Because they are REM sleep–related dreams, terminated with arousal the individual remembers the content. There is seldom any talking, screaming, walking, or striking out associated with nightmares (in contrast to sleep terrors). Table 21-11 lists criteria used to diagnose nightmare disorder.

A. Repeated awakenings from the major sleep period or naps with detailed recall of extended and extremely frightening dreams, usually involving threats to survival, security, or self-esteem. The awakenings generally occur during the second half of the sleep period.
B. On awakening from the frightening dreams, the person rapidly becomes oriented and alert (in contrast to the confusion and disorientation seen in sleep terror disorder and some forms of epilepsy).
C. The dream experience, or the sleep disturbance resulting from the awakening, causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
D. The nightmares do not occur exclusively during the course of another mental disorder (e.g., a delirium, posttraumatic stress disorder) and are not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition.

Table 21-11 DSM-IV Diagnostic Criteria for Nightmare Disorder

Ten to 50 percent of children between ages 3 and 6 years may experience occasional nightmares. Approximately 1 percent of adults have nightmares weekly or more often. There may be nightmares in children younger than age 3 years, but unless the child is linguistically fluent, the reported frightening dream may be misunderstood by parents. A subgroup of patients continues to have nightmares after childhood into adolescence and adulthood. In general, however, the prevalence of nightmares decreases with advancing age. Patients with schizotypal personality, borderline personality disorder, and schizophrenia are predisposed to nightmares. However, 50 percent of patients suffering from nightmares have no diagnosable psychiatric illness. One theory is that nightmares are more common in individuals with "thin boundaries" who are open, trusting, and who often have creative or artistic inclinations. Levoclapa b-adrenergic receptor antagonists antagonists), and withdrawal from REM-suppressant medications can induce or potentiate nightmares. Severity ranges from occasional (less than 1 episode per week) nightmares with no evidence of psychosocial impairment to nightly episodes that severely impair daily functioning.

Sleep Terror Disorder ICSD defines the essential feature of sleep terrors as "characterized by a sudden arousal from slow wave sleep with a piercing scream or cry, accompanied by autonomic and behavioral manifestations of intense fear" (Fig. 21-9). Table 21-12 lists DSM-IV criteria for diagnosing sleep terror disorder.

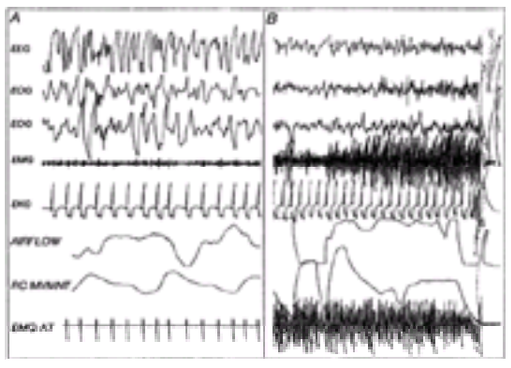

FIGURE 21-9 Polysomnogram of a sleep terror. **A** shows approximately 14 seconds of tracing occurring immediately before the sleep terror. Prominent EEG slow wave activity and other characteristics of stage 4 sleep are seen. **B** shows the awakening, accompanied by tachycardia and movement. EEG activity is ambiguous, and the patient eventually disconnected his electrodes as he thrashed about in bed (visible at *far right of figure*). Although the patient was screaming and greatly agitated, no dreaming was reported. In the morning, he had little recollection of anything having occurred during the night.

A. Recurrent episodes of abrupt awakening from sleep, usually occurring during the first third of the major sleep episode and beginning with a panicky scream.
B. Intense fear and signs of autonomic arousal, such as tachycardia, rapid breathing, and sweating, during each episode.
C. Relative unresponsiveness to efforts of others to comfort the person during the episode.
D. No detailed dream is recalled and there is amnesia for the episode.
E. The episodes cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
F. The disturbance is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition.

Table 21-12 DSM-IV Diagnostic Criteria for Sleep Terror Disorder

Sleep terrors occurs in 3 percent of children and less than 1 percent of adults. Children have higher percentages of slow wave sleep than adults. Furthermore, during childhood, delta electroencephalographic (EEG) activity has greater amplitude and is more hypersynchronous. Sleep terrors are not dreamlike, and usually there is no memory of what provoked the fright; however, fragments of brief, vivid images may be reported. After awakening from a sleep terror, a patient is usually unresponsive to stimuli, confused, or disoriented. Vocalizations are usually incoherent. Fever, sleep deprivation, and central nervous system (CNS) depressants may potentiate sleep terror episodes. A familiar pattern has been reported. In children, sleep terrors are not associated with psychopathology; however, adults often have a positive psychiatric history. Severity ranges from less than once per month to almost nightly occurrence (with injury to patient or others).

Sleepwalking Disorder Sleepwalking is another parasomnia associated with slow wave sleep. In its most extreme form, it consists of ambulating during sleep (somnambulism). However, many types of complex behaviors arising from slow wave sleep are typically regarded as sleepwalking. Because it arises from slow wave sleep, the patient is difficult to awaken, confused, and amnestic. Sleep talking may also occur. Table 21-13 lists DSM-IV criteria for diagnosing sleepwalking disorder.

A. Repeated episodes of rising from bed during sleep and walking about, usually occurring during the first third of the major sleep episode.
B. While sleepwalking, the person has a blank, staring face, is relatively unresponsive to the efforts of others to communicate with him or her, and can be awakened only with great difficulty.
C. On awakening (either from the sleepwalking episode or the next morning), the person has amnesia for the episode.
D. Within several minutes after awakening from the sleepwalking episode, there is no impairment of mental activity or behavior (although there may initially be a short period of confusion or disorientation).
E. The sleepwalking causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
F. The disturbance is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition.

Table 21-13 DSM-IV Diagnostic Criteria for Sleepwalking Disorder

There have been rare reports of homicide and attempted suicide associated with sleepwalking. The person attempting to awaken the sleepwalker may be violently attacked. Common in children, sleepwalking peaks between ages 4 and 8 years and usually disappears after adolescence. Severity ranges from less than once per month without injury to nightly episodes associated with physical injury to patient and others.

Parasomnia Not Otherwise Specified Of the 23 specific parasomnias described in ICSD, DSM-IV lists 3. In DSM-IV, all parasomnias other than nightmares, sleep terrors, and sleepwalking should be coded as parasomnia not otherwise specified (Table 21-14).

The parasomnia not otherwise specified category is for disturbances that are characterized by abnormal behavioral or physiological events during sleep or sleep-wake transitions, but that do not meet criteria for a more specific parasomnia. Examples include:
1. REM sleep behavior disorder: motor activity, often of a violent nature, that arises during rapid eye movement (REM) sleep. Unlike sleepwalking, these episodes tend to occur later in the night and are associated with vivid dream recall.
2. Sleep paralysis: an inability to perform voluntary movement during the transition between wakefulness and sleep. The episodes may occur at sleep onset (hypnagogic) or with awakening (hypnopompic). The episodes are usually associated with extreme anxiety and in some cases, fear of impending death. Sleep paralysis occurs commonly as an ancillary symptom of narcolepsy and, in such cases, should not be coded separately.
3. Situations in which the clinician has concluded that a parasomnia is present but is unable to determine whether it is primary, due to a general medical condition, or substance induced.

Table 21-14 DSM-IV Diagnostic Criteria for Parasomnia Not Otherwise Specified

CONFUSIONAL AROUSALS Confusional arousals are the mildest form of the three slow wave sleep–related parasomnias and are common in young children. Typically the child partially awakens from slow wave sleep and sits up. The episodes are marked by confusion, but usually the child lies back down and resumes sleep. Confusional arousals, sleepwalking, and sleep terrors are thought to lie on a continuum.

RHYTHMIC MOVEMENT DISORDER Rhythmic movement disorder has also been called jactatio capitis nocturna, headbanging, headrolling, bodyrocking, and rhythmie du sommeil. It is marked by repetitive, rhythmic movements usually involving the head and neck. It usually occurs at the transition from wakefulness to sleep and may continue during light sleep. Most infants bodyrock. Some think bodyrocking develops from the soothing effect of vestibular stimulation. If the rhythmic movement persists into childhood and involves headbanging, the risk of injury increases. Male to female ratio is 4 to 1. Severity ranges from less than one episode weekly to nightly episodes that produce injury.

SLEEP STARTS Sleep starts are sudden, brief muscle contractions that occur at the transition between wakefulness and sleep in 60 to 70 percent of adults. The contractions commonly involve the legs; however, sometimes there is movement in the arms and head. This “hypnic jerk,” as it is sometimes called, is usually benign. The sleep start, however, can interfere with the ability to fall asleep and may be accompanied by sensations of falling, a hallucinated flash of light, or a loud crackling sound. In severe cases the sleep start produces profound sleep-onset insomnia.

SLEEP TALKING As the name implies, sleep talking in classic form involves unconscious speech during sleep. It is seldom recognized in an individual unless it annoys the bedpartner. It can be induced by fever, stress, or conversing with the sleeper. Somniloquy may accompany sleep terror, sleepwalking, confusional arousals, OSA, and REM sleep behavior disorder.

NOCTURNAL LEG CRAMPS Nocturnal leg cramps are much like wakeful leg cramps. They usually affect the calf and are painful muscle contractions. The pain awakens the sleeper and thereby disrupts sleep. Metabolic disorders, diabetes, and pregnancy are known precipitators. Why some individuals have repeated leg cramps during sleep and not during the day is not known.

SLEEP PARALYSIS Usually occurring at sleep onset or upon awakening, sleep paralysis is an inability to move volitionally. Although it is usually very frightening, it is actually a normal REM sleep feature briefly intruding into wakefulness. Eye movements and respiratory movements are unaffected. In predisposed individuals, sleep deprivation and stress may exacerbate sleep paralysis. The paralysis may last from 1 to several minutes, and voluntary rapid eye movements or being touched by someone often terminates the episode.

IMPAIRED SLEEP-RELATED PENILE ERECTIONS Under normal circumstances, sleep-related erections occur several times nightly in association with REM sleep in all healthy, potent men (Fig. 21-10). Impaired sleep-related erections in the presence of normal REM sleep usually result from organic impotence. The impairment can range from reduction to absence of sleep erections. Sleep-related erections are of particular interest because they are one of the few reliable, objective techniques for differentially diagnosing impotence as psychogenic or organic.

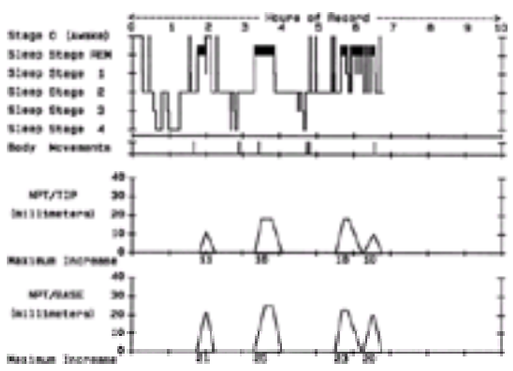

FIGURE 21-10 Nocturnal penile tumescence (NPT). Figure illustrating the pattern of sleep-related penile erections that occur in all normal potent men. Recordings of penile circumference increase from the flaccid stage are made at the penile base and coronal sulcus (tip). Numbers under each episode indicate the maximum circumference increase in millimeters. Under normal circumstances, tumescence episodes are closely linked to REM sleep. Sleep erection monitoring provides useful diagnostic information for parceling out organic and psychogenic components of impotence in men reporting erectile failure.

SLEEP-RELATED PAINFUL ERECTIONS Although sleep-related painful erections are rare, afflicted men have severely disturbed sleep. In its severe form, a patient may awaken with erectile pain from every REM sleep episode, thereby producing profound REM sleep deprivation, hypersomnia, and impaired daytime function. Daytime erections are normal and not painful. Why the normal, naturally occurring REM sleep–related erections are associated with pain is unknown, and to the authors' knowledge no reliable treatment has been described.

REM SLEEP–RELATED SINUS ARREST The rare condition, REM sleep–related sinus arrest is usually discovered incidentally during nocturnal cardiac monitoring for another purpose. REM sleep–related sinus arrest was originally described in otherwise healthy volunteer subjects participating in a sleep research project. There may be vague complaints of chest pain, tightness, or intermittent palpitations during the daytime and lightheadedness, faintness, and blurred vision upon awakening from sleep. Sinus pauses can range from 3 to 9 seconds and may occur in clusters. When clinically warranted, REM sleep–related sinus arrest is managed by implantation of a pacemaker.

REM SLEEP BEHAVIOR DISORDER REM sleep behavior disorder involves dream enactment permitted by a failure of mechanisms that normally produce REM sleep atonia. A patient may run, leap, kick, or punch as part of fictive dream action. These behaviors frequently injure the sleeper, the bed partner, or both. In some cases injuries are serious, involving lacerations, ecchymoses, and fractures. In animals, presumed REM sleep behavior disorder (RBD) can be produced with bilateral peri–locus coeruleus lesions. In humans, there is a suggestion that this parasomnia may result from diffuse hemispheric lesions, bilateral thalamic abnormalities, or brainstem lesions. It may also be prodromal for Parkinson's disease. Clonazepam has been used successfully to treat REM sleep behavior disorder.

SLEEP BRUXISM Sleep-related teeth grinding can produce periodontal damage and the sound can disturb the bed partner (Fig. 21-11). Facial pain and headaches may also result from teeth grinding or clenching. An estimated 85 to 90 percent of the population brux at some time during their lives, but it is clinically significant in only about 5 percent of people. Sleep bruxism may occur during stage 2 or REM sleep or both. Some evidence indicates that REM sleep–related bruxism may be more disruptive and destructive. Oral appliances are commonly used to treat destructive sleep bruxism. Teeth guards, while they do not prevent bruxism, can help protect the teeth from the consequences of destructive grinding. However, such devices usually do not alleviate mandibular pain produced by clenching or grinding the teeth.

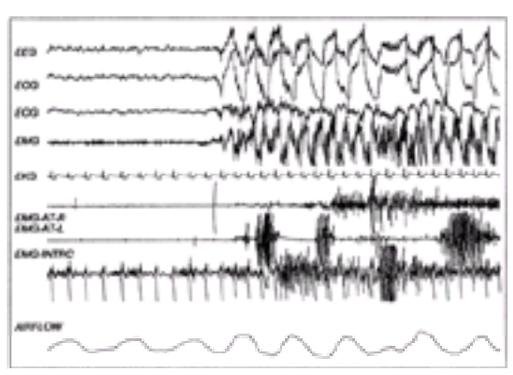

FIGURE 21-11 Sleep-related bruxism. Figure showing approximately 25 seconds of tracing was obtained from a patient during an episode of bruxism. Bruxism can occur during any stage of sleep or wakefulness. The interference pattern of EEG-EOG-EMG channels is typical and reflects the rhythmic jaw movement and grinding of the teeth. This patient had many such episodes, and some caused awakening. Readily observable tooth damage and jaw pain were noted.

SLEEP ENURESIS Nocturnal bed wetting is subclassified as primary (since infancy) or secondary (relapse after toilet training was complete). Prior to toilet training, sleep enuresis is normal and resolves spontaneously before age 6 years. Prevalence progressively declines (30, 10, 5, 3, and 1 to 3 percent at ages 4, 6, 10, 12, and 18 years, respectively). A single recessive gene is suspected in cases of primary enuresis. Embarrassment is usually the most serious direct problem; however, it may lead to psychosocial impairment without appropriate intervention. Properly administered behavioral treatments have good success. Fluid restriction and avoiding caffeine in the evening is helpful. Drug therapy with vasopressin (DDAVP) is also used, especially in older children. Severity can range from less than weekly episodes to nightly wettings associated with severe shame and guilt.

SLEEP-RELATED ABNORMAL SWALLOWING SYNDROME Individuals with sleep-related abnormal swallowing syndrome have inadequate swallowing of saliva during sleep, which produces aspiration. The resulting coughing and choking lead to arousals from sleep and should not be confused with sleep apnea. Sedating medications exacerbate sleep-related abnormal swallowing syndrome.

NOCTURNAL PAROXYSMAL DYSTONIA ICSD describes nocturnal paroxysmal dystonia as characterized by “repeated dystonic or dyskinetic (ballistic, choreo-athetoid) episodes that are stereotyped and occur during NREM sleep.” Additionally, the patient may vocalize. Episodes can last from 15 to 60 seconds to an hour. After its description in ICSD as a parasomnia, nocturnal paroxysmal dystonia was found to result from seizure activity. Carbamazepine (Tegretol) at low dosage usually produces therapeutic benefit.

SUDDEN UNEXPLAINED NOCTURNAL DEATH SYNDROME Sudden unexplained nocturnal death syndrome is sudden death during sleep in apparently healthy

young adults. Laotian, Kampuchean, and Vietnamese male refugees are particularly affected. Asian languages contain descriptors for this syndrome (e.g., *non-laita* [sleep death], *gangungut* [to arise and moan], *pokkuri* [sudden death]). No anatomical pathology has been found to account for the deaths.

PRIMARY SNORING Primary snoring consists of loud snoring in the absence of recurrent apnea or hypopnea episodes. The sound may cause the bedpartner to sleep in another room. To be classified as primary snoring, the individual must not be suffering from excessive sleepiness. Snoring may become louder when the individual sleeps supine or during REM sleep. A variety of oral appliances have been developed to decrease snoring.

INFANT SLEEP APNEA Infant sleep apnea is sleep-disordered breathing that occurs in infants. Breathing events may be central or obstructive sleep apnea episodes. Some data suggest that these "apparently life-threatening events" represent "near-miss" sudden infant death syndrome (SIDS). The episodes may be associated with color change (pallor or cyanosis), noisy breathing during leep, significant oxygen desaturations, bradycardia, or sustained hypoventilation. Complications include need for cardiopulmonary resuscitation, right heart failure, chronic hypercapnia, and severe hypoxia.

CONGENITAL CENTRAL HYPOVENTILATION SYNDROME Sometimes called "Ondine's curse," congenital central hypoventilation syndrome cannot be explained by primary pulmonary disease or ventilatory muscle weakness. The sleep-related hypoventilation results from a failure in automatic control of breathing. Although present at birth, congenital central hypoventilation syndrome may initially be unrecognized. In severe forms, treatment requires continual ventilatory support.

SUDDEN INFANT DEATH SYNDROME Often referred to as "crib death," 80 percent of SIDS occurs when the infants were presumed to be sleeping. No postmortem results explain pathophysiology. There is debate whether the SIDS originates with cardiac or respiratory failure. Ninety percent of deaths occur before age 6 months, with a peak rate at 10 to 12 weeks. Incidence is estimated as 1 to 2 per 1000 live births. Factors increasing SIDS risk include teenage pregnancy, short interpregnancy interval, smoking during pregnancy, preterm birth, lower socioeconomic status, and a familial pattern. The psychological effect of SIDS on the surviving family is usually devastating. Divorce, social isolation, relocation, and depression are common without professional counseling or support group help.

BENIGN NEONATAL SLEEP MYOCLONUS Benign neonatal sleep myoclonus is characterized by asynchronous jerking of limbs and trunk during quiet sleep in neonates. This benign, apparently rare, parasomnia usually begins within the first week of life and may last for a few days or several months. No treatment is recommended.

SLEEP DISORDERS RELATED TO ANOTHER MENTAL DISORDER

Among patients seen at sleep disorders centers with a chief complaint of insomnia, an underlying psychiatric disorder is the most common cause (35 percent). Half (50 percent) of these patients have major depressive disorders. Table 21-15 provides DSM-IV diagnostic criteria for insomnia related to another mental disorder.

A. The predominant complaint is difficulty initiating or maintaining sleep, or nonrestorative sleep, for at least one month that is associated with daytime fatigue or impaired daytime functioning.
B. The sleep disturbance (or daytime sequelae) causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
C. The insomnia is judged to be related to another Axis I or Axis II disorder (e.g., major depressive disorder, generalized anxiety disorder, adjustment disorder with anxiety), but is sufficiently severe to warrant independent clinical attention.
D. The disturbance is not better accounted for by another sleep disorder (e.g., narcolepsy, breathing-related sleep disorder, a parasomnia).
E. The disturbance is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition.

Table 21-15 DSM-IV Diagnostic Criteria for Insomnia Related to Another Mental Disorder

Ninety percent of patients with major depressive disorders have sleep disturbances by EEG criteria. Sleep alterations associated with depression include both general and architectural sleep disturbances. General sleep disturbance consists of increased latency to sleep, increased awakenings, and early morning awakenings with difficulty returning to sleep. Macroarchitectural anomalies include shifting of the center of mass of slow wave sleep from the first NREM-REM cycle to later in the sleep period. Latency to REM sleep is also shortened (Fig. 21-12). Microarchitectural analysis reveals increased eye movement rate (density), especially early in the sleep period.

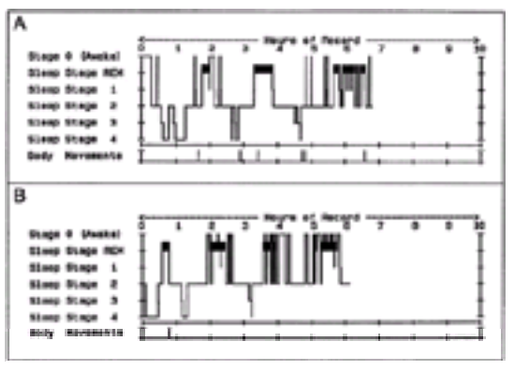

FIGURE 21-12 Sleep stage histograms comparing normal sleep **(A)** with that found in a patient with major depressive disorders **(B)**. Difficulty maintaining sleep and early morning awakenings are common complaints in patients with depression. **B** illustrates the electrophysiological correlates of these complaints beginning after approximately 2 hours of sleep. Sleep continuity becomes disrupted as morning approaches. Also present is a markedly reduced latency to REM sleep, a feature characteristic of this patient population and thought by some to reflect cholinergic-aminergic imbalance.

Selective REM sleep deprivation can improve mood. The effect may persists for days in some patients. Interestingly, traditional medications used to treat depression are powerful REM sleep suppressors (tricyclic drugs and monoamine oxidase inhibitors). SSRIs also suppress REM sleep. Arecoline infusion induces REM sleep in depressed patients, and scopolamine withdrawal mimics depression in normal subjects (including EEG sleep changes). These sleep phenomena support the cholinergic-aminergic imbalance theory of depression.

Patients with mania and hypomania seldom complain of sleep problems, even though they sleep only a short time (2 to 4 hours per night), have very prolonged latency to sleep, and sometimes have reduced slow wave sleep. Patients with schizophrenia have no consistent EEG sleep changes except that they do not have REM sleep rebound in response to REM sleep deprivation. The only other consistent finding is that the patients with schizophrenia frequently deny having slept, even though polysomnographic sleep appears normal. Other findings include reduced slow wave sleep and sometimes reduced REM sleep latency. Patients with anxiety and personality disorders often have sleep-onset, and sleep maintenance insomnia.

Since most depressive disorders are associated with disturbed sleep, a sedating antidepressant, taken at bedtime, can be doubly helpful. The general paradigm is to treat the depression and monitor for improvement in sleep. Interestingly, some antidepressants, especially tricyclics drugs and fluoxetine can produce or exacerbate sleep-related movement dyssomnias (i.e., periodic limb movement disorder, restless legs syndrome, and fragmentary myoclonus).

Sleep disturbance accompanies many psychiatric conditions. Insomnia is included as a diagnostic feature in DSM descriptions of major depressive, generalized anxiety, bipolar, posttraumatic stress, and obsessive-compulsive personality disorders. When anxiety represents a critical component of the sleep problem, anxiolytic

medications may be helpful. Typically taken at bedtime, these antianxiety agents can relieve tension that prevents sleep initiation. Sleep symptoms should be carefully monitored to ensure that a sleep-onset problem is not reemerging as sleep maintenance insomnia. Anxiolytics may also provide relief for patients afflicted by sleep-related panic attacks.

Psychiatric consultation, psychotherapy, or both can facilitate management when applied in conjunction with pharmacological or behavioral therapy. Many patients with insomnia deny emotional problems. Insomnia may be one of several psychosomatic manifestations in “repressors.” Unresolved grief can also underlie insomnia. In some cases, excessive sleepiness can be a symptom of an Axis I or Axis II mental disorder. Table 21-16 shows DSM-IV diagnostic criteria for such hypersomnia related to another mental disorder.

A. The predominant complaint is excessive sleepiness for at least 1 month as evidenced by either prolonged sleep episodes or daytime sleep episodes that occur almost daily.
B. The excessive sleepiness causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
C. The hypersomnia is judged to be related to another Axis I or Axis II disorder (e.g., major depressive disorder, dysthymic disorder), but is sufficiently severe to warrant independent clinical attention.
D. The disturbance is not better accounted for by another sleep disorder (e.g., narcolepsy, breathing-related sleep disorder, a parasomnia) or by an inadequate amount of sleep.
E. The disturbance is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition.

Table 21-16 DSM-IV Diagnostic Criteria for Hypersomnia Related to Another Mental Disorder

Although not specifically mentioned, psychiatric conditions may also underlie some parasomnias. Sleep terror and nightmares in older children and adults should alert the clinician to a possible history of trauma or abuse. Psychotherapy plays an important role in treating survivors of sexual assault or other forms of posttraumatic stress disorder. Some consider nightmares to be the cardinal feature of posttraumatic stress disorder. The association between sleep and terrifying dreams produces a fear of sleep in some patients. A hypervigilant state ensues, and sleep integrity declines.

The suggestion of psychotherapeutic treatment meets strong opposition from most patients with insomnia. In one review, psychotherapy was recommended to a carefully selected subgroup of patients. Only one third of the group was willing to try it. However, of those patients who began psychotherapy, 75 percent rated it as beneficial.

SLEEP DISORDER DUE TO GENERAL MEDICAL CONDITION

Insomnia, excessive sleepiness, or a parasomnia may be related to a physical condition. Constant pain, obstructive lung disease, neurological diseases, and stroke can disturb the integrity and architecture of sleep, rendering it restless and unrefreshing (see Table 21-17 for DSM-IV diagnostic criteria). Sleep can sometimes unmask pathophysiologies that are difficult to detect with awake-state diagnostic procedures (Fig. 21-13).

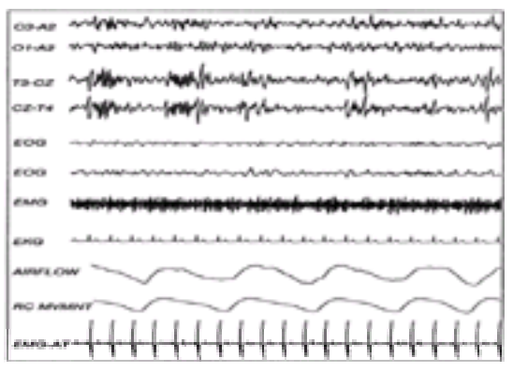

FIGURE 21-13 Polygraphic tracing from a patient with complex partial seizures. EEG sleep spindles of excessive magnitude and duration mixed with sharp activity are visible, especially in temporal lobe derivations. The slow paper speed used in sleep studies makes it difficult to classify this activity precisely; however, the abnormality is apparent. Such a finding should be confirmed with standard clinical EEG techniques during both wakefulness and sleep.

A. A prominent disturbance in sleep that is sufficiently severe to warrant independent clinical attention.
B. There is evidence from the history, physical examination, or laboratory findings that the sleep disturbance is the direct physiological consequence of a general medical condition.
C. The disturbance is not better accounted for by another mental disorder (e.g., an adjustment disorder in which the stressor is a serious medical illness).
D. The disturbance does not occur exclusively during the course of a delirium.
E. The disturbance does not meet the criteria for breathing-related sleep disorder or narcolepsy.
F. The sleep disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.

Specify type:
Insomnia type: if the predominant sleep disturbance is insomnia
Hypersomnia type: if the predominant sleep disturbance is hypersomnia
Parasomnia type: if the predominant sleep disturbance is a parasomnia
Mixed type: if more than one sleep disturbance is present and none predominates

Table 21-17 DSM-IV Diagnostic Criteria for Sleep Disorder Due to a General Medical Condition

SUBSTANCE-INDUCED SLEEP DISORDER

Alcohol, anxiolytics, opioids, and sedative-hypnotics all promote sleep by sedation. However, the resulting sleep, while apparently of greater quantity, is of poorer quality. Many benzodiazepine hypnotic medications alter the basic architecture of sleep. Most reduce slow wave sleep, and some reduce REM sleep. Abnormally increased EEG beta and sleep spindle activity result from ingesting some hypnotic drugs (Fig. 21-14). Alcohol may relax a tense person and thereby decrease latency to sleep; however, sleep later in the night is fragmented by arousals. As tolerance develops to chronic drug and alcohol use, increased dosage is needed to sustain effects; lower dosage produces an abstinence syndrome, and sleep regresses to its initial abnormal pattern. Furthermore, during withdrawal or after tolerance has developed, the sleep disturbance can rebound to a more severe level than the initial problem. DSM-IV diagnostic criteria are shown in Table 21-18.

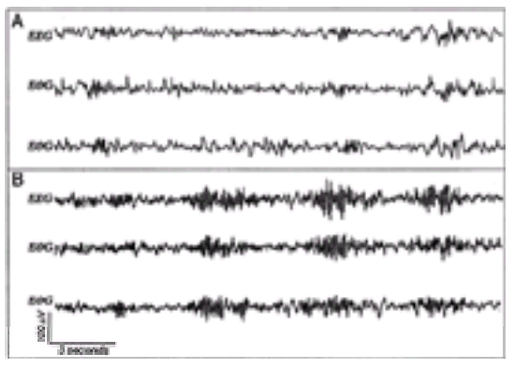

FIGURE 21-14 Tracings comparing normal sleep spindle activity during stage 2 sleep **(A)** with that of a patient chronically using a benzodiazepine **(B)**. This patient had been treated with benzodiazepines for more than a decade (and was currently taking an extremely high dose) before being seen at the sleep disorders center. Sleep was grossly abnormal. The most obvious aberration was the tremendous increase in the frequency, magnitude, and duration of EEG spindle activity **(B)**. Additionally, slow wave sleep was absent, stage 2 was grossly elevated, and spindles even intruded into REM sleep.

Table 21-18 DSM-IV Diagnostic Criteria for Substance-Induced Sleep Disorder

By contrast, psychostimulant use poses a different problem. Cocaine, amphetamine and related stimulants, caffeine, and theobromine all produce CNS arousal that may persist into the sleep period and produce insomnia. Especially in cases of stimulant abuse, an individual usually becomes severely sleep deprived. Over time a massive sleep debt accumulates, and upon substance discontinuation, profound hypersomnia results. This compensatory sleep, or sleep rebound, continues for an extended time (several weeks or more in some instances).

FUTURE DIRECTIONS

Sleep disorders significantly affect an individual's cognitive function, mood, and overall quality of life. Sleep disorders may be primary. However, many are secondary to other mental or medical conditions. Finally, disturbances in sleep or wakefulness may result from substance use or abuse. For psychiatrists, leep disorders are particularly important because insomnia and hypersomnia commonly occur in a wide range of psychiatric conditions. With appropriate treatment, most sleep disorders can be effectively managed. The extent of improvement in a patient's general well being after appropriate treatment is usually dramatic. A good night of sleep is as important to general health as nutrition and exercise.

SUGGESTED CROSS-REFERENCES

The basic science of sleep is discussed in Section 1.19. Mood disorders are covered in Chapter 14 and anxiety disorders in Chapter 15. Light therapy, sleep deprivation, and sleep delay are discussed in Section 31.33 and sleep disorders among the elderly in Section 51.3b.

CHAPTER 22. IMPULSE-CONTROL DISORDERS NOT ELSEWHERE CLASSIFIED

VIVIEN K. BURT, M.D., PH.D., AND JEFFREY WILLIAM KATZMAN, M.D.

Impulse-control disorders not elsewhere classified include impulse disorders not classified in other sections of the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV). All of the disorders in this grouping are characterized by the failure to resist an impulse, drive, or temptation to perform some act that is harmful to the patient or others. In most cases the person senses increasing tension or arousal prior to the act and experiences pleasure, gratification, or relief during or following the act. Impulse-control disorders not elsewhere classified include six disorders: kleptomania, pathological gambling, trichotillomania, pyromania, intermittent explosive disorder, and the residual category of impulse-control disorder not otherwise specified, which includes clinical entities such as self-mutilation and compulsive buying.

The 10th edition of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) classifies these entities as habit and impulse disorders. It states that these disorders are “characterized by repeated acts that have no clear rational motivation, cannot be controlled and generally harm the patient's own interests and those of other people. The patient reports that the behavior is associated with impulses to action.” The ICD-10 further states that these disorders “are grouped together because of broad descriptive similarities, not because they are known to share any other important features.” This category excludes habitual use of alcohol or psychoactive substances as well as habitual behavior involving sexual activity.

Disorders of impulse control have long been recognized. In 1838 Jean Etienne Esquirol proposed the term *monomanies instinctives* to describe behaviors characterized by irresistible urges and without apparent motive. The impulse-control disorders were first categorized in the third edition of DSM (DSM-III). The revised third edition of DSM (DSM-III-R) added the diagnosis of trichotillomania, eliminated the diagnosis of isolated explosive disorder, and modified the criteria for the remaining categories. DSM-IV retains the class of impulse-control disorders not elsewhere classified and (with some modification) the diagnoses of pathological gambling, kleptomania, pyromania, trichotillomania, intermittent explosive disorder, and impulse-control disorder not otherwise specified.

Controversy continues about whether these disorders should be placed in a distinct category or should be listed as variations of other Axis I or Axis II disorders. Those who argue that impulse-control disorders are subgroups of other psychiatric disorders point to similarities with obsessive-compulsive disorder, mood disorders, substance dependence, paraphilias, and mental disorders due to a medical condition. Others suggest that impulse-control disorders share features with certain personality disorders such as antisocial personality disorder or borderline personality disorder. DSM-IV, however, emphasizes that the category of impulse-control disorders is a residual group separate from all others.

Recently, investigators have proposed that the impulse-control disorders are more aptly included in an entity that has been called obsessive-compulsive pectrum disorders. Included within this category are the disorders involving preoccupation with bodily appearance or sensations such as the somatoform disorders (i.e., body dysmorphic disorder and hypochondriasis), eating disorders, dissociative disorders, and neurological disorders (Tourette's disorder, Sydenham's chorea, parkinsonism, and autistic disorder). Features proposed to be common to these disorders include epidemiological data (age of onset, family history, and clinical course), clinical presentation (repetitive thoughts or behaviors), proposed causes (serotonin alterations and modified frontal lobe activity), and response to common treatments such as selective serotonin reuptake inhibitors (SSRIs) and behavior therapy.

Some attempt has been made to delineate these disorders further as a subcategory of obsessive-compulsive spectrum disorder, based on the presence of risk-seeking (impulsive) endpoints versus risk-aversion (compulsive) endpoints (Fig. 22-1).

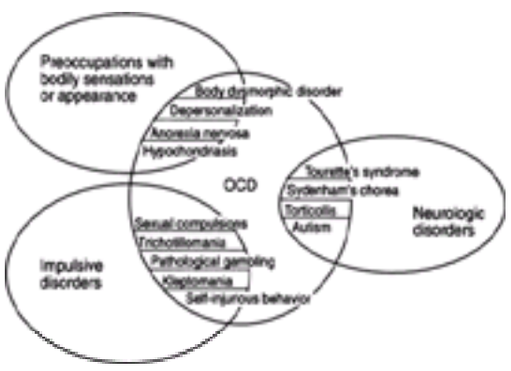

FIGURE 22-1 Obsessive-compulsive-related disorders. (Reprinted with permission from Hollander E, Kwon JH, Stein DJ, Broatch J, Rowland CT, Himelein CA: Obsessive-compulsive and spectrum disorders: Overview and quality of life issues. J Clin Psychiatry *57*[Suppl]:3, 1996.)

Researchers have also pointed to the similarities between impulse-control disorders and mood disorders, suggesting that in fact they may belong to a spectrum of affective disorders. This idea derives primarily from the fact that many patients with these disorders have a comorbid major depressive disorder at some point in their lives, and both disorders respond to selective serotonin reuptake inhibitors. Similarities between impulse-control disorders and bipolar disorders include impulsive and often harmful, dangerous, or pleasurable behaviors, affective lability, high comorbidity with one another and similar comorbidity with other psychiatric disorders, and similar age of onset, clinical course, and response to mood stabilizers and SSRIs.

Thus, while similarities exist between the impulse-control disorders and other major psychiatric disorders, the nature of these relationships awaits further delineation. Similarly, despite theoretical constructs, the primary etiological factor in impulse-control disorders remains unknown. Much remains to be learned about the phenomenology, epidemiology, etiology, and treatment of impulse-control disorders.

KLEPTOMANIA

Definition and History

References to kleptomania, a disorder of nonsensical pilfering, date to the early nineteenth century. The term *kleptomaniac* was coined in 1838 by Jean Etienne Esquirol and Charles-Chretien-Henri Marc, who used it to describe the behavior of a number of kings who stole worthless objects. Kleptomania was also historically considered part of a hysterical disorder in women, often felt to be associated with diseases of the uterus. Kleptomania is included as a disease of impulse control because of the characteristic irresistible urge to steal that is relieved by the act of stealing itself. Persons with kleptomania do not steal items for personal use or monetary gain, often can afford the objects, and may give away, hide, or return the stolen goods. The stealing behavior is usually inconsistent with the general character of the individual. Since the original reference to the disorder more than 150 years ago, there have been no formal, rigorous studies of kleptomania.

Comparative Nosology Kleptomania has been recognized as a discrete disease entity by DSM-III, DSM-III-R, and DSM-IV. The disorder was excluded from the second edition of DSM (DSM-II) and was mentioned in the first edition of DSM (DSM-I) as an accessory term only. Features include a recurrent impulse to steal objects that are not needed for personal use or monetary value. DSM-IV diagnostic criteria stipulate that the stealing is not an expression of anger or revenge, is not

associated with a delusion or hallucination, and is not due to a conduct disorder, manic episode, or antisocial personality disorder.

ICD-10 characterizes pathological stealing as a repeated failure to resist impulses to steal objects that are not acquired for personal use or monetary gain. The objects may be discarded, given away, or hoarded. It goes on to describe a characteristic sense of tension prior to the act of stealing and a sense of gratification during and immediately after the act. The ICD-10 criteria for kleptomania are listed in Table 22-1.

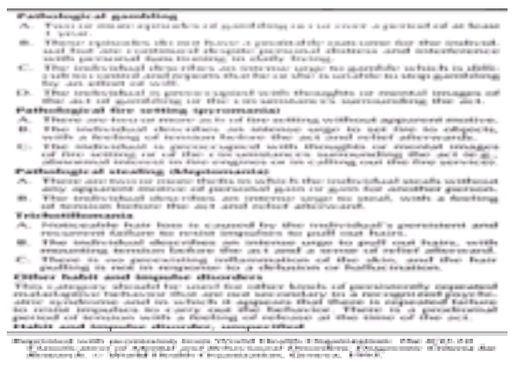

Table 22-1 ICD-10 Diagnostic Criteria for Habit and Impulse Disorders

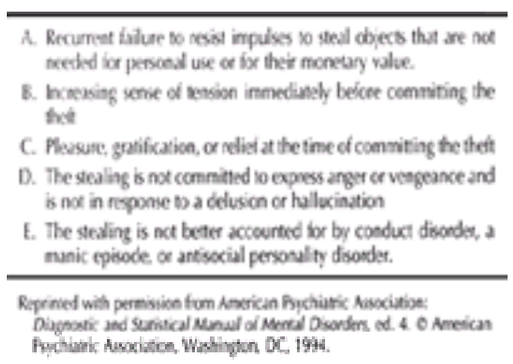
Epidemiology Because of the absence of studies, little is known about kleptomania. An estimated 6 out of 1000 people in the general population suffer from kleptomania. According to DSM-IV fewer than 5 percent of identified shoplifters actually have kleptomania. However, many factors that influence these data result in an underestimated rate of kleptomania. Persons with kleptomania are ashamed and rarely report their behavior. Since kleptomania is a recurrent disorder, individuals apprehended multiple times are often viewed as recidivist criminals and thus not referred for psychiatric evaluation. Furthermore, some apprehended shoplifters are misdiagnosed as having an antisocial personality.

Information from case reports points to a preponderance of kleptomania in women. Recent studies show that approximately three quarters of reported cases meeting DSM-III-R criteria for kleptomania were in women. However, women are more likely to present for psychiatric evaluation than men. Similarly, they are more likely to be referred by the courts for psychiatric evaluations, whereas male shoplifters are more likely to be sent to prison. Men tend to be older at first presentation, approximately 50 years old, compared with 35 years old for women. The time between onset of symptoms and presentation may be years to several decades.

Etiology No definitive cause for kleptomania is known. It appears that rates of shoplifting in general increase when the availability of goods increases. Psychodynamic theories center on the concept of pathological stealing as a defense against forbidden unconscious impulses, wishes, conflicts, or needs. These impulses or wishes may reflect sexual or masochistic themes, and the act of stealing may represent a mechanism whereby a narcissistically vulnerable individual prevents a fragmentation of the self by carrying out the impulse. Most studies suggest that persons with kleptomania have typically had a stormy and dysfunctional childhood; this history is used to support the analytic premise that impulsive stealing is an attempt to restore early childhood losses.

Phenomenological theories suggest that kleptomania may in fact be part of a larger spectrum disorder. Studies have demonstrated a high comorbidity with mood disorders, both major depressive disorder and bipolar disorders. A higher rate of mood disorders is reported in the families of these patients as well, which suggests that pathological stealing may in fact be part of affective spectrum disorders. However, many individuals with kleptomania demonstrate obsessive and compulsive symptoms including compulsive hand washing, cleaning, checking, hoarding, collecting, and buying. In one study of 20 patients with kleptomania, 7 percent of first-degree relatives met criteria for obsessive-compulsive disorder. This supports the idea of pathological stealing as part of obsessive-compulsive spectrum disorders. A high rate of pathological stealing also appears among patients with eating disorders (particularly bulimia nervosa). Given that kleptomania is at least partially responsive to serotonergic agents, these conditions may in fact have a common pathophysiological link. However, further definitive studies are necessary to determine the viability of this hypothesis.

Diagnosis and Clinical Features The DSM-IV criteria for kleptomania are listed in Table 22-2. The individual with kleptomania usually comes to clinical attention through court referral or through a disclosure in the course of treatment for a comorbid diagnosis. Most patients describe their impulse to steal as intrusive and unpleasurable. However, during the act of stealing, many patients report feeling a sense of pleasure or thrill. Some individuals sexualize the act in some fashion. The act is often done impulsively without any premeditation. Most patients describe their activity as neutralizing a sense of discomfort. Once the impulse has arisen, they report mounting anxiety if they do not carry out the act of stealing. Afterward, individuals frequently feel shame or remorse about the act. Most patients feel that what they do is wrong. Some go to great lengths to protect others and themselves from their impulse to steal and to relieve their sense of guilt about their activity. Individuals may warn shops that are identified as a potential target, return to stores to pay for stolen items, or donate stolen goods to charity. They may avoid places where stealing is a temptation or avoid shopping completely. These individuals rarely reveal their problem to family or friends. Many individuals report traumatic childhoods, but few pinpoint one traumatic event as an immediate precipitant for stealing. Patients with kleptomania have an increased lifetime rate of major mood disorders, anxiety disorders, and eating disorders. They frequently have a history of sexual dysfunction. Persons with kleptomania do not meet the criteria for antisocial personality disorder. Those with a psychiatric disorder in addition to kleptomania generally state that of all their difficulties, stealing causes them the greatest grief.



A. Recurrent failure to resist impulses to steal objects that are not needed for personal use or for their monetary value.
B. Increasing sense of tension immediately before committing the theft
C. Pleasure, gratification, or relief at the time of committing the theft
D. The stealing is not committed to express anger or vengeance and is not in response to a delusion or hallucination
E. The stealing is not better accounted for by conduct disorder, a manic episode, or antisocial personality disorder.

Table 22-2 DSM-IV Diagnostic Criteria for Kleptomania

Differential Diagnosis Kleptomania may be distinguished from ordinary stealing in that the objects stolen are not taken for personal use or monetary gain. Occasionally, a shoplifter may feign kleptomania to avoid prosecution by the law; malingering should therefore be considered in the differential diagnosis. Other disorders to be considered include conduct disorder, antisocial personality disorder, and manic episodes that exist as part of bipolar I disorder. In each of those cases the act of stealing is clearly related to the primary disorder, and the patient exhibits a spectrum of associated unacceptable behaviors, of which stealing is only one example. On occasion, a schizophrenia patient may steal in response to a command hallucination. Finally, in certain mental disorders due to a general medical condition, ostensible stealing results from a memory lapse involving failure to remember to pay for merchandise.

Course and Prognosis Kleptomania is a chronic illness, generally beginning in late adolescence and continuing over many years. The spontaneous remission rate and long-term prognosis are unknown.

Treatment The literature describes the use of psychodynamic psychotherapy, behavioral techniques, and somatic interventions in the treatment of kleptomania, with variable outcomes. However, there are no controlled studies in the treatment of kleptomania. The use of long-term insight-oriented psychotherapy is of questionable

value to this patient population. Behavioral techniques have met with some success. Successful pharmacological interventions have been described in case reports, including the use of fluvoxamine (Luvox), amitriptyline (Elavil), imipramine (Tofranil), nortriptyline (Pamelor), trazodone (Desyrel), fluoxetine (Prozac), lithium (Eskalitte), and valproate (Depakote). The use of electroconvulsion therapy (ECT) has also met with some success in case reports.

PATHOLOGICAL GAMBLING

Definition and History Pathological gambling is characterized by the failure to resist the impulse to gamble despite severe and devastating personal, family, or vocational consequences. Pathological gambling should be distinguished from heavy social gambling, professional gambling, or gambling problems that do not meet criteria for pathological gambling.

Comparative Nosology Pathological gambling was first officially recognized in DSM-III. In DSM-III-R the criteria were modified to reflect similarities between pathological gambling and psychoactive substance use and dependence. Included in the DSM-III-R criteria were items that emphasized physiological symptoms such as tolerance and withdrawal. Nevertheless, a number of criticisms were leveled at the DSM-III-R criteria. Some appeared too vague, while others overlapped one another. A survey of treating professionals revealed dissatisfaction with the DSM-III-R criteria and some preference for a return to the DSM-III criteria that emphasized effects on legal, social, vocational, and interpersonal issues in the life of the pathological gambler. A questionnaire combining criteria from DSM-III and DSM-III-R as well as other modifications was sent to several hundred pathological gamblers and substance-abusing control subjects. As a result, a new set of criteria that combined elements of DSM-III and DSM-III-R was incorporated into the revised criteria published in DSM-IV. Importantly, DSM-IV has reinstated the essence of DSM-III descriptors that detail the multilevel consequences of pathological gambling.

ICD-10 characterizes pathological gambling as “a disorder of frequent, repeated episodes of gambling that dominate the patient's life to the detriment of social, occupational, material and family values and commitments.” Diagnoses of exclusion include “excessive gambling by manic patients, gambling and betting not otherwise specified, and gambling in dissocial personality disorder.” ICD-10 criteria are listed in Table 22-1.

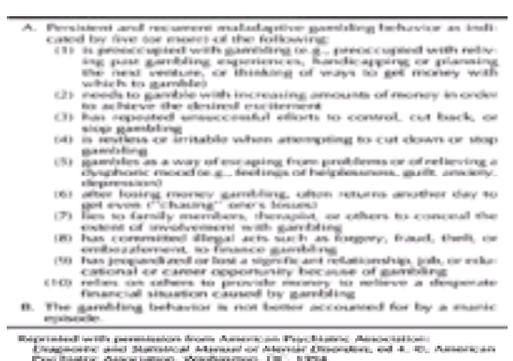
Epidemiology Up to 3 percent of adults in the general population may be classified with probable pathological gambling. Based on treatment samples, the typical pathological gambler is an upper-middle-class or middle-class white man between the ages of 40 and 50. However, pathological gamblers in treatment may differ significantly from those in the general population. Surveys demonstrate that rates of pathological gambling are higher among the poor and minorities and that these individuals are underserved by current treatment resources. Although male pathological gamblers outnumber women, the previous ratio of 2 to 1 may be high. Individuals under the age of 30 are probably underrepresented in treatment centers, and data suggest that the prevalence of pathological gambling among adolescents is increasing. Some surveys have shown higher rates of pathological gambling among high school students than in the general population. Pathological gamblers tend to have had an alcohol- or other substance-abusing parent, and approximately 25 percent had a parent who was probably a pathological gambler. Surveys also demonstrate that rates of pathological gambling are considerably higher in locations where gambling is legal.

Pathological gamblers have multiple addictions to alcohol and other substances. The prevalence of pathological gambling among substance abuse patients in treatment programs is also quite high. Substance abusers who are also pathological gamblers appear to have greater social dysfunction than those who are exclusively substance dependent. Dually addicted individuals report higher rates of substance use, greater unemployment, and higher rates of interpersonal conflict. The presence of multiple addictions places pathological gamblers at increased risk for incarceration. One study demonstrated that when substance abuse coexisted with pathological gambling, there was often a history of childhood exposure to gambling and a large family size. In another recent study, early adolescents who revealed impulse-control deficits by self-report were more likely to exhibit gambling problems by late adolescence.

Etiology Numerous theories have been advanced to explain the cause of compulsive gambling despite ongoing losses. Psychoanalytic theory has focused on a number of core character difficulties. One suggestion is that the gamblers are narcissists whose grandiose and omnipotent fantasies lead them to believe they can control events and even predict their outcome. More-classical analytic theories extending back to Sigmund Freud have suggested that compulsive gamblers have an unconscious desire to lose and gamble to relieve unconscious psychic guilt. Behavior theorists view uncontrolled gambling as a learned maladaptive behavior, while cognitive scientists hypothesize that gamblers suffer from a number of erroneous perceptions regarding locus of control.

Several studies have suggested that gamblers' risk-taking behavior may have an underlying neurobiological cause. These theories have centered around both serotonergic and noradrenergic receptor systems. Male pathological gamblers may have subnormal 3-methoxy-4-hydroxyphenylglycol (MHPG) concentrations in plasma, increased cerebrospinal fluid (CSF) MHPG concentrations, and increased urinary output of norepinephrine. Evidence also implicates serotonergic regulatory dysfunction in the pathological gambler. Chronic gamblers have low platelet monoamine oxidase (MAO) activity, a marker of serotonin activity also linked to difficulties with inhibition. However, a recent study of 27 male pathological gamblers found no correlation between platelet MAO activity and psychological ratings. Another study evaluating CSF 5-hydroxyindoleacetic acid (5-HIAA), a serotonin metabolite, found no difference in concentrations between pathological gamblers and controls. Neuroendocrine studies evaluating prolactin response to challenge agents have also yielded mixed results; some demonstrate a serotonin receptor hyposensitivity, and others show a hypersensitivity. The conflicting data call for further studies into the neurobiology of pathological gambling.

Diagnosis and Clinical Features The DSM-IV criteria for pathological gambling are outlined in Table 22-3. Features essential to the diagnosis of pathological gambling include a progressive course, inability to control the behavior despite heavy losses, and disregard for the consequences of the behavior. Like substance abusers, pathological gamblers are driven by the need to achieve an aroused or euphoric state. Pathological gamblers also exhibit tolerance and withdrawal. Thus, they tend to increase the size of their bets or the odds against them to achieve adequate arousal, and when forced to decrease the extent or frequency of gambling, they exhibit characteristic withdrawal symptoms, including irritability, restlessness, depressed mood, and poor concentration.



A. Persistent and recurrent maladaptive gambling behavior as indicated by five (or more) of the following:
(1) is preoccupied with gambling (e.g., preoccupied with reliving past gambling experiences, handicapping or planning the next venture, or thinking of ways to get money with which to gamble)
(2) needs to gamble with increasing amounts of money in order to achieve the desired excitement
(3) has repeated unsuccessful efforts to control, cut back, or stop gambling
(4) is restless or irritable when attempting to cut down or stop gambling
(5) gambles as a way of escaping from problems or of relieving a dysphoric mood (e.g., feelings of helplessness, guilt, anxiety, depression)
(6) after losing money gambling, often returns another day to get even ("chasing" one's losses)
(7) lies to family members, therapist, or others to conceal the extent of involvement with gambling
(8) has committed illegal acts such as forgery, fraud, theft, or embezzlement to finance gambling
(9) has jeopardized or lost a significant relationship, job, or educational or career opportunity because of gambling
(10) relies on others to provide money to relieve a desperate financial situation caused by gambling
B. The gambling behavior is not better accounted for by a manic episode.

Table 22-3 DSM-IV Diagnostic Criteria for Pathological Gambling

Differential Diagnosis Pathological gambling should be distinguished from social gambling, which does not seriously compromise relationships or vocational performance. Patients whose judgment is impaired by a manic episode or by acute substance abuse do not exhibit the insidious, protracted course that characterizes pathological gambling.

A number of diagnoses are frequently comorbid with pathological gambling. Coexisting and preexisting disorders include multiple substances and alcohol use disorders, major depressive disorder and bipolar disorders, anxiety disorders, attention-deficit/hyperactivity disorder, Tourette's disorder, and personality disorders, particularly narcissistic and antisocial personality disorders.

Course and Prognosis The course of pathological gambling is insidious, and conversion to pathological gambling probably is precipitated either by increased exposure to gambling or by the occurrence of a psychological stressor or significant loss. In males, the onset of pathological gambling begins in adolescence; in females the onset occurs later in life.

The natural history of the illness has been divided into four phases. In the first (winning) phase, a big win stimulates feelings of omnipotence. Women do not generally experience a big win initially. They may see gambling as a means of escaping overwhelming problems in their environment or in their past. Thus, there are apparently

two possible motivators for ongoing gambling activity: action seeking (characterized by the big win) or escape seeking. In the second (losing) phase, the person either has a string of bad luck or begins to find losing intolerable. Gamblers then alter their strategy in an attempt to win back everything at once (chasing). Debts accrue, and there is a sense of urgency and an attempt to cover up both the behavior and the losses by lies. Relationships suffer as the gambler becomes irritable and secretive. In the third (desperation) phase gamblers engage in uncharacteristic, often illegal behaviors. Bad checks are written, funds are embezzled, and they desperately seek ways to obtain money to continue gambling, both to recoup losses and to regain the feeling of arousal characteristic of the initial phase. Relationships deteriorate further. Symptoms of depression appear, including neurovegetative signs, suicidal ideation, and suicide attempts. The fourth and final phase (hopelessness) involves an acceptance that losses can never be made good. Nevertheless, gambling continues, with the main motivator being the attainment of arousal or excitement.

Although a few gamblers seek help while in the winning phase, most seek help much later, generally because their relationships are threatened or they have committed illegal acts.

The course of the disorder is accelerated by the use of alcohol or drugs, the death or loss (possibly through divorce) of a significant other, the birth of a child, physical illness, a job or career disappointment, or increasing interpersonal difficulties. Job promotion or success may also hasten the course of the disorder.

Treatment Some pathological gamblers find participation in Gamblers Anonymous extremely helpful and require nothing more. However, the rate of dropout from this organization is quite high and rate of continued abstinence is low. Psychodynamic psychotherapy attempts to confront the sense of omnipotence and self-deceptions and should address the maladaptive nature of the various defenses. Family therapy is often valuable. Comorbid disorders such as major depressive disorder or substance abuse should be addressed and treated. Inpatient hospitalization may be considered, particularly if the patient is severely depressed and suicidal. Behavioral approaches such as imaginal desensitization, in which relaxation is paired with visualization of avoidance of gambling, have had some success. Little is known about the efficacy of psychopharmacology with pathological gambling. Case reports indicate some benefit from lithium and clomipramine (Anafranil).

Mr. T. was a 47-year-old white male who presented to a community mental health center for evaluation of depression. In the course of the initial interview with the psychiatrist and social worker, he disclosed that he had previously been a quite successful manager of a restaurant in a Las Vegas hotel. He had been married, had two children, and supported a nice lifestyle. He became well known in several casinos and was given free nightly stays by a number of casinos. His gambling accelerated to the point at which he spent the entire family savings. He became unavailable at work as he spent his time around gambling activities. The business collapsed, and his wife later divorced him. He then moved to Los Angeles where he lived in an apartment while managing the other units in the building. He was responsible for collecting the rent from the tenants and turning it over to the building owner. However, on three occasions, he gambled a good portion of this money at the race track. The third episode involved a loss of $8000. He was fired from this job and over the past year was unable to find work as he had no references. Prior to his presentation to the mental health clinic, he was homeless for 6 months and was increasingly hopeless and suicidal.

An initial treatment plan involved mandatory daily attendance at Gamblers Anonymous and work with a sponsor in the 12-step model. He was started on a course of fluoxetine. He met weekly with his case manager in the clinic. His short-term goals involved acquiring housing and employment with continued abstinence from gambling. His long-term goals included reconnecting with his children whom he had not seen in many years.

TRICHOTILLOMANIA

Definition and History Trichotillomania is a chronic disorder characterized by the irresistible urge to pull out one's hair.

Trichotillomania was first characterized by the French dermatologist Francois Hallopeau in 1889. Though the description of the disorder dates back over a century, understanding of the condition remains elusive. Patients with this diagnosis wait years to seek treatment and may never be seen by a physician at all. Patients often disguise the condition with makeup or wigs. This appears to be related to shame about the condition and lack of knowledge about possible treatment strategies.

Comparative Nosology Trichotillomania was first formally recognized as a distinct entity in DSM-III-R, which classified it as an impulse-control disorder largely because like other impulse-control disorders, it is characterized by heightened tension prior to the behavior, inability to resist the impulse, and a feeling of gratification immediately after the act. DSM-IV added to the exclusion criteria both a primary medical etiology and another mental disorder (such as delusional disorder). Additionally, DSM-IV includes severe distress or impairment as a diagnostic criterion.

ICD-10 includes trichotillomania as a disorder of habit and impulse in which “noticeable hair loss is caused by the individual's persistent and recurrent failure to resist impulses to pull out hairs with mounting tension before its act and a sense of relief afterward.” Hair pulling in response to preexisting inflammation of the skin, command hallucinations, and stereotyped movements is not considered trichotillomania. ICD-10 criteria for trichotillomania are in Table 22-1.

Researchers have questioned whether trichotillomania is in fact more similar to the other impulse-control disorders or whether the ritualistic, repetitive nature of the disorder is more properly related to obsessive-compulsive disorder. Some have proposed that hair-pullers are heterogeneous in their presentation; some patients describe class symptoms of impulse-control disorder including a rising tension preceding the action and relief following, while others pull or pluck their hair without these tension and gratification experiences. Many describe pulling their hair in an automatic ritualistic fashion during sedentary activity such as watching television. Still others describe a more highly ritualized behavior including searching for particular kinds of hair, pulling the hair out in a particular manner, ingestion of all or part of the hair, or having to pull out hair to retain body symmetry.

Epidemiology Studies applying strict DSM-IV criteria have found the prevalence to be below 1 percent. However, in one large-scale study of 2579 college freshmen, when the criteria of rising tension and gratification were relaxed to include all hair pullers, the prevalence rose to over 3 percent in women and 1.5 percent of men. In large-scale sample of Israeli 17-year-olds, none of the identified hair pullers met the tension and gratification criteria, and the prevalence of obsessive-compulsive symptoms was significantly elevated. Previous studies that suggested female to male ratios up to 9 to 1 have involved much smaller groups of subjects. These clinical population studies may also have been confounded by such factors as the relative reluctance of males to seek psychiatric treatment. Males with trichotillomania tend to pull from the beard and moustache area and can shave this area to camouflage the problem; this too may confound determination of the female to male ratio.

The mean age of onset of trichotillomania is in the early teens, most frequently before age 17. Most patients do not present for treatment at this time and may wait for decades before detection. The literature describes both early- and late-onset forms of the disorder, though this has not been demonstrated systematically. The early-onset form, beginning before age 6, appears to have a more evenly divided sex distribution and tends to remit more readily, responding to simple interventions such as suggestion, support, and simple behavioral techniques. The late-onset form, typically occurring after age 13, tends to become a chronic disorder with a less hopeful prognosis.

Etiology The cause of trichotillomania remains unclear and both psychological and biological mechanisms have been proposed. Psychodynamic explanations suggest that the disorder is a response to loss or separation in childhood. Mothers of patients are often characterized as critical, and fathers are frequently passive or emotionally weak. Alternatively, behaviorists point out that the disorder is common in children and adolescents, and when it persists, it takes on the characteristics of a habit that remits with behavioral techniques. Biochemical explanations stem from the finding that patients have an increased prevalence of both mood and anxiety disorders and some symptoms of obsessive-compulsive disorder. The family history of patients with trichotillomania often includes tics, habits, and obsessive-compulsive symptoms. This disorder responds preferentially to serotonergic agents, which lends credence to a biochemical relation to either mood or anxiety disorders. However, since serotonergic agents are not always effective, perhaps the disease has more than one biochemical cause. Another biochemical theory points to the potential role of the opiate system, largely on the basis of the response of dogs with canine acral lick dermatitis to opioid antagonists. It was proposed that patients with trichotillomania have a general hypoalgesia that allows them to continue plucking hair without the perception of pain, but a recent study found no difference in pain perception thresholds.

Diagnosis and Clinical Features The DSM-IV diagnostic criteria for trichotillomania are presented in Table 22-4. Trichotillomania can be quite difficult to diagnose for a number of reasons. Although this disorder disrupts most patients' lives, they tend to deny the illness and frequently disguise it successfully for decades. Most often, people with this disorder pull hair from the scalp, most commonly the vertex, though people also pull frequently from the temperoparietal, occipital, and frontal regions. Generally, hair plucking involves multiple sites on the scalp or other body regions such as the eyebrows, eyelashes, facial hair, and the pubic area. The average dermatologist sees three to seven cases of trichotillomania a year. The affected site usually shows a mixture of short and long hairs in a linear or circular pattern. A biopsy is often necessary to confirm the diagnosis and distinguish it from alopecia areata or tinea capitis. (Fig. 22-2, Fig. 22-3 and Fig. 22-4).

A. Recurrent pulling out of one's hair resulting in noticeable hair loss.
B. An increasing sense of tension immediately before pulling out the hair or when attempting to resist the behavior.
C. Pleasure, gratification, or relief when pulling out the hair.
D. The disturbance is not better accounted for by another mental disorder and not due to a general medical condition (e.g., a dermatologic condition).
E. The disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.

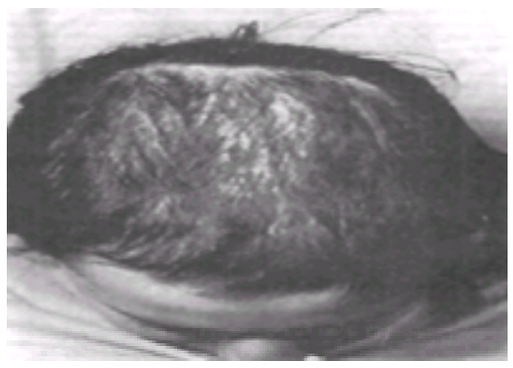

FIGURE 22-4 Trichotillomania with a mixture of short and long hairs with hair loss in a linear fashion. (Courtesy of Victor Newcomer, M.D.)

A 48-year-old woman presented to her internist for a routine physical examination. She became somewhat tearful during the interview, explaining that she was under tremendous pressure at home taking care of her three children and that she recently separated from her husband. During the physical examination, the patient pointed to her head saying that her hair had been falling out during this recent period of stress and that she was somewhat concerned about this. The physician noted that the patient had two distinct areas of hair thinning, one at the vertex of the scalp and one in the frontal region. He also noted that the eyebrow regions were covered with pencil. Otherwise results of the physical examination and routine blood work were normal. He suggested the possibility of a condition other than spontaneous stress-induced hair loss and referred her to a dermatologist. Quite reluctantly, she agreed to the referral.

The patient followed up with the dermatologist who noted a mixture of long and short hairs in the thinning regions of the scalp. Pathological specimens were negative. When the dermatologist asked the woman whether she might be pulling out her hair, she hesitatingly disclosed that she was. Tearfully, she requested complete confidentiality and asked the physician if he had ever encountered this before. When he reassured her that he had numerous patients with her condition and that treatment was available, she was visibly relieved.

Differential Diagnosis Trichotillomania may be mistaken for obsessive-compulsive disorder because both involve patterned, ritualistic behavior. The types of behavior in which patients with obsessive-compulsive disorder participate involve a conscious urge to achieve a precise goal, whereas trichotillomania occurs in response to an irresistible urge without a goal as the primary motive. Recently, however, discussion has focused on features common to trichotillomania and obsessive-compulsive disorder. Furthermore, since a large proportion of patients with trichotillomania also meet criteria for obsessive-compulsive disorder, the idea that these disorders are in fact related in an obsessive-compulsive spectrum has become more popular.

In a recent small, preliminary study of 61 patients with Tourette's disorder, obsessive-compulsive disorder, or both, it appeared that having a tic disorder increased the likelihood of trichotillomania. Although obsessive-compulsive disorder was not correlated with hair pulling, some form of trichotillomania may be more likely to coexist with the disorder than with obsessive-compulsive disorder.

Since patients with trichotillomania often avoid medical attention for years despite desiring relief from their symptoms, trichotillomania may be distinguished from factitious disorder with physical features, a disorder in which people mutilate themselves to get medical attention. Patients with stereotypic movement disorder have stereotypic, rhythmic movements and, unlike those with trichotillomania, are depressed about their symptoms. Because of high rates of comorbidity with multiple other psychiatric disorders including major depressive disorder, generalized anxiety disorder, alcohol and other substance abuse or dependence, social phobia, and various

personality disorders, trichotillomania is often not recognized as a discrete disorder. Trichotillomania can also be difficult to distinguish from hair loss from organic causes.

Course and Prognosis The clinical course is varied. Some evidence suggests that early-onset trichotillomania may be more self-limited and more easily treated, whereas the later-onset version is more chronic and tends to be refractory to treatment. The reluctance of the patient to seek treatment and the inconsistency of treatment strategies to bring about long-term relief of symptoms are both responsible for the chronicity of late-onset trichotillomania.

Trichotillomania can lead to serious long-term complications including infection at the hair-pulling site, change in texture of the hair, and carpal tunnel syndrome from repetitive pulling. More serious complications may arise from the avoidance of pelvic examinations because of shame over the exposure of pulled pubic hair. Finally, hair ingestion can lead to development of trichobezoars and resultant bowel obstruction and peritonitis.

Treatment Treatment strategies include a wide range of psychotherapeutic and pharmacological modalities. Regardless of the method used, the treating physician must tell the patient what is known about the condition and underscore that the patient is not alone with the problem. The physician must remember that patients often wait decades before seeking treatment and frequently feel both humiliated and devalued when their condition is finally revealed.

Psychological treatment approaches have been varied. For young children, kind, supportive acknowledgment of the problem with common-sense instructions about ways to forestall future hair pulling may be all that is necessary to treat the illness. For more chronic forms of the disorder, treatment approaches have included insight-oriented dynamic psychotherapy, behavioral techniques, and hypnotherapy. For children, family therapy should be included to understand and attempt to reduce the various family stressors that may have partially precipitated the illness. Psychoanalytic psychotherapy has underscored losses that may have precipitated the hair-pulling behavior and has been intermittently successful. Behavioral modalities are directed toward maximizing the assets of the patient and may involve simple self-monitoring strategies or more-complex programs such as covert desensitization or habit reversal, the latter seeming to have the greatest efficacy.

Psychopharmacological treatment has incorporated a wide range of drug classes. In recent years, trials have investigated serotonergic agents, primarily because of the initial finding that canine acral lick dermatitis responds to serotonergic agents and the growing awareness that certain features are common to trichotillomania and obsessive-compulsive disorder. Though multiple case reports and open studies have demonstrated the efficacy of these agents for trichotillomania, double-blind, placebo-controlled studies have yielded mixed results. Efficacy was demonstrated for the serotonergic agent clomipramine, though the sustainability of symptom improvement remains controversial. Two placebo-controlled studies conducted with fluoxetine showed no advantage of drug over placebo, but a study comparing fluoxetine and clomipramine found them equally efficacious in promoting symptom reduction. The efficacy of fluoxetine therefore remains unclear. Case reports have also shown efficacy for sertraline (Zoloft), paroxetine (Paxil), and trazodone, though no controlled studies have been done. The addition of pimozide (Orap) to fluoxetine or clomipramine also appears to be beneficial.

Case reports have also shown efficacy of some of the tricyclic drugs, lithium, the MAO inhibitor isocarboxazide (Marplan), the anxiolytic agents buspirone (BuSpar) and clonazepam (Klonopin), the progestogen levonorgestrel (Ovnette), and the anorectic agent fenfluramine. One placebo-controlled study of the opioid antagonist naltrexone (ReVia) showed reduction in severity of symptoms.

PYROMANIA

Definition and History Pyromania is the recurrent, deliberate, purposeful setting of fires. The disorder has been identified as a discrete entity for more than a century. With the designation of specific criteria to define it as a characterizable disorder in the DSM-III, most fire-setting behavior does not appear to qualify as pyromania. Nevertheless, despite the addition of pyromania in DSM-III-R and again in DSM-IV as a disorder under the category of impulse-control disorders not elsewhere classified, there are no rigorous studies of the disorder and no clear data on epidemiology, course, prognosis, etiology, or treatment. Pyromania as a valid diagnosis, either individually or as a subcategory under impulse-control disorder, has been questioned.

References in the literature to fire setting extend back to the nineteenth century, when conflicting schools of thought were represented by Marc, who believed that pyromania was an authentic disorder, and Wilhelm Griesinger, who viewed pyromania as symptomatic of other psychological processes. Prominent references to pyromania as a discrete disorder surfaced in the 1930s and in a 1951 monograph on the subject by Nolan Lewis and Helen Yarnell.

Comparative Nosology Pyromania was first mentioned in DSM-I as an accessory term but was excluded in DSM-II. The disorder was officially recognized in DSM-III, where it was classified under the larger category of impulse-control disorders not elsewhere classified, along with pathological gambling, kleptomania, intermittent explosive disorder, and isolated explosive disorder. Formal reference to pyromania was retained in DSM-III-R, with some modification of the criteria to objectify the characterization. DSM-IV retains pyromania with no significant changes to the defining criteria.

To qualify as pyromania, fire-setting behavior must, like other impulse-control disorders, be a response to an irresistible urge and a rise in tension and be followed by relief, pleasure, or gratification on commission of the act or behavior. Fire setting for purposes of monetary gain (arson), expression of political ideas, concealment of criminal activity, or demonstration of anger or vengeance may not be classified as pyromania.

DSM-III-R criteria incorporated the impulsive nature of the act of setting fires operationally, removing the DSM-III criterion that characterized pyromania as an inability to resist impulses to set fires. Additionally, DSM-III-R added criterion C, which describes the disorder in terms of preoccupation or fascination with fires or associated effects. Criterion E expanded the exclusionary characteristics, stipulating that fire setting cannot occur in response to a delusion or hallucination. In DSM-IV criterion F stipulates that the fire setting may not occur as part of a manic episode and cannot be accounted for by conduct disorder or antisocial personality disorder.

ICD-10 criteria for pyromania are similar (Table 22-1). Diagnostic criteria include two or more acts of fire setting, lack of motive, feelings of tension before the act with subsequent relief, and preoccupation with fire and mental images of fire setting.

Epidemiology Retrospective studies of the literature on arsonists indicate that true pyromania is rare. Fire setters tend not to meet DSM-IV criteria for pyromania because of the exclusionary criteria. Most arsonists set fires in search of monetary gain, in response to psychotic experiences, or in conjunction with a conduct or antisocial personality disorder. Because few studies of pyromania using DSM-IV criteria exist, little is really known about the epidemiology of pyromania. Nevertheless, studies of fire setters have revealed a preponderance of males with a history of fascination or involvement with fire dating back to childhood or adolescence. Recent studies have shown that a high percentage of fire setters are under the influence of alcohol at the time of the arson and that many have alcohol dependence. The correlation of fire setting and alcohol appears stronger in adults than in adolescents. Recent studies have also shown a high degree of psychosis among arsonists. Finally, a substantial number of fires are set by homeless, mentally ill persons.

Etiology The cause of pyromania is not known. Both psychodynamic and biological hypotheses have been proposed. Sigmund Freud suggested that fire setting represents a masturbatory equivalent with homosexual underpinnings. Some researchers proposed revenge as an underlying motive for repeated acts of fire setting. Some have suggested that fire setting represents a primitive attempt by persons with limited social skills to communicate.

Attempts have been made to identify biological markers common to fire setters. Lowered 5-HIAA and CSF MHPG concentrations suggest possible serotonergic or adrenergic involvement, which suggests that pyromania may be part of an affective spectrum disorder. The possibility of reactive hypoglycemia has been raised by reported blood glucose concentrations on glucose tolerance testing. Further studies using controlled subjects and operational criteria are needed to expand these preliminary findings.

Diagnosis and Clinical Features The DSM-IV diagnostic criteria for pyromania are listed in Table 22-5. Fire setting has been suggested to be common to many different diagnoses, which raises questions about the entity of pyromania as an impulse-control disorder. Fire setters, however, seem to share some common clinical features. Many have a history of involvement with fire or fascination with fire early in life. DSM-IV suggests that there may be advanced preparation for the act itself. Most fire setters deny the act when questioned or apprehended. Many are often seen lingering in the vicinity of the arson after the fact or are involved in setting off false fire alarms.

A. Deliberate and purposeful fire setting on more than one occasion.
B. Tension or affective arousal before the act.
C. Fascination with, interest in, curiosity about, or attraction to fire and its situational contexts (e.g., paraphernalia, uses, consequences).
D. Pleasure, gratification, or relief when setting fires, or when witnessing or participating in their aftermath.
E. The fire setting is not done for monetary gain, as an expression of sociopolitical ideology, to conceal criminal activity, to express anger or vengeance, to improve one's living circumstances, in response to a delusion or hallucination, or as a result of impaired judgment (e.g., in dementia, mental retardation, substance intoxication).
F. The fire setting is not better accounted for by conduct disorder, a manic episode, or antisocial personality disorder.

Table 22-5 DSM-IV Diagnostic Criteria for Pyromania

Differential Diagnosis Before a diagnosis of pyromania can be made, a number of other conditions must be excluded. Fires set for monetary gain, for political statement, or for revenge do not qualify as pyromania. Patients with schizophrenia and mania can have psychotic experiences leading them to set fires. In certain cases, patients with dementia may set fires because of their inability to anticipate the consequences of an act. Children with conduct disorder may set fires as one of a number of inappropriate and antisocial activities. Individuals who fulfill criteria for antisocial personality disorder are excluded from the diagnosis of pyromania.

Treatment There is little to suggest a predictably effective treatment for pyromania. Psychodynamic psychotherapy is limited by patients' denial, lack of insight, and the frequent coexistence of alcohol abuse. Behavioral techniques include aversive therapy and positive reinforcement, though the usefulness of this approach is questionable. Conclusive information regarding the efficacy of pharmacotherapy is also lacking. Until substantive studies suggest the benefits of a single modality of treatment, an appropriate approach would be to invoke a number of associated treatments, including behavioral approaches and, in the case of children, adolescents, or young adults, family therapy.

INTERMITTENT EXPLOSIVE DISORDER

Definition The notion that explosive violence may be linked to a discrete diagnosable condition is controversial. In DSM-IV intermittent explosive disorder is characterized by aggressive impulses out of proportion to any precipitating psychosocial stressor. In the intervals between episodes there is no sign of impulsiveness or aggressiveness.

Comparative Nosology Intermittent explosive disorder was not recognized as a mental disorder in DSM-I. The closest diagnoses at the time were emotionally unstable personality and passive-aggressive personality. DSM-II described explosive personality, specifying character pathology associated with outbursts of aggression, perhaps linked to ictal episodes. The first formal recognition of intermittent explosive disorder came with DSM-III, when, with isolated explosive disorder, it was one of two recognized aggressive disorders of impulse control. DSM-III-R deleted isolated explosive disorder but retained intermittent explosive disorder. The category of intermittent explosive disorder is retained in DSM-IV with criteria that exclude the diagnosis if symptoms occur during the course of another mental disorder, as part of antisocial or borderline personality disorder, or as the direct physiological effect of substance use or a general medical condition, such as head trauma or Alzheimer's disease.

Intermittent explosive disorder is not recognized as a unique subcategory of habit and impulse disorders in ICD-10. It is mentioned as an example of other habit and impulse disorders with no diagnostic criteria provided specifically for intermittent explosive disorder (Table 22-1).

The existence of intermittent explosive disorder as a unique entity remains controversial. Many have difficulty with the idea of a normal baseline with superimposed periods of aggressive episodes. In addition, anger outbursts are a part of many other disease entities.

Epidemiology Intermittent explosive disorder is thought to be rare and occurs more frequently in males. High rates of fire-setting behavior in persons with the disorder have been reported. Recent studies suggest higher than normal rates of intermittent explosive disorder in families of patients with the diagnosis. First-degree relatives of patients with the disorder appear to have higher than expected rates of depressive disorders and alcohol and substance abuse.

Etiology Hypotheses about the cause of impulsive aggression derive from both psychological and biological perspectives. Psychoanalytic reports suggest that such outbursts occur in response to narcissistic injurious events. Rage outbursts serve as defenses that regulate interpersonal distance and protect against further narcissistic wounding. Typical patients appear to be large men with dependent personality features who respond to feelings of uselessness or impotence with violent outbursts.

Researchers supporting biological causes of aggression cite a number of important facts. In most case series of individuals with aggression, an extremely high number appear to display organic causes, a medical condition resulting in rage outbursts or neurological soft signs of neuropathology. One small case study of patients with episodic rage showed that they had lower levels of platelet serotonin reuptake than control subjects. Another sample demonstrated an association between a low CSF 5-HIAA concentration and impulsivity, whereas a high CSF testotesterone concentration correlated with aggressiveness and interpersonal violence. Restoring serotonergic activity by administration of the serotonin precursor L-tryptophan or drugs that increase synaptic serotonergic levels appears to restore control of episodic violent tendencies. Further, biological relatives of patients meeting criteria for categories A and B of DSM-IV criteria for this disorder were found more likely to have histories of temper outbursts than were adopted relatives of these patients.

Diagnosis and Clinical Features The DSM-IV diagnostic criteria for intermittent explosive disorder are presented in Table 22-6. Intermittent explosive disorder should not be diagnosed on the basis of one discrete episode of violence. A complete developmental history is needed to make the diagnosis, since the condition is characterized by recurrent episodic aggressive outbursts. Patients with this disorder also characteristically have a developmental history that includes alcohol dependence, violence, and emotional instability. Unstable interpersonal relationships, repeated job losses, and illegal behavior are also typical.

A. Several discrete episodes of failure to resist aggressive impulses that result in serious assaultive acts or destruction of property
B. The degree of aggressiveness expressed during the episodes is grossly out of proportion to any precipitating psychosocial stressors.
C. The aggressive episodes are not better accounted for by another mental disorder (e.g., antisocial personality disorder, borderline personality disorder, a psychotic disorder, a manic episode, conduct disorder, or attention-deficit/hyperactivity disorder) and are not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition (e.g., head trauma, Alzheimer's disease).

Table 22-6 DSM-IV Diagnostic Criteria for Intermittent Explosive Disorder

Intermittent explosive disorder is mainly a diagnosis of exclusion. The clinician must first rule out medical conditions that can account for recurrent aggression. Assessment includes a comprehensive neurological examination and blood chemistry (with fasting blood glucose, liver function tests, electrolytes, and thyroid function tests), syphilis serology, urinalysis, and a urine toxicology screen. Further evaluation would include neuropsychological assessment, a computed tomographic (CT) scan of the head, and an electroencephalogram. If an organic condition is detected, a diagnosis of personality change due to a general medical condition, disinhibited type, should be made. If the diagnosis of a medical condition is equivocal, then other psychiatric disorders that might account for the rage episodes must be ruled out

(e.g., borderline and antisocial personality disorders or mood disorders). If the condition is not clearly due to organic causes or other psychiatric conditions, the diagnosis of intermittent explosive disorder is made.

Differential Diagnosis Impulsive acts of aggression that happen in the context of an organic condition must be ruled out. These conditions are better understood as a personality change due to a general medical condition, aggressive or disinhibited type. Impulsive aggression that occurs during a delirium or dementia also rules out intermittent explosive disorder as a diagnosis. Other psychiatric conditions must also be ruled out. Individuals with borderline personality disorder, antisocial personality disorder, and narcissistic personality disorder can certainly display explosive aggression. The difference in general is that the aggression seen in those with intermittent explosive disorder is more impulsive and continuous. Irritability can be seen in individuals with major depressive illness or in hypomanic or manic states. However, patients with intermittent explosive disorder do not display other components of a mood disorder. Although individuals with posttraumatic stress disorder can also display highly charged anger and irritability as a component of a hyperaroused state, other symptoms including the reexperiencing of a traumatic event and avoidance of reminders of this event are also present. Psychotic individuals can also display impulsive aggression. Careful assessment often reveals such features as command hallucinations and delusions of persecution. Finally, aggressive outbursts secondary to substance intoxication or substance withdrawal rule out a primary diagnosis of intermittent explosive disorder.

Course and Prognosis The course of intermittent explosive disorder is episodic and chronic. The unpredictable aggressive outbursts result in impaired interpersonal relationships and social isolation.

Treatment Treatment methods include both pharmacological and psychosocial approaches. Anticonvulsants and b-adrenergic receptor antagonists have been used for episodic aggressive outbursts. Some reports suggest that carbamazapine (Tegretol) may be preferable for intermittent explosive disorder and b-adrenergic receptor antagonists for temper proneness of organic etiology. Antianxiety agents have been used to decrease the anxiety that may lead to temper outbursts, though at times these agents in fact disinhibit certain patients, making control of their aggression more difficult. Multiple studies have evaluated the use of SSRIs to control anger across multiple diagnoses. Patients with a personality disorder and impulsive aggression appear to show significantly reduced anger and irritability after treatment with these agents. Additional studies need to assess the efficacy of these drugs for individuals specifically diagnosed with intermittent explosive disorder. An important adjunct to treatment with pharmacological agents is an ongoing and supportive therapeutic alliance between clinician and patient. Such a relationship increases the likelihood that a patient will immediately seek help in time of stress and thus avoid a dangerous outburst.

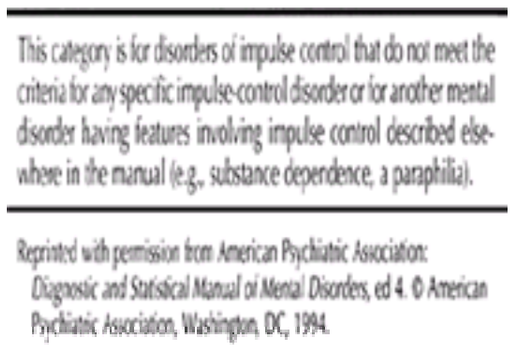
A 36-year-old real estate agent sought assistance for difficulty with his anger. He was quite competent at his job, though he frequently lost clients when he became enraged over their indecisiveness. On a number of occasions he became verbally abusive, leading clients to find ways out of escrow closings. The impulsive aggression also led to termination of multiple relationships because sudden angry outbursts contained demeaning accusations toward his girlfriends. This occurred frequently in the absence of any clear conflict. On multiple occasions, the patient became so uncontrollably enraged that he threw things across the room including books, his desk, and the contents of the refrigerator. Between episodes he was a kind and likable individual with many friends. He enjoyed drinking on the weekends and had a history of two arrests for driving while intoxicated. On one of these occasions he became involved in a verbal altercation with a police officer. He had a history of drug experimentation in college that included cocaine and marijuana.

Mental status examination revealed a generally cooperative patient. However, he became quite defensive when questioned about his anger and easily felt accused and blamed by the interviewer for his past behaviors. He had no significant medical history and no signs of neurological problems. He had never been in psychiatric treatment prior to this evaluation. He was on no medications. He denied any symptoms of a mood disorder or any other antisocial activity.

Treatment included the use of carbamazepine and a combination of supportive and cognitive-behavioral psychotherapy. The patient's angry outbursts improved as he became aware of early signs that he was about to lose control. He learned techniques to avoid confrontation when he was faced with these warning signs.

IMPULSE-CONTROL DISORDERS NOT OTHERWISE SPECIFIED

Impulse-control disorder not otherwise specified is a diagnosis reserved for disorders that involve the inability to resist an impulse but are not described by any of the other five categories (Table 22-7). Examples include compulsive sexual behavior, compulsive face picking, and self-mutilation. Recently it was suggested that compulsive buying also falls in this category.



This category is for disorders of impulse control that do not meet the criteria for any specific impulse-control disorder or for another mental disorder having features involving impulse control described elsewhere in the manual (e.g., substance dependence, a paraphilia).

Table 22-7 DSM-IV Diagnostic Criteria for Impulse-Control Disorder Not Otherwise Specified

ICD-10 provides two categories similar to the category of impulse-control disorder not otherwise specified in DSM-IV (Table 22-1). The category of other habit and impulse disorders includes kinds of “persistently repeated maladaptive behavior that are not secondary to a recognized psychiatric syndrome and in which it appears that the patient is repeatedly failing to resist impulses to carry out the behavior. There is a prodromal period of tension with a feeling of release at the time of the act.” Intermittent explosive disorder is included as one such potential entity. ICD-10 also provides a category of habit and impulse disorder, unspecified, with no description of criteria for this category.

Compulsive Buying

Definition and History Although little attention has been paid until recently to compulsive buying, the entity was recognized by both Emil Kraeplin and Eugen Bleuler. It was originally referred to as oniomania and categorized as one of the “reactive impulses” or “impulsive insanities.” Although not recognized by DSM-IV or ICD-10 as a unique subcategory of the impulse-control disorders, some attempt has been made to develop a formal definition and diagnostic criteria of compulsive buying for both research and clinical purposes, based on the phenomenology of cases in the literature to date.

Epidemiology Current estimates of the prevalence of compulsive buying range from 1.1 to 5.9 percent of the general population. General population surveys of people meeting criteria for compulsive buying have shown that 80 to 92 percent are women. The onset of the disorder appears to be approximately 18 years of age, though frequently a decade passes before the buying pattern is recognized as a problem.

Etiology The cause of compulsive buying is not known. The psychoanalytic literature has suggested that a variety of central issues are responsible for this behavior. These patients have diminished self-esteem, and buying temporarily allows them to feel better about themselves. This helps explain why the most frequently purchased items include clothing and jewelry, items that often attract recognition from the external world. Others consider castration anxiety etiological, stating that women attempt to resolve the loss of the penis through the purchase of desired items. Another theory suggests that the act of purchasing makes a statement that there is a future, thus transiently reducing a central death anxiety. Other theorists suggest that compulsive buying is a form of psychological dependence like that with drugs and alcohol and that it shares qualities addictions such as tolerance, in which the shopper must make larger and larger purchases to feel relief.

Biological theorists point to similarities between compulsive buying and mood disorders, obsessive-compulsive disorder, and the other impulse-control disorders.

Compulsive buying shares symptoms with these entities, and some comorbidity seems to exist with these disorders, particularly mood disorders.

Diagnosis and Clinical Features Compulsive buyers frequently describe feelings of tension, power, or excitement before and while shopping, with relief or pleasure immediately following the experience. Nevertheless, at times distant from shopping, the experience is ego-dystonic; compulsive buyers appreciate the negative impact that the behavior has on their lives. Buying urges are episodic and tend to last about an hour. Urges may be as frequent as every hour but can occur as infrequently as once a month. Urges most commonly arise at home but can arise anywhere and anytime throughout the day. Most people at some point attempt to resist the urges but are often unsuccessful. Compulsive shoppers generally buy for themselves, although sometimes they shop for others. They tend to purchase items that they do not need and often give the purchases away as gifts. They generally shop in stores but also use catalogs and the home shopping network. Most purchases are made on credit, and these individuals tend to have numerous credit cards.

Buying urges occur throughout the year and are not centered specifically around holidays and birthdays. Buyers frequently shop alone and tend to buy a large number of inexpensive things rather than a few expensive items. Frequently purchased items are those that are worn (e.g., clothing and perfume), though men tend to focus somewhat more on electronic equipment, automobile equipment, and hardware. Proposed diagnostic criteria for compulsive buying are listed in Table 22-8.

A. Maladaptive preoccupation with buying or shopping, or maladaptive buying or shopping impulses or behavior, as indicated by at least one of the following:
   1. Frequent preoccupation with buying or impulses to buy that are experienced as irresistible, intrusive, and/or senseless.
   2. Frequent buying of more than can be afforded, frequent buying of items that are not needed, or shopping for longer periods of time than intended.
B. The buying preoccupations, impulses, or behaviors cause marked distress, are time consuming, significantly interfere with social or occupational functioning, or result in financial problems (e.g., indebtedness or bankruptcy).
C. The excessive buying or shopping behavior does not occur exclusively during periods of hypomania or mania.

Table 22-8 Diagnostic Criteria for Compulsive Buying

Differential Diagnosis Compulsive buying must be distinguished from spending that occurs exclusively during a hypomanic or manic period. Compulsive shoppers demonstrate a more enduring pattern of behavior that is not limited to episodes in which other symptoms of mania can be observed.

These individuals show a high comorbidity with other Axis I conditions. In one study of 20 patients, all met criteria for two or more Axis I conditions, and 13 met criteria for four or more conditions. All of these patients met criteria for some form of mood disorder, most commonly bipolar I or bipolar II disorder. Symptoms seemed to increase when individuals felt more dysphoric and to decrease when patients were hypomanic. Many of these individuals stated that buying relieved their depressive symptoms.

Other disorders comorbid with compulsive buying include anxiety disorders such as obsessive-compulsive disorder, panic disorder, and phobias. Substance abuse and dependence, eating disorders, and other impulse-control disorders are frequently seen in these patients.

Course and Prognosis Compulsive buying is a chronic condition that can have devastating financial, marital, and vocational consequences. Though individuals frequently attempt to stop the behavior on their own, they are usually unsuccessful. Limiting access to shopping including credit cards, home catalogs, the Internet, and the home shopping network has met with some success for this disorder.

Most patients run into debt problems, with the average debt in one study being $23,000. Some are forced to declare bankruptcy. This financial burden results in discord within relationships and, not infrequently, divorce. Jobs are compromised because of the increasing amount of time devoted to compulsive shopping.

Treatment Information regarding treatment is based on case reports; no formal, rigorously controlled, treatment studies exist for compulsive shopping. Treatment of compulsive buying has included both psychological and pharmacological modalities, though information is based upon case reports rather than formal clinical trials. Some patients receiving supportive or insight-oriented therapy report gaining some control over their buying compulsions. Others have been helped by supportive self-help groups like Debtors Anonymous. Pharmacological data are limited, with mixed results. In one series, 9 of 20 patients receiving pharmacological interventions had complete or partial remission of symptoms. Medications that were at least partially effective included anitidepressants, mood-stabilizing agents, anxiolytics, and antipsychotics used singly or in conjunction with other agents. Some individuals who did not improve had discontinued pharmacotherapy early in treatment because of adverse effects or induction of hypomania.

A 46-year-old married woman presented to a psychiatrist for help with grieving the loss of her father. She met with the psychiatrist twice before disclosing that she was experiencing great discord in her marriage. This centered primarily on a financial debt that was now building as a result of her continued purchases. Her husband had been a highly successful attorney. However, he had had a stroke and could no longer continue his practice, which greatly limited the family income. Although the patient's spending had not been a problem in the past, she could no longer control it despite increasingly limited funds. She continued to spend over $10,000 a month on credit card purchases, generally items of clothing and jewelry for herself. She was extremely attracted to the lights and smells of a particular clothing designer, stating that she felt “forever young” when she shopped there.

Despite numerous attempts to control her spending, she was unable to do so. When she limited her visits to shopping malls, she turned to the home shopping network and continued to build a large debt. Despite the painful knowledge that her family could no longer afford this and that her action might threaten her son's private school tuition, she was unable to resist the impulse to shop. She described feelings of tension before shopping and power while she was shopping. Shortly afterward, however, she felt quite remorseful with the realization that she could not control herself and that this behavior was becoming a great problem for her family.

Treatment consisted of a combination of insight-oriented psychotherapy and psychopharmacology. Dynamic therapy focused on long-term issues of vulnerability that were stimulated by the loss of her father and the illness of her husband. She was placed on an SSRI to treat her continued dysphoric feelings. Over the next 2 years, she was able to curtail her uncontrolled shopping greatly. Ultimately the family's financial crisis was resolved.

SUGGESTED CROSS-REFERENCES

Obsessive-compulsive disorder, discussed in Chapter 15, has both significant similarities to and differences from the various impulse-control disorders. Chapter 14 on mood disorders and Chapter 20 on eating disorders contain details on features common to a number of possibly related syndromes, including impulse-control disorders not elsewhere specified. Section 11.1, describing substance dependence and abuse, and Section 11.2 on alcohol-related disorders describe features such as dependence and withdrawal that parallel those of impulse-control disorders (especially pathological gambling). Information in Chapter 10 on personality change due to a medical condition is important in distinguishing organic from presumably functional causes of explosive episodes. Compulsive sexual behavior and sexual addiction are discussed in Section 19.1a.

CHAPTER 23. ADJUSTMENT DISORDERS

JEFFREY H. NEWCORN, M.D., JAMES J. STRAIN, M.D., AND JUAN E. MEZZICH, M.D., IH.D.

The adjustment disorders are diagnoses that are seldom the subject of research, but are nonetheless widely used in clinical practice. The appeal of this diagnostic category may be attributable to several factors: (1) In a diagnostic system that is principally atheoretical, adjustment disorders remain one of the few conditions that are linked to an etiological event; (2) the notion that adjustment problems follow from stressful events has been a mainstay of psychodynamic thinking, and often forms the basis of psychotherapeutic treatment; and (3) because the development of transient psychiatric symptoms in the context of stress is virtually a universal experience, an adjustment disorders is considered by many to be a nonstigmatizing diagnosis to assign when making a patient's psychiatric status public.

Despite these considerable strengths, adjustment disorders is one of the most problematic diagnostic categories in the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV). The fact that the relationship between stress and psychiatric disorder is both complex and uncertain has caused many to question the theoretical basis of adjustment disorders. In addition, the absence of operationalized, symptom-based criteria and a threshold level of symptomatology required for diagnosis has resulted in the use of this category for patients who might otherwise fulfill criteria for another, more specific mental disorder. Since incorrect diagnosis may result in inadequate treatment, inappropriately conceptualizing a patient's problem as constituting an adjustment disorder may result in delays or inaccuracies in treatment planning. Misdiagnosis of other, more specific disorders when an adjustment disorder should appropriately be diagnosed is also a problem. For example, in one study, medical residents frequently diagnosed major depressive disorder when adjustment disorder with depressed mood was considered the correct diagnosis by an attending psychiatrist.

Problems with the use of the adjustment disorders category among child and adolescent psychiatrists were highlighted in a survey that was conducted as a means of informing the DSM-IV work groups about the use of psychiatric disorders in clinical practice. Of those who responded to the survey, 55 percent indicated that they used adjustment disorders to avoid stigmatization of patients. Many of those who favored the use of this category were not formally trained in the revised third edition of DSM (DSM-III-R) and were not inclined to use not otherwise specified categories. Over half of these psychiatrists did not consider the temporal onset criterion for adjustment disorders or the relevant exclusionary criteria in applying this diagnosis.

The survey results indicate that the adjustment disorders diagnoses may be used excessively and incorrectly by some clinicians. Nevertheless, there are individual patients for whom use of this category represents the correct formulation. Examples include high-functioning adults who experience mood or anxiety symptoms in response to change of occupational status or loss of a loved one, adolescents who become distraught in the face of parental separation or academic failure, and individuals who develop transient psychiatric symptoms in the context of a newly diagnosed or ongoing medical condition.

DEFINITION

Adjustment disorders are characterized in DSM-IV by the development of emotional or behavioral symptoms in the context of one or more identified psychosocial stressors. The resultant symptomatology is deemed to be clinically significant by virtue of either impairment in social, occupational, or educational function, or the subjective experience of distress in excess of what would normally be expected for the given stressors. The nature and severity of the stressors are not specified. However, the stressors are more often everyday events that are ubiquitous (e.g., loss of a loved one, change of employment or financial situation) rather than rare, catastrophic events (e.g., natural disasters, violent crimes). The symptomatology must, by definition, occur within 3 months of the occurrence of the stressor, and must remit within 6 months following the cessation of the stressor. Finally, the disturbance must not fulfill the criteria for another major psychiatric disorder or bereavement (not considered a mental disorder, although it may be a focus of clinical attention). A variety of symptomatic presentation subtypes of adjustment disorders are identified. The scope of symptomatology covered by these subtypes indicates that virtually any subthreshold condition deemed to be associated with a psychosocial stressor could potentially meet the criteria for adjustment disorders.

HISTORY

The notion that psychiatric disorders frequently occur in the context of stressful life events has a time-honored tradition. In the second edition of DSM (DSM-II) the category transient situational disorder was used to describe the phenomenon now labeled adjustment disorders. The disorder was understood in a developmental context, and the subtypes were defined accordingly. Although the condition was described as transient and situational, the clinical presentation was linked to severe stress. Dissatisfaction with this definition followed from the observations that the disorders were not always transient and did not necessarily require an unusually severe precipitating event.

The diagnosis of transient situational disorder was reworked considerably in the third edition of DSM (DSM-III) and was renamed adjustment disorders. Severe and unusual stress was no longer required, and the subtypes were redefined according to their symptomatic presentation. The duration of adjustment disorders was not specified; however, the symptoms were presumed to remit with the cessation of the stressor. There were no major theoretical changes from the third edition of DSM (DSM-III) to DSM-III-R. However, the duration of the disorder was restricted to 6 months, with the expectation of return to baseline function or establishment of a new steady state characterized by a more specific diagnosis; in addition, the subtype adjustment disorders with physical complaints was added.

The most important change from DSM-III-R to DSM-IV was that the duration of the disorder was allowed to extend beyond the 6-month limit imposed in DSM-III-R. The current criterion states that the symptoms may not persist for greater than 6 months following the cessation of the stressor. The duration of the disorder is coded as *acute* (less than 6 months) or *chronic* (greater than 6 months). This change better accounts for the persistence of adjustment disorders symptoms in the context of chronic stress, while still maintaining some limitations to prevent overuse once the stressor remits or a new steady state has been reestablished. Other changes involved rewording of criteria to reflect current thinking regarding this condition. The symptoms are no longer described as a reaction to a stressor (implying causality), nor are they described as maladaptive, but rather as clinically significant. Finally, the exclusionary criterion for other mental disorders is more clearly articulated to permit the diagnosis of comorbid conditions, provided that the stress-related symptoms are not better accounted for by the coexisting disorder.

COMPARATIVE NOSOLOGY

DSM Criticism of the adjustment disorders diagnosis has focused on uncertainty regarding the nature and meaning of the predisposing psychosocial stressors, the extent to which inference and value judgement may be required in order to make the diagnosis, and problems in reliability and validity. Equally problematic but not as clearly articulated in the published literature are difficulties in distinguishing adjustment disorders from subthreshold pathology that is not stress-related (e.g., not otherwise specified categories) and other posttraumatic disorders. Both these latter categories were expanded in DSM-IV, making their distinction from adjustment disorders more challenging.

Stressor Criterion The linear model of stress-disease interaction, which has served as the model for adjustment disorders in DSM, has been criticized by several authors. This model presupposes that a direct and clearly identifiable pathological reaction follows a stressful event. However, there are many possible ways in which stress may be related to psychiatric illness which are not adequately taken into account by this model. For example, there may be multiple stressors or insidious or chronic circumstances, as opposed to discrete events. Recent studies suggest that pathology is more often associated with an accumulation of stressors over time, rather than the occurrence of any one stressor. Stressors that result in dependent function are particularly noxious. Classification of individuals with chronic disturbance, chronic stress, or both may be difficult using the DSM model of adjustment disorders. The development of psychopathology in individuals exposed to chronic stress is not always direct, and relatively minor precipitating events may generate symptomatology in individuals who have previously been sensitized to

stress.

The stressor criterion in adjustment disorders has also been criticized for its lack of specificity. Several authors note that there is no mechanism to measure the stressors in adjustment disorders and, as a result, their clinical implications are often uncertain. These authors question whether patients with adjustment disorders are unusually sensitive to psychosocial events that are not likely to cause disturbance in others, or whether these individuals have been exposed to high levels of stress, the severity or accumulation of which would likely produce negative consequences in most people. The current DSM definition clearly favors the former explanation because unusually high levels of stress are more characteristic of posttraumatic stress disorder and acute stress disorders than adjustment disorders. Another criticism of the stressor criterion in adjustment disorders is that it is not specific enough to adequately facilitate discrimination of adjustment disorders from other subthreshold disorders that are not linked to stress. The failure to define what represents a normal and expectable reaction to stress has also been a source of criticism. Although cultural factors often play an important role in determining what types of events are most stressful and define how an individual is likely to respond to stress, they are not factored into the diagnostic algorithm.

Implicit in many of these criticisms is the importance of individual differences relative to the development of psychopathology in the context of stressful events, and the failure of current classification schemes to adequately account for these factors. In addition to individual or group sensitivity to stress, factors that buffer the individual from stress or those that mitigate the development of psychopathology need to be included in the assessment matrix. Recent publications that have focused on protective features relative to the development of psychopathology in children and adolescents demonstrate the importance of a variety of individual (e.g., positive temperament, absence of preexisting mood or conduct problems) and family (e.g., warm and nurturant relationship with primary caregivers) factors in mitigating pathological response to stress. How to create an interactive model that takes into account both stress and resiliency factors, which is responsive to individual and cultural differences, remains a challenge for future editions of DSM.

Reliability The few extant studies of reliability in adjustment disorders have produced unimpressive results. One study determined the inter-rater agreement (k) for adjustment disorders to be 0.05 (*P* = not significant) in a survey of psychiatrists and psychologists using 27 case histories of child and adolescent cases. The k for the DSM-II category transient situational disorder was somewhat higher in this study (k = 0.28; $P < 0.05$). The results of the U.K.–World Health Organization (UK-WHO) study of reliability of the ninth revision of *International Statistical Classification of Disease* (ICD-9) categories in children and adolescents were consistent with these findings. The k for adjustment disorders was 0.23, which was considerably lower than for many other categories. Reclassification using a glossary improved reliability to 0.33, suggesting that structured assessment can partially ameliorate the limited reliability of adjustment disorders.

There are many potential sources of poor reliability, although the lack of an operationalized symptom checklist and a threshold level of symptoms that demarcate entrance into the diagnosis seem paramount. Other sources of poor reliability include (1) difficulties in determining when subjective distress or observable symptomatology exceeds what would normally be expected for a given stressor in an “average” individual; (2) the absence of any impairment criterion in the diagnostic algorithm that defines maladaptation to stress; and (3) the variability produced by cultural expectations regarding the reaction to and management of stressful events. The low reliability of adjustment disorders is consistent with the fact that measurement of psychosocial stress on Axis IV has repeatedly been found to be questionable. Nevertheless, recent efforts to create a more rigorous adjustment disorders diagnosis offer promise for improved reliability in the future. One such study utilized an extensive symptom checklist and required a minimum of four symptoms for diagnosis, and was able to accurately classify the majority of cases of adjustment disorder.

Temporal Criteria Two studies have examined the onset of adjustment disorders following stress. One was conducted in 92 school-age children with a recent diagnosis of new-onset insulin-dependent diabetes; 33 of these children developed adjustment disorders. The highest risk occurred in the first month after diagnosis (73 percent), and 31 of the 33 had onset of symptoms by 3 months. Another study, conducted in adults who underwent cardiac surgery, observed that over half developed psychiatric symptoms before surgery, probably as a consequence of the impairment resulting from the illness or the anticipation of surgery. The other half experienced symptom formation 1 month afterwards, more likely as a consequence of the recuperation from surgery or the resultant change in lifestyle. Both studies demonstrate the close temporal association of psychiatric symptoms with the stressor, and thereby support the DSM onset criterion of 3 months. However, the latter study also illustrates that it may be difficult to ascertain what the actual stressor is in any given situation, thereby complicating the determination of onset of symptoms.

Several published studies have provided data regarding the duration of adjustment disorders. A chart review study at the University of Iowa reported that 66 percent of adolescents and 35 percent of adults with adjustment disorders were symptomatic for greater than 6 months, while 47 percent of adolescents and 23 percent of adults were ill for over 1 year. Another study, which examined the correlates of depressive disorders in children, including adjustment disorders with depressed mood, found that the mean duration of an episode was 25 weeks. The peak interval-specific probability of recovery was 6 to 9 months. Similar findings were reported in the study that examined the psychological adjustment of children following the onset of insulin-dependent diabetes. The mean episode length was 3 months, with the majority recovering within 6 months. However, 15 percent of the sample was symptomatic for greater than 6 months. In the study of adjustment disorders following cardiac surgery, 30 percent of patients had not recovered within 6 months. These findings all support the decisions in DSM-IV to extend the duration of symptoms in adjustment disorder beyond 6 months and to establish acute and chronic designations.

Results of studies examining the onset of psychopathology following stress, not linked to any specific disorder, also provide useful data with which to evaluate the temporal criteria in adjustment disorders. One such study assessed the timing and number of life events occurring in the year prior to the onset of emotional or behavioral problems or both in school-aged children compared with community controls. The onset of symptoms occurred within 16 weeks of the event in only 49 percent of cases, with a subgroup of children developing symptoms more than 6 months following the event. This finding of a relatively long latency of onset of symptoms following stress stands in contrast to the results in samples with a circumscribed diagnosis of adjustment disorders. It may be that symptomatology in response to stress is quicker in adjustment disorders than other disorders, or it may be that latency is shorter following serious medical illness as opposed to other stressors.

ICD There is an analogous category of adjustment disorders in the 10th revision of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10), which is placed in a cluster of stress-related disorders. Although the construct of “adjustment disorders” is quite similar in DSM-IV and ICD-10, certain defining characteristics differ. In ICD-10 the disorder has its onset within 1 month of the occurrence of the stressor, rather than the 3 months required in DSM-IV. Also, there are differences in the subtypes identified in the two systems. ICD-10 identifies a brief depressive reaction and a prolonged depressive reaction; the latter subtype may last up to 2 years. Similar to DSM-IV, ICD-10 identifies subtypes for mixed anxiety and depression, disturbance of conduct, mixed disturbance of emotions and conduct, and other specific predominant symptoms. However, ICD also highlights particular features of maladjustment to stress in children, best exemplified by regressive behaviors such as bedwetting, babyish speech, or thumb-sucking. These behaviors, when present, are coded under the subtype adjustment disorders with predominant disturbance of other emotions.

Unresolved Questions Several important questions regarding adjustment disorders remain unresolved and should receive attention in future classification efforts. What is the relationship between adjustment disorder and other stress-related disorders, such as posttraumatic stress disorder and acute stress disorder, and should these conditions be grouped together, as in ICD-10, or separately, as in DSM-IV? Are the subtypes of adjustment disorders more appropriately conceptualized as minor disorders of mood, anxiety, and behavior? As increased attention is focused on these various subthreshold disorders, and criteria for their use are developed, it may be more difficult to distinguish adjustment disorders from subthreshold categories that are not stress-related. Finally, should adjustment disorders be placed with the problem-level diagnoses rather than the psychiatric disorders? Against the latter option are the findings from a large outpatient sample that indicate that, although patients with adjustment disorders present with less severe symptomatology than those with specific psychiatric disorders, they more closely resemble the patients with specific disorders in terms of impairment and level of function than they do the individuals who do not qualify for a psychiatric diagnosis.

EPIDEMIOLOGY

There is only one published epidemiological study that included adjustment disorders, and that was conducted in children and adolescents in Puerto Rico. The prevalence rate of adjustment disorders was determined to be 7.6 percent using a cutoff of 70 for “caseness” on the Children's Global Assessment Scale (CGAS). However, if children with CGAS scores between 61 to 70 were excluded, the prevalence of adjustment disorders dropped to 4.2 percent. While this suggests a low level of impairment in about 40 percent of children with adjustment disorders, the 4.2 percent figure indicates that a large number of individuals have the disorder and that it is often associated with impairment.

Similar epidemiological data are not available in adults because the structured interviews used as a source of diagnosis in the major epidemiological studies in this age group did not include algorithms for adjustment disorders. However, reanalyses of data from the Epidemiologic Catchment Area study have identified a subthreshold mood disorder, subsyndromal symptomatic depression, whose prevalence exceeded that of all proposed DSM-III mood disorders combined. Approximately half of the individuals who met criteria for this disorder presented with depressed mood. Another large group presented with two or more related symptoms, such as vegetative symptoms, trouble concentrating, decreased energy or suicidal thoughts, for over 2 weeks, but did not report depressed mood. It is

likely that many of these individuals would have qualified for diagnoses of minor depressive disorder, another subthreshold diagnosis (e.g., anxiety disorder not otherwise specified) or adjustment disorders. However, it is not known what percentage of cases were related to psychosocial stressors.

The prevalence of adjustment disorders has more often been evaluated in clinical samples. The largest and most systematically assessed database was obtained by evaluating all patients on entry to the Western Psychiatric Institute clinical services using a semistructured assessment form and DSM-III criteria sheets. Ten percent of a sample of over 11,000 patients (all ages) were found to have adjustment disorders, making it the second largest diagnostic category. In children and adolescents under 18 years old, over 16 percent had adjustment disorders. In adults, females predominated over males by approximately 2 to 1. The sex ratio was more equal in children and adolescents, although there was still a slight excess of female cases.

Prevalence estimates of adjustment disorders in other clinical populations have been characterized by considerable variability, though reported rates are generally high. In a study of over 1300 psychiatric outpatients in Switzerland, 26 percent qualified for a diagnosis of adjustment disorders as determined by two evaluating psychiatrists. A survey of emergency room visits found that 13 percent of adults and 42 percent of adolescents were diagnosed with adjustment disorders. Adjustment disorders was twice as common as any other diagnosis among adolescents in that study, including substance abuse. Adjustment disorders is also highly prevalent in medical settings. In a multisite consortium of teaching hospitals, adjustment disorder was diagnosed in 125 out of over 1000 patients (12 percent). In another study, 9 percent of 1072 patients evaluated on an adult medical-surgical consultation-liaison service were diagnosed with this disorder. Approximately 50 percent of 71 patients who received cardiac surgery met criteria for adjustment disorders, almost all had adjustment disorders with depressed mood. Among pediatric patients sampled from four different clinics, 25 to 65 percent of those who presented with psychiatric disturbance were given a diagnosis of adjustment disorders. In evaluating these 11 prevalence figures, it is important to remember that structured methods are generally not used in clinical settings, and that clinician preferences regarding diagnosis or sample bias may have contributed to the high prevalence estimates of adjustment disorders.

ETIOLOGY

By definition, adjustment disorders is associated with psychosocial stress; it is presumed that without the occurrence of the stressor, the condition would not arise. However, many important questions regarding etiology remain unanswered. For example, why is there so much individual variation in the development of psychopathology in individuals who experience apparently similar life events? Are all individuals likely to develop symptoms if stress levels are increased sufficiently? When a pathological reaction to stress does occur, why is the nature of the pathology so variable—ranging from no disorder, to subthreshold pathology or adjustment disorders, to major disorders? Does an initial episode of adjustment disorders predict the subsequent development of more specific and severe pathology? What modifiers of stress attenuate or accentuate its effects?

Few studies have evaluated the types and duration of stressors in adjustment disorders. One such study highlighted differences between adolescents and adults in the nature and duration of stress. Stressors were more likely to be chronic (>1 year) in adolescents than adults (59 percent versus 36 percent). School problems were the most frequently identified precipitant for symptomatology among adolescents (>60 percent), although a variety of family, boyfriend-girlfriend, and substance use problems were also common. In adults, marital problems, including separation and divorce, were the most common stressors. A similar profile of stressors was found in a recent study of Swiss outpatients with adjustment disorders.

The results of studies that have examined the relationship of stress to the development of psychopathology provide additional information to be considered in evaluating the model of stress-disease interaction in adjustment disorders. Several studies have found that individuals with and without preexisting symptoms respond differently to the presence of stressful events. This has been observed both in samples with adjustment disorders as well as other conditions. Preexisting mood symptomatology was the only factor that predicted a prolonged course of adjustment disorders following cardiac surgery. In Israeli children who suffered the loss of their father in war, preexisting conduct symptoms were highly correlated with poor adjustment (although not necessarily adjustment disorders).

Other studies have focused on those factors that protect individuals from developing stress-related symptoms. For example, preexisting adaptive skills decrease the likelihood of symptoms developing in the face of stress. In child and adolescent populations, a warm and supportive relationship with the primary caregiver, easy and adaptable child temperament, and healthier adjustment of the family to stress all predict a more positive response to stress within the child. Finally, the nature of the life events has important implications for the level of adjustment. Control over life events has generally been associated with improved adjustment even though it may increase stress. Similarly, pleasurable events are generally linked to psychological well-being, even though they may be stressful. In contrast, life events of a more dependent nature, which are undesirable and outside the control of the affected individual, are more likely to produce psychiatric symptoms.

The relationship of family, environmental, and genetic factors to adverse life events must also be considered. Findings from a study of over 2000 twin pairs indicate that life events are modestly correlated in twin pairs, with monozygotes showing greater concordance than dizygotes. Family-environmental and genetic factors each accounted for approximately 20 percent of the variance in that study. Another twin study that examined genetic contributions to the development of symptoms of posttraumatic stress disorder (not necessarily at the level of full disorder, and therefore relevant to adjustment disorders) similarly concluded that the likelihood of developing symptoms in the context of traumatic life events is partially under genetic control. The findings of these studies suggest that the occurrence of adverse life events and their consequences are not necessarily random. Certain individuals appear to be at increased risk both for the occurrence of these events and for the development of pathology once they occur.

In summary, although the occurrence of psychosocial stress is an essential component of adjustment disorders, data indicate that stress is just one of many factors that determines the development, nature, and extent of psychopathology. Specific types of stressful events and individual patterns of stress response appear to be preferentially related to the development of psychiatric symptoms in vulnerable individuals. Protective factors play a role in mitigating the stress response. Moreover, development of psychiatric symptoms is most often associated with an accumulation of stressors rather than any single event. How to best integrate these findings into a more robust conceptual framework for adjustment disorders represents a challenge for the future.

DIAGNOSIS AND CLINICAL FEATURES

Table 23-1 lists the DSM-IV diagnostic criteria for adjustment disorders, and Table 23-2 presents the ICD-10 diagnostic criteria for adjustment disorders.

A. The development of emotional or behavioral symptoms in response to an identifiable stressor(s) occurring within 3 months of the onset of the stressor(s).
B. These symptoms or behaviors are clinically significant as evidenced by either of the following:
(1) marked distress that is in excess of what would be expected from exposure to the stressor
(2) significant impairment in social or occupational (academic) functioning
C. The stress-related disturbance does not meet the criteria for another specific Axis I disorder and is not merely an exacerbation of a preexisting Axis I or Axis II disorder.
D. The symptoms do not represent bereavement.
E. Once the stressor (or its consequences) has terminated, the symptoms do not persist for more than an additional 6 months.

Specify if:
Acute: if the disturbance lasts for less than 6 months
Chronic: if the disturbance lasts for 6 months or longer

Adjustment disorders are coded based on the subtype, which is selected according to the predominant symptoms. The specific stressor(s) can be specified on Axis IV

With depressed mood
With anxiety
With mixed anxiety and depressed mood
With disturbance of conduct
With mixed disturbance of emotions and conduct
Unspecified

Table 23-1 DSM-IV Diagnostic Criteria for Adjustment Disorders

Table 23-2 ICD-10 Diagnostic Criteria for Adjustment Disorders

Several studies have described the nature of the symptomatic presentation of adjustment disorders in clinical samples. In most samples depressive symptoms have been found to predominate, leading some authors to assert that depressive symptoms represent a core feature of adjustment disorders. In the Western Psychiatric Institute study half of a mixed child and adult population with adjustment disorders had depressed mood. An earlier publication from the same data set reported that 76 percent of adjustment disorders patients had depressed mood. Additional symptoms prominently represented in the adjustment disorders group were insomnia (53 percent), other vegetative symptoms, social withdrawal (29 percent), and suicidal indicators (29 percent).

The development of depressive symptoms is characteristic of children and adolescents with adjustment disorders as it is in adults, although behavioral symptoms and mixed clinical presentations are also frequently encountered. These findings are consistent with data from studies of mood disorders in children and adolescents, which indicate that comorbidity with behavior disorders is common. In the University of Iowa study, a large percentage of both adults and adolescents with adjustment disorders had depressive symptoms (87 percent of adults and 63 percent of adolescents). However, 77 percent of adolescents but only 25 percent of adults had behavioral symptoms. The prominence of mixed syndromes in youth was highlighted in two other studies of children and adolescents with adjustment disorders, in which the majority of subjects were found to have mixed emotional or mixed emotional and behavioral features.

Several recent investigations have begun to delineate symptom profiles for adjustment disorders. Youth who developed adjustment disorders following the onset of diabetes mellitus presented with an average of five symptoms, including feeling sad, suicidal ideation, pessimism, anhedonia, irritability or anger, and fatigue. The most common symptoms of adjustment disorders in the Western Psychiatric Institute data set reanalyzed for DSM-IV included depressed mood, low self-esteem, suicidal behavior, increased motor activity, impulsive behavior, substance use, hypervigilance, and hostility. Many of these symptoms have also been described in subthreshold mood and anxiety disorders that are not stress related. One proposed category of subsyndromal symptomatic depression included symptoms of trouble falling asleep or early waking, fatigue, thoughts of death, sadness, and trouble concentrating. Similarly, the field trial for mixed anxiety-depression conducted for DSM-IV indicated that difficulty concentrating, hypervigilance, hopelessness, feelings of worthlessness, tearfulness, fatigue, worry, anticipating the worst, irritability, and sleep disturbance are frequently present. The collective findings from these studies indicate that it is possible to identify core symptoms for subthreshold mood and anxiety disorders. However, similarity of symptom profiles among the various subthreshold conditions, as well as with related, above-threshold disorders, suggests that symptomatology alone may not be the most important distinguishing feature of the subthreshold disorders. In addition, it is unknown whether symptoms of subthreshold disorders are in any way modified when they present in the context of stress.

Adjustment disorders has been described as a transitional diagnostic category, because the level of symptomatology and impairment in adjustment disorders was found to be intermediate between that observed in comparison groups who only had a DSM-III problem-level diagnosis, and patients with specific, above-threshold diagnoses. The symptomatic profile and level of impairment in patients with adjustment disorders with depressed mood was quite similar to that found in dysthymic disorder and atypical (minor) depression, although it was distinct from major depressive disorder and bipolar I disorder, suggesting poor discriminant validity of adjustment disorders with depressed mood with respect to minor depressive disorders. Adjustment disorders has also been described as an admission diagnosis or initial diagnosis for many adolescent and adult psychiatric inpatients. In one study, a large number (40 percent) of patients given this preliminary diagnosis were assigned a different diagnosis at the time of discharge. An even smaller number (18 percent) of those who were subsequently readmitted to the hospital were again diagnosed as having adjustment disorders.

Studies of adjustment disorders using structured diagnostic instruments have reported a fairly high level of comorbidity. In a mixed group of children, adolescents, and adults, approximately 70 percent of patients with adjustment disorders had at least one additional Axis I diagnosis. In the study of correlates of depressive disorder in children, 45 percent of those with adjustment disorders with depressed mood had another diagnosis. However, comorbidity of adjustment disorders with other Axis I disorders was less than in dysthymic disorder or major depressive disorder, suggesting a more pure or encapsulated disturbance in adjustment disorders. The extent to which comorbidity exists may be an important determinant in the level of impairment and risk for poor outcome in samples with adjustment disorders. One study, which compared the risk for continued pathology in individuals with adjustment disorders and psychiatric controls matched for comorbidity, found that adjustment disorders added no risk above that accounted for by comorbidity.

Studies have consistently reported a significant association of adjustment disorders with suicidal behavior, particularly in adolescents and young adults. In an urban hospital setting, 56 percent of all admissions for suicidal behavior were classified as having transient situational disorders using DSM-II criteria. Similarly, a retrospective review of 325 consecutive hospital admissions for deliberate self-poisoning found that 58 percent of cases met criteria for adjustment disorders with depressed mood. The majority were aged 15 to 24, with females predominating over males. Psychological autopsy data from several studies also indicate a high representation of adjustment disorders among suicide completers. In a Scandinavian sample of 58 consecutive suicide victims aged 15 to 29, 14 percent were classified as having adjustment disorders with depressed mood. In a U.S. population, 9 percent of suicide victims aged 10 to 29 were reported to have adjustment disorders. When compared with a group of patients with major depression who made suicide attempts, suicidal patients with adjustment disorders were more likely to make their attempt in the context of substance abuse. Moreover, suicidal behavior among patients with adjustment disorders was less likely to be planned. These findings underscore the seriousness of adjustment disorders in a subset of individuals and suggest that although the diagnosis may be subthreshold its morbidity may be highly significant, including risk of serious self-harm and death.

A 21-year-old college senior was in her usual state of health, vacationing with her aunt and uncle in Arizona during spring break. While she was away, a letter containing a copy of her full college transcript arrived at her parents' home. On reading the letter, her parents noticed that the grades on the transcript did not match those which they had previously seen at the end of each semester since freshman year. The mother called her daughter and confronted her with this information. During the conversation it became apparent that the daughter had been changing the grades on the transcripts that were sent home so that the grades her parents saw were better than was actually the case. An argument ensued and harsh words were exchanged. Following these events, the daughter became extremely upset and experienced feelings of anxiety and depressed mood. She felt ashamed about the situation and saw no way out. She spent most of the next 2 days in her room and did not participate in pleasurable activities; there were periods of crying as well as decreased eating and sleeping. Her aunt and uncle were only somewhat able to comfort her. Two days later, without warning, the patient ingested ten tablets of an over-the-counter sleep preparation. Later that day, the aunt found the patient to be fairly lethargic, and upon questioning, determined that she had made a suicide attempt. The patient was brought to a local emergency room, where she was admitted and retained in the psychiatric inpatient unit for several days. The patient's mother flew to Arizona to meet with her daughter and the hospital staff. Following crisis intervention, the patient was released with her mother to return home, where they consulted with another psychiatrist. By the time of this second evaluation, there were no longer signs of depressed or anxious mood, nor was there any suicidal ideation. The treatment plan consisted of crisis intervention, continued individual therapy for the patient on return to school, counseling for the parents, and conjoint family sessions to be held monthly during scheduled home visits. Despite continued individual and family upset over the precipitating event and the subsequent suicide attempt, the patient was able to return to school the following week to complete her spring semester.

Subtypes The diagnostic criteria for adjustment disorders define the contextual and temporal characteristics of a subthreshold response to a psychosocial stressor; the specific nature of the resultant symptom presentation is used as a means of subtyping. Six subtypes of adjustment disorders are described. Three of the subtypes define discrete symptomatic presentations (e.g., depressed mood, anxious mood, disturbance of conduct); two describe mixed clinical presentations (e.g., mixed emotional features; mixed disturbance of emotions and conduct); and one is a residual category for presentations not accurately described by any of the other subtypes (e.g., adjustment disorders unspecified). Previous editions of DSM included additional subtypes of adjustment disorders (e.g., adjustment disorders with physical complaints, work or academic inhibition, and withdrawal), but these were eliminated in DSM-IV because they were found to be infrequently used, even in

medical settings with physically ill patients. One additional subtype, adjustment disorders with suicidal behavior, was proposed for inclusion in DSM-IV. However, it was ultimately rejected because of concern that inclusion of this subtype might discourage systematic assessment and differential diagnosis of suicidal behavior, possibly resulting in the overidentification of adjustment disorders instead of a specific above-threshold diagnosis when suicidal behavior was present.

DSM-IV does not identify specific symptom profiles for the individual subtypes of adjustment disorders. However, an attempt was made to more accurately describe these subtypes and determine whether they are unique from above-threshold disorders. Symptoms found to be particularly salient for individual adjustment disorders subtypes were (1) depressed mood: depression, hyposomnia, low self-esteem and suicidal indicators; (2) anxiety: generalized anxiety, increased motor activity and situational anxiety; (3) disturbance conduct: impulsivity, lack of insight and violent behavior; and (4) mixed disturbance of emotions and conduct: excessive alcohol ingestion, depressant drugs that do not act on the central nervous system (CNS), suspiciousness, hostility, defrauding behavior, and homicidal ideation. Adjustment disorder subtypes did not differ from each other in the overall stressor severity or the highest level of functioning in the past year. However, impairment in current function was greatest in the depressive and mixed emotions and conduct subtypes.

DIFFERENTIAL DIAGNOSIS

The combination of subsyndromal symptomatology and the presence of an identified psychosocial stressor distinguishes adjustment disorders from all other Axis I and Axis II disorders in DSM-IV. Other conditions are either stress related but have an established diagnostic threshold, or subthreshold but not linked to stress. Posttraumatic stress disorder is characterized by a more narrowly defined concept of severe psychosocial stress, and a specific constellation of affective and autonomic symptoms lasting a minimum of 3 months. Acute stress disorder describes a similar, although possibly less severe, clinical presentation of less than 3 months' duration. In contrast, adjustment disorders can be triggered by a stressor of any severity, may present with a wide range of possible symptoms, and has no minimum or maximum duration. The individual subtypes of adjustment disorders must also be distinguished from atypical or subthreshold presentations of many of the major mental disorders (e.g., anxiety mood, conduct). However, the latter conditions need not be stress related and are therefore classified under the appropriate symptom domain using the designation not otherwise specified. Differential diagnosis should also include conditions that may be associated with impairment but are not deemed to be of sufficient severity to warrant a psychiatric diagnosis (e.g., bereavement).

Differences between adjustment disorders subtypes with respect to each other and to relevant above-threshold disorders were investigated in a reanalysis of the Western Psychiatric Institute data set in anticipation of DSM-IV. Each of the adjustment disorders subtypes was characterized by a set of 5 to 8 relatively discrete symptoms. In adults, adjustment disorders with depressed mood could be distinguished from above-threshold mood disorders both in terms of symptomatic presentation, severity and duration of impairment, and stressor severity. Similar trends were observed between adjustment disorders with anxious mood and above-threshold anxiety disorders. However, stressor severity was not found to be significantly different in adjustment disorders with anxious mood and posttraumatic stress disorder due to the low number of cases. In youth, symptomatic and functional differences were also detected between adjustment disorders with depressed mood and above-threshold depressive disorders. However, stressor severity was not found to differ between adjustment disorders and a variety of other disorders, quite possibly because stressor severity was high for all disorders in this age group. The fact that adjustment disorders does not appear to be more highly associated with stress in youth than a variety of other disorders raises questions regarding discriminant validity of the construct in this age group.

Similarities and differences between adjustment disorders and other subthreshold disorders represents an area of increasing interest. DSM-IV conducted field trials to investigate the proposed category of mixed anxiety-depression, in which threshold levels of symptomatology for each disorder alone were not achieved, but the total number of symptoms of both disorders combined exceeded a pre-determined threshold. Symptom profiles and descriptive features of mixed anxiety-depression were found to be relatively distinct from those of above-threshold mood and anxiety disorders. However, this study did not adequately examine the relationship of subthreshold symptomatology to stress, and ruled out overlap with adjustment disorders only by the extended duration of symptomatology in the proposed anxiety-depression category (i.e., distinguishing it from adjustment disorders as defined in DSM-III-R but not as modified in DSM-IV. A similar symptoms profile was also determined to be present in individuals who fulfilled criteria for the proposed diagnosis of subthreshold symptomatic depression. Interestingly, the symptom profiles for mixed anxiety-depression and subthreshold symptomatic depression were strikingly similar to those most frequently encountered among individuals with adjustment disorders in the Western Psychiatric Institute data. Taken together, these findings indicate that it is possible to more accurately describe symptomatic profiles of individuals with adjustment disorders and other subthreshold disorders. However, adequate discrimination among these various conditions remains elusive.

COURSE AND PROGNOSIS

Historically, adjustment disorders has not been considered to be an enduring diagnosis; individuals with this disorder have generally been thought to either experience a resolution of symptoms or progress to a more serious illness. However, this is not always the case, and DSM-IV now recognizes chronic as well as acute presentations of adjustment disorder. Nevertheless, the question of whether adjustment disorder predicts future psychiatric morbidity has considerable relevance for understanding whether the symptoms in adjustment disorder constitute a normal or pathological reaction to stress. It is also important to understand whether an episode of adjustment disorder might predict subsequent occurrences of symptomatically related, above-threshold disorders.

Studies of adults with adjustment disorder have generally indicated a benign clinical course. A follow-up study of military recruits using DSM-II criteria found that transient situational disorder was the least severe and disabling condition of those studied. Approximately 60 percent of this group was well at follow-up. Many of the 40 percent who demonstrated continued impairment were diagnosed as having a personality disorder. Follow-up of the University of Iowa sample indicated a high rate of recovery in adults with adjustment disorder, but a lower likelihood of recovery in adolescents (71 percent versus 44 percent). An additional 13 percent of the adolescent sample were well at follow-up but had intervening difficulties. In total, nearly 70 percent of the original sample of adolescents with adjustment disorder was ill at one time during the follow-up period. Adolescents were more likely than adults to have severe diagnoses at follow-up; some developed major mental disorders such as schizophrenia, bipolar I disorder, major depressive disorder, antisocial personality disorder, and drug abuse. Chronicity of behavioral problems was the best predictor of poor outcome. However, the original adjustment disorder subtype did not predict the follow-up diagnosis.

Other studies of adjustment disorder among children and adolescents have also reported poor outcome. In a survey of all adolescents receiving mental health treatment in a single geographical region, 52 percent of those originally diagnosed with transient situational disorder required treatment on 10-year follow-up. Another study, which examined the outcome of children with speech and language disorders, also indicated poor outcome in children with adjustment disorder. Of the 19 patients with this diagnosis at the time of initial assessment, only 26 percent were recovered after 4 years. The most frequent follow-up diagnoses were attention-deficit disorder, overanxious disorder, oppositional disorder, and avoidant disorder.

The longitudinal course of adjustment disorder with depressed mood was not characterized by increased risk for major depressive disorder in a study at the University of Pittsburgh that examined the course and prognosis of depressive disorders in children and adolescents. It is not known whether these children went on to develop different disorders outside the spectrum of mood disorders (and therefore may have still experienced poor outcome). However, a subsequent publication using a sample that included those and other children with adjustment disorder (not all of whom had adjustment disorder with depressed mood) found that adjustment disorder added no additional risk for poor outcome when compared with a psychopathological control group matched for comorbidity who did not have adjustment disorder. Those findings raise questions as to whether some of the risk for poor outcome reported in children and adolescents with adjustment disorder might be attributable to comorbidity with other disorders.

In contrast to this latter finding, high school students with adjustment disorder with depressed mood were at increased risk for major depressive disorder in young adulthood. Also, the University of Pittsburg group reported that adjustment disorder with depressed mood was commonly observed following the acute onset of diabetes mellitus, and predicted later psychiatric maladjustment. Of 92 children studied, 38 (41 percent) developed a new psychiatric disorder; 30 of these children met criteria for adjustment disorder. The disorder had a relatively rapid onset after diagnosis and was resolved in most cases within 2 to 3 months. Nevertheless, the cumulative probability of developing a psychiatric disorder in the subsequent 5 years was over three times as great in the children with adjustment disorder as compared to those without adjustment difficulties. Thus, development of adjustment disorder following the new onset of a medical illness predicted subsequent psychiatric dysfunction in a previously healthy population whereas it did not appear to affect later adjustment in a population with a high degree of psychiatric comorbidity. Taken together, these findings suggest that while the relationship between adjustment disorder and subsequent mental health function may be less dramatic than it is for other disorders, it is nonetheless real.

TREATMENT

Adjustment disorder may present with subthreshold pathology in one or several symptom domains. A variety of treatment interventions may therefore be useful in treating the heterogeneous group of individuals with this disorder. There are few, if any, treatment studies in individuals with adjustment disorder; indeed, very little is known or written about the treatment of individuals with subthreshold pathology of any kind. However, since adjustment disorder and other subclinical conditions

represent common psychiatric diagnoses in private practice, consultation-liaison situations, and primary care settings, systematic clinical trials with these conditions are warranted.

The treatment of individuals with adjustment disorder entails careful assessment of the nature and severity of the disturbance, taking into account the presence of risk factors that are known to be associated with poor outcome—for example, continuation of stressors, poor premorbid functioning. Interventions should be designed to minimize the impact of these stressors on day-to-day function. It is essential to understand the meaning of the stressor to the patient and why it seems to have been associated with the development of psychiatric symptoms at this time. Moreover, the clinician should appreciate the patient's level of vulnerability and capacity for adaptation. Is this a previously healthy, high-functioning individual who has become symptomatic in the context of a serious life stress? Or is this an individual with chronic, ill-defined coping problems who is having difficulty dealing with a variety of longstanding circumstances?

It is also important to understand and facilitate those factors that may mitigate the pathological response to stress. Examples include helping to develop a warm and supportive relationship with family members and helping the patient increase the breadth of social support. Attempting to minimize factors that maintain symptoms represents another important strategy. Examples might include working with parents of a child with adjustment disorder to help them better cope with the stressful events in their family because positive parental adjustment minimizes the likelihood of pathological adjustment in children.

In addition to these general recommendations, a range of specific treatment interventions may be considered in individuals with adjustment disorder, including psychodynamic, cognitive-behavioral, and supportive psychological interventions, counseling regarding life circumstance problems, and concrete assistance in the resolution of problematic situations. Short-term treatment may be sufficient for many patients with adjustment disorder, consistent with the conceptualization of the disorder as time limited. However, referral for more extended treatment following the reestablishment of baseline functioning may be desirable if there was pre-existing symptomatology or if there are individual characteristics that predispose the patient to stress intolerance. Crisis intervention and case management may be required on a short-term basis, often involving direct environmental manipulation in order to bring about a lessening of stress and enhanced external support. Individual psychotherapy may be either supportive or exploratory, although the latter strategy may be more suitable following resolution of the acute situation. Individual psychotherapy offers the patient an opportunity to better understand the meaning of the stressor and why it resulted in an impaired ability to function. Group therapies may be particularly useful for individuals who have experienced similar stresses—for example, in individuals who have recovered from a specific medical illness or surgical procedure.

There are no studies assessing the efficacy of pharmacological interventions in individuals with subsyndromal pathology; however, it may be reasonable to consider the judicious use of medication to treat specific symptoms associated with adjustment disorder. One report presented a rationale for the use of benzodiazepines in the treatment of adjustment disorder with anxious mood. Selective serotonin reuptake inhibitors have been found to be useful in treating symptoms of traumatic grief, and may be useful for other groups with subthreshold depressive symptoms. Indeed, a recent survey of prescribing practices among outpatient physicians indicated a robust increase in antidepressant use in individuals with adjustment disorder. It should be stressed, however, that pharmacological intervention in this population is most often used to augment psychosocial strategies rather than serving as the primary modality. Controlled clinical trials are needed to more accurately specify the role of pharmacotherapy in adjustment disorder and other minor disorders.

SUGGESTED CROSS-REFERENCES

Anxiety disorders, including posttraumatic stress disorder, are discussed in Chapter 15 and mood disorders in Chapter 14. Suicide is presented in Section 29.1 and Chapter 45. Separation and divorce are covered in Section 30.5 on couples therapy, Section 25.9 on stress, and Chapter 26 on relational problems. Bereavement is discussed in Section 28.5, and physical and sexual abuse is discussed in Section 28.7.

CHAPTER 24. PERSONALITY DISORDERS

C. ROBERT CLONINGER, M.D., AND DRAGAN M. SVRAKIC, M.D., ḥH.D.

Personality disorders have become a major social, medical, and scientific problem. Serious concerns about these disorders have been raised by both experts and lay persons, including mental health professionals, sociologists, public health workers, politicians, charity activists, community leaders, and news analysts. No demographic group is immune to personality disorders. Indeed, estimates of the prevalence for these disorders in the general population range from 11 to 23 percent, depending on the severity of impairment required for diagnosis. This translates into an alarming 1 in every 4 to 10 individuals in our neighborhoods having personality disorder, regardless of location or socioeconomic status. These individuals have chronic impairments in their ability to work and love and tend to be less educated, single, drug addicts, and sex offenders, and to have marital difficulties and be unemployed. In addition, many perpetrators of violent and nonviolent crime as well as most prison inmates have a personality disorder.

In psychiatry, about one half of all patients have personality disorder, frequently comorbid with Axis I conditions. Personality factors interfere with the response to treatment of all Axis I syndromes and increase personal incapacitation, morbidity, and mortality of these patients. Moreover, personality disorders are a predisposing factor for many other psychiatric disorders, including substance use disorders, suicide, mood disorders, impulse-control disorders, eating disorders, and anxiety disorders. Patients with personality disorders are often perceived as “aggravating” and “demanding,” and may be rejected by therapists who expect them to have a poor prognosis. Alternatively, they may be seductive and dependent and elicit inappropriate responses from their therapist, such as sexual interest or the urge to rescue. This blurring of professional boundaries can lead to loss of objectivity, when patient's verbal and nonverbal communication takes on personal, rather than diagnostic and therapeutic, significance. Indeed, these patients test the limits of any physician's theoretical knowledge, practical skills, and maturity of character. The rare physician with low narcissism, high energy, and high tolerance is optimal for treating patients with personality disorder.

A somewhat lower, but still substantial, proportion of patients in somatic medicine have personality disorders comorbid with their physical illnesses. Personality factors have been associated with increased risk for coronary artery disease, angina pectoris, human immunodeficiency virus (HIV) infection, psoriasis, ulcerative colitis, and many other so-called psychosomatic diseases. Yet, patients with personality problems who seek medical help frequently have a negative workup and no medical explanation for their complaints. Clearly, people with personality disorder consume a large portion of community services, public health resources, charity, and social programs.

Since the 1980s there has been a dramatic increase in interest in personality disorders. For example, in 1975, the MEDLINE search service of the National Library of Medicine listed 69 published articles about personality disorder, in 1985 the number was 262, and in the years 1996 and 1997 the number escalated to 3079. In addition, numerous monographs dealing with personality disorders have been published over the last two decades. Reflecting this trend, the International Society for the Study of Personality Disorders and its official journal, the *Journal of Personality Disorders,* were founded during the past decade.

Several phenomena help explain the dramatic shift in professional sensitivity to personality disorders and a growing interest in their systematic study. First, personality disorders are diagnosed far more frequently nowadays than in the past. This reflects the introduction of operationalized diagnostic criteria and the multiaxial diagnostic system in the third edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III) in 1980. By specifying precise descriptive criteria based on typical behaviors and feelings for each of the classified personality syndromes, DSM-III enabled clinicians to diagnose personality disorders more systematically. These criteria were revised and standardized in the revised third edition of DSM (DSM-III-R) in 1987 and the fourth edition of DSM (DSM-IV) in 1994. The multiaxial diagnostic system means that personality disorders and mental retardation are classified on Axis II, whereas other clinical syndromes are classified on Axis I. The availability of these two diagnostic axes facilitates the diagnosis of personality disorders because it ensures that personality disorders are not overlooked, even when they co-occur with a clinically more prominent Axis I syndrome.

Second, the increased clinical recognition of personality disorders probably reflects their increased prevalence in the general population. At the turn of the twentieth century, when Freud was pioneering his understanding of our human nature, neuroses and neurotic problems were the dominant “psychopathology of every day life.” At the time, the central psychological task people faced was finding socially acceptable ways to express their “asocial” impulses, predominantly aggression and sexuality. The full complexity of this struggle with personal conflicts and demands for self control is illustrated in Karen Horney's masterpiece *The Neurotic Personality of Our Time* in the 1950s. Obviously, behavior codes of our present ethically more liberal society differ substantially from the ethical conservativism at the turn of the century. Both aggression and any kind of sexuality are much easier to express. Personal descriptors such as “dominant,” “powerful,” or “competitive” have gained wide social approval. Even modern psychology has begun to distinguish between “angry” (unacceptable) and “instrumental” (competitive, acceptable) aggression, the former having as reward “discomfort of the victim” and the latter “dominance in the society.” Instead of searching for ways to express their impulses, people are currently faced with questions of identity, meaning, and choice. Clearly, the objective of the psychological puzzle has shifted from morality to identity and, therefore, from the society to the person. The modern day “psychopathology of everyday life” has changed accordingly. Nowadays, one more frequently encounters patients who need help but cannot precisely describe their problems, who are more angry than anxious, who struggle with questions of purpose rather than with guilt, who are ambivalent rather than inhibited, who feel empty rather than sad, and who manifest a peculiar inability to learn from experience and tend to repeat maladaptive behaviors over and over again. Such people are likely to be diagnosed as having personality disorder. Due to the obviously increased number of such patients, and motivated by the desire to help them, psychiatrists have started to study them more thoroughly and more frequently.

Third, personality disorder is the clinical arena in which psychodynamic psychiatry and biological psychiatry is most likely to be reconciled. In many ways, this disorder is somewhere in between minor and major psychiatric problems (e.g., adjustment disorder and schizophrenia), and it is thus interesting from both sociodynamic and biological standpoints.

Fourth, personality disorders are fairly common and underlie susceptibility to many other psychiatric and medical problems. Accordingly, the diagnosis and treatment of any patient with psychosocial problems, as well as prevention planning in many medical syndromes, are inadequate without a systematic approach to assessing and classifying personality.

Fifth, the development of psychiatry as a whole has generated increased interest in personality disorders. Every science in its initial stages has a tendency to define its subject as clearly as possible. Once sufficiently developed, it naturally begins to recognize various mixed and transitional forms. Clearly personality disorders represent a deviance from normality that psychiatry, because of its development, has begun to recognize. Consequently, numerous questions about personality disorder remain to be answered definitively, but recent progress in understanding their underlying psychobiological mechanisms is giving psychiatry a stronger foundation for understanding both normal and abnormal behavior.

BASIC DEFINITIONS AND TERMINOLOGY

Personality, temperament, motivation, and *character* are often used interchangeably. Unfortunately, this ambiguity is both misleading and unjustified. In what follows, each of these concepts is reviewed and clearly distinguished.

Personality Personality is both complex and unique in that individuals differ greatly from one another in multiple components of behavior, and each expresses only one of many potential lifestyles. All existing definitions of personality are functional (i.e., they focus on questions related to motivation and mental adaptation of the organism). Specifically, Gordon Allport defined personality as the “dynamic organization within the individual of those psychophysical systems that determine his or her unique adjustment to the environment.”

Allport elaborated on this definition by explaining that “dynamic organization” emphasizes that personality is an organized system (“unitas multiplex”) that is constantly evolving and changing. The phrase “within the individual” means that personality is what lies behind a specific individual's acts. The term “psychophysical” reminds one that personality is neither exclusively mental nor exclusively neural but a combination of the two. The verb “determine” indicates that systems that constitute personality guide expressive and adaptive behaviors. The expression “adjustment to the environment” has both functional and evolutionary significance pointing to personality as a mode of survival and, more generally, adaptation.

It is widely accepted that personality develops through the interaction of hereditary dispositions and environmental influences. The notion of genetic canalization (or “epigenetic landscape”) has been revised to include the reciprocal necessity of genetic endowment and environmental stimulation in the development of behaviors. Genetic differences account for about half of the variance in most normally distributed temperament traits. Of the remaining 50 percent of the variance, 25 to 30 percent is explained by nonshared environmental effects (i.e., experiences unique to the individual), and 15 to 20 percent by measurement error. Contrary to common belief, environmental factors shared by siblings reared together have little or no effect on basic temperament traits but do influence other aspects of personality.

From the structural standpoint, most authors agree that personality consists of temperament, character, and intelligence. Roughly speaking, temperament reflects biological contributions, and character reflects social and cultural contributions, to personality. Intelligence impregnates both constitutional and social traits and modifies overall personality functions. Basic functions of personality are to feel, think, and perceive and to incorporate these into purposeful behaviors.

Temperament Pioneering work by Alexander Thomas and Stella Chess conceptualized temperament as the stylistic component (how) of behavior, as differentiated from motivation (why) and content (what) of behavior. Modern concepts of temperament, however, emphasize its emotional, motivational, and adaptive aspects. Specifically, four major temperament traits have been identified: harm avoidance, novelty seeking, reward dependence, and persistence. Remarkably, this four-factor model of temperament can, in retrospect, be seen as a modern interpretation of the ancient four temperaments: individuals differ in the degree to which they are melancholic (harm avoidant), choleric (novelty seeking), sanguine (reward dependent), and phlegmatic (persistent). However, the four temperaments are now considered genetically independent dimensions that occur in all possible factorial combinations rather than mutually exclusive categories.

Distinction Between Temperament and Character The four dimensions of human temperament correspond closely to those observed in other mammals, such as rodents or dogs. Multiple levels in the phylogeny of learning abilities in animals from invertebrates to man indicate that learning has multiple component processes that are hierarchically organized and interact extensively throughout development (Fig. 24-1).

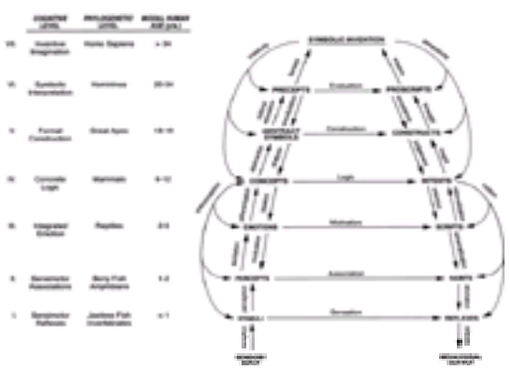

FIGURE 24-1 A hierarchical model of learning.

In Figure 24-1, temperament corresponds to the processes of sensation, association, and motivation that underlie the integration of skills and habits based on emotion. Character corresponds to the processes of symbolization and abstraction that are based on conceptual learning. Figure 24-1 is useful to specify the hierarchical phylogenetic and ontogenetic organization of learning and its relevance to the concepts of temperament and character not to compare learning in humans at a particular age with learning in lower animals. Specifically, temperament and character are conceptualized on the basis of two types of memory and learning, propositional and procedural, which have been described in humans and primates. Temperament (or the “emotional core” of personality) involves procedural memory regulated by the corticostriatolimbic system, primarily the sensory cortical areas, amygdala, and the caudate and putamen. Procedural memory underlies associative learning and involves presemantic perceptual processing of visuospatial information and affective valence that can operate independently of abstract conceptual or volitional processes or both. Propositional learning involves higher cognitive functions of abstraction and symbolization. These two major memory and learning systems can be dissociated functionally. For example, individuals with Parkinson's disease, characterized by striatal lesions, exhibit deficits in procedural learning but not in propositional learning. In contrast, individuals with an amnestic syndrome, characterized by lesions in the medial temporal lobe, have deficits in propositional learning but not in procedural learning.

Temperament traits of harm avoidance, novelty seeking, reward dependence, and persistence are defined as heritable differences underlying one's automatic response to danger, novelty, and various types of reward, respectively. These four temperament traits are closely associated with the four basic emotions of fear (harm avoidance), anger (novelty seeking), attachment (reward dependence), and mastery (persistence). Individual differences in temperament and basic emotions modify the processing of sensory information and critically shape early learning characteristics, especially associative conditioning of unconscious behavior responses. In other words, temperament is conceptualized as heritable biases in emotionality and learning that underlie the acquisition of emotion-based, automatic behavior traits and habits observable early in life and relatively stable over one's life span.

Each of the four major dimensions is a normally distributed quantitative trait. The four dimensions were shown to be genetically homogeneous and independently inherited from one another in large, independent twin studies in the United States and Australia. Temperamental differences, which are not very stable initially, tend to stabilize during the second and third years of life. Accordingly, ratings of these four temperament traits at age 10 years predicted personality traits at ages 15, 18, and 27 years in a large sample of Swedish children. The four dimensions have been repeatedly shown to be universal across different cultures, ethnic groups, and political systems on five continents. In summary, these aspects of personality are called “temperament” because they are heritable, observable early in childhood, relatively stable in time, moderately predictive of adolescent and adult behavior, and consistent in different cultures. Table 24-1 summarizes contrasting sets of behaviors that distinguish extreme scorers on the four dimensions of temperament. Note that each extreme of these dimensions has specific adaptive advantages and disadvantages (i.e., neither high nor low scores inherently means better adaptation).

Temperament Dimension	Descriptors of Extreme Variants	
	High	Low
Harm avoidance	Pessimistic	Optimistic
	Fearful	Daring
	Shy	Outgoing
	Fatigable	Energetic
Novelty seeking	Exploratory	Reserved
	Impulsive	Deliberate
	Extravagant	Thrifty
	Irritable	Stoical
Reward dependence	Sentimental	Detached
	Open	Aloof
	Warm	Cold
	Affectionate	Independent
Persistence	Industrious	Lazy
	Determined	Spoiled
	Enthusiastic	Underachieving
	Perfectionist	Pragmatic

Table 24-1 Descriptors of Individuals Who Score High and Low on the Four Temperament Dimensions

The component traits (“facets”) for each of the four temperament dimension are more strongly correlated with one another than with any other component; they have

distinct learning characteristics and independent genetic antecedents. In other words, they share a common source of covariation that is strong and invariant regardless of environmental change and past experience.

Neurobiological studies of animals, most often rodents, have been highly informative about the functional organization of brain systems underlying procedural learning and temperament. Explicit animal models have been described on the basis of extensive work in rodents and other nonprimates, providing hypotheses being tested in humans with modern techniques of brain imaging, neurochemistry, and neurogenetics. The most comprehensive neurobiological model of learning in animals that has been systematically related to the structure of human temperament is summarized in Table 24-2. This model distinguishes four dissociable brain systems for behavioral activation (novelty seeking), behavioral inhibition (harm avoidance), social attachment (reward dependence), and partial reinforcement (persistence).

Brain System–Related Personality Dimension	Principal Neuromodulators	Relevant Stimuli	Behavioral Response
Behavioral activation–novelty seeking	Dopamine	Novelty CS of reward CS or LCS of relief of monotony or punishment	Exploratory pursuit Appetitive approach Active avoidance Escape
Behavioral inhibition–harm avoidance	GABA Serotonin (dorsal raphe)	Aversive conditioning (pairing CS+LCS) Conditioned signals for punishment, novelty, frustrative nonreward	Formation of aversive CS Passive avoidance, extinction
Social attachment–reward dependence	Norepinephrine Serotonin (median raphe)	Reward conditioning (pairing CS+UCS)	Formation of appetitive CS
Partial reinforcement–persistence	Glutamate Serotonin (dorsal raphe)	Intermittent reinforcement	Resistance to extinction

GABA, γ-aminobutyric acid; CS, conditioned signals; UCS, unconditioned signals.

Table 24-2 Four Dissociable Brain Systems Influencing Stimulus-Response Patterns Underlying Temperament

HARM AVOIDANCE Harm avoidance involves a heritable bias in the inhibition of behavior in response to signals of punishment and frustrative nonreward. High harm avoidance is observed as fear of uncertainty, social inhibition, shyness with strangers, rapid fatigability, and pessimistic worry in anticipation of problems, even in situations that do not worry other people. Adaptive advantages of high harm avoidance are cautiousness and careful planning when hazard is likely. The disadvantages occur when hazard is unlikely but still anticipated, which leads to maladaptive inhibition and anxiety. Persons low in harm avoidance are carefree, courageous, energetic, outgoing, and optimistic, even in situations that worry most people. The advantage of low harm avoidance is confidence in the face of danger and uncertainty, leading to optimistic and energetic efforts with little or no distress. The disadvantages are related to unresponsiveness to danger or unreasonable optimism with potentially severe consequences when hazard is likely.

The psychobiology of harm avoidance is complex. In animal studies, ascending serotonergic projections from the dorsal raphe nuclei to the substantia nigra inhibit nigrostriatal dopaminergic neurons and are essential for conditioned inhibition of activity by signals of punishment and frustrative nonreward. Benzodiazepines disinhibit passive avoidance conditioning by g-aminobutyric acid (GABA)-ergic inhibition of serotonergic neurons originating in the dorsal raphe nuclei. The anterior serotonergic cells in the dorsal raphe nucleus intermingle with the dopaminergic cells of the ventral tegmental area, and both groups innervate the same structures (e.g., basal ganglia, accumbens, amygdala), providing opposing dopaminergic-serotonergic influences in the modulation of approach and avoidance behavior. The anterior serotonergic projections from the dorsal raphe to striatum, accumbens, amygdala, and frontal cortex are usually associated with serotonin (5-hydroxytryptamine [5-HT]) type 2 (5-HT_2) receptors. Individuals high in both harm avoidance and novelty seeking are expected to have frequent approach-avoidance conflicts, as seen in cycles of binging and purging in patients with bulimia. More generally, excessive behavioral inhibition (i.e., high harm avoidance) predisposes individuals to anxiety, depression, and low self-esteem. Effective antidepressant treatment lowers harm avoidance scores, but higher harm avoidance scores predict poorer responses to antidepressants, including tricyclic drugs and selective serotonin reuptake inhibitors.

Recent neuropsychological studies confirm that harm avoidance is associated with individual differences in classical aversive conditioning, whereas other dimensions of personality are uncorrelated (Table 24-3). Harm avoidance (and not other dimensions of temperament) is also replicably associated with potentiation of startle responses. Neuropsychological tests also confirm that harm avoidance is associated with other aspects of behavioral inhibition. For example, harm avoidance is associated with the Posner validity effect. The Posner task uses a detection reaction time paradigm with discrete presentation of simple visual stimuli in the periphery. Cues that correctly direct attention to the spatial location where the target stimulus will appear are called *valid cues,* whereas those that direct attention to incorrect locations are called *invalid cues.* In three large samples of healthy college students, those higher in harm avoidance had greater slowing of their reactions after invalid cues, or less benefit from valid cues, than others.

Variable	Effect
Neuroanatomy (PET)	
Medial prefrontal (L)	Increased activity (behavioral inhibition)
Anterior paralimbic (R)	Increased activity (sensitivity to threat)
Neuropsychology	
Aversive conditioning	Greater associative pairing with punishment ($r = .4$)
Eyeblink startle reflex	Potentiation of response to aversive stimulus (effect size, 1.9)
Posner validity effect	Greater slowing of responses after invalid cues ($r = .3$)
Spatial delayed response	Better ability to delay responses after ingesting amphetamines ($r = .5$)
Neurochemistry	
Platelet 5-HT_2 receptor	Fewer receptors ($r = -.6$)
Plasma GABA	Lower concentration ($r = -.5$)
Neurogenetics	
5-HT transporter promoter	Greater reuptake

PET, positron emission tomography.

Table 24-3 Reported Psychobiological Correlates of Harm Avoidance

Positron emission tomography (PET) at the National Institute of Mental Health (NIMH) with ^{18}F-deoxyglucose (FDG) in 31 healthy adult volunteers during a simple, continuous, performance task showed that harm avoidance was associated with increased activity in the anterior paralimbic circuit, specifically the right amygdala and insula, the right orbitofrontal cortex, and the left medial prefrontal cortex. This activation pattern corresponds well to the 5-HT_2 terminal projections of the dorsal raphe. However, 5-HT_2 receptor numbers have been correlated with harm avoidance only in studies of platelets (Table 24-3).

Higher plasma GABA concentrations have also been correlated with low harm avoidance. Plasma GABA concentration has also been correlated with other measures of anxiety proneness, and it correlates highly with brain GABA concentration. Finally, a gene on chromosome 17q12 that regulates the expression of the serotonin transporter accounts for 4 to 9 percent of the total variance in harm avoidance in four of six tests of this relation. These findings support a role for both GABA and serotonergic projections from the dorsal raphe underlying individual differences in behavioral inhibition as measured by harm avoidance.

NOVELTY SEEKING Novelty seeking reflects a heritable bias in the initiation or activation of appetitive approach in response to novelty, approach to signals of reward, active avoidance of conditioned signals of punishment, and skilled escape from unconditioned punishment. All four of these behaviors are hypothesized to covary as part of one heritable system of learning. They are observed as exploratory activity in response to novelty, impulsiveness, extravagance in approach to cues of reward, and active avoidance of frustration. Individuals high in novelty seeking are quick-tempered, curious, easily bored, impulsive, extravagant, and disorderly. Adaptive advantages of high novelty seeking are enthusiastic explorations of new and unfamiliar stimuli, potentially leading to originality, discoveries, and reward. The disadvantages are frequent and easy boredom, excessive impulsivity and angry outbursts, potential fickleness in relationships, and impressionism in efforts.

Persons low in novelty seeking are slow tempered, uninquiring, stoical, reflective, frugal, reserved, tolerant of monotony, and orderly. Their reflectiveness, stoical resilience, systematic efforts, and meticulous approach are clearly advantageous when these features are adaptively needed. The disadvantages reflect an uninquiring attitude, lack of enthusiasm, and tolerance of monotony, potentially leading to prosaic routinization of activities.

Mesolimbic and mesofrontal dopaminergic projections have a crucial role in incentive activation of each aspect of novelty seeking in animals. For example, dopamine-depleting lesions in the nucleus accumbens or the ventral tegmentum lead to neglect of novel environmental stimuli and reduce both spontaneous activity and investigative behavior. Behavioral activation by dopaminergic agonists depends on integrity of the nucleus accumbens but not the caudate nucleus. In human studies, individuals at risk for Parkinson's disease have low premorbid scores in novelty seeking but not other dimensions of personality, supporting the importance of dopamine in incentive activation of pleasurable behavior. The initiation and frequency of hyperactivity, binge eating, sexual hedonism, drinking, smoking, and other substance abuse (especially stimulants) are each associated with high scores in novelty seeking.

The psychobiological correlates reported for novelty seeking are summarized in Table 24-4. High scores correlate with increased metabolic activity during continuous performance tasks on PET in cingulate cortex and left caudate. In addition, high novelty seeking is associated with decreased activity in the left prefrontal cortex, including the medial prefrontal region associated with increased activity in individuals scoring high in harm avoidance. This suggests that medial prefrontal cortex may be an important site in the processing of approach-avoidance conflicts.

Variable	Effect
Neuroanatomy (PET)	
Medial prefrontal (L)	Decreased activity (behavioral disinhibition)
Dorsolateral prefrontal	Decreased activity (behavioral disinhibition)
Cingulate	Increased activity (behavioral activation)
Caudate (L)	Increased activity (behavioral activation)
Neuropsychology	
Reaction time	Slower to respond if not reinforced (neutral stimuli, $r = -.4$)
Stimulus intensity (N1/P2 ERP)*	Augmentation of intensity of cortical responses to novel auditory stimuli ($r = .5$)
Sedation threshold	More easily sedated by diazepam (Valium) (lower threshold, $r = -.3$)
Key word list memory	Deterioration of verbal memory when excited (after ingesting amphetamine, $r = .6$)
Neurochemistry	
Dopamine transporter	Higher density observed in striatum
Platelet MAO_B	Lower activity (associated with cigarette smoking)
Neurogenetics	
Dopamine receptor D_4	Association with long alleles of exon III variant
Dopamine transporter	Greater reuptake

Table 24-4 Reported Psychobiological Correlates of Novelty Seeking

Evoked potential studies of stimulus-intensity dependence confirm that novelty seeking is associated with augmentation of stimulus intensity, particularly with novel stimuli. Novelty seekers are also unusually sensitive to both sedatives and stimulants; they are easily oversedated by benzodiazepines and overstimulated by amphetamines, leading to deterioration in their information processing. Their reaction times are slow when they are not reinforced.

The association of increased striatal activity with high novelty seeking is more specifically associated with higher density of the dopamine transporter, suggesting that novelty seeking involves increased reuptake of dopamine at presynaptic terminals, thereby requiring frequent stimulation to maintain optimal levels of postsynaptic dopaminergic stimulation. Novelty seeking leads to various pleasure-seeking behaviors, including cigarette smoking, which may explain the frequent observation of low platelet monoamine oxidase type B MAO_B activity because cigarette smoking has the effect of inhibiting MAO_B activity in platelets and brain.

Studies of candidate genes involved in dopamine neurotransmission, such as the dopamine transporter gene (*DAT*1) and the type 4 dopamine receptor gene (*DRD*4) have provided evidence of association with novelty seeking and no other dimension of temperament. The dopamine transporter, responsible for presynaptic reuptake of dopamine and a major site of action of drugs including stimulants such as methylphenidate (Ritalin) and the antidepressant bupropion (Wellbutrin) is encoded by locus SLC6A3 (alias *DAT*1) on chromosome 5p. Polymorphisms at this locus are associated with attention-deficit disorder and other disorders related to variation in novelty seeking. Likewise polymorphisms at the *DRD*4 locus have been associated with attention-deficit disorders, opioid dependence, and other traits related to novelty seeking.

REWARD DEPENDENCE Reward dependence reflects a heritable bias in the maintenance of behavior in response to cues of social reward. It is observed as sentimentality, social sensitivity, attachment, and dependence on approval by others. Individuals high in reward dependence are tender hearted, sensitive, socially dependent, and sociable. One of the major adaptive advantages of high reward dependence is the sensitivity to social cues that facilitates affectionate social relations and genuine care for others. The disadvantage is related to suggestibility and loss of objectivity frequently encountered with people who are excessively socially dependent.

Individuals low in reward dependence are practical, tough minded, cold, socially insensitive, irresolute, and indifferent if alone. The advantages of low reward dependence are personal independence and objectivity not biased by efforts to please others. Its adaptive disadvantage is related to social withdrawal, detachment, and coldness in social attitudes.

Noradrenergic projections from the locus ceruleus and serotonergic projections from the median raphe are thought to influence such reward conditioning (Table 24-2). In animals, stimulation of the noradrenergic locus ceruleus or its dorsal bundle or direct application of norepinephrine decreases the firing rate of terminal neurons and increases their sensitivity to other afferents, so that targeted stimuli can stand out from nontargeted stimuli. In humans, short-term reduction of norepinephrine release by short-term infusion of the a_2 presynaptic agonist clonidine (Catapres) selectively impairs paired-associate learning, particularly the acquisition of novel associations. The noradrenergic locus ceruleus is located at the same posterior level of the brainstem as the serotonergic median raphe, and both of these posterior monoamine cells innervate structures important to formation of paired associations, such as the thalamus, neocortex, and hippocampus. Neurophysiological studies show that the anterior temporal lobe decodes social signals, such as facial images and social gestures. Consequently, individuals high in reward dependence are expected to be particularly sensitive in their social communication, whereas those low in reward dependence are expected to be socially aloof.

The psychobiological correlates reported about reward dependence are summarized in Table 24-5. As predicted, reward dependence is associated with individual differences in formation of conditioned signals of reward. This is also supported by its association with individual differences in paired-associate learning.

Variable	Effect
Neuroanatomy (PET)	
Thalamus	Increased activity (facilitates sensory processing)
Neuropsychology	
Reward conditioning	Increased associative pairing with rewards ($r = .3$)
Paired associates	Better learning of novel associations ($r = .5$)
Posner validity effect	Faster responses after valid cues ($r = -.4$)
Neurochemistry	
Urinary MHPG	Less excretion of norepinephrine metabolite ($r = -.4$)
Plasma cortisol	Higher morning cortisol concentration when depressed ($r = .3$)
Urinary harman	Greater excretion of indoleamine product in alcoholics high in reward dependence ($r = .7$)
Neurogenetics	
5-HT_{1d} receptor	Allelic association (effect size, 2.0)

Table 24-5 Reported Psychobiological Correlates of Reward Dependence

High reward dependence is associated with increased activity in the thalamus, which is consistent with proposals about the importance of serotonergic projections to the thalamus from the median raphe in modulation of social communication. This is further supported by the finding of low 3-methoxy-4-hydroxyphenylglycol (MHPG) concentration with high reward dependence. High reward dependence is also associated with hypercortisolemia in patients with melancholia but not in individuals who are not depressed.

PERSISTENCE Persistence reflects a heritable bias in the maintenance of behavior despite frustration, fatigue, and intermittent reinforcement. It is observed as

industriousness, determination, ambitiousness, and perfectionism. Highly persistent people are hard-working, perseverant, and ambitious overachievers who tend to intensify their effort in response to anticipated reward and perceive frustration and fatigue as a personal challenge. High persistence is an adaptive behavioral strategy when rewards are intermittent but contingencies remain stable. When the contingencies change rapidly, perseveration becomes maladaptive. Individuals low in persistence are indolent, inactive, unstable, and erratic; they tend to give up easily when faced with frustration, rarely strive for higher accomplishments, and manifest little perseverance even in response to intermittent reward. Accordingly, low persistence is an adaptive strategy when reward contingencies change rapidly and may be maladaptive when rewards are infrequent but occur in the long run.

Persistence can be objectively measured by the partial reinforcement extinction effect, in which persistent individuals are more resistant to the extinction of previously intermittently rewarded behavior than individuals who have been continuously reinforced. Recent work in rodents showed that the integrity of the partial reinforcement extinction effect depends on projections from the hippocampal subiculum to the nucleus accumbens. This glutaminergic projection may be considered a short circuit from the behavioral inhibition system to the behavioral activation system, thereby converting a conditioned signal of punishment into a conditioned signal of anticipated reward. This connection is probably disrupted in humans by lesions of the orbitomedial cortex that may have a specific antipersistence effect of therapeutic benefit to some severely obsessive-compulsive patients. Bilateral cingulotomy, which reduces harm avoidance only, is less effective in reducing persistent compulsive behavior than cingulotomy combined with orbitomedial lesions.

The reported psychobiological correlates of persistence are summarized in Table 24-6. Less work is available about this than the other three temperament dimensions, because it has been distinguished as an independently inherited dimension only since 1993. Neuropsychological studies do confirm that people high in persistence make more effort to learn without reinforcement. In laboratory gambling tasks, individuals high in persistence are more perseverative; that is, they exhibit the “gambler's fallacy” by maintaining the same bet size despite repeated losses. There is one report that a polymorphism at the 5-HT $_{2C}$ receptor gene locus is associated with both reward dependence and persistence. These effects were further facilitated by interactions with *DRD*4 and *DRD*3.

Variable	Effect
Neuroanatomy	
Orbitomedial cortex	Disconnection reduces perseveration
Neuropsychology	
Gambling style	Perseveration in bet size despite continuing losses
Key word list learning	Learning without reinforcement (r = .5)
Neurochemistry	
Glutaminergic connection Subiculum to nucleus accumbens	Essential for PREE* in rodents
Neurogenetics	
5-HT$_{2C}$ receptor	Allelic association (effect size, 2.0)

* Partial reinforcement extinction effect (PREE) is persistence or increased resistance to extinction following intermittent reinforcement.

Table 24-6 Reported Psychobiological Correlates of Persistence

Motivation Survival and reproduction, the basic drives for all animal species, are expressed in humans primarily through their experiential derivatives, emotions. In contrast to the limited motivational spectrum of the basic drives, emotions have an independent motivational power that makes them not only the primary motivational system for human beings, but also the personality processes that give meaning to human existence.

Temperament traits of harm avoidance, novelty seeking, reward dependence, and persistence, with their respective primary emotions of fear, anger, attachment, and ambition, are observable early in development. Research in children has shown that during the first several months of life, fear and anger differentiate from the disposition to *distress* (a tendency to become upset and aroused autonomically easily and intensely). In this period, characterized by active regressive changes in the organization of neuronal circuits and density of synapses, especially in frontal, temporal, and limbic cortical areas, many other complex and social functions in human behavior emerge. These new functions are, however, organized around an early set of enduring behavioral and emotional dispositions referred to in this work as *temperament traits*.

Emotional states associated with the four temperaments depend on whether a person has a high or low disposition for that particular temperament trait and whether the occurring experience is positive (gratifying) or negative (frustrating) (Table 24-7).

Temperament Dimension	High Scorers		Low Scorers	
	+	–	+	–
Harm avoidance	Anxious (agitated)	Depressed (retarded)	Cheerful	Fearless
Novelty seeking	Euphoric	Angry	Placid	Stoical
Reward dependence	Sympathetic	Disgusted	Aloof	Indifferent
Persistence	Enthusiastic	Steadfast	Unstable	Discouraged

Table 24-7 Effects of Positive (+) and Negative (–) Reinforcement on Emotional State of Four Temperaments

As can be inferred from Table 24-7, the same external stimulus is likely to elicit responses via activation of multiple temperament dimensions. For example, novel or unfamiliar stimuli elicit interest in approach in proportion to novelty seeking, as well as inhibition of approach in proportion to harm avoidance. Each temperament trait clearly involves an integration of multiple emotional drives that may be conflicting (competitive) or facilitatory (synergistic). Such shared environmental effects mean that the genetic and phenotypic structure of personality cannot be assumed to be the same.

Temperament involves a relatively small set of emotions associated with one's basic needs (e.g., safety), so-called primary motives. Excessive fear and anger, associated with temperament, are motivationally monopolistic and take over the personality by altering perception, learning, and behavior in a biased way. However, under normal circumstances, after survival needs are met, the goals of normally developing personality change to include not only the integrity of the physical self, but also that of the mental self (e.g., self-esteem) as well as numerous social goals and emotions (e.g., shame, pride, empathy). These are called “secondary,” “social,” or “growth” motives. These secondary emotions are closely related etiologically to the development of character. Specifically, basic emotions of fear, anger, disgust, and excitement are transformed to more-complex, predominantly positive secondary emotions, such as love, empathy, compassion, and resourcefulness. This transformation occurs through the interaction of internalized concepts associated with character with basic emotions associated with temperament. Even though some basic character components develop early in life, such as trust and confidence, the completion of self-object differentiation (“me” vs. “not-me”) between 18 months and 3 years of age sets the stage for the full development of character traits and secondary emotions.

The secondary emotions take over as primary motivators of further character development and maturation. They are not as monopolistic motivationally, and they initiate development of more-flexible and adaptable personality traits. As shown in Table 24-8, each of the three character traits is associated with a characteristic pattern of secondary emotions.

Character Dimension	High Scorers		Low Scorers	
	+	-	+	-
Self-directed	Hopeful	Resourceful	Vain	Shameful
Cooperative	Loving	Forgiving	Scornful	Revengeful
Transcendent	Joyful	Peaceful	Greedy	Miserable

Table 24-8 Effects of Positive (+) and Negative (–) Reinforcement on Emotional State of Three Characters

In conclusion, abnormal (deviant, immature) motivation derives from two or three excessive, monopolistic, elementary emotional needs associated with threats to survival and physical integrity. In contrast, mature motivation develops after basic needs are met and the person is freed to experience numerous secondary growth motives. This explains the motivational inflexibility and poverty of deviant personality and accounts for all the rich motivational diversity and flexibility of those with a mature personality.

Character In contrast to temperament, which is mostly inherited, character is less heritable and is moderately influenced by social learning, culture, and random life events unique to the individual. The seven-factor psychobiological model of personality is the only model that has addressed the issue of character and its structure in a systematic way. The psychodynamic concepts of character have created many intriguing clinical formulations on the subject.

Psychobiology of Character Character (or the conceptual core of personality) involves higher cognitive functions regulated by the hippocampus and neocortex (e.g., abstraction and symbolic interpretation, analytical and nductive logic). These functions (also called *propositional memory*) are critical for cognitive processing of sensory percepts and affects regulated by temperament, leading to the development of concepts about the self and the external world. Three major character traits have been distinguished: self-directedness, cooperativeness, and self-transcendence. When fully developed, these traits define mature personality. These character traits are adaptive, but their low ends are less advantageous because of a limited spectrum of circumstances in which immaturity, especially low self-directedness and cooperativeness, means better adaptation than maturity.

Self-directedness quantifies the extent to which an individual is responsible, reliable, resourceful, goal-oriented, and self-confident. The most advantageous summary feature of self-directed individuals is that they are realistic and effective; that is, they are able to adapt their behavior in accord with individually chosen, voluntary goals based on a realistic assessment of facts. Individuals low in self-directedness are blaming, helpless, irresponsible, unreliable, reactive, and unable to define, set, and pursue meaningful internal goals, which is often disadvantageous to the individual.

Cooperativeness quantifies the extent to which individuals consider themselves integral parts of human society. Highly cooperative persons are described as empathetic, tolerant, compassionate, supportive, and principled. These features are advantageous in teamwork and social groups but not for individuals who prefer to live in a solitary manner. Low cooperativeness involves self-absorbed, intolerant, critical, unhelpful, revengeful, and opportunistic behavior in persons who primarily look out for themselves and tend to be inconsiderate of others' rights or feelings.

Self-transcendence quantifies the extent to which individuals consider themselves integral parts of the universe as a whole. Self-transcendent individuals are spiritual, unpretentious, humble, and fulfilled. These traits are adaptively advantageous when people are confronted with suffering, illness, or death, which is inevitable with advancing age. They are disadvantageous in most modern societies where idealism, modesty, and meditative search for meaning might interfere with the acquisition of wealth and power. People who are low in self-transcendence are described as practical, self-conscious, materialistic, and controlling. Such individuals are expected to be well adapted in most Western societies because of their rational objectivity and materialistic success. However, they consistently have difficulty accepting suffering, loss of control, personal and material losses, and death, which lead to adjustment problems, particularly with advancing age. Contrasting sets of descriptors that distinguish the three dimensions of character are summarized in Table 24-9.

Character Dimension	Descriptors of Extreme Variants	
	High	Low
Self-directedness	Responsible	Blaming
	Purposeful	Goal-less
	Resourceful	Passive
	Self-accepting	Wishful
	Disciplined	Undisciplined
Cooperativeness	Tender hearted	Intolerant
	Empathic	Insensitive
	Helpful	Selfish
	Compassionate	Revengeful
	Principled	Opportunistic
Self-transcendent	Imaginative	Conventional
	Intuitive	Logical
	Acquiescent	Doubtful
	Spiritual	Materialistic
	Idealistic	Relativistic

Table 24-9 Descriptors of Individuals Who Score High and Low on the Three Character Dimensions

As shown in Table 24-9, high and low scorers in each character dimension are distinguished by behavior traits that arise from differences in concepts that are each internally consistent but not logically falsifiable. For example, people low in self-transcendence live in the material world, skeptical of whatever they cannot prove objectively and use practically. In contrast for individuals who are highly self-transcendent, the meaning of life goes beyond material things and includes issues that cannot always be known objectively. Each set of beliefs is internally consistent and may be satisfying to different people, but spiritual people cannot prove a materialist is wrong or vice versa.

Character matures in a stepwise manner in incremental shifts from infancy through late adulthood. The timing and rate of transitions between levels of maturity are nonlinear functions of antecedent temperament configurations, systematic cultural biases, and random life events. The developing character traits (i.e., newly internalized concepts about one's self and the external world) optimize adaptation of temperament to the environment by reducing discrepancies between one's emotional needs and norm-favoring social pressures.

In Figure 24-1, character corresponds to the processes of logic, construction, evaluation, and invention of abstract symbols that are based on conceptual representation of information and are well developed only in some mature humans. Recent work shows that psychophysiological markers of neocortical processing, such as the P300 event-related potential and contingent negative variation, are correlated with measures of character but not temperament. More specifically, self-directedness, but not other temperament or character traits, correlates moderately with the evoked potential P300 in parietal leads. Likewise, cooperativeness correlates moderately with contingent negative variation. Individuals with Parkinson's disease differ from others in temperament (they are lower in novelty seeking premorbidly) but not in character. These clinical and empirical observations associate character, but not temperament, to higher cortical functions in the central nervous system (CNS).

Basic differences between temperament and character are summarized in Table 24-10.

Variable Properties	Temperament	Character
Awareness level	Automatic	Intentional
Memory form	Percepts Procedures	Concepts Propositions
Learning principles	Associative Conditioning	Conceptual Insight
Role of subject in mental activity	Passive Reproductive	Active Constructive
Key brain system	Limbic system Striatum	Temporal cortex Hippocampus
Form of mental representation	Stimulus-response sequences varying additively in strength	Interactive networks (conceptual schema) varying qualitatively in configuration
Etiological components		
Genetic heritability	40–60%	15–40%
Family environment	0%	10–15%
Random environment	40–60%	25–35%

Table 24-10 Key Differences between Temperament (Associative or Procedural Learning) and Character (Conceptual or Propositional Learning)

Psychodynamic Concept of Character Psychodynamic thinking about character is based on the concept of *defense mechanisms*, defined as automatic, unconscious psychological processes (both cognitive and emotional) that protect against anxiety generated by intrapsychic conflicts. All defense mechanisms are grouped into three levels: mature, neurotic, immature. Psychodynamic concepts developed by Anna Freud and by Otto Fenichel define *character traits* as residues of previous mature defense mechanisms (e.g., sublimation, anticipation, altruism, and humor) that have become incorporated into everyday behavior patterns. In other words, normal character reflects one's capacity to postpone immediate gratification of internal needs through sublimation, anticipation, altruism, and humor. Behaviors reflecting these particular defense mechanisms correspond to the above description of cooperativeness (especially altruism) and self-transcendence (especially anticipation). Psychodynamic theories have also recognized that the ego not only protects from, but shifts, organizes, and reacts to, internal impulses and external stimuli. The pattern in which one utilizes and combines these integrative functions to satisfy multiple external and internal pressures also constitutes character. Again, ego strength corresponds closely to the description of self-directedness.

Psychodynamic theories describe two forms of character disorders: neurotic character and character neurosis. Neurotic character traits are postulated to derive from neurotic defenses (e.g., reaction formation, projection, repression, undoing) that have dissociated from their original conflict and have become inflexible, pervasive, and ego-syntonic patterns of everyday behavior (“the armor plating” of character). As extensions of previous defensive solutions to conflicts between one's emotional needs and opposing social pressures, neurotic character traits protect a person from being involved in such situations again. For example, hypermorality is a “reaction formation” against aggression that protects obsessive persons from consciously experiencing aggression and thus from intrapsychic conflicts. Character neurosis is observed when an inflexible neurotic character trait interferes with healthy parts of personality. For example, when obsessive hypermorality interferes with the need for social contacts generated in healthy parts of obsessive personality and, instead of being perceived as natural, is perceived as frustrating, one observes character neurosis. Character neurosis has been included in the 10th edition of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) but not in DSM IV.

Individual differences in defense mechanisms (i.e., normal, neurotic, and immature) appear to covary with the severity of psychopathology (i.e., normality, anxiety disorders, personality disorder, respectively). Interestingly, patients with personality disorder tend to “favor” certain immature defense mechanisms, which in turn shape their behavioral style and clinical presentation. These “favorite” defenses are, for example, projection for those with paranoid personality disorder, acting out for those with antisocial personality disorder, and fantasy for patients with schizoid personality disorder. Note, however, that in addition to these favorite immature defenses, persons with personality disorders also use other immature defenses that contribute to their irresponsibility, tendency to blame others, and so forth. Reflecting these and similar observations about the importance of defense mechanisms for the overall understanding of deviant personality, the DSM-IV classification now enables clinicians to classify the use of a particular, dominant defense mechanism on Axis II.

Descriptively, psychodynamic and psychobiological perceptions of character are obviously similar. Conceptually, both approaches underscore the adaptive function of character traits in the overall adaptation of emotional needs to the environment. However, the two concepts differ in other etiological and classificatory aspects of character. The psychobiological model explains individual differences in character as quantitative variation on the three character traits. In contrast to this dimensional approach, the psychodynamic concept distinguishes categorically between character subtypes (e.g., neurotic character is further divided into anal, oral, phallic) and discrete character disorders (i.e., neurotic characters and character neurosis). Some dimensionality is preserved, since most people use all defense mechanisms, and it is the relative predominance of immature versus mature defenses that classifies them into personality disorders (i.e., the transition between character types is gradual, not abrupt). The psychobiological model underlines the preconscious or conscious nature of character, whereas the psychodynamic concept understands character traits, (with the possible exception of anticipation) as predominantly unconscious processes. Moreover, the psychodynamic concept does not provide guidelines for further etiological studies of character. However, this concept is very important in treatment, especially for the revision of emotional and conceptual biases inherent in immature defenses and deviant character traits.

Integrated View of Personality Recent reports about complex and fundamental processes underlying neurophysiology, development, and phenomenology of personality provide powerful guidelines for the formulation of a comprehensive psychobiological model of personality. The model integrates earlier phenotypic observations about behavior with contemporary concepts based on neuroimaging, biology of behavior, genetics, psychometric advances, and nonlinear modeling of normal and deviant personality development. Personality is conceptualized as a complex adaptive system involving a bidirectional interaction between temperament and character once self-concepts emerge with the maturation of the conceptual or propositional learning system (Fig. 24-2).

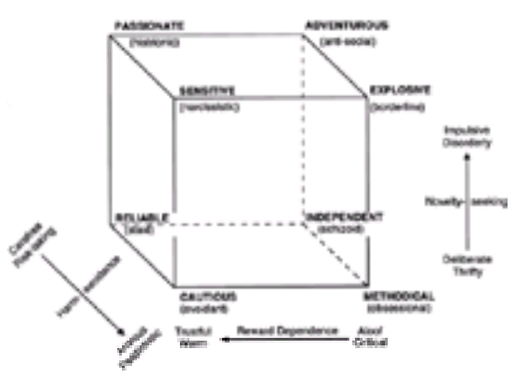

FIGURE 24-2 Temperament configurations.

Through the interaction of temperament and character, different aspects of internalized concepts of the self and the external world modify the significance and the salience of sensory percepts and affects regulated by temperament and vice versa. In other words, temperament regulates what one notices, and in turn, character modifies its meaning, so that the salience and significance of all experience depends on both one's temperament and one's character.

CONCEPTUAL AND PSYCHOMETRIC ISSUES

Personality Traits: Person Versus Situation Debate Personality traits are neuropsychic structures with the capacity to render many stimuli functionally equivalent and to initiate and guide equivalent (consistent) forms of adaptive and expressive behavior. Accordingly, the DSM defines *personality traits* as “enduring patterns of perceiving, relating to, and thinking about oneself and the environment” (i.e., other people and the world as a whole). The major value of personality traits, therefore, lies in their usefulness in identifying predictable regularities in an individual's behavior.

The stability of personality traits in time and across situations has been the central issue in personality theory for decades, as it is directly relevant to whether internal dispositions or external situations determine behavior. The “person versus situation” debate was initiated in the early 1900s by two groups of scientists (“situationists”

versus “personologists”). The former viewed behavior as highly situationally specific, the latter as centrally organized and purposive. The dilemma remained unresolved for decades because it was not realized that single items of behavior have limited reliability and generality. They must be aggregated over situations and occasions to reveal stable traits that allow predictions of behavioral tendencies but, less accurately, prediction of single behavioral acts.

On the other hand, global personality traits also do not explain behavior completely because people do not exhibit unmodulated consistencies in behavior across time and situations. Complete invariance in behavior is associated more with psychopathology than with normality. The current understanding of traits differs from the conservative one of 20 years ago. The emerging consensus is an interactionist position allowing room for both situational (external) and dispositional (internal) determinants of behavior in a variety of complex combinations.

Phenotypic and Developmental Trait Personality Models The major difficulty in relating observed variation in personality to its underlying biological processes is that the observed phenotypic structure differs from the underlying biogenetic structure because learning and environmental factors also influence phenotypic variation. Phenotypic traits do not explain behavior but themselves require etiological explanation. Factor analysis can determine only the minimal number of distinguishing behavior traits, not their underlying causal structure. Hence, the phenotypic trait personality models, which are usually factor analytically derived (e.g., Hans Eysenck's tridimensional model, Paul Costa and Robert McCrae's five factor model), account for the much of the observed phenotypic variance but may not correspond to the underlying biogenetic processes. For example, sociability and impulsivity, phenotypic behavioral traits described by Heinz Eysenck, have independent genetic antecedents; still, Eysenck regards them as components of a single phenotypic trait—extraversion. Likewise, the five factor model, as measured by the Neuroticism Openness Extraversion (NEO) personality inventory, defines neuroticism, extraversion, openness, agreeableness, and conscientiousness as basic personality traits. Extensive heterogeneity within and among these traits has been suggested (e.g., benzodiazepines increase extraversion and decrease neuroticism, suggesting common biological background for these two phenotypic traits). In addition an exonic polymorphism of *DRD*4 that accounts for a portion of the genetic variance in novelty seeking is correlated with 3 of 6 facets of extraversion and 1 of 6 facets of conscientiousness in the five factor model. This indicates that extraversion and neuroticism are heterogeneous composites of the underlying genetic factors. The dopamine transporter is associated with novelty seeking but with none of the five factors of the NEO model.

In contrast, models of personality as developmental traits take into account both the underlying biological dispositions to observable behaviors and individual differences in responses to experience during personality development. The most recognized dimensional models are those of Henrik Sjobring, Marvin Zuckermann, and Robert Cloninger. Despite some limitations, Sjobring's developmental model in the late 1940s was a heuristic attempt to take personality research beyond the level of phenotypic observations and factor analysis. The model defines three dimensions of latent variation predisposing to personality: “validity” (the degree of energy available in adaptation to experience), “solidity” (the consistency of adaptation), and “stability” (referring to the maximum potential of a person to develop skillful habits in adapting to routine). These three dispositions were postulated to be causally independent from one another and from the factor of general intelligence (referred to as “capacity”) and also to define one's susceptibility to behavior disorders.

Personality has often been described in terms of a linear sequence of qualitatively discrete developmental stages and structural types. The frequent occurrence of heterotypic individuals with intermediate or mixed features calls into question the assumption that personality structures are limited to a finite number of discrete and homogeneous types. Likewise, there is not only variation in the rate and direction of personality development as a whole, but also asynchrony and inconsistency among its major components that are reorganized through time. The following section outlines a nonlinear quantitative theory of personality development that does not make restrictive assumptions about a finite number of qualitatively discrete structural types.

PERSONALITY DEVELOPMENT: FUNDAMENTALS OF A SELF-ORGANIZING PSYCHOBIOLOGICAL COMPLEX

Nenad Svrakic and coworkers in 1996 formulated a quantitative model of normal and deviant personality development as a complex dynamic system that is self-organizing and partly molded by familial and sociocultural influences. The model allows for nonlinear interactions among etiologically distinct components of personality. It also accounts for the frequent, but not invariant, development of stagelike periods of moderately stable personality configurations (similar to personality types) punctuated by abrupt transitions with structural reorganization and emergence of qualitatively new features. The model is based on a sophisticated mathematical framework that can be implemented and tested with readily accessible data.

The central ideas behind this model are the following. First, Personality, as a dynamic multidimensional system, comprises more-elementary operating components (traits) organized in an interdependent way that is critical to carrying out a particular function. Such a system is characterized by particular rules of operation (e.g., the principles of associative learning within the temperament function or propositional learning within the character function). Satisfying such multiple constraints results in nonlinear dynamics, which is characteristic of all systems involving growth and development in biology, neuroscience, psychology, and sociology. Such multidimensional dynamic systems are usually called *complex adaptive systems*. Second, the correlations observed among multiple personality traits can be used to explain the spontaneous organization of stable multidimensional configurations (i.e., personality types); these types develop in a stagelike fashion, with successive periods of prolonged stability punctuated by rapid transitions. Third, the model accounts for functional interactions among multiple types of influence, including genetic factors, family environment, sociocultural norms, and random events unique to each individual. Based on the specified basic differences between temperament and character (Table 24-10), this model takes into account all aspects of information processing from associative conditioning of habits and skills to enculturation about goals and values.

Personality development is presented as a walk on an adaptive (or fitness) landscape with two or more hills (representing high adaptive values) separated by valleys (representing low adaptive values). *Fitness* is defined as the ability to produce change in personality. In general, a complex system subjected to constraints responds to these constraints by optimizing fitness, that is, by adaptive changes in personality. As personality change is motivated by optimization of fitness, individuals most likely and most rapidly move toward the greatest increase in adaptive value (i.e., the nearest hill). Once they have reached the peak of the hill, they stay there for a relatively long time because they would first have to decrease fitness (i.e., descend into the valley) to find a hill with a higher peak (i.e., better adaptation). Such adaptive development is called *U-shaped*.

Temperament and character traits are etiologically distinct but functionally related. Such an interactive system is self-organizing because of the collective dynamics among its multiple components. In other words, the organism is spontaneously driven to find patterns of behavior that satisfy all internal and external constraints. For example, harm avoidance interacts with both novelty seeking and reward dependence, inhibiting approach to novel stimuli and inhibiting social attachments by increasing fear of the unfamiliar and sensitivity to social criticism. Accordingly, the authors have found weak, but consistent, negative correlations of harm avoidance with novelty seeking and reward dependence. In contrast, novelty seeking and reward dependence are positively synergistic, facilitating sociability and seeking of social approval. Such interactions influence the stability of each of the eight possible multidimensional configurations or profiles of temperament traits (Fig. 24-3) and make some more stable than others.

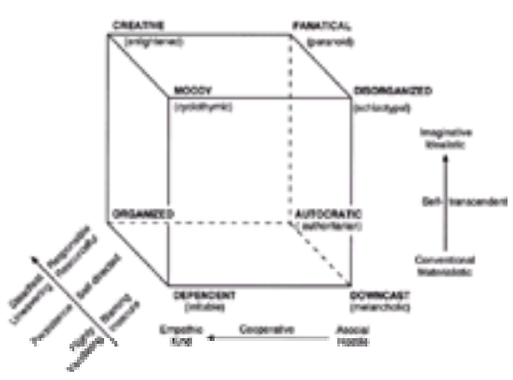

FIGURE 24-3 Character configurations.

In the fitness landscape, the valleys (or adaptive minima) are unstable because even such small perturbations as random events will drive the system away from these points of low fitness. In contrast, hills (i.e., adaptive maxima) are stable because they act as “attractors” for all lower points in the neighborhood. Consequently, personality interactions tend to self-organize into an attractor state and to remain in that configuration in the absence of external pressure or maturational processes.

Understanding both the chronicity and the treatment resistance of personality disorders requires realizing that a particular personality configuration may be highly stable, even though it may not be the most adaptive behavior possible for that individual.

The authors are mainly concerned with patterns of change of character traits as a function of relatively stable temperament traits and various other influences discussed below. The three character traits interact to produce eight possible character configurations or profiles (Fig. 24-4).

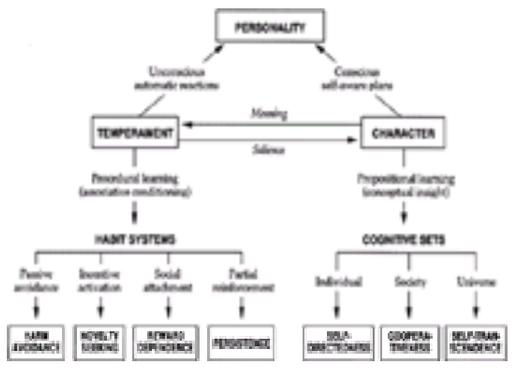

FIGURE 24-4 Personality: An integrated psychobiological schema.

Each of these character configurations can be predicted from the initial temperament configuration, taking into account temperament-character interactions and the effects of sociocultural norms, random events unique to the individual, social learning within the family, and genetic factors. All these sources of individual differences influence the likelihood for different stable character configurations in the outcome. The sociocultural norms can be additionally accounted for as the systematic bias in development associated with demographic variables such as subculture, gender, race, age, and occupation. These norms and social education in the family create environments that support or oppress specific character development. With all this taken into account, a single initial temperament configuration may lead to several different stable character configurations, an aspect of development referred to as *multifinality*. These results are graphically represented in Figure 24-5, Figure 24-6 and Figure 24-7, with four different initial temperament configuration and their possible character outcomes.

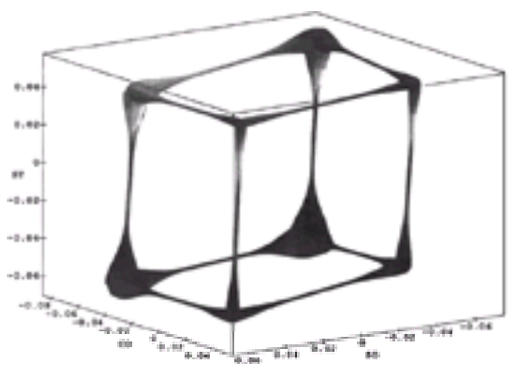

FIGURE 24-5 Most-probable character outcomes for the adventurous antecedent temperament traits.

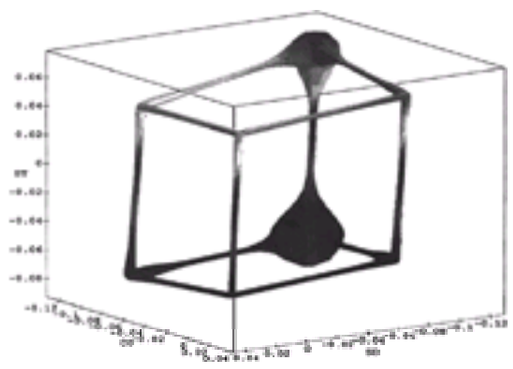

FIGURE 24-6 Most-probable character outcomes for the explosive (borderline) antecedent temperament traits.

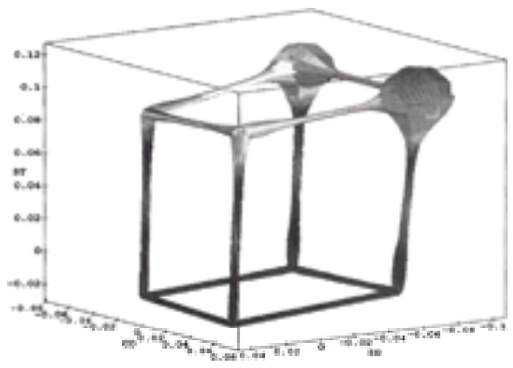

FIGURE 24-7 Most-probable character outcomes for the sensitive antecedent temperament traits.

Three dimensions of character (self-directedness [SD], cooperativeness [CO], and self-transcendence [ST]) are drawn along three orthogonal axes, and each character configuration is represented by a point in this abstract space. Eight possible combinations of high versus low scores on the three character dimensions are represented by the corners of the cube. The size of the bulging at a particular character configuration is proportional to the probability of that outcome. These figures show that the same temperament type leads to several possible stable character outcomes, each with certain probability, a feature characteristic of nonlinear systems. Figures 20-5 through 20-7 illustrate such multifinality for the adventurous (high NS, low HA, low RD), explosive (high NS, high HA, low RD), and sensitive (high NS, high HA, high RD) temperament types. Similar results can be obtained for the remaining five temperament configurations.

Individuals are born with one temperament profile, which has several possible character outcomes. This multifinality reflects the fact that the fitness landscape in personality development has both objective and subjective components. Feelings and internalized concepts unique to the individual do influence one's evaluation of the “objectively” worthwhile goals and values. The observed discrepancies between the natural directions influenced by antecedent temperament traits and actually

achieved character configurations point to the importance of external events such as social learning and random fluctuations in the final character outcome.

Because points of high and low adaptive values exist in the fitness landscape, personality development is characterized by periods of relative stability alternating with more-rapid transitions to new adaptive levels. The subscale structure of the Temperament and Character Inventory (TCI) was formulated to specify character in terms of 15 component steps of its development, as shown in Table 24-11.

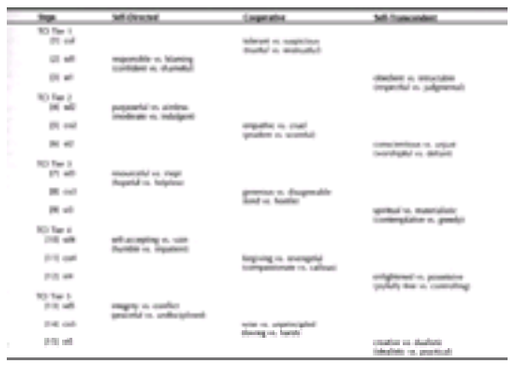

Table 24-11 15-Step Personality Development

The 15 steps in character development are a theoretical ideal, corresponding to the modal pathway that leads to full character development with high scores on all three character dimensions, which is not optimal for everybody. Observe that the overall character developmental line describes a spiral, in which each revolution around the spiral (presented as each of the five TCI tiers in Table 24-11) introduces a new set of developmental issues associated with the component facets of the major character traits. For example, during the first revolution around the spiral, a person encounters problems of trust versus mistrust (cooperativeness, facet 1: social acceptance), confidence versus shame (self-directedness, facet 1: responsibility), and obedience versus rebelliousness (self-transcendence, facet 1: self-forgetfulness). As can be inferred from Table 24-5, as individuals move along the spiral, they successively face new developmental tasks associated with the component facets in self-directedness, cooperativeness, and self-transcendence. This spiral pattern of character development provides an opportunity to correct developmental errors that were made at any earlier step within the same trait. For example, as character develops around the spiral to reach a new step of self-directedness (e.g., resourcefulness), one gets “in line” historically with issues of purposefulness and responsibility (steps of self-directedness encountered during earlier revolutions) (Table 24-11). This alignment facilitates retrospective revisions of errors at earlier developmental levels. The possibility of retrospective healing of old character errors has implications for psychotherapy planning, specifically, simultaneous intervention at different levels along the same trait. However, such retrospective healing does not always occur, so character development cannot be fully described by any simple linear schema. This 15-step developmental sequence is consistent with prior qualitative descriptions of developmental stages by Jean Piaget, Sigmund Freud, and Erik Erikson but allows more complete quantitative specification (Table 24-12).

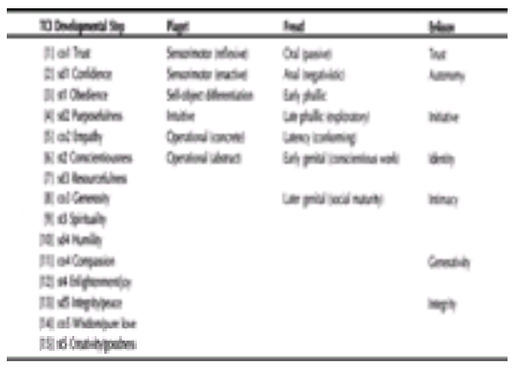

Table 24-12 Different Descriptions of Personality Development

Computer-simulated self-organized development of character, beginning with average initial temperament traits and taking into account all of the above contributing factors, demonstrated that children first increase in self-transcendence (i.e., become imaginative and enjoy fantasy), then increase in cooperativeness (i.e., become conforming and rule based), and only later increase in self-directedness (i.e., behavior becomes increasingly self-reliant and autonomous). This prediction is consistent with the description of the stages of ego-development by Jane Loevinger and her colleagues. This early sequence does not exclude subsequent further development of other character dimensions in response to demands of changing social roles with age. This subsequent development in response to external social pressures may explain adult self-actualization and moral development as described by Erikson, Lawrence Kohlberg, and others.

PERSONALITY DISORDER

Normal Versus Deviant Personality Normal personality is usually defined (1) directly, using criteria of health ideals; (2) indirectly, as the opposite to deviant personality; or most frequently (3) statistically, by behaviors most common in the given environment. However, the distinction between “normal” and “abnormal” personality is inherently relative as it relies on a largely arbitrary cutoff point on the continuum between two extremes of a behavior trait. This distinction is also context dependent, as the same behavior manifested in different situations could be viewed as normal or maladaptive (e.g., invariant fearfulness when danger is unlikely versus when it is likely). However, attempts to define *abnormal personality* based solely on the social context are not satisfactory because personality disorders involve many noninterpersonal traits as well (e.g., narcissistic persons satisfy many aspects of their grandiosity internally, in fantasy). Furthermore, personal deviance alone does not reliably distinguish between normal behavior and personality disorders (e.g., some individuals are very socially withdrawn without impairment in professional functioning or signs of personal suffering and distress). In other words, both personal and social aspects are needed to account fully for the symptoms of personality disorder.

Classification of Personality Disorders The leading classifications of personality disorders are the International Classification of Diseases (ICD) of the World Health Organization, and DSM of the American Psychiatric Association. The ICD classification of personality disorders, ninth revision of *International Statistical Classification of Diseases* (ICD-9) relied extensively on Kurt Schneider's book *Psychopathic Personalities* and his description of 10 discrete, socially deviant personality types. ICD-10, published in 1987, corresponds more closely to DSM, however. Anglo-American concepts of personality disorder originate in James Pritchard's description of moral insanity, which was later termed “sociopathy” and finally became antisocial personality disorder in the second edition of DSM (DSM-II) in 1968. However, as John Gunderson and Katharine Phillips showed in the previous edition of this textbook, other classified personality disorders in the DSM system can be traced to Kurt Schneider's work. This chapter uses the DSM-IV classification of personality disorders, which is descriptively similar to that of ICD-10. A noteworthy exception to this is that ICD-10 classifies schizotypal personality disorder on Axis I, among schizophrenic disorders, whereas DSM-IV keeps this disorder on Axis II among personality disorders.

DSM-IV Classification According to DSM-IV, the crucial criterion for distinguishing deviant personality traits is the presence (evidence) of long-term maladaptation and inflexibility, manifested as subjective distress, or socioprofessional functional impairment, or both. DSM-IV defines personality disorders as:

> an enduring pattern of inner experience and behavior that deviates markedly from the expectations of the individual's culture. The pattern is manifested in two (or more) of the following areas:
>
> 1. cognition (i.e., ways of perceiving and interpreting self, other people, and events)

2. affectivity (i.e., the range, intensity, lability, and appropriateness of emotional response)
3. interpersonal functioning
4. impulse control

The pattern is stable and of long duration and its onset can be traced back at least to adolescence or early adulthood. It is inflexible and pervasive across a broad range of personal and social situations and leads to clinically significant distress or impairment in social, occupational, or other important areas of functioning.

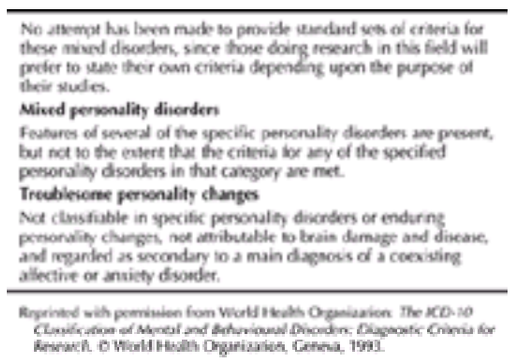
Personality disorder subtypes classified in DSM-IV are schizotypal, schizoid, paranoid, narcissistic, borderline, antisocial, histrionic, obsessive-compulsive, dependent, and avoidant. In addition to these 10 standard disorders, DSM-IV classifies two disorders, passive-aggressive and depressive among “Criteria Sets and Axes Provided for Further Study” in Appendix B.

DSM-IV arranges categorical personality disorders into three clusters, each sharing some clinical features: Cluster A includes three disorders with odd, aloof, and eccentric features (paranoid, schizoid, and schizotypal); Cluster B includes four disorders with dramatic, impulsive, and erratic features (borderline, antisocial, narcissistic, and histrionic); and Cluster C includes three disorders sharing anxious and fearful features (avoidant, dependent, and obsessive-compulsive). Several studies have supported the construct validity of these clusters except that the symptoms for compulsive disorder sometimes tend to form a fourth cluster. Note that the three dimensions underlying Clusters A, B, and C (i.e., detachment, impulsivity, and fearfulness) correspond closely to normal temperament traits (reward dependence, novelty seeking, and harm avoidance, respectively), suggesting that variation in these temperament traits might be significant in distinguishing among the three clusters of disorders.

ICD-10 In ICD-10, personality disorders are described as severe disturbance of personality and behavior that are pronounced deviations, from normal cultural patterns. ICD-10's diagnostic guidelines include disturbances of long-standing duration in several areas of functioning; pervasive and maladaptive behavior; onset in childhood or adolescence; continuation into adulthood; considerable personality distress (although sometimes apparent only late in the disorder's course); and usually, but not always, significant problems in work and in social behavior. ICD-10 also allows for the possibility of criteria developed to describe personality disorders in different cultures. The diagnostic criteria for specific personality disorders appear in Table 24-13.

Table 24-13 ICD-10 Diagnostic Criteria for Specific Personality Disorders

Other related disorders in ICD-10 are mixed and other personality disorders (Table 24-14); enduring personality changes not attributed to brain damage and disease (Table 24-15); other disorders of adult personality and behavior (Table 24-16); and a residual category, unspecified disorder of adult personality and behavior.



No attempt has been made to provide standard sets of criteria for these mixed disorders, since those doing research in this field will prefer to state their own criteria depending upon the purpose of their studies.

Mixed personality disorders

Features of several of the specific personality disorders are present, but not to the extent that the criteria for any of the specified personality disorders in that category are met.

Troublesome personality changes

Not classifiable in specific personality disorders or enduring personality changes, not attributable to brain damage and disease, and regarded as secondary to a main diagnosis of a coexisting affective or anxiety disorder.

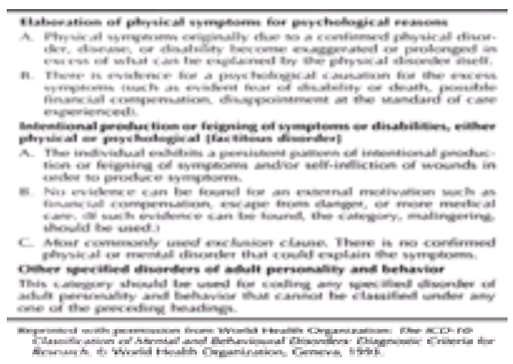
Table 24-14 ICD-10 Diagnostic Criteria for Mixed and Other Personality Disorders

Table 24-15 ICD-10 Diagnostic Criteria for Enduring Personality Changes, Not Attributable to Brain Damage and Disease



Elaboration of physical symptoms for psychological reasons

A. Physical symptoms originally due to a confirmed physical disorder, disease, or disability become exaggerated or prolonged in excess of what can be explained by the physical disorder itself.

B. There is evidence for a psychological causation for the excess symptoms (such as evident fear of disability or death, possible financial compensation, disappointment at the standard of care experienced).

Intentional production or feigning of symptoms or disabilities, either physical or psychological (factitious disorder)

A. The individual exhibits a *persistent pattern* of intentional production or feigning of symptoms and/or self-infliction of wounds in order to produce symptoms.

B. No evidence can be found for an external motivation such as financial compensation, escape from danger, or more medical care. (If such evidence can be found, the category, malingering, should be used.)

C. *Most commonly used exclusion clause.* There is no confirmed physical or mental disorder that could explain the symptoms.

Other specified disorders of adult personality and behavior

This category should be used for coding *any* specified disorder of adult personality and behavior that cannot be classified under any one of the preceding headings.

Table 24-16 ICD-10 Diagnostic Criteria for Other Disorders of Adult Personality and Behavior

DSM-IV PERSONALITY DISORDERS

Qualitative features considered diagnostic of a personality disorder in DSM-IV are summarized in Table 24-17.

Cluster	Subtype	Discriminating Features
Odd/eccentric	Schizoid	Socially indifferent
	Paranoid	Suspicious
	Schizotypal	Eccentric
Erratic/impulsive	Antisocial	Disagree
	Borderline	Unstable
	Histrionic	Attention seeking
	Narcissistic	Self-centered
Anxious/fearful	Avoidant	Inhibited
	Dependent	Submissive
	Obsessive	Perfectionistic
Not otherwise specified	Passive-aggressive	Negativistic
	Depressive	Pessimistic

Table 24-17 DSM-IV Qualitative Clusters and Subtypes of Personality Disorders

General Diagnostic Guidelines DSM-IV introduces the following general guidelines for the diagnosis of personality disorder (Table 24-18). Many of the features of various personality disorders may also be seen during an episode of another mental disorder. The diagnosis of personality disorder is made only when the features are typical of long-term functioning and are not limited to a discrete episode of another mental disorder. Likewise, when maladaptive behavior features are due to the direct psychological effects of a substance (e.g., various psychoactive substances including medication), general medical condition, or catastrophic experience, diagnosis of personality disorder is not warranted.

A. An enduring pattern of inner experience and behavior that deviates markedly from the expectations of the individual's culture. This pattern is manifested in two (or more) of the following areas:
   (1) cognition (i.e., ways of perceiving and interpreting self, other people, and events)
   (2) affectivity (i.e., the range, intensity, lability, and appropriateness of emotional response)
   (3) interpersonal functioning
   (4) impulse control
B. The enduring pattern is inflexible and pervasive across a broad range of personal and social situations.
C. The enduring pattern leads to clinically significant distress or impairment in social, occupational, or other important areas of functioning.
D. The pattern is stable and of long duration and its onset can be traced back at least to adolescence or early adulthood.
E. The enduring pattern is not better accounted for as a manifestation or consequence of another mental disorder.
F. The enduring pattern is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition (e.g., head trauma).

Table 24-18 DSM-IV General Diagnostic Criteria for a Personality Disorder

Judgments about personality functioning must take into account an individual's ethical, social, and cultural background. Personality disorder should not be confused with acculturation following immigration or with the expression of customs and religious and political values characteristic of a person's culture of origin.

Diagnosis of specific personality disorder may be made in children or adolescents when observed maladaptive personality traits are pervasive, persistent, and unlikely to be limited to a particular developmental stage or an episode of an Axis I disorder. Diagnosis of a personality disorder in an individual under 18 years of age requires that the features be present for more than 1 year. The only exception to this is antisocial personality disorder, which cannot be diagnosed in individuals under 18 years of age.

Clinical experience points to a potential sex bias in diagnosing personality disorders. Certain personality disorders are diagnosed more frequently in men (e.g., antisocial and schizoid), whereas some disorders are more frequently diagnosed in women (e.g., borderline, histrionic, and dependent). Even though real gender differences likely exist in the prevalence of these disorders, clinicians are cautioned not to diagnose certain personality disorders in males and females because of social stereotypes about typical gender roles and behaviors.

Observed maladaptive behavior traits must be pervasive, that is, manifest in a wide range of personal and social contexts (e.g., at home, at work, with family and friends), not isolated aspects of the person's life. Data collection from collateral informants is thus considered critical to ensure high-quality personality assessment, diagnostic reliability, and validity.

In addition to designated diagnostic criteria, DSM-IV specifies a group of “associated features” that are given as loose descriptions of optional, but fairly frequent, behaviors, intended to help clinicians when diagnosis is not certain.

Cluster A Personality Disorders

Paranoid Personality Disorder The hallmarks of paranoid personality disorder are excessive suspiciousness and distrust of others expressed as a pervasive tendency to interpret actions of others as deliberately demeaning, malevolent, threatening, exploiting, or deceiving (Table 24-19). Frequently impairment is mild, but the disorder typically includes occupational and social difficulties.

A. A pervasive distrust and suspiciousness of others such that their motives are interpreted as malevolent, beginning by early adulthood and present in a variety of contexts, as indicated by four (or more) of the following:
   (1) suspects, without sufficient basis, that others are exploiting, harming, or deceiving him or her
   (2) is preoccupied with unjustified doubts about the loyalty or trustworthiness of friends or associates
   (3) is reluctant to confide in others because of unwarranted fear that the information will be used maliciously against him or her
   (4) reads hidden, demeaning, or threatening meanings into benign remarks or events
   (5) persistently bears grudges, i.e., is unforgiving of insults, injuries, or slights
   (6) perceives attacks on his or her character or reputation that are not apparent to others and is quick to react angrily or to counterattack
   (7) has recurrent suspicions, without justification, regarding fidelity of spouse or sexual partner
B. Does not occur exclusively during the course of schizophrenia, a mood disorder with psychotic features, or another psychotic disorder and is not due to the direct physiological effects of a general medical condition

Note: *If criteria are met prior to the onset of schizophrenia add "premorbid," e.g., "paranoid personality disorder (premorbid)."*

Reprinted with permission from American Psychiatric Association: *Diagnostic and Statistical Manual of Mental Disorders*, ed 4. © American Psychiatric Association, Washington, DC, 1994.

Table 24-19 DSM-IV Diagnostic Criteria for Paranoid Personality Disorder

COMORBIDITY These patients are at increased risk for major depressive disorder, obsessive-compulsive disorder, agoraphobia, and substance abuse or dependence. The most common co-occurring personality disorders are schizotypal, schizoid, narcissistic, avoidant, and borderline personality disorders. The disorder may be complicated by brief psychotic disorder, particularly in response to stress. Paranoid personality disorder has been postulated to be a prepsychotic antecedent of delusional disorder, paranoid type.

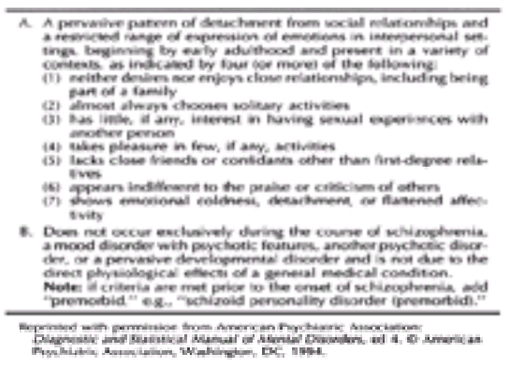
EPIDEMIOLOGY DSM-IV reports prevalence rates of 0.5 to 2.5 percent in the general population, 10 to 30 percent for psychiatric inpatients, and 2 to 10 percent for psychiatric outpatients. According to DSM-IV, this disorder is more commonly diagnosed in males.

ETIOLOGY Some studies have demonstrated increased prevalence of this personality disorder among relatives of probands with chronic schizophrenia and delusional disorder, paranoid type.

DIFFERENTIAL DIAGNOSIS Paranoid personality disorder is distinguished from schizophrenia (especially paranoid type), delusional disorder, paranoid type, and mood disorder with psychotic features on the basis of periods with positive psychotic symptoms such as delusions and hallucinations in the latter. When a brief reactive psychosis with delusions complicates the clinical picture of paranoid personality disorder, this distinction is far more difficult. The duration of the latter and its frequent association with stress usually suffices for differential diagnosis.

Paranoid personality disorder is sometimes difficult to distinguish from the following personality disorders: (1) schizotypal personality disorder (which includes magical thinking, unusual perceptual experiences, oddities in speech, appearance, and thought processes), (2) obsessive-compulsive, schizoid, borderline, and histrionic personality disorders (all with no prominent paranoid ideation), (3) avoidant personality disorder (which includes fear of embarrassment), (4) antisocial personality disorder (which includes personal gains from antisocial behavior), and (5) narcissistic personality disorder (which includes fear of having their “hidden” imperfections and flaws revealed).

Schizoid Personality Disorder The hallmarks of schizoid personality disorder are a pervasive pattern of social detachment and a restricted range of expressed emotions in interpersonal settings (Table 24-20). Frequently these individuals exhibit severe problems in social relations and occupational problems when interpersonal involvement is required. Social isolation sometimes favorably affects overall performance.



A. A pervasive pattern of detachment from social relationships and a restricted range of expression of emotions in interpersonal settings, beginning by early adulthood and present in a variety of contexts, as indicated by four (or more) of the following:
(1) neither desires nor enjoys close relationships, including being part of a family
(2) almost always chooses solitary activities
(3) has little, if any, interest in having sexual experiences with another person
(4) takes pleasure in few, if any, activities
(5) lacks close friends or confidants other than first-degree relatives
(6) appears indifferent to the praise or criticism of others
(7) shows emotional coldness, detachment, or flattened affectivity

B. Does not occur exclusively during the course of schizophrenia, a mood disorder with psychotic features, another psychotic disorder, or a pervasive developmental disorder and is not due to the direct physiological effects of a general medical condition.
Note: If criteria are met prior to the onset of schizophrenia, add "premorbid," e.g., "schizoid personality disorder (premorbid)."

Table 24-20 DSM-IV Diagnostic Criteria for Schizoid Personality Disorder

COMORBIDITY This personality disorder sometimes appears as the prepsychotic antecedent of delusional disorder, schizophrenia, or (rarely) major depressive disorder. These individuals may exhibit brief psychotic disorder, particularly in response to stress. The most common co-occurring personality disorders are paranoid, schizotypal, and avoidant personality disorders.

EPIDEMIOLOGY Reported prevalence rates vary from “uncommon” (DSM-IV) to 7.5 percent in the general population. According to DSM-IV, this disorder is more commonly diagnosed in males and may cause more impairment in them.

ETIOLOGY An increased prevalence among the relatives of probands with schizophrenia or schizotypal personality disorder has been reported.

DIFFERENTIAL DIAGNOSIS Schizoid personality disorder is distinguished from schizophrenia, delusional disorder, and mood disorder with psychotic features on the basis of periods with positive psychotic symptoms, such as delusions and hallucinations, in the latter. When brief psychotic disorder complicates the clinical picture of schizoid personality disorder, this distinction is far more difficult. The duration of the latter and its frequent association with stress usually suffices for differential diagnosis.

Schizoid personality disorder is distinguished from autistic disorder and Asperger's disorder by more severely impaired social interactions and stereotypic behaviors and interests in the latter two disorders. Schizoid disorder is distinguished from the following personality disorders: schizotypal personality disorders (which include magical thinking, unusual perceptual experiences, oddities in speech, appearance, and thought processes), avoidant personality disorder (adequate emotionality in the latter, also social isolation because of fear of embarrassment, not indifference); obsessive-compulsive personality disorder (adequate capacity for intimacy, despite sometimes excessive isolation due to perfectionism and workaholic attitudes); and paranoid personality disorder (which includes suspiciousness, ideas of reference, and guarded facade).

Schizotypal Personality Disorder The hallmarks of schizoid personality disorder are pervasive discomfort with and reduced capacity for close relationships, as well as cognitive and perceptual distortions and eccentric behavior (not severe enough to meet criteria for schizophrenia) (Table 24-21). Patients with this disorder typically experience occupational and social difficulties.

A. A pervasive pattern of social and interpersonal deficits marked by acute discomfort with, and reduced capacity for, close relationships as well as by cognitive or perceptual distortions and eccentricities of behavior, beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:
(1) ideas of reference (excluding delusions of reference)
(2) odd beliefs or magical thinking that influences behavior and are inconsistent with subcultural norms (e.g., superstitiousness, belief in clairvoyance, telepathy, or "sixth sense"; in children and adolescents, bizarre fantasies or preoccupations)
(3) unusual perceptual experiences, including bodily illusions
(4) odd thinking and speech (e.g., vague, circumstantial, metaphorical, overelaborate, or stereotyped)
(5) suspiciousness or paranoid ideation
(6) inappropriate or constricted affect
(7) behavior or appearance that is odd, eccentric, or peculiar
(8) lack of close friends or confidants other than first-degree relatives
(9) excessive social anxiety that does not diminish with familiarity and tends to be associated with paranoid fears rather than negative judgments about self

B. Does not occur exclusively during the course of schizophrenia, a mood disorder with psychotic features, another psychotic disorder, or a pervasive developmental disorder.
Note: If criteria are met prior to the onset of schizophrenia, add "premorbid," e.g., "schizotypal personality disorder (premorbid)."

Reprinted with permission from American Psychiatric Association: Diagnostic and Statistical Manual of Mental Disorders, ed 4, © American Psychiatric Association, Washington, DC, 1994.

Table 24-21 DSM-IV Diagnostic Criteria for Schizotypal Personality Disorder

COMORBIDITY Transient psychotic episodes can complicate this disorder, particularly in response to stress. Symptoms sometimes become so significant that subjects may meet criteria for schizophreniform disorder, delusional disorder, or brief psychotic disorder. More than a half of these patients have had at least one episode of major depression, and 30 to 50 percent have major depression concurrent with this personality disorder. The most common co-occurring personality disorders are

schizoid, paranoid, avoidant, and borderline.

EPIDEMIOLOGY DSM-IV reports a prevalence rate of 3 percent in the general population. Earlier reports suggested a range between 2 and 6 percent. The sex ratio is unknown. The disorder is frequently diagnosed in females with fragile X syndrome.

ETIOLOGY Empirical findings about this disorder are difficult to interpret because it appears to have several clinical subtypes with potentially differential relation to the schizophrenic spectrum. Prevalence of this personality disorder is increased among the first-degree relatives of probands with schizophrenia, and the prevalence of schizophrenia and other psychoses is increased in the relatives of probands with schizotypal personality disorder. Adoption, family, and twin studies demonstrated an increased prevalence of schizotypal features in the families of schizophrenia patients, especially when schizotypal features were not associated with comorbid affective symptoms. Small anticipatory saccades that disrupt smooth pursuit eye movement (hypothesized to be a marker of genetic vulnerability to schizophrenia), have also been detected in schizotypal and introverted personalities. The relation of this personality disorder and schizophrenia is still controversial; some genetic studies find no relation, and some studies find a gradation in multifactorial liability from schizotypal personality (mild), to broad schizophrenia (moderate) to narrow schizophrenia (severe).

DIFFERENTIAL DIAGNOSIS Schizotypal personality disorder is distinguished from schizophrenia, delusional disorder, and mood disorder with psychotic features on the basis of periods with positive psychotic symptoms such as delusions and hallucinations in the latter. When brief psychotic disorder with delusions complicates the clinical picture of schizotypal personality disorder this distinction is far more difficult.

Schizotypal personality disorder is difficult to distinguish from the heterogeneous group of disorders in solitary, odd children whose behavior is characterized by social isolation, eccentricity, and peculiarities in language (autistic disorder, Asperger's disorder, expressive language disorder, and mixed receptive-expressive language disorder). Communication disorders might be distinguished by the primacy and the severity of the disorder in language accompanied by compensatory efforts of the child to communicate by other means and also by specialized language assessment. Autistic and Asperger's disorders are distinguished on the basis of the more severely impaired social interactions and stereotypic behaviors and interests in these two disorders. Schizotypal personality disorder is distinguished from the following personality disorders: schizoid and paranoid personality disorders (which rarely have magical thinking, unusual perceptual experiences, or oddities in speech, appearance, and thought processes), narcissistic personality disorders (with predominant sense of grandiosity, fragile self-esteem, and fear of having “hidden” imperfections or flaws revealed), avoidant personality disorders (which rarely have oddities in appearance and behavior, and in which fear of embarrassment, not disinterest and detachment, causes social avoidance and isolation); and borderline personality disorders (characterized by affective instability and stormy relationships as well as impulsive and manipulative behavior).

Cluster B Personality Disorders Narcissistic, antisocial, and histrionic personality disorder qualify for the so-called spectrum disorders. The three disorders have been shown to aggregate in the same family and co-occur in the same person. Phenotypically distinguishable disorders may be referred to as spectrum disorders if they meet the above two conditions. Spectrum disorders sometimes reflect differential expression of the same liability. Antisocial, narcissistic, and histrionic personality disorders exemplify the spectrum in which a tendency to aggressivity (associated with high novelty seeking) interferes with character development and maturity. Empirical data show that symptoms of the three disorders tend to group around impulsivity, aggression, and dramatic affects. A spectrum disorder may also reflect a less deviant form of the other on an underlying liability scale. In that regard, the underlying antisocial behaviors decrease in severity as one proceeds from antisocial (violent and property crime), via narcissistic (exploitation), to histrionic personality disorder (manipulation).

Antisocial Personality Disorder Antisocial personality disorder is characterized by pervasive disregard for, and violation of, rights of others since the age of 15. A person must be at least 18 years old and have displayed evidence of conduct disorder before the age of 15 (Table 24-22). Antisocial personality disorder may be complicated by dysphoria, tension, low tolerance for boredom, depressed mood, and premature violent death. Impairment is extremely variable, but typically includes social difficulties.

A. There is a pervasive pattern of disregard for and violation of the rights of others occurring since age 15 years, as indicated by three (or more) of the following:
   (1) failure to conform to social norms with respect to lawful behaviors as indicated by repeatedly performing acts that are grounds for arrest
   (2) deceitfulness, as indicated by repeated lying, use of aliases, or conning others for personal profit or pleasure
   (3) impulsivity or failure to plan ahead
   (4) irritability and aggressiveness, as indicated by repeated physical fights or assaults
   (5) reckless disregard for safety of self or others
   (6) consistent irresponsibility, as indicated by repeated failure to sustain consistent work behavior or honor financial obligations
   (7) lack of remorse, as indicated by being indifferent to or rationalizing having hurt, mistreated, or stolen from another
B. The individual is at least age 18 years.
C. There is evidence of conduct disorder with onset before age 15 years.
D. The occurrence of antisocial behavior is not exclusively during the course of schizophrenia or a manic episode.

Reprinted with permission from American Psychiatric Association: Diagnostic and Statistical Manual of Mental Disorders, ed 4. © American Psychiatric Association, Washington, DC, 1994.

Table 24-22 DSM-IV Diagnostic Criteria for Antisocial Personality Disorder

COMORBIDITY These patients are at increased risk for impulse control disorders, major depression, substance abuse or dependence, pathological gambling, anxiety disorders, and somatization disorder. The most common co-occurring personality disorders are narcissistic, borderline, and histrionic.

EPIDEMIOLOGY Prevalence rates of 3 percent for males and 1 percent for females in the general population and 3 to 30 percent in clinical settings, with even higher rates for forensic samples and substance abusers, have been reported. DSM-IV notes concern that this disorder may be underdiagnosed in females, given the emphasis on aggressive items in diagnosing conduct disorder. A high frequency of antisocial personality disorder is associated with low socioeconomic status and urban settings.

ETIOLOGY Antisocial personality disorder is more frequent among the first-degree biological relatives of probands with this disorder. Biological relatives of women with antisocial personality disorder are at greater risk for the same disorder than biological relatives of men with antisocial personality disorder. Genetic studies have suggested familial transmission of antisocial personality disorder, substance use, and somatization disorder, with the former two being characteristic of males and the latter of females in the same family. Adoption studies show that both genetic and environmental factors contribute to the risk for this disorder since both adopted and biological children of parents with antisocial personality disorder are at increased risk for this disorder.

Conduct disorder (before the age of 10) and accompanying attention-deficit/hyperactivity disorder increase the likelihood of developing antisocial personality disorder in adult life. Conduct disorder is more likely to develop into antisocial personality disorder when there is erratic parenting, neglect, or inconsistent parental discipline.

DIFFERENTIAL DIAGNOSIS Antisocial personality disorder is distinguished from manic episodes of bipolar disorder I on the basis of episodic course and euphoric mood in the latter. Antisocial disorder is distinguished from the following personality disorders: narcissistic personality disorder (which rarely manifests serious criminality, aggression, and deceit, and is characterized by excessive need for admiration and envy of others), histrionic personality disorder (which includes seductiveness, attention seeking, superficiality, and rarely serious criminality and aggressiveness), paranoid personality disorder (which includes suspiciousness, guarded attitude, rarely serious antisocial behaviors), and borderline personality disorder (which includes manipulativeness to gain nurturance, and affective instability). Contrary to common belief, persons with explosive temperaments (which underlie borderline symptoms and are characterized by high harm avoidance with high novelty seeking and low reward dependence) frequently manifest antisocial behaviors (this corresponds to the old term “secondary psychopathy” in the literature). Secondary psychopathy is distinguished from antisocial personality proper (or “primary psychopathy”) by high novelty seeking with low harm avoidance and low reward dependence, which corresponds to the adventurous temperament profile. Antisocial personality disorder must also be distinguished from adult antisocial behavior (with no personality pathology in the background).

Course After the age of 30, both the most flagrant antisocial behaviors (promiscuity, crime) and less severe behaviors and substance use tend to decrease.

Narcissistic Personality Disorder The hallmarks of narcissistic personality disorder are a pervasive sense of grandiosity (in fantasy or in behavior), need for

admiration, lack of empathy, and chronic intense envy (Table 24-23).

A pervasive pattern of grandiosity (in fantasy or behavior), need for admiration, and lack of empathy, beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:

(1) has a grandiose sense of self-importance (e.g., exaggerates achievements and talents, expects to be recognized as superior without commensurate achievements)
(2) is preoccupied with fantasies of unlimited success, power, brilliance, beauty, or ideal love
(3) believes that he or she is "special" and unique and can only be understood by, or should associate with, other special or high-status people (or institutions)
(4) requires excessive admiration
(5) has a sense of entitlement, i.e., unreasonable expectations of especially favorable treatment or automatic compliance with his or her expectations
(6) is interpersonally exploitative, i.e., takes advantage of others to achieve his or her own ends
(7) lacks empathy: is unwilling to recognize or identify with the feelings and needs of others
(8) is often envious of others or believes that others are envious of him or her
(9) shows arrogant, haughty behaviors or attitudes

Table 24-23 DSM-IV Diagnostic Criteria for Narcissistic Personality Disorder

This disorder may be complicated by social withdrawal or depressed mood. Frequently severe, impairment typically includes marital problems and poor interpersonal relationships in general.

COMORBIDITY These patients are at increased risk for major depression and substance abuse or dependence (especially cocaine use). Dysthymic disorder or major depressive disorder may develop in reaction to criticism or failure. The most common co-occurring personality disorders are borderline, antisocial, histrionic, and paranoid personality disorders.

EPIDEMIOLOGY DSM-IV reports prevalence rates of 2 to 16 percent in clinical populations and less than 1 percent in the general population. According to DSM-IV, this disorder is more commonly diagnosed in males.

ETIOLOGY A higher risk for this personality disorder may exist in the offspring of narcissistic parents who give their children an unrealistic sense of grandiosity. In addition, most narcissistic persons are realistically talented, beautiful, or highly intelligent as these features serve as the nucleus around which the sense of specialness is further organized.

DIFFERENTIAL DIAGNOSIS Narcissistic personality disorder is distinguished from a manic or hypomanic episode by the episodic course, euphoria, and functional impairments in the latter two. Narcissistic personality disorder is distinguished from the following personality disorders: Antisocial personality disorder (narcissistic exploitativeness is more driven by the wish to establish one's dominance than by material gains, history of conduct disorder, and no excessive need for admiration); borderline personality disorder (which includes unstable self-concept, chaotic behaviors, self-destructive gestures, chronic anxiety, and rarely high achievements); histrionic personality disorder (which includes capacity for empathy, emotional display, and rarely unscrupulousness and exploitation of others); obsessive-compulsive personality disorder (which includes inflexibility, orientation to detail, and social isolation in addition to perfectionism and belief that others cannot do things as well); and paranoid and schizotypal personality disorders (which include suspiciousness and social withdrawal).

COURSE The course is chronic; however, narcissistic symptoms tend to diminish after the age of 40, when pessimism usually develops.

Histrionic Personality Disorder The hallmarks of histrionic personality disorder are pervasive and excessive self-dramatization, excessive emotionality, and attention seeking (Table 24-24).

A pervasive pattern of excessive emotionality and attention seeking, beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:

(1) is uncomfortable in situations in which he or she is not the center of attention
(2) interaction with others is often characterized by inappropriate sexually seductive or provocative behavior
(3) displays rapidly shifting and shallow expression of emotions
(4) consistently uses physical appearance to draw attention to self
(5) has a style of speech that is excessively impressionistic and lacking in detail
(6) shows self-dramatization, theatricality, and exaggerated expression of emotion
(7) is suggestible, i.e., easily influenced by others or circumstances
(8) considers relationships to be more intimate than they actually are

Table 24-24 DSM-IV Diagnostic Criteria for Histrionic Personality Disorder

Frequently impairment is mild. The patients may exhibit frequent suicidal gestures and threats to coerce better caregiving. Interpersonal relations are unstable, shallow, and generally ungratifying. Frequent marital problems result from the tendency to neglect long-term relationships for the excitement of new relationships.

COMORBIDITY These patients are at increased risk for major depression, somatization disorder, and conversion disorder. The most common co-occurring disorders are narcissistic, borderline, antisocial, and dependent.

EPIDEMIOLOGY DSM-IV reports prevalence rates of 2 to 3 percent in the general population and 10 to 15 percent for psychiatric inpatients and outpatients. This disorder is generally agreed to occur far more frequently among women. According to DSM-IV, it might be equally frequent among men and women.

ETIOLOGY This disorder tends to run in families. A genetic link between histrionic and antisocial personality disorders and alcohol use disorders has been suggested, but many of those previously described as having histrionic personality disorder would now be classified as having borderline personality disorder.

DIFFERENTIAL DIAGNOSIS Histrionic personality disorder is distinguished from the following personality disorders: antisocial personality disorder (which includes antisocial behaviors and crime to gain profit, power, or some other material gratification; history of conduct disorder; no excessive self-dramatization; no exaggerated emotional expression), borderline personality disorder (which includes bunstable self-concept, chaotic behaviors, self-destructive gestures, chronic anxiety, and identity disturbance, and narcissistic personality disorder (which includes fear of having “hidden” imperfections and flaws revealed, sense of grandiosity, and sense of specialness).

Borderline Personality Disorder The hallmarks of borderline personality disorder are pervasive and excessive instability of affects, self-image, and interpersonal relationships as well as marked impulsivity (Table 24-25).

A pervasive pattern of instability of interpersonal relationships, self-image, and affects, and marked impulsivity by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:
(1) frantic efforts to avoid real or imagined abandonment. **Note:** do not include suicidal or self-mutilating behavior covered in criterion 5.
(2) a pattern of unstable and intense interpersonal relationships characterized by alternating between extremes of idealization and devaluation
(3) identity disturbance: markedly and persistently unstable self-image or sense of self
(4) impulsivity in at least two areas that are potentially self-damaging (e.g., spending, sex, substance abuse, reckless driving, binge eating). **Note:** do not include suicidal or self-mutilating behavior covered in criterion 5.
(5) recurrent suicidal behavior, gestures, or threats, or self-mutilating behavior
(6) affective instability due to a marked reactivity of mood (e.g., intense episodic dysphoria, irritability, or anxiety usually lasting a few hours and only rarely more than a few days)
(7) chronic feelings of emptiness
(8) inappropriate, intense anger or difficulty controlling anger (e.g., frequent displays of temper, constant anger, recurrent physical fights)
(9) transient, stress-related paranoid ideation or severe dissociative symptoms

Table 24-25 DSM-IV Diagnostic Criteria for Borderline Personality Disorder

The disorder may be complicated by psychotic-like symptoms (hallucinations, body image distortions, hypnagogic phenomena, ideas of reference) in response to stress and premature death or physical handicap from suicide and suicidal gestures, failed suicide, and self-injurious behavior. Frequent and severe impairment may involve frequent job losses, interrupted education, and broken marriages.

Comorbidity These patients are at increased risk for major depression, substance abuse or dependence, eating disorder (notably bulimia), posttraumatic stress disorder, and attention-deficit/hyperactivity disorder. Borderline personality disorder co-occurs with most other personality disorders.

EPIDEMIOLOGY DSM-IV reports prevalence rates of 2 percent in the general population, 10 percent for psychiatric outpatients, 20 percent for psychiatric inpatients, and 30 to 60 percent among patients with personality disorders. According to DSM IV, this disorder is more commonly iagnosed in females.

ETIOLOGY Numerous studies have pointed to early traumatic experiences as a cause of this personality disorder. Recently, a tripartite etiological model, including childhood trauma, vulnerable temperament, and a series of triggering events was formulated. Dynamic and biological psychiatry agree that a combination of early traumatic events and certain biological vulnerabilities (mostly in the emotional domain) represent primary etiological factors for this disorder. Physical and sexual abuse, neglect, hostile conflict, and early parental loss or separation are more common in childhood histories of patients with this disorder. Familial aggregation of borderline personality disorder has been repeatedly demonstrated. Borderline personality disorder is five times more common among relatives of probands with this disorder than in the general population. This disorder is also associated with increased familial risk for antisocial personality disorder, substance abuse, and mood disorders.

DIFFERENTIAL DIAGNOSIS Borderline personality disorder is distinguished from mood disorder, dysthymic disorder, and cyclothymia (with depression and mood swings mimicking borderline affective problems) on the basis of efforts to avoid abandonment, unstable relationships with alternation between idealization and devaluation, identity disturbance, impulsivity in potentially self-damaging areas, chronic feelings of emptiness, and inappropriately intensive anger or difficulty controlling anger, which are rarely observed in mood disorder, dysthymia, or cyclothymia).

Borderline disorder shares many features and is difficult to distinguish from all other personality disorders. Frequently it is an exclusion diagnosis based on typical clinical symptoms for other personality disorders. Borderline disorder is distinguished from identity problems, which is limited to a developmental stage.

COURSE The variable course most commonly follows a pattern of chronic instability in early adulthood with episodes of serious affective and impulsive dyscontrol. Impairment and the risk of suicide are greatest in the young adult years and gradually wane with advancing age. In the fourth and fifth decade these individuals tend to attain greater stability in their relationships and functioning.

Cluster C Personality Disorders

Avoidant Personality Disorder Clinical Criteria Avoidant personality disorder is characterized by pervasive and excessive hypersensitivity to negative evaluation, social inhibition, and feelings of inadequacy (Table 24-26). Impairment can be severe and typically includes occupational and social difficulties.

A pervasive pattern of social inhibition, feelings of inadequacy, and hypersensitivity to negative evaluation, beginning by early adulthood and present in a variety of contexts, as indicated by four (or more) of the following:
(1) avoids occupational activities that involve significant interpersonal contact, because of fears of criticism, disapproval, or rejection
(2) is unwilling to get involved with people unless certain of being liked
(3) shows restraint within intimate relationships because of the fear of being shamed or ridiculed
(4) is preoccupied with being criticized or rejected in social situations
(5) is inhibited in new interpersonal situations because of feelings of inadequacy
(6) views self as socially inept, personally unappealing, or inferior to others
(7) is unusually reluctant to take personal risks or to engage in any new activities because they may prove embarrassing

Table 24-26 DSM-IV Diagnostic Criteria for Avoidant Personality Disorder

COMORBIDITY These patients are at increased risk for mood and anxiety disorders (especially social phobia, generalized type). The most common co-occurring personality disorders are schizotypal, schizoid, paranoid, dependent, and borderline personality disorders.

EPIDEMIOLOGY DSM-IV reports prevalence rates of 0.5 to 1 percent in the general population and 10 percent for psychiatric outpatients. According to DSM-IV, this disorder is equally frequent in males and females.

DIFFERENTIAL DIAGNOSIS Avoidant personality disorder is very difficult to distinguish from social phobia (many authors believe these are alternative labels for the same or similar condition). In social phobia, specific situations rather than interpersonal contact are avoided. Panic disorder with agoraphobia also manifests avoidance but usually after the onset of panic attacks.

Avoidant disorder is distinguished from schizotypal and schizoid personality disorders (social isolation of avoidant personalities is accompanied by the desire for social relations, which is not observed in schizoid and schizotypal personality disorder), paranoid personality disorder (which includes guarded attitude, preoccupation with hidden meanings and conspiratorial explanations of events), and dependent personality disorder (which focuses on being taken care of rather than on the fear of negative evaluation).

COURSE Frequently beginning in childhood with shyness and fear of strangers and new situations, disfiguring illness and shyness in childhood predispose children to avoidant personality disorder.

DEPENDENT PERSONALITY DISORDER The hallmark of dependent personality disorder is a pervasive, excessive need to be taken care of, leading to clinging behavior, submissiveness, fear of separation, and interpersonal dependency (Table 24-27). Complications include low socioeconomic status and poor family and marital functioning.

A pervasive and excessive need to be taken care of that leads to submissive and clinging behavior and fears of separation, beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:

(1) has difficulty making everyday decisions without an excessive amount of advice and reassurance from others
(2) needs others to assume responsibility for most major areas of his or her life
(3) has difficulty expressing disagreement with others because of fear of loss of support or approval. **Note:** do not include realistic fears of retribution.
(4) has difficulty initiating projects or doing things on his or her own (because of a lack of self-confidence in judgment or abilities rather than a lack of motivation or energy)
(5) goes to excessive lengths to obtain nurturance and support from others, to the point of volunteering to do things that are unpleasant
(6) feels uncomfortable or helpless when alone because of exaggerated fears of being unable to care for himself or herself
(7) urgently seeks another relationship as a source of care and support when a close relationship ends
(8) is unrealistically preoccupied with fears of being left to take care of himself or herself

Table 24-27 DSM-IV Diagnostic Criteria for Dependent Personality Disorder

Impairment is frequently only mild and typically includes poor interpersonal relationships and occupational functioning if independence is required.

COMORBIDITY These patients are at increased risk for major depressive and other mood disorders, anxiety disorders, adjustment disorder, and social phobia. The most common co-occurring personality disorders are histrionic, avoidant, and borderline personality disorders.

EPIDEMIOLOGY DSM-IV reports it to be the most frequent personality disorder. The disorder is equally frequent in males and females.

ETIOLOGY Chronic physical illness or separation anxiety disorder may predispose for dependent personality disorder, whose familial pattern and genetics are unknown.

DIFFERENTIAL DIAGNOSIS Dependent personality disorder is distinguished from dependency seen in mood disorders, panic disorder, agoraphobia, and as a result of general medical condition.

Dependent disorder is distinguished from borderline personality disorder (which includes unstable, stormy relationships and reaction to abandonment with rage, emptiness, and demands as opposed to increasing appeasement and submissiveness seen with dependent personalities), histrionic personality disorder (which includes gregarious flamboyance with active demands for attention), and avoidant personality disorder (which includes social isolation because of the fear of negative evaluation, rather than the clinging and submissive behavior of dependent personalities).

Obsessive-Compulsive Personality Disorder The hallmark of obsessive-compulsive personality disorder is pervasive preoccupation with orderliness, perfectionism, and mental and interpersonal control, at the expense of flexibility, openness, and efficiency (Table 24-28). Complications include distress and difficulties when confronted with new situations that require flexibility and compromise and myocardial infarction (secondary to features typical of type A personalities, such as time urgency, hostility, competitiveness). Frequently severe, impairment typically includes occupational and social difficulties.

A pervasive pattern of preoccupation with orderliness, perfectionism, and mental and interpersonal control, at the expense of flexibility, openness, and efficiency, beginning by early adulthood and present in a variety of contexts, as indicated by four (or more) of the following:

(1) is preoccupied with details, rules, lists, order, organization, or schedules to the extent that the major point of the activity is lost
(2) shows perfectionism that interferes with task completion (e.g., is unable to complete a project because his or her own overly strict standards are not met)
(3) is excessively devoted to work and productivity to the exclusion of leisure activities and friendships (not accounted for by obvious economic necessity)
(4) is overconscientious, scrupulous, and inflexible about matters of morality, ethics, or values (not accounted for by cultural or religious identification)
(5) is unable to discard worn-out or worthless objects even when they have no sentimental value
(6) is reluctant to delegate tasks or to work with others unless they submit to exactly his or her way of doing things
(7) adopts a miserly spending style toward both self and others; money is viewed as something to be hoarded for future catastrophes
(8) shows rigidity and stubbornness

Table 24-28 DSM-IV Diagnostic Criteria for Obsessive-Compulsive Personality Disorder

COMORBIDITY These patients are at increased risk for major depression, anxiety disorder, and obsessive-compulsive disorder.

EPIDEMIOLOGY DSM-IV reports prevalence rates of 1 percent in the general population and 3 to 10 percent for psychiatric outpatients. According to DSM-IV, this disorder is twice as common in males as in females.

ETIOLOGY Obsessions and compulsions have been repeatedly linked to high central serotonergic function. However, the latter is associated with anxiety in general, which supports the hypothesis that obsessions and compulsions represent psychological and behavioral mechanisms against anxiety. Some studies have demonstrated familial aggregation of this disorder.

Differential Diagnosis Obsessive-compulsive personality disorder is distinguished from obsessive-compulsive disorder on the basis of true obsessions and compulsions in the latter.

This personality disorder is distinguished from schizoid personality disorder (which includes lack of capacity for intimacy and social isolation secondary to emotional detachment, as opposed to devotion to work and discomfort with emotions), antisocial personality disorder (which includes material goals in antisocial behavior and criminality as opposed to hypermorality of obsessive personalities), and narcissistic personality disorder (which includes sense of grandiosity, self-aggrandizement, exhibitionism, and fear of having “hidden” imperfections and flaws revealed).

Disadvantages of DSM-IV Classification In addition to general problems shared by all categorical models of personality, the DSM classification has its own specific limitations. First, DSM-IV is an etiologically atheoretical classification of personality disorder based solely on descriptive criteria derived from observations of prototypical cases. This atheoretical approach was expected to stimulate work on the etiology of deviant behaviors classified as personality disorders. Unfortunately, this has not happened. The introduction of descriptive criteria in DSM-III inspired extensive research on some basic psychometric aspects of the personality disorder diagnosis but rarely studies of etiology, underlying dynamics, or pathogenesis. While this emphasis on elementary psychometrics obviously reflects an attempt of this new field to delineate its subject, it also reflects the purely descriptive approach that provided no testable etiopathogenetic models or hypotheses. Consequently, after almost two decades of research based on DSM criteria, our conceptual understanding of personality disorders as specified by DSM is still at a basic descriptive level similar to that introduced in 1980.

Second, DSM-IV describes as pathognomonic for personality disorders maladaptive response patterns that are enduring, that is, appearing before adulthood and typical of long-term functioning. In practice, however, it can be difficult to distinguish long-term maladaptation indicating personality disorder from chronic personality changes caused by other factors, such as other mental disorders (e.g., chronic depression), long-term situational factors (e.g., job-related behavior requirements), and other medical disorders (e.g., irritability associated with hyperthyroidism).

Third, the DSM definition of personality disorders is inherently imprecise because it requires that maladaptive behaviors cause clinically significant subjective distress or clinically significant impairment in social and occupational function or both. The quantifier “significant” is an arbitrary diagnostic element that can hardly be

objectivized. In addition, subjective distress usually means low self-esteem, which often leads to anxiety, guilt, depression, and hypochondriasis, which are frequently diagnosed and treated as independent Axis I disorders while the background personality disorder is overlooked.

CLINICAL AND PSYCHOMETRIC ISSUES

Ego-Syntonic and Alloplastic Nature of Personality Disorder Patients with personality disorder typically blame other people or unfavorable circumstances for their own problems. This externalizing of responsibility results from two characteristics of these disorders. First, most of these patients perceive their own deviant behaviors as adequate; in other words, their symptoms are ego-syntonic. The exception are patients with cluster C dependent and avoidant personality disorders. Both of these disorders are characterized by prominent anxiety associated with maladaptive behaviors, which frequently causes patients to perceive their symptoms as disturbing (i.e., ego-dystonic). Second, patients with personality disorder try to change others, instead of changing themselves; in other words, their attitude is described as alloplastic. The exception are patients with avoidant and schizoid personality disorders. Avoidant persons usually try to improve their own performance to avoid negative evaluation by others. Those with schizoid personalities are so socially detached that they are usually indifferent to what others might do, think, or feel.

Personality Disorder: Social or Clinical Diagnosis? One of the general DSM-IV requirements for personality disorder is that maladaptive behavior “deviates markedly from the expectations of the individual's culture.” This requirement introduces a significant social connotation to a clinical classification of behaviors. Indeed, clinical diagnosis of a personality disorder is often based solely on the extent to which certain behavior is adjusted to the local society. To what extent should mental health professionals serve as designated gate keepers for behavior traits considered unusual in a particular social setting? Most temperament profiles with high reward dependence have a low incidence of diagnosed personality disorder, whereas those with high harm avoidance, high novelty seeking, or both increase this risk. In general, sociocultural pressures promote phenotypes that fall within the range of accepted behavior norms. In Western societies, the normative phenotype is not the one with average personality traits (as one would expect given the adaptive flexibility of such configuration) but the one with high reward dependence. High reward dependence leads to much easier conditioning of socially accepted behaviors than do novelty seeking and harm avoidance. Similarly child psychiatry classifies three broad groups of mental disorders characterized by high novelty seeking (e.g., attention-deficit/hyperactivity disorder, conduct disorder), high harm avoidance (e.g., depressive and anxiety disorders), and low reward dependence (e.g., schizophrenia, autistic disorder). Most children with these extreme temperaments are diagnosed and treated when young, whereas children with high reward dependence (sociable, attached, dependent) are selectively encouraged to mature without psychiatric intervention. This raises a general question about the role of our society in shaping psychological profiles of its members that is beyond the scope of this chapter. Suffice it to say, anatomical adaptation appears to have become less critical for our survival than behavioral adaptation. Natural selection may be targeting not our morphological features but our personality features and intelligence. Through its suppression of certain temperament traits and its modeling effects on character development, modern human society obviously has an important role in this process.

Categorical Versus Dimensional Approach to Personality Disorder Medical diagnosis has historically been categorical, and most clinicians tend to think categorically for two reasons. First, one of the most important functions of diagnosis is to prescribe appropriate corrective action (i.e., treatment). Deciding whether a person is affected or unaffected is functionally equivalent to deciding whether or not that person needs treatment (hence, categorical diagnosis facilitates treatment decisions in practical work). Second, categorical systems simplify professional communication because they describe prototypical and severe cases that meet all or most of the specified criteria. Just one categorical label (e.g., antisocial personality disorder) can communicate a great deal of vivid clinical information about the patient. However, categorical descriptions convey useful information about prototypical and severe cases, but little or no information about atypical, mixed, or mild cases.

Categorical Approach The categorical approach adopts the medical diagnostic model that a personality disorder is either present or absent. Categorical models are optimal for discontinuous variables (e.g., pregnancy, skin cancer). However, when the distinguishing characteristics of a disorder are quantitative variants of normally occuring phenomena, such as personality traits, any categorical decision about the presence or absence of a disorder is arbitrary. In other words, one of the major disadvantages of categorical models of personality disorders is that they establish arbitrary cutoff points or thresholds for continuous behavior traits. This becomes clear especially in those with mild cases close to the cutoff point who cannot be well classified as affected or unaffected. In an attempt to reduce this problem, DSM-IV now allows clinicians to classify maladaptive personality traits that do not meet the threshold for a personality disorder on Axis II.

Next, a categorical approach is not optimal for patients who do not perfectly fit their pigeonhole in the classification, and an additional wastebasket category for “atypical” or “mixed” cases must be established. Finally, categorical approach to personality disorder does not establish a prescriptive relation between diagnosis and treatment. Reflecting a significant overlap of diagnostic criteria for personality disorder subtypes, categorical systems usually yield multiple personality diagnoses for individual patients. In such cases, treatment priorities are easily and frequently confused.

Dimensional Approach Dimensional models define a number of graded and continuous behavior dimensions and specify individual differences as quantitative variations along these dimensions. These models are optimal for features that vary quantitatively and have different adaptive significance in different situations (such as personality traits). These models recognize that everyone has multiple personality traits that are more or less prominent and adaptive rather than simply present or absent. This eliminates the need for multiple, overlapping categorical diagnoses. By quantifying their position on a continuous personality trait, dimensional models conserve more information about individual patients than categorical models. Personality dimensions are as easily applied to common atypical and mild cases as they are to the rare prototypical, severe cases. Finally, a dimensional system facilitates mathematical manipulation of complex data with many variables.

Research shows that normal personality traits tend to generalize to personality disorders, indicating that deviant traits may be conceptualized as extreme variants of normal, adaptive behaviors. Note, however, that dimensional models do explain what makes some traits disorders. Statistical deviance alone does not suffice to define dysfunction. In addition, extreme variants can be labeled normal or maladaptive in different contexts. Finally, natural breaks or points of rarity on the continuum of normal and maladaptive personality traits have not been detected. Hence, dimensional models must introduce cutoff points for continuous traits (which are usually arbitrary, unless there are natural steps as described for character in Table 24-12) or use probability estimates for categorical personality disorders on the basis of the severity of measured personality traits.

Measurement of Personality Disorders

Self-report or Interview? No convincing evidence favors self-report or interview, still, interviews are considered more reliable and valid diagnostic tools than self-reports for personality disorders. Many of these patients tend to be biased in reporting their ego-syntonic deviant behaviors. The problem is reduced when the patient is interviewed because unclear, inconsistent, or defensive responses can be clarified, and the patient's demeanor and appearance observed. On the negative side, interviews tend to be affected by systematic biases and rating idiosyncrasies of interviewers. In selfreports, various response sets (e.g., careless inconsistency, defensiveness, and exaggeration) and validity items can aid interpretation. Recently, a set of performance scales, independent of the item content, based on the observed regularities in the technical pattern of responding to questions was defined in some tests, such as the TCI. These performance scales are used to test the validity of self-reported personality traits. Specifically, self-report to questions, regardless of the content of the questions, tends to follow specific patterns that correlate with personality traits. For example, low reward dependence is indicated by endorsement of a large number of items that are rare in the general population. These performance scales are used to predict scores on each of the temperament and character dimensions, which are then compared with self-reported, content-dependent scores on these same traits. Substantial score differences between subjective and performance-based scores on personality traits indicate either significant cognitive distortion about own behaviors or intentional mispresentation.

Note that both self-reports and interviews depend on the patient's accuracy, honesty, and insightfulness. Hence, collection of data from collateral informants and expert ratings is usually considered critical to ensuring high-quality personality diagnosis.

State-Trait Effect Most Axis I disorders have less-severe variants, or “representatives,” on Axis II (Table 24-29). The state-trait distinction between symptoms reflecting long-term personality traits and those reflecting transient Axis I states can be difficult. Indeed, transient variation in one's emotional state can influence both self-report and clinical evaluation of long-term personality characteristics. The susceptibility to such state effects has been demonstrated for some self-report categorical measures of personality disorders. In contrast, only those personality dimensions that underlie susceptibility to depression and anxiety (e.g., neuroticism and harm avoidance) tend to covary with mood and anxiety syndromes. Also, increased anxiety or depression leads to mild and transient decreases in self-directedness and cooperativeness. Consequently, a person with no enduring personality disorder may act immaturely when depressed or under stress. Self-reports of temperament traits unrelated to this susceptibility (e.g., novelty seeking and reward dependence) are largely independent of comorbid mood and anxiety. This remarkable finding suggests that most aspects of personality are unaffected by current anxiety and mood states. The state effect can be reduced (but not eliminated) when subjects are repeatedly reminded to describe their usual, not their current, behavior, feelings, and attitudes.

Axis I Disorders "Major Variant"	Axis II Disorders "Minor Variant"	Shared Symptoms
Schizophrenia spectrum	Schizoid PD* Schizotypal PD	Negative and positive
Delusional disorder	Paranoid PD	Suspiciousness
Major depression	Depressive PD Borderline PD	Proneness to depressed mood; self-destruction;
Cyclothymia/bipolar disorder/mania	Narcissistic PD Histrionic PD Antisocial PD	Mood swings; impulsiveness;
Obsessive-compulsive disorder	Obsessive-compulsive PD	Hypochondriasis; inflexibility
Social phobia	Avoidant PD	Shyness; avoidant behavior;
Panic disorder with agoraphobia	Dependent PD	Dependency

* PD, personality disorder.

Table 24-29 Phenotypic Similarity Between Axis I and Axis II Disorders

Categorical Tests for Personality Disorder Most categorical tests for personality disorders are based on the DSM criteria and share all the advantages and disadvantages of that polythetic categorical approach. In the DSM-III field trials, the interrater reliability was .61 and the test-retest reliability was .54 for any personality disorder. The reliability is usually lower for individual subtypes than for any personality disorder because of the difficulty of distinguishing among the subtypes.

Among the categorical self-reports, the two most frequently used are the Personality Diagnostic Questionnaire (PDQ-R), and the Minnesota Multiphase Personality Inventory (MMPI) scales for personality disorders (MMPI-PD). The PDQ-R is a self-report version of the DSM-III-R criteria for personality disorders, along with the impairment/distress scale to quantify the significance of impairment or subjective distress required by DSM criteria. In practice, this instrument overdiagnoses personality disorders compared with expert clinical diagnosis. To the authors' knowledge, no PDQ-IV version matching the DSM-IV criteria for personality disorders has been published.

The MMPI-PD scales were derived from the MMPI item pool to evaluate symptoms for DSM-III personality disorders. The MMPI-PD scales are incorporated into MMPI so that, in addition to obtaining a reliable evaluation of personality disorders and other clinical syndromes, clinicians and researchers can also use other MMPI scales (e.g., Lie, Validity, Defensiveness) for validity and response-set analyses.

Among the interviews that categorically diagnose personality disorders, the most commonly used is the Structured Interview for DSM-IV Personality Disorders (SIDP-IV). The original SIDP was developed for personality disorders described in DSM-III and it has been regularly updated with each new DSM revision and edition (SIDP-R for DSM-III-R, SIDP-IV for DSM-IV). To increase its diagnostic validity, the SIDP-IV requires that answers for selected questions be obtained from a collateral informant. This test can be combined with a 10-minute SIDP-IV screen for personality disorder, which can considerably reduce testing time in opulations with many individuals who do not have personality disorder.

Other popular interviews for categorical classification of personality disorders include the Structured Clinical Interview for DSM-III-R Personality Disorders Revised (SCID-II), the Diagnostic Interview for Personality Disorders (DIPD), and the Personality Disorder Examination (PDE). The PDE, available in an international version from the World Health Organization in several languages, makes diagnoses according to ICD in addition to DSM.

Dimensional Assessment of Personality Disorders Historically, personality has been evaluated dimensionally and personality disorders categorically. Reflecting this unfortunate separation, conceptual advances in the field of normal behavior and personality have had little or no effect on research in the field of personality disorder, and vice versa. For example, if the features associated with the extremes of Eysenck's personality traits (i.e., neuroticism, extraversion, and tough mindedness) are combined, the resulting combinations do not correspond closely to traditional categories of personality disorders.

The popular five factor model of normal personality was recently advocated as a potential model for personality disorders. However, the homogeneity of postulated traits and their specificity for personality disorders is questionable. The ability of the five factor model to account for the structure of abnormal personality was tested primarily in nonclinical samples and normal individuals. It provides no measures of response bias or validity as needed in clinical samples. The few studies that have tested the NEO Personality Inventory (NEO-PI) in clinical samples showed that neuroticism, extraversion, and low agreeableness predict personality disorder symptoms. However, these studies did not control for mood and anxiety disorders, leaving open to question the generalizability of the findings to clinical subjects with comorbid Axis I syndromes. In fact, after controlling for age and depression (which is considered standard for high-quality personality diagnosis), only high neuroticism and low agreeableness remained significant predictors of personality disorder symptoms. Obviously, these two dimensions define personality disorder nonspecifically, as a general predisposition to psychopathology (high neuroticism) accompanied by an antagonistic facade (low agreeableness). In addition, neuroticism appears to be confounded with nonspecific factors (e.g., depression or anxiety) that reduce its ability to distinguish those with personality disorder, those with other psychopathology (e.g., mood and anxiety disorders), and well-adjusted individuals with high neuroticism.

Dimensional tests of personality disorders are formatted as self-reports (except for Tyrer's Personality Assessment Schedule). The most frequently used are the Millon Clinical Multiaxial Inventory (MCMI), the NEO PI (which evaluates the five factor personality model), the TCI, and the Dimensional Assessment of Personality Pathology Disorder (DAPP) by John Livesley. These tests have been originally designed to evaluate normal personality (NEO-PI), psychiatric patients (MCMI), personality disorders (the DAPP), and both normal and deviant personality (TCI).

The Millon Clinical Multiaxial Inventory-II (MCMI-II), designed to match DSM-III-R personality disorders, evaluates long-term behavior traits systematized as 10 basic personality patterns (dependent, avoidant, schizoid, passive-aggressive, narcissistic, antisocial, hysterical, compulsive, aggressive, and self-defeating) and 3 pathological personality disorders (borderline, schizotypal, and paranoid). When present, the latter indicate the severity of the 10 basic personality patterns. The test also evaluates nine Axis I clinical syndromes. Some reports suggest that MCMI-II tends to overdiagnose personality disorders in comparison to expert clinicians. A study comparing the MCMI-II and the TCI pointed to a considerable overlap of Millon's measures of Axis I syndromes and Axis II personality disorders.

Several lines of evidence suggest that some common, core features, distinct from other forms of psychopathology that causes personal dysfunction, characterize personality disorder subtypes classified in DSM-IV as discrete categories. In the literature, the number of proposed dimensions for deviant personality ranges from 2 to 24, but, in most cases, can be reduced to 4 basic traits: fearful, agressive or impulsive, detached, and compulsive. Most of the proposed dimensions are phenotypic, factor analytically derived. More importantly, no consensus has been reached about neither the optimal number nor the content of dimensions that purport to describe personality and its disorders most efficiently. These commonly described traits are quite similar to the DSM-IV Clusters A, B, and C (plus compulsivity) and to the four temperament traits described in the TCI (high harm avoidance, high novelty seeking, low reward dependence, and persistence). Livesley and colleagues recently reported that four phenotypic and genetic factors account for most of the variance in both normal personality and personality disorder. The factors are: emotional dysregulation, dissocial behavior, inhibition, and compulsivity. These traits fit nicely the description of personality disorder, but emotional dysregulation, dyssocial behavior, inhibition, and compulsivity do not seem optimal to describe adaptive behavior traits observed in normal personality. Moreover, these four traits do not answer the question of what makes individuals with personality disorder maladaptive. In brief, these four traits most closely correspond to extreme variants of normal temperament traits described in the TCI. The structure of character needs to be determined in order to evaluate maturity versus immaturity and maladaptive versus adaptive behaviors. In other words, the distinction between temperament and character is essential to improve both the etiopathogenetic understanding and the diagnosis of personality disorder. Fortunately, structural equation analysis of the causes of individual differences in the resemblance in twin pairs varying in degree of genetic relationship can specify a unique model of the genetic structure of normal and deviant personality.

TCI The TCI evaluates four major temperament dimensions (harm avoidance, novelty seeking, reward dependence, and persistence) and three major character dimensions (self-directedness, cooperativeness, and self-transcendence). Each of these higher-order temperament and character dimensions is composed of component facets (or subscales) to evaluate response patterns associated with specific stimuli (e.g., harm avoidance can be manifested as worry and pessimism, fear of uncertainty, shyness, or fatigability depending on the stimulus). Recently, the TCI home page has been developed on the World Wide Web. The seven major dimensions and their component traits are presented Table 24-30.

Table 24-30 Temperament and Character Inventory (TCI) Scales and Subscales

The TCI is a family of tests with several specialized versions designed for varying types of informants (self-report, peer ratings, interviewers), varying age groups (for 7 to 14 years, the so-called Junior TCI; for 15 years or above, Adult TCI), scope of information (temperament, character, both), and level of clinical detail (144 items for major dimensions only, or 295 items for multiple facets of each dimension). The test measuring temperament dimensions only was originally called the Tridimensional Personality Questionnaire. This test measured novelty seeking, harm avoidance, reward dependence, and persistence, but persistence was originally scored as a component of reward dependence. The name of the test was changed to TCI when the character scales were added and persistence was recognized as a fourth, separately inherited temperament dimension in twin studies in Australia and the United States. The self-report version of the TCI is a 295-item, true/false test. Its psychometric properties are presented in the *TCI Manual*.

The ability of the TCI to predict categorical symptoms and diagnoses of personality disorders was clinically tested in samples of psychiatric inpatients and outpatients with and without personality disorders and varying mood and anxiety states. Low scores on character dimensions, especially self-directedness and cooperativeness, were associated with high symptom counts for personality disorders in general and for each of the DSM clusters of personality disorders. Note that each DSM cluster is primarily predicted by one of the TCI temperament dimensions (Table 24-31).

		Symptoms		
TCI Scales	Total	Cluster A	Cluster B	Cluster C
Novelty seeking	.22‡	.02	.44*	−.06
Harm avoidance	.31†	.23†	.08	.43*
Reward dependence	−.14	−.37*	−.08	−.04
Persistence	.00	−.07	.04	−.01
Self-directedness	−.56*	−.35*	−.43*	−.50*
Cooperativeness	−.44*	−.44*	−.40*	−.28†
Self-transcendence	.02	−.08	.03	.04

*$p < .0001$; †$p < .001$; ‡$p < .01$.

Table 24-31 Correlations Between TCI Scales and the Total Number of Symptoms for Inpatients With Cluster A, Cluster B, and Cluster C Personality Disorders (*N* = 136)

Low scores on character dimensions have been repeatedly shown to correlate with symptoms for each personality disorder subtype. Clearly, low scores on character traits represent a core feature extending across clusters and subtypes of personality disorder. In addition, four TCI temperament traits correlate with each subtype of personality disorder in a unique way (Fig. 24-8). Based on this, personality disorder subtypes are distinguished on the basis of temperament scores with no overlap.

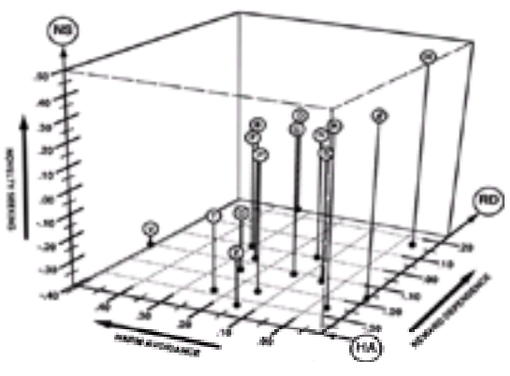

FIGURE 24-8 Correlations between individual personality disorder subtypes and temperament traits of harm avoidance, novelty seeking, and reward dependence.

Regression analyses confirmed that the TCI character scales of self-directedness, cooperativeness, and self-transcendence predict the number of personality disorder symptoms, after controlling for age, anxiety, and depression (Table 24-32).

		Partial R^2	*F*
Inpatients ($N = 136$)			
Total number of interview PD symptoms predicted by TCI (controlled for age and depression)			
Age and depression		.35	.0001
Novelty seeking		—	ns
Harm avoidance		—	ns
Reward dependence		—	ns
Persistence		—	ns
Self-directedness		.13	.0001
Cooperativeness		.03	.0076
Self-transcendence		.02	.0376
Cumulative	R^2	.18	.0001
Model	R^2	.53	.0001
Outpatients ($N = 109$)			
Total number of self-report PD symptoms predicted by TCI (controlled for age, depression, and anxiety)			
Age, anxiety and depression		.45	.0001
Novelty seeking		—	ns
Harm avoidance		—	ns
Reward dependence		—	ns
Persistence		—	ns
Self-directedness		.20	.0001
Cooperativeness		.05	.0001
Self-transcendence		.05	.0001
Cumulative	R^2	.30	.0001
Model	R^2	.75	.0001

Table 24-32 Regression Analyses of Personality Disorder Symptoms Predicted by TCI Scales and Observed

These results have critical diagnostic and treatment ramifications for personality disorders.

DIAGNOSIS OF PERSONALITY DISORDERS Character and temperament traits delineate both the core features and the distinguishing features of personality disorders

(Table 24-30, Fig. 24-8). Poorly developed character traits, especially self-directedness and cooperativeness, are a common denominator extending across all subtypes of personality disorder. Together with self-transcendence, character traits predict categorical personality disorder symptoms (Table 24-21). Clinically, this explains chronic difficulties in accepting responsibility, setting long-term goals, having fragile self-esteem, and other features associated with low self-directedness that are so characteristic of individuals with personality disorders. Usually (but not always) these patients are also uncooperative as well (i.e., revengeful, opportunistic, self-centered, socially intolerant, unhelpful to others, and lacking in empathy, compassion, or principles). Self-transcendence correlates with schizotypal and paranoid symptoms (depicting primary process thinking and fanaticism, respectively) and with personality subtypes characterized by dissociation and mood swings (e.g., borderline, histrionic), much as predicted in Figure 24-4. In addition, self-transcendence appears to be a critical component in defining the underlying susceptibility to psychosis (when the other two character traits are low) or to high creativity (when the other two character traits are high).

Note that high self-directedness does not always protect against personality disorder. Some narcissistic and antisocial persons can be resourceful, self-disciplined, and successful, but their low cooperativeness (i.e., intolerance, revengefulness, low empathy, etc.) makes them maladapted.

Once the probability for the presence of personality disorder is established on the basis of character, temperament traits are used for differential diagnosis. Membership in cluster A (aloof, eccentric personalities) is most clearly determined by low reward dependence, which is characterized by social detachment. Membership in cluster B (dramatic, erratic personalities) is determined by high novelty seeking, which is characterized by impulsivity. Membership in cluster C (anxious personalities) is determined by high harm avoidance, which is characterized by fearfulness (Table 24-20). Recent data indicate that persistence predicts obsessive-compulsive traits. In summary, individual subtypes are distinguished on the basis of their unique pattern of correlations with temperament traits without any overlap (Fig. 24-8). Based on these data and those cited above about the structure of deviant personality, it seems safe to claim that the clinical presentation of personality disorder varies along four underlying dimensions, corresponding to the four temperament traits of harm avoidance, novelty seeking, reward dependence, and persistence. Quantifiable dimensional features of personality disorders are summarized in Table 24-33.

Consistent features
Low self-directedness
Irresponsible, blaming
No mature goals
Resourceless, helpless
Poor self-esteem
Undisciplined
Low cooperativeness
Intolerant of others
Lack of empathy
Unhelpful
Revengeful
Unprincipled
Variable features
High persistence (obsessive-compulsive symptoms only)
Low reward dependence (odd cluster only)
High novelty seeking (erratic cluster only)
High harm avoidance (anxious cluster only)

Table 24-33 Quantifiable (Dimensional) Features of Personality Disorder

This model does not require arbitrary cutoffs for the presence or absence of personality disorder. Personality disorder can be quantified in terms of severity or the probability of diagnosis can be estimated. As shown in Table 24-34, the probability of the presence or absence of personality disorder based on the self-directedness scores alone ranges from very low (about 10 percent) to very high (about 95 percent) in clinical samples.

Self-Directedness Scores	Predicted Percentage (%) with PD	Observed with PD f/N	%
44–39	13	4/18	22 ± 0.10
38–34	23	5/17	29 ± 0.11
33–30	33	4/16	25 ± 0.11
29–27	44	8/20	40 ± 0.11
26–23	55	8/19	42 ± 0.11
22–20	66	6/12	50 ± 0.14
19–16	70	14/16	88 ± 0.08
<16	85	17/18	94 ± 0.05

* Predicted % = 100 e^y/(1 + e^y), where y = −3.37 + .13 (SD score).

Table 24-34 Predictions of Personality Disorders (PD) From Self-Directedness (SD) Scores*

This model integrates categorical and dimensional aspects with personality disorders. It specifies temperament and character dimensions to account for individual differences in behavior. However, as shown in Figure 24-3 and Figure 24-4, unique combinations of temperament and character dimensions are categorically classified as eight clinical types, profiles, or configurations. In other words, this model is dimensional but retains the notion of categorical clinical diagnosis because each temperament and character profile corresponds to one multidimensional clinical category (which is useful in practice for description and prediction of clinical course). On the other hand, quantified dimensions constituting a particular temperament and character profile are used for individualized treatment planning and studies of etiology and pathophysiology.

ETIOPATHOGENESIS OF PERSONALITY DISORDER

Only a few etiopathogenetic models of personality disorder are available. Of those, the psychodynamic model elaborates the effects of early traumatic experiences, whereas the spectrum disorder hypothesis postulates a common cause of personality syndromes with Axis I disorders. A growing body of evidence points to a multifactorial, nonlinear etiopathogenesis (including genetic, neurophysiological, learning, maturational, and cultural factors, which are fully incorporated into the psychobiological model of personality disorder).

Spectrum Disorder Hypothesis Echoing Ernest Kretchmer's work from many decades ago, some experts still consider subtypes of personality disorders minor variants of major Axis I syndromes. Indeed, most Axis I disorders have their less severe variants, or representatives, on Axis II (e.g., schizophrenia is represented by schizotypal and schizoid personality disorders; delusional disorder, paranoid type, by paranoid personality disorder; social phobia by avoidant personality disorder; cyclothymic disorder by the group of emotionally unstable cluster B personality disorders).

These Axis I and Axis II disorders are symptomatologically similar and are frequently differentiated only by a severity criterion. The etiopathogenetic nature of this Axis I–Axis II relationship has not been established, aside from the obvious symptomatic similarity. Plausible alternatives include Axis II disorders as predisposing factors, premorbid features, subclinical expression, or *forme frustes* of Axis I disorders. The possibility of a common etiopathogenesis thus remains open. So far, a close etiological relation has been solidly supported for schizotypal personality disorder and the spectrum of schizophrenia.

Psychodynamic Model of Personality Disorder The central idea behind this model is that personality disorder subtypes classified as separate nosologic units reflect different behavioral expressions of the same core deficit in personality. The so-called borderline level of personality organization has been postulated to represent the nucleus shared by most subtypes of personality disorder.

As defined by Otto Kernberg in 1975, the borderline level of personality organization is characterized by nonspecific manifestations of ego weakness (e.g., lack of impulse control, lack of anxiety tolerance, and lack of sublimatory potentials), specific ego defects (manifested as partially blurred self-object boundaries, mild-to-moderate primary process thinking, periodically distorted reality testing), partial object relations (manifested as alternations between “all good” and “all bad” perception of the same object), primitive defense mechanisms (centered around splitting), and identity disturbance. In addition, an inadequately developed superego

is either sadistic (e.g., obsessive personalities) or rigid in some, but completely absent in other areas, permitting conflict-free expression of impulses and behaviors.

Immature defenses and a fragmentary self-concept, very similar to the above-described borderline personality organization, are a normal early phase in mental development. In the case of personality disorder, however, this early developmental phase pathologically persists in later periods. Etiologically, this pathological persistence is postulated to reflect either constitutional factors (e.g., poor anxiety tolerance, high aggressivity, genetic vulnerability to certain affects) or environmental traumatic factors (e.g., early separation, loss of a parent, physical or mental abuse, neglect). According to the theory, because of such traumatic etiological factors, aggressively charged, negative representations of the self and external objects are predominantly incorporated into the internal world. This, in turn, interferes with the crystallization of the early ego, which normally occurs around positive, libidinally cathected representations of the self and external objects. In other words, normal early motivation and growth are centered around positive primary emotions, particularly interest and joy. It is the relative predominance of strong negative emotions, particularly anger and fear, that interferes with normal development. As a consequence, primitive defenses (splitting and the related defenses), which normally predominate in this early phase of life, pathologically persist in the inner world and interfere with normal development. More-mature defenses, such as repression, require more energy for their operation than splitting (e.g., repression requires at least as much energy for its operation as is contained in unacceptable impulses). In contrast, splitting simply keeps opposite good and bad self- and object-representations apart. As Kernberg pointed out, splitting and early ego mutually perpetuate each other. By keeping predominantly negative self- and object-representations apart from a few positive representations, primitive defenses ensure at least some development around positive experiences but interfere with neutralization of aggression and fear. These primary emotions and their related pregenital impulses (or a chaotic combination of pregenital and genital ones) persist as dominant motivators of behavior and significantly interfere with normal personality development.

Borderline Core of Personality Disorders Clinically, the borderline personality organization is observed as (1) chronic, free-floating anxiety, (2) polysymptomatic neurosis (e.g., multiple phobias related to one's body or appearance, bizarre conversion symptoms, dissociative reactions, hypochondriasis), (3) polymorphous perverse sexual trends (e.g., coexistence of genital and pregenital elements, bizarre forms of perversions involving aggression), (4) impulse control problems and addictions, (5) shift toward primary process thinking (magical thinking, primitive fantasies), and (6) partially impaired reality testing. These borderline symptoms and signs are shared by other subtypes of personality disorder as well. James Reich and Allen Frances concluded in 1984 that the diagnosis of borderline personality organization is “essentially equivalent” to the diagnosis of any personality disorder. Likewise, a hierarchical cluster analysis of identical and fraternal twins, their siblings, and parents showed that 12 DSM personality disorder subtypes can be grouped into eight heritable syndromes, which can be further aggregated into one borderline condition.

Christopher Perry and George Vaillant wrote: “Just as fever, pus, and callus formation are the body's physiological reactions to insults of disease, personality disorder reflects persons' efforts to heal themselves.” Indeed, a personality disorder reflects a person's attempt to overcome underlying fragility through maladaptive, but purposeful, behaviors. These maladaptive behaviors are referred to as “purposeful” because they compensate for the fragility and proneness to decompensation associated with the borderline nucleus. Persons with personality disorder become less fragile (because the personality deviation becomes the principal motivator of specific behaviors) but more abnormal (because an already immature personality is being complicated by additional distortions of self- and object-representations). These compensatory behaviors can have different types of symptomatic styles (e.g., avoidant, paranoid, antisocial, schizoid, dependent). Note that compensatory behavior styles help us give a syndrome a descriptive label (e.g., avoidant, antisocial) but tell us little about the disorder underlying that description. Clinical presentation (i.e., distinguishing behavior style) depends on internal factors (e.g., fearfulness causes avoidant behaviors), external factors (e.g., social class shapes antisocial behaviors), or both. In other words, depending on certain constitutional and environmental factors, persons with a borderline level of personality organization create the clinical picture of their personality disorder.

A subgroup of borderline patients manifests the core symptoms (e.g. storrmy affects, vague identity, unstable rrelationship) in a rather stable way (stable instability). These patients are fragile and prone to fragmentation but do not develop any defensive maladaptive behavior facade to compensate for this fragility. Some of them can periodically mimic behaviors of any personality disorder subtype (avoidant, antisocial, obsessive) as a temporary, chameleon-like solution to their chronic internal problems. These core borderline patients correspond closely to the DSM-IV category of borderline personality disorder.

The described compensatory process generates a two-level personality structure with the dominant compensatory self-concept and the split-off real self-concept. Consequently, clinical expression of personality disorders is dominated by overt, prototypical behaviors, but a set of subtle, covert symptoms and signs associated with the underlying borderline nucleus are regularly observed clinically. These difficult-to-detect symptoms and signs are usually overlooked as diagnostic criteria of personality disorders. For example, the clinical picture of narcissistic personality disorder is dominated by the grandiose self, a deviant self-concept that generates an unrealistic sense of one's specialness, entitlement, arrogance, and other prototypical narcissistic behaviors or symptoms. The hidden real self of a narcissistic person is recognizable through chronic feelings of inferiority, hypochondriasis, envy, and pessimism that regularly accompany their clinical picture. Similar overt and covert clinical features have been established for other personality disorders as well.

Further Conceptual and Methodological Issues The borderline level of personality organization can be reliably distinguished from the schizophrenic spectrum disorders but less reliably from affective syndromes. This is related to the fact that the same immature personality processes that increase susceptibility to deviant behaviors may also increase susceptibility to mood disorders. Indeed, extreme temperament variants increase the risk for personality disorder and are associated with excessive basic emotions such as fear and anger. In many cases, mood disorders and personality disorders are comorbid and can be so interwoven that no meaningful distinction between them can be made (as implied in concepts of depressive personality, hysteroid dysphoria, or characterological depression).

An increasing number of psychometric tests for psychodynamic constructs are available (e.g., the Defense Style Questionnaire, Kernberg's Structural Interview). Satisfactory diagnostic stability and discriminant validity in patients given the diagnosis borderline personality organization has been demonstrated.

PSYCHOBIOLOGICAL SUMMARY OF PERSONALITY DISORDER

The psychodynamic and psychobiological model of personality disorder share many conceptual views. Both models define a common denominator (the core feature) that extends across discrete subtypes of personality syndromes. This core feature is the borderline personality organization in the psychodynamic model and poorly developed character traits, mostly self-directedness, in the psychobiological model. Descriptively, low self-directedness and borderline personality organization are for all practical purposes identical (e.g., both describe blaming, helpless, irresponsible, unreliable individuals with no internal direction and with difficulties in defining and pursuing stable goals; rather, they tend to experience numerous short-term, frequently mutually exclusive motives, none of which can develop to the point of real personal significance). Low self-directedness correlates highly with the use of immature defense mechanisms that are central in the psychodynamic concept of borderline personality. Etiologically both concepts postulate that excessive negative emotionality, such as fear and anger (or extreme harm avoidance and novelty seeking), interferes with developmental processes and increases the risk of personality disorder. Clearly, the psychodynamic understanding of personality disorder was a useful first step in understanding human behaviors. However, the psychodynamic model neither accounts for nor provides, directions for expanding our understanding of the full etiopathogenetic complexity of observed behaviors (e.g., neurochemical, genetic, learning factors). As an etiopathogenetic theory, the psychodynamic model addresses only a portion of the iceberg of deviant behaviors. However, as a treatment tool, its unique understanding of emotional and cognitive processes behind deviant behaviors is used effectively in the therapy of personality disorder, especially in reorganizing internalized concepts about the self and the external world. In summary, psychodynamic strategies are an integral part of a comprehensive psychobiological understanding of and approach to the treatment of personality disorder.

In contrast, modern psychobiology of behaviors provides an integrative, multifactorial, and developmental etiopathogenetic model of personality and its disorders. This approach is based on four fundamental ethiopathogenetic perspectives: genetic, neurophysiological, learning, and phenomenological. These factors interact in a nonlinear way to produce phenotypic differences in cognitive styles and behavior traits. Psychobiology of temperament and character traits is discussed throughout this chapter (see Table 24-2, Table 24-3, Table 24-4, Table 24-5 and Table 24-6 for review).

Genetic and environmental factors interact in complex ways to influence the risk of personality disorder. Available genetic observations about twins, adoptees, and families are explained by the hypothesis that quantitative inheritance of underlying personality dimensions influences the risk of personality disorder, rather than positing separate inheritance of personality disorder subtypes. More than one half of the variance in the four major temperament traits is inherited. These temperament traits have their dissociable genetic, neurobiological, and phenomenological correlates (Table 24-2, Table 24-3, Table 24-4, Table 24-5 and Table 24-6). Temperament traits determine one's susceptibility to specific neurochemical processes leading to individual differences in basic emotions and biased learning. These antecedent temperament factors, along with systematic cultural biases and random life events, critically influence character development, represented as internalized concepts about the self and the external world. As shown in Table 24-18, various temperament types differentially affect one's risk of immature character and personality disorder. Some configurations (mostly those with high reward dependence) protect against personality disorders, whereas some increase this risk (e.g., the explosive or borderline profile with low reward dependence, high novelty seeking, and high harm avoidance). Contrary to common belief, average scores on the temperament dimensions do not protect against maladaptation and immaturity. People with average temperament traits have an average (not a decreased) risk of

personality disorder (Table 24-35).

Temperament Type	Configuration*	N	% Immature
High risk			
Borderline	NHr	39	72
Obsessional	nHr	44	59
Antisocial	Nhr	25	48
Passive-aggressive	NHR	30	40
Average risk			
Average profile	—	15	33
Low risk			
Avoidant	nHR	30	17
Schizoid	nhr	31	16
Histrionic	NhR	50	12
Reliable	nhR	16	6
Total		300	33

* Lower-case letters (h, n, r) and upper-case letters (H, N, R) indicate low and high values for temperament traits, respectively.

Table 24-35 Relative Risk of Personality Disorder as a Function of Temperament Type in a General Community Sample

Extreme temperament variants do not necessarily indicate personality pathology. They are expected to be associated with long-term personal, social, or occupational impairments that warrant the personality disorder diagnosis only when accompanied by low character traits. In other words, poorly developed character is what makes some behavior traits maladaptive and increases the risk of personality disorders. An individual high in novelty seeking and low in harm avoidance may have an impulsive personality disorder if they are low in self-directedness and cooperativeness or may be an energetic businessman or inquisitive scientist without personality disorder if they are self-directed and cooperative. Mature character traits (i.e., mature concepts about one's self and the external world) optimize adaptation of temperament (i.e., basic emotionality) to the environment by reducing discrepancies between one's emotional needs and norm-favoring social pressures. In personality disorder, immature character traits and extreme temperament configurations mutually perpetuate each other.

The concepts of temperament and character are essential to divide the symptoms of personality disorder into common features shared by all personality disorders and distinguishing features that permit discrimination among personality disorder clusters and individual subtypes. This is not possible in models that confound temperament and character. This also indicates that personality disorder reflects deviations in both temperament and character, that is, in both emotional and conceptual personality processes with critical treatment implications.

Extreme temperament configurations tend to be stable. The stability of nonoptimal configurations (i.e., they are maladaptive relative to the global adaptive optimum possible for that individual) occurs because each step in personality development must increase the adaptive fitness so that it is more successful in balancing multiple internal and external constraints. In other words, search for higher adaptive maxima is discouraged because it initially necessitates decreasing overall fitness (the U-shaped pattern). This necessity to decrease current adaptation to achieve a better one accounts for both the chronicity and the treatment resistance of personality disorders.

Behavioral geneticists have demonstrated that the effect of sociocultural factors on personality is less specific than that of genetic factors and influences success in adaptation rather than its form or personality style. This is consistent with recent findings about the importance of family and local culture in character development. Family environment does not influence temperament, but explains about 35 percent of variability of character traits. Hence, psychosocial disorganization in the rearing environment of a child substantially influences the risk of personality disorders. This is essential for preventive strategies as even temperament configurations with high risk of personality disorder might be overcome in homes and communities that provide security and limit behavior in a warm, compassionate manner, as well as encouraging self-directed choice and respect for other people.

Personality disorder is associated with younger age, which indicates maturation (i.e., remission of deviant behaviors) with increasing age. In general, three dimensions of personality change substantially with age. Novelty seeking decreases with age by approximately 18 percent; thus older individuals are less impulsive (more reflective), less rule breaking (more orderly), and less quick-tempered (more stoical). Cooperativeness increases markedly in most children during school age and then increases by 12 percent on average after age 18. Self-directedness increases markedly in most people during adolescence and young adulthood, increasing on average by 9 percent after age 18.

The decreasing prevalence of personality disorder with age is attributable to increased development of both self-directedness and cooperativeness with age. The additional tendency for novelty seeking to decrease with age explains why patients with impulsive personality disorders show more improvement than those with anxious or eccentric personality disorders. The best-documented finding about change in deviant behaviors is the remission of criminal behavior in individuals with antisocial personality disorder. These individuals nearly always remained impulsive (high novelty seeking), risk taking (low harm avoidance), and aloof (low reward dependence) but became mature enough to maintain work and family life in a stable manner.

TREATMENT

Most individuals with personality disorder perceive their lifestyles as normal and seldom seek treatment. Typically, they seek help when their maladaptive behaviors cultminate in unbearable marital, family, and career circumstances with secondary anxiety, depression, substance abuse, or eating disorders.

Temperament traits are primarily treated by pharmacological intervention. However, given the importance of associative learning in the development of these traits, some psychotherapeutic correction is theoretically possible, especially with behavioral techniques. Alternatively, commonly used psychotropic drugs rarely induce changes in internalized self-concepts, that is, character, which is more amenable to psychotherapeutic intervention. Character optimizes adaptation of temperament to the environment because it modulates the salience of percepts and primary emotions, thereby reducing the maladaptive impact of extreme temperament traits. Hence, extreme temperament and immature character traits are optimally treated simultaneously with combined psychotherapy and pharmacotherapy.

Psychotherapy It is hard to find a psychotherapeutic method that has not been tried for personality disorders. This primarily reflects ambiguities in the conceptual understanding of these disorders. The psychobiological evaluation of temperament and character traits and their component facets enables clinicians to tailor psychotherapy and pharmacotherapy to the specific needs of each individual patient.

General Issues Each school of psychotherapy provides a specific understanding of behavior and a particular method of intervention. In practice, different schools are not mutually exclusive, but overlap and complement one another. Dynamic psychotherapy addresses the internal world of the patient's emotions and needs and treats symptoms as external manifestations of internal conflicting motivations. Behavior therapy focuses on external manifestations (or symptoms) and enables patients to change behavior or better control their behaviors. Cognitive therapy helps patients to correct their distorted cognitive appraisal of the significance of environmental cues and their underlying core beliefs that lead to maladaptive behaviors. Humanistic approaches, by increasing both self-directedness and cooperativeness, help patients achieve personal and social maturity in a form of altruistic individualism. No one of the above goals is invariably more correct than the others, and each orientation is expected to make a specific contribution to the overall efficacy of treatment. This seems especially relevant to personality disorders, where the reduction of symptoms and the improvement of social functioning are equally important. For example, a combination of dynamic therapy (insight oriented) and cognitive-behavioral therapy (action oriented) efficiently helps patients transform their insights into actual behavioral change. Recently, dialectical behavioral therapy based on a biosocial theory that borderline symptoms primarily reflect dysfunction of the emotion-regulation system has shown superiority in both reducing core symptoms and increasing social adjustment of borderline patients. A growing number of therapists are beginning to ignore ideological barriers dividing different schools and attempt both technical synthesis (eclecticism) and theoretical synthesis (integration) of various orientations (called *integrativeeclectic psychotherapy*).

As a rule of thumb, combinations of various orientations and formats and emphasis on teamwork are optimal in the psychotherapy of personality disorders. Some basic rules and values are strictly observed, however. Probably most crucial is having a stable therapeutic framework with consistent and reliable care. Next, behavior and feelings are used as the principal mode of communication. The therapist is active and uses high-energy confrontation and care (so-called therapeutic pressing). The central message is always “doing something with the patient, not something to the patient.” This way patients feel somewhat in control, which might keep them in treatment. Reflecting their splitting mechanism, these patients alternatively feel inferior and omnipotent, angry at others and self-destructive, sensitive to rejection but usually provoking it. Flexibility in approach, but firmness in basic values, with creativity and readiness to step away from the rules to get out of frustrating “no way out”

situations, is essential. Many of these patients cannot tolerate feeling better, as this means that the therapist is successful. These and similar frustrative situations cause countertransference problems, with a potential loss of professional objectivity; constant supervision and a support network are therefore necessary. Remember, these patients are almost never as good as they look when they are doing well and almost never as bad as they look when they are not doing well.

Pure supportive psychotherapy is rarely used for personality disorder. Pure support, aimed at strengthening existing coping styles (which are by definition maladaptive in personality disorder), often reinforces the problems of these patients. Kernberg has formulated a modification of supportive therapy that can be useful in treating patients with personality disorders. Also, modified supportive therapy can be used as the initial phase of the treatment, during the contract and trust-building phase.

The psychobiological approach incorporates these psychodynamic strategies into a comprehensive treatment plan aimed at stimulating character development, primarily self-directedness and cooperativeness. The primary focus is to change internalized conceptual representations of the self and the external objects (i.e., concepts about self, society, and the world as a whole). This is attempted either with cognitive methods (aimed at revising these concepts), with dynamic methods (aimed at stimulating maturation of internalized object-relations), or most frequently with a combination of the two. Cognitive methods use emotions as the royal road to cognition. Also, object relations are a special kind of internalized concept about self and others associated with either positive or negative affects, depending on the nature of the relation. In other words, both cognitive and psychodynamic methods address emotional and conceptual aspects of deviant behaviors. Dynamic and cognitive methods are complemented by behavioral and experiential techniques, which are efficient in transforming concepts and insights into everyday life.

During therapy, as character matures and new concepts and their associated secondary emotions develop, they neutralize extreme temperament traits and their related basic emotions of fear and anger. Behaviors change accordingly, from being primarily reactive (i.e., steered by basic emotions and automatic responses regulated by temperament) to being primarily proactive (i.e., steered predominantly by secondary emotions and active symbolic constructs regulated by character traits).

Practical Issues Psychotherapy of personality disorders is a specific strategy rather than a strictly defined method because the therapy takes place constantly (during any contact with the patient) not only during the psychotherapy sessions proper. In fact, what is happening between sessions may be critical for the outcome of the treatment as a whole. With these patients, psychotherapy essentially means reparenting, which, although sometimes demanding, leaves space for various types of interventions, such as education, help with real-life problems, and encouragement. Frequent sessions (at least once a week) are needed to develop reasonably complex interactions in the relationship for diagnostic and (especially) treatment purposes.

Patients with personality disorder are required to clarify their goals and objectives in treatment. These may be simple and concrete (e.g., “to reduce alcohol use”), more complex (e.g., “to become independent”), or very ambitious (e.g., “to be able to love”). The therapist evaluates each treatment goal and determines the likelihood of successful outcome. Most authors agree that the therapist and the patient must be in agreement regarding these goals in at least one area. Patients with personality disorder cannot all be helped to achieve their goals. In general, patients who have never had a meaningful relationship with at least one person are less likely to benefit from psychotherapy. Additional prognostic factors are the patient's intelligence quotient (I.Q.) and psychological mindedness, the therapist's training, and the compatibility of desired treatment goals with baseline personality characteristics. Efficient treatment is expected to stimulate development of character traits; this, in turn, sets the stage for a better adaptation of congenital temperament traits to the environment. As shown in Figure 24-5, Figure 24-6, and Figure 24-7, one temperament configuration may lead to several, but not all possible, character outcomes. Obviously, some treatment goals chosen by individuals with incompatible temperament traits simply might not be achievable. In other cases, where desired treatment goals are not incompatible with the baseline temperament configuration desired goals are achieved through character changes that range from ideal to optimal to compromises. Ideal outcomes correspond to preset concepts of an ideally mature personality with full development of all three character traits. These outcomes are not always possible, especially for patients with personality disorders, who usually have temperament configurations incompatible with high scores on all character dimensions (Fig. 24-5, Fig. 24-6, and Fig. 24-7). However, whenever possible, ideal outcomes are pursued as the ultimate standard of maturity. More frequently, treatment is planned to enable patients to achieve the best possible adaptation for their given temperament traits. This is called an “optimal character outcome” If for any reason optimal outcome cannot be achieved, the alternative is the so-called compromise outcome, which improves the patient's adaptation over baseline but does not achieve ideal or optimal adaptation possible for that patient.

For patients who are unlikely to benefit from psychotherapy, symptom control might be achieved through pharmacological intervention. In addition, many areas of everyday life (e.g., friendships, romantic relationships, media, education, and such valued life opportunities as stable marriage, work-related progress, and religious conversion) increase their chances for maturation. Often the emergent changes are sudden and associated with a new perspective on life and new goals and values, which cannot be achieved by logic, medication, or advice alone.

At least initially, the therapy is supplemented by as much structuring of the patient's life as needed. This may range from directing behaviors, to day-hospital programs, to hospitalization. Complications often require additional structuring such as phone calls or extra sessions. Structuring, advice, and logic are not expected to generate personality change, only to temporarily improve behavior control. As Kernberg noted, psychotherapy begins where common sense ends. Prolonged structuring robs patients of the opportunity to become more self-reliant or to learn from their failure to do so.

These patients usually want psychotherapy their way, with many conditions. In general, genuine personal motivation or strong social pressure are preconditions for a real change in personality. These patients rarely manifest personal motivation for change (especially after depression or anxiety is reduced). In fact, they frequently minimize or deny the existence of even serious problems, such as a suicide attempt. These blind spots for their problems reflect the fact that these patients, since an early age, have developed efficient mechanisms to avoid disturbing feelings and insights. Hence, they generally feel much less distress with their symptoms than their environment. Confrontations (not explanations!) are used to increase the patients' discomfort with their symptoms, which then improves their recognition of these symptoms and their motivation to change them. Most of these patients tolerate confrontations well if they trust their therapist. They need an extraordinary amount of stimulation (sometimes achieved through confrontations) in any relationship, including their therapy. This hunger for stimuli is related to either lack of stimulation (neglect) or extreme stimulation (abuse) by their caregivers.

Resistance to change is strong in patients with personality disorders, whose symptoms reflect their attempt to overcome their own fragility through compensatory deviant behaviors. The achieved compensatory facade (e.g., avoidant, schizoid, antisocial) is maladaptive but stable. In psychotherapy, these patients are expected to give up their purposeful, if maladaptive, behavior traits. In the process, they temporarily become similar to the core borderline patients without any behavioral compensation for their fragility. In other words, most patients with personality disorders first must regress briefly to a more primitive (but less deviant) level of personality organization and then develop more mature object relations and better adapted personality traits. This exposure of their fragility and proneness to fragmentation underlies their strong resistance to change. The progressive regression, or back-to-the-future, strategy derives directly from the U-shaped pattern, in which better adaptation is achieved only after initially decreased adaptation. Each personality disorder subtype requires specific modifications and careful timing of this strategy in addressing their distinguishing symptomatic facade and specific social deviations.

Group therapy is generally considered useful for persons with personality disorders as it both exposes and treats their social deviance. It is usually done in conjunction with individual therapy, which often elaborates experiences from group sessions.

Pharmacotherapy Increasing evidence shows pharmacotherapy to be at least as important as psychotherapy in the overall treatment of personality disorders. Pharmacotherapy is either (1) causal, aimed at correcting neurobiological dispositions underlying deviant traits, or (2) symptomatic, aimed at correcting target behaviors and symptoms of personality disorders. The third approach, based on the expectation that the treatment of diagnosable comorbid Axis I disorders might indirectly improve personality symptoms, receives least support in the literature.

Causal Pharmacotherapy of Personality Disorder The central idea behind causal pharmacotherapy is that enduring personality changes may result from pharmacological manipulation of the underlying neurobiological dispositions to deviant traits (the so-called trait vulnerability). When directed toward the deepest level of personality (i.e., the neurochemical systems mediating dispositions to mood and learning), pharmacotherapy may modify these dispositions. This, in turn, is expected to facilitate changes in affective and learning processes, leading ultimately to changes in observable behaviors and better overall adaptation.

In contrast to factor-analytically derived models, psychobiological models provide testable guidelines for pharmacological manipulation of the underlying neurochemical trait-vulnerability. Harm avoidance, novelty seeking, and reward dependence have been postulated to reflect individual differences in serotonergic, dopaminergic, and noradrenergic neurotransmitter systems. Pharmacological trials based on these and similar postulates might lead to pharmacological dissection of the underlying biological vulnerabilities.

How different patients with major depression will respond to antidepressants is better predicted by their temperament than by the number, type, severity, or course of their depressive symptoms. Patients who are dysphoric and highly sensitive to social approval (i.e., who are high in reward dependence and harm avoidance) are

most likely to improve on selective serotonin reuptake inhibitors (SSRIs). In contrast, those who are highly fearful but not socially dependent are most likely to improve on noradrenergic uptake inhibitors such as desipramine (Norpramine). Children with attention-deficit/hyperactivity disorder (who are high in novelty seeking) are efficiently treated with drugs that increase dopamine release and inhibit its reuptake, such as methylphenidate. Likewise, central serotonergic mediation is important in those with obsessive-compulsive behaviors, characterized by high harm avoidance. These behaviors are modified by drugs that change serotonergic system activity, such as SSRIs. Cerebrospinal fluid (CSF) shows high basal serotonergic activity in obsessive patients who respond to serotonin reuptake blockers and normalization of serotonin activity following long-term treatment (the treatment suppresses serotonin activity, presumably by reducing postsynaptic serotonin sensitivity).

Most of the presented treatment strategies remain tentative and experimental and need further testing. However, they are based on modern biology of behavior and provide guidelines that may potentially lead to a better understanding of biological vulnerabilities underlying deviant personality traits, to a more prescriptive relation between diagnosis and treatment, and to a more-specific therapy of deviant personality and mental disorder in general.

Symptomatic Pharmacotherapy of Personality Disorders Pharmacotherapy cannot be usefully organized around discrete subtypes of personality disorder. First, the efficacy of drug treatment is best evaluated on a symptom level, not the syndrome level. Second, the target symptoms likely to respond to particular drugs are not unique to any subtype, but are shared by various personality disorders. Third, the state-trait effect tends to interfere with effective evaluation of pharmacotherapy of personality disorders, which are frequently comorbid with mood and anxiety states. Fourth, some of the classified personality disorder subtypes are heterogenous composites that can be further subtyped into one or more subcategories, each potentially requiring specific pharmacotherapy.

Phenotypic similarity between some Axis I and Axis II disorders (Table 24-18) together with the lack of understanding of the underlying mechanisms of deviant personality traits explains the attempts to treat patients with personality disorders with drugs proved effective for the corresponding Axis I disorders. However, no common pathogenesis for the Axis I syndromes and their corresponding Axis II counterparts has been established, leaving open to question the validity of these treatments by analogy. Such treatments are neither theory driven nor hypothesis testing, and none has proved superior or ptimal for any individual personality disorder.

Nonetheless, symptomatic treatments are the standard of care for patients with personality disorder at present. In general, symptom improvement of 20 to 30 percent over placebo is expected. Pharmacological trials usually focus on short-term symptoms (e.g., suicidality, paranoia), but an increasing number of authors advocate treatment of long-term pathology (e.g., impulsiveness, anxiety, affective dysregulation) as well. In that regard, most authors agree that four symptom domains underlie chronic pathology of personality disorders: (1) aggression and behavioral dyscontrol, (2) affective symptoms and mood dysregulation, (3) anxiety, and (4) cognitive-perceptual distortions including psychotic symptoms.

These four symptom domains are clinically related to the underlying temperament dimensions that distinguish DSM-IV clusters of personality disorders: high novelty seeking and cluster B disorders correspond to the target symptom domain of impulsiveness and aggression; high harm avoidance and cluster C disorders correspond to the target symptom domain of anxiety and depression symptoms; and low reward dependence and cluster A disorders correspond to the target symptom domain of affective dysregulation, detachment, and cognitive disturbances. In other words, identification of these four target symptom domains has narrowed the gap between causal and symptomatic pharmacotherapy of personality disorders.

The interaction between biological and psychological factors in deviant behaviors is complex. For example, high aggressivity may cause splitting, which in turn prevents neutralization of aggressivity. Hence, the feed-back pattern between the unfavorable biology and unfavorable psychology can only be interrupted when drug treatment of the biological vulnerability is combined with psychotherapy of associated psychological mechanisms.

Pharmacological treatment of the four target symptom domains is nonspecific, as the selected drug regularly affects both its target symptom domain and other symptom domains. This nonspecificity may reflect many factors, such as diagnostic heterogeneity of subjects, or the equifinality phenomenon in which similar behaviors derive from different underlying antecedents, or the nonspecific action profile of the drug, affecting several neurophysiological systems at the same time. More-sophisticated, receptor-specific drugs might help answer some of these questions.

AGGRESSION It is useful, though sometimes difficult, to distinguish different types of aggression. The most common form of aggression occurs when a quick-tempered person is provoked by frustration or threats (affective aggression), which is frequent in impulsive-aggressive individuals. Biological correlates of impulsive aggression and poor behavior inhibition include low concentrations of CSF 5-hydroxyindoleacetic acid (5-HIAA), and altered serotonin neurotransmission. Unprovoked aggression can occur in patients with cerebral instability documented by an abnormal electroencephalogram (EEG) (ictal aggression), regardless of any associated personality traits. Predatory aggression (cruelty) involves hostile revengefulness and taking pleasure in victimizing others, often with intact impulse control; predatory aggression is most frequent in individuals with low cooperativeness, which is most likely in antisocial and borderline personalities. Organic-like impulsivity and aggression, often accompanied by poor social judgment, is distinguished from other impulsive-aggressive syndromes by prominent distractibility, inattention, emotional lability, and high somatic anxiety with panic and cardiorespiratory symptoms, often seen in patients with frontal lobe lesions.

Multiple double-blind trials have shown that lithium (Eskalith) reduces affective display and aggression in both normal subjects and impulsive-aggressive individuals. Lithium may help reduce cruelty and hostility, but this may be an indirect result of reducing impulsivity. Anticonvulsant mood stabilizers such as carbamazepine (Tegretol) and valproate (Depakene) reduce both the intensity and the frequency of unprovoked angry outbursts, improve behavior dyscontrol, and reduce anxiety and suicidality in some patients regardless of the normality of their EEGs. Carbamazepine is nonspecific in targeting both impulsivity and other chronic symptom domains and acute manifestations. Ictal aggression can also be treated with benzodiazepines, but anticonvulsants are recommended, because of frequent tolerance to the anticonvulsive effects of benzodiazepines.

Double-blind trials have shown that psychostimulants such as methylphenidate benefit inattentive and hyperactive adults who are impulsive and aggressive, especially when their symptoms began in early childhood.

As noted by Paul Soloff, impulsivity is most dramatically expressed as self-destructive or assaultive acts, but can also manifest in a wide spectrum of symptomatic behaviors (e.g., binge eating, spending, sex, drugs), or as cognitive impulsivity (e.g., rush to judgment). Consistent with the postulated serotonergic correlates for impulsive aggression, antidepressants (mostly SSRIs) benefit those with some chronically impulsive personality disorders (e.g., borderline personality disorders). In many cases, SSRIs, in addition to improving depressed mood and impulsivity, also nonspecifically improve affective lability, rejection sensitivity, impulsiveness, self-mutilation, and psychoticism. Monoamine, oxidase inhibitors (MAOIs) such as tranylcypromine (Parnate) benefit some patients with hysteroid dysphoria with somatic anxiety, hostility, and destructive impulsivity.

Patients with organic aggression subtype may respond to imipramine, psychostimulants (e.g., methylphenidate) and some of the novel cholinergic agonists (donepezil [Aricept]).

b-Adrenergic receptor antagonists (beta-blockers) reduce aggression and violence in patients with dementia, brain injury, schizophrenia, mental retardation, and organic brain syndrome.

Low-dose neuroleptics may be useful in modifying affective or predatory aggression in some patients. A variety of neuroleptics, from thioridazine (Mellaril) to haloperidol (Haldol), have been used at dosages much lower than those for psychoses (full antipsychotic dosages have generally not proved useful). The usefulness of new atypical neuroleptics for aggressive behaviors has yet to be established. In general, neuroleptics are used cautiously and short term to avoid potentially irreversible adverse movement effects. Also, dosage adjustment is crucial to maintain compliance because patients with personality disorders often have little tolerance for adverse effects.

Some relative pharmacological contraindications exist in treating impulsivity and aggression. For example, lithium should not be given to antisocial persons without aggression and impulsivity; it does not diminish nonaggressive antisocial behaviors (such as lying or stealing). It is also poorly tolerated by anxious schizoid individuals. Likewise, benzodiazepines and alcohol have disinhibiting effects on violence, reduce conditioned avoidance behavior (loosen inhibitions), and further impair passive avoidance learning in impulsive antisocial persons. Benzodiazepine use seems appropriate only in those with nonaggressive, dyssocial behaviors (e.g., schizoid personalities). In some borderline patients, carbamazepine was behaviorally toxic as it precipitated melancholic depression.

MOOD DYSREGULATION Target symptoms in the domain of mood dysregulation include emotional instability, emotional detachment, depression, and dysphoria. Emotional instability and mood swings respond to lithium, carbamazepine, or valproate. Low-dose neuroleptics such as haloperidol also have a mood-stabilizing effect. Tricyclic drugs such as amitriptyline (Elavil) increase impulsivity, suicidality, and assaultiveness in emotionally unstable patients with borderline features and

depression. These paradoxical effects are unrelated to anticholinergic or sedating effects of tricyclic drugs and are postulated to reflect cognitive and behavioral disorganization under catecholamine stress (i.e., increased catecholamine levels with tricyclic drug treatment).

Emotional detachment, cold and aloof emotions, and disinterest in social relations (chronic asociality) is typical of schizoid, schizotypal, and some antisocial and paranoid personalities. When social withdrawal reflects an underlying depression, antidepressants (SSRIs or MAOIs) may help. One should use tricyclic drugs cautiously in those with schizotypal personality disorder, for they may worsen psychosis. Emotional detachment often responds to serotonin-dopamine antagonists (atypical antipsychotics) such as risperidone (Risperdal), olanzapine (Zyprexa), or quetiapine (Seroquel), which may reduce social withdrawal and other features of eccentric personality disorders and carry less risk of extrapyramidal symptoms than the dopamine receptor antagonists (typical antipsychotics). These pharmacological responses suggest that the psychobiology of affective dysregulation in personality disorder subtypes may involve multiple neurotransmitter systems (e.g., dopaminergic, serotonergic) that regulate anger and inhibition.

Atypical depression and dysphoria, frequent in personality disorders, rarely respond to tricyclic drugs but rather to SSRIs or MAOIs. A lack of specificity of effect is also seen with MAOIs and SSRIs in borderline patients; several target symptom domains respond to these drugs: impulsivity, anger, hostility, mood reactivity, hypersomnia, hyperphagia, rejection sensitivity. In fact, at least half of patients with personality disorder and atypical depression worsen when given tricyclic drugs. In contrast, typical depressive episodes, which may complicate any personality disorder, are treated with antidepressants, including heterocyclic drugs, in dosages suggested for Axis I major depression. Paradoxically, neuroleptics are often effective in treating the affective symptom domain. Low-dose trifluoperazine (Stelazine) significantly reduces anxiety, suicidality, depression, and rejection sensitivity. Likewise, depoflupenthixol improves recurrent parasuicidal behavior in Cluster B patients (the same could not be demonstrated for antidepressants). This nonspecific effect has been attributed to reduced depersonalization, obsessive rumination, sense of helplessness, and paranoid ideation, not to improvement in core symptoms of depression. Recently, an open label trial of venlafaxine (Effexor), which is believed to block both serotonergic and noradrenergic reuptake, demonstrated that patients with borderline personality disorder improve globally on all Symptom Checklist-90 (SCL-90) scales (after 12 weeks of treatment with dosages as high as 400 mg a day), including reduction in somatic anxiety and complaints and self-injurious behavior. Atypical antipsychotics may reduce cognitive deficits and increase self-directedness.

ANXIETY Cluster C personality disorders (dependent, avoidant, and obsessive-compulsive personality disorders) are characterized by high harm avoidance and are thus expected to manifest chronic anxiety. With other personality disorder subtypes a state effect increase in their harm avoidance scores up to 25 percent with episodes of depression has been repeatedly observed. Empirical studies have demonstrated the background role of serotonin in harm avoidant behaviors and anxiety. This is clinically supported by the antianxiety efficacy of the SSRIs, 5-HT $_{1A}$ receptor agonists such as buspirone (BuSpar) and mixed serotonin reuptake inhibition and 5-HT$_{1C}$ and 5-HT$_2$ antagonism such as nefazodone (Serzone). The postulated role of the GABA system is supported by the efficacy of benzodiazepines. Patients with personality disorder usually manifest chronic anxiety, which makes the state-trait distinction very difficult; that is, it is not always clear whether a chronic state symptom (anxiety) becomes a stable personality characteristic, or vice versa. In addition, they often exhibit both cognitive anxiety (i.e., anticipatory worrying) and somatic anxiety (i.e., concern about bodily pains and psychophysiological reactions). Cognitive anxiety is most responsive to benzodiazepines, whereas somatic anxiety is more responsive to MAOIs and SSRIs. Again, benzodiazepines have a nonspecific effect as they also tend to reduce hostility, suspiciousness, cognitive disturbance, and sleep problems in borderline patients. Remember, they can also cause severe behavior toxicity and disinhibition. Patients with severe behavior inhibition (avoidance, in particular) may improve with phenelzine (Nardil) or fluoxetine (analogous to social phobia). Buspirone has a potentially important role in the treatment of anxiety associated with personality disorder given its low potential for dependence. Some components of somatic anxiety (e.g., sweating, palpitations, diarrhea, and tremor) can be treated with b-adrenergic receptor antagonists. Severe, psychotic-like anxiety responds to low-dosage antipsychotics, including the atypical antipsychotics.

COGNITIVE-PERCEPTUAL DISTURBANCES Cognitive disturbances, as defined by most authors, refer to magical thinking, odd beliefs, illusions, and long-term, low-grade psychotic symptoms observable primarily in schizotypal personality disorder. Every personality disorder subtype manifests cognitive disturbances and biased perception of reality because of the underlying specific learning and emotional biases. These disturbances are alternatively called a *nonpsychotic thought disorder* or *partial loss of reality testing*. Brief psychotic disorder may complicate most personality disorders. These are treated symptomatically, according to accepted pharmacological practices. In general, psychotic patients with personality disorder are likely to respond to, and comply with, low doses of neuroleptics. Acute psychotic symptoms requiring medication may subside when environmental stressors are brought under control; then one should lower the dosage or discontinue the medication.

Some patients with certain personality disorders (particularly borderline and schizotypal personality disorders) manifest chronic, low-grade cognitive symptoms such as nonpsychotic thought disorder (ideas of reference, magical thinking, odd fantasies, suspiciousness), unusual perceptual experiences (illusions), depersonalization, derealization, and eccentric behaviors. These chronic, low-level, psychotic-like symptoms respond to low-dose neuroleptics, typical and atypical. Sometimes, chronic cognitive disturbances, such as mild ideas of reference or suspiciousness, may subside when the background emotional tension is reduced by anxiolytics.

Neuroleptics also act nonspecifically as they improve several target symptom domains in borderline and schizotypal personalities. Symptoms that respond most clearly to low-dose neuroleptics are anger, hostility, suspiciousness, illusions, ideas of reference, anxiety, and obsessive-compulsive symptoms. The effect is most impressive when symptoms are severe, which leads some authors to speculate that these drugs might be a nonspecific treatment for symptom severity.

Table 24-36 summarizes drug choices for various target symptoms of personality disorders.

Table 24-36 Pharmacotherapy of Target Symptom Domains of Personality Disorders

Psychobiological Integration of Treatment The presented psychobiological model distinguishes components of personality that differ in etiology, pattern of development, and responses to psychotherapy and pharmacotherapy. This provides a foundation for integrating diagnosis and treatment planning in a manner that is generalizable but sensitive to differences among individual patients. Based on the established structural and clinical, and postulated neurochemical, characteristics of temperament and character, pharmacotherapy and psychotherapy can be systematically matched to the personality structure and stage of character development of each individual, clearly a unique advantage over other available approaches. Personality development can be described in terms of a sequence of 15 character steps in which attitudes, values, and emotions are transformed as a result of complex interactions among heritable predispositions, social learning, and individual experiences (Table 24-11). Each step in development results from a complex set of nonlinear facilitating and inhibitory influences.

A hierarchical model of the different types of underlying problems occurring at each step in personality development is shown in Table 24-37.

Character Deficits	Associated Mental Health Features
Level I "Walking together"	(Disorganized disorders)
[1] co1 - restless	Self-injurious behavior
[2] st1 - doubt and shame	Sadomasochistic sexuality
Level II "Working together"	(Severe personality disorders)
[3] st1 - poor impulse control	Bipolar affective lability
[4] st2 - aimlessness	Unemployment, criminality
[5] co2 - lack of empathy	Polysubstance abuse
Level III "Feeling together"	
[6] st2 - no conscience	Mild personality disorder
[7] st3 - low self-esteem	Social dysfunction
[8] co3 - selfishness	Frequent negative emotions
Level IV "Reflecting together"	
[9] st3 - materialism	Personal dissatisfaction
[10] st4 - arrogance	Lack of generativity
[11] co4 - revengefulness	Occasional negative emotions
Level V "Minds thinking as one"	
[12] st4 - possessiveness	Mature but lack of joy and lack of serenity
[13] st5 - integrated	
Level VI "Listening in silence"	
[14] co5 - unloving at times	Mature but lack of intuitive wisdom
Level VII "Experiencing in unity"	
[15] st5 - dualistic	Mature but judgmental and not fully harmonious

Relationships are designated by tail (self-directedness), co (cooperativeness), or st# (transcendence), and the number of the subscale shown in Table 24-37.

Table 24-37 A Hierarchical Model of Mental Order and Disorder Based on Level of Personality Development

Problems at the first level, involving basic trust (step 1) and confidence (step 2), are characteristic of individuals with a history of sexual or physical abuse beginning in early infancy and are associated with highly disorganized disorders. Following T. Byram Karasu, such patients are considered to have severe borderline and narcissistic disorders with dyadic deficits if they are arrested at step 1 (which leads to an impaired sense of self and impaired mother-child relations) or dyadic conflicts if they are arrested at step 2 (which leads to severely impaired object relations, such as difficulty of the child separating from the mother). Such fundamental impairments predispose to vulnerability to psychosis.

Problems at the second level involve severe personality disorders with negativism, disobedience, and lack of purposefulness, and empathy. They are described as mild borderline and narcissistic disorders characterized by problematic three-person (i.e., mother-child-father) relationships. Following Karasu, this group includes patients with triadic deficits if they are arrested at step 3 (which leads to poor impulse control and severe Oedipal problems, such as a lack of capacity for intimacy and social commitment) or triadic conflicts (arrested at steps 4 or 5, leading to milder Oedipal conflicts, such as inhibited sexuality or impaired internalization of group values). Such individuals have severe problems in working, socialization, and impulse-control.

Problems at the third level, with low conscientiousness, low self-confidence and resourcefulness, and little generosity, typify individuals with mild personality disorders or type 1 alcoholism and many with anxiety disorder or major depression, which are associated with mild problems in self-esteem, social intimacy, or group identification. Progress through level three reflects ego strength, which can be measured as the sum of TCI scores on self-directedness and cooperativeness, consistent with Freud's notions of mature personality organization.

The fourth and higher levels involve progressive steps in cognitive and spiritual development among socially mature individuals seeking fulfillment with better health and happiness. Such overall personality integration can be measured by the sum of scores on all three character dimensions, consistent with Carl Jung's notion of the self-transcendent leader. These higher levels of personality integration may be associated with psychopathology at times of existential crisis.

Practical Strategies Character development depends on both temperament configuration and prior development. Taking such information into account requires reliable and systematic assessments. This information provides guidelines for comprehensive treatment planning tailored for each patient. Early in treatment, nonlinear modeling can be used to evaluate possible character outcomes to predict alternative outcomes for given baseline conditions and interventions. These developmental observations indicate which techniques are likely to benefit the patient depends on the stage of personality integration. A brief outline of this integrative psychobiological approach is given in Table 24-38.

Table 24-38 A 15-Step Program for Integrative Psychobiological Treatment of Personality and Psychopathology

Treatment is organized into seven levels corresponding to the seven underlying problem levels described above. Levels 1, 2, 3, and (rarely) 4 are of particular interest to personality disorders.

The first treatment level involves supportive and reality-based techniques, including basic trust-building, encouragement, and teaching basic living skills (“walking together”). The goal is to ensure the safety of patients with severe disorganization and destructive impulses. Trust building and encouragement within safe limits, basic components of all therapy, are essential at this level because patients are filled with all the negative emotions, such as most patients whose temperaments are explosive (borderline) or whose characters are severely immature (melancholic or schizotypal). However, with psychotic or prepsychotic patients, therapy may be supportive, with such somatic therapies as electroconvulsive therapy or high doses of antipsychotic medication. The holding, or reparenting, aspects of the psychotherapeutic environment are crucial at this level, including a therapist who is dependable, nonretaliatory, and compassionate despite frequent crises, who has a more optimistic understanding of the patient's needs and opportunities than the patient. This allows the patient to build trust and self-confidence.

The second treatment level involves direction and cognitive-behavioral techniques that emphasize rational cognitive analysis and repetitive behavioral drills to improve discipline and impulse control (“working together”). This level involves initial treatment of individuals with moderately severe personality and mood disorders with poor impulse control and emotional lability (e.g., most antisocial, severe obsessional, or mild borderline patients). Pharmacotherapy for labile affect and impulsivity (e.g., mood stabilizers) and for hostility (e.g., low-dose neuroleptics) may be beneficial. In addition, firm structure and limit setting, direction, and advice are of critical importance at this level. Based on their improved understanding of their temperament structure and basic emotional needs, patients are encouraged to explore more mature ways of satisfying those needs. For example, hatha yoga or martial arts training are appealing ways to teach self-control at this level, leading to enhanced self-esteem and impulse control. Such structured approaches minimize conflict about setting limits but require much repetition of practical problem-solving skills and encouragement by discussion of attractive role models. This makes constructive use of such a patient's craving for pleasure and power.

The third treatment level involves nondirective, dynamic, humanistic, and interpersonal techniques to foster increased conscientiousness, resourcefulness, and generosity (“feeling together”). Direction is counterproductive at this stage because patients need to internalize group values and to develop confidence in their self-willed action. Depression and anxiety are common and may be treated with antidepressants as needed in combination with the nondirective therapy. The standard six exercises of autogenic training are useful and provide relaxation and preparation for meditative exercises at more advanced levels.

The fourth treatment level involves experiential and existential therapy techniques such as meditation and spiritual identification exercises (“reflecting together”). This involves conscious expansion of the self-concept to include a transpersonal (i.e., spiritual component in addition to the mind and body). Antidepressant or antianxiety medication may be useful during existential crises but are used sparingly and transiently because strong motivation is needed to promote the leaps of faith needed to transform consciousness and self-concepts.

Levels five through seven involve advanced guidance in meditation and other techniques needed to transcend ordinary self-concepts. Patients with such mature

personality development are often little impaired by ordinary standards, but they seek superior character integration, emotional fulfillment, and healthy longevity.

SUGGESTED CROSS-REFERENCES

Adult antisocial behavior is discussed in Section 27.3; personality disorder in elderly adults is discussed in Section 51.3g; theories of personality and psychopathology are discussed in Chapter 6; and impulse-control disorders are discussed in Chapter 22. Psychotherapy is discussed in Chapter 30, and Pharmacotherapy is discussed in Chapter 31.

CHAPTER 25. PSYCHOLOGICAL FACTORS AFFECTING MEDICAL CONDITIONS

25.1 HISTORY, CLASSIFICATION, AND CURRENT TRENDS IN PSYCHOSOMATIC MEDICINE

ALAN STOUDEMIRE, M.D., AND JOHN STEPHEN McDANIEL, M.D.

Although use of the word “psychosomatic” dates to the early 1800s, concepts of psychosomatic orientation in health beliefs have been traced to primitive societies in which spiritual powers and religion dominated the practice of medicine. Regular use of the term “psychosomatic” can be found in the nineteenth-century writings of the German psychiatrist Johann Christian Heinroth and the British psychiatrist John Charles Bucknil. Although the word “psychophysiologic” was in common use by the late 1800s and was used in association with the scientific investigations of Ivan Petrovich Pavlov and Walter Cannon, the term “psychosomatic” was rarely used prior to the 1930s. The phrase “psychosomatic medicine” was introduced by Felix Deutsch in 1922. Helen Flanders Dunbar firmly established the term and designated it a legitimate area of scientific investigation.

Psychosomatic medicine is an area of scientific investigation concerned with the relation between psychological factors and physiological phenomena in general and disease pathogenesis in particular. In a broader context, the term is applied to a philosophical approach to the care of patients that emphasizes the psychosocial aspects of medical care. These two meanings have predominated during most of the twentieth century. Conceptual problems with the word “psychosomatic” have been acknowledged (primarily based on the split in the mind-body relation implied by use of the compound word), but no other satisfactory term has gained complete acceptance, although many terms have been proposed, such as “integrative,” “holistic,” and “biopsychosocial.” Acceptance of the field by the medical community and the general public has been complicated by the pejorative use *psychosomatic*, referring to illness generated by persons who imagine or otherwise psychologically generate physical symptoms.

COMPARATIVE NOSOLOGY

In the American Psychiatric Association's diagnostic manuals, the term “psychophysiologic” formerly designated conditions in which psychological and emotional factors result in somatic symptom formation. In the second edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-II), published in 1968, such conditions were designated psychophysiologic disorders.

The third edition of DSM (DSM-III), published in 1980, saw a substantial change in terminology with adoption of the category psychological factors affecting physical conditions. The argument proposed by Robert Spitzer for abandoning the term “psychophysiologic” was based on eight major points: (1) the DSM-II term “psychophysiologic” was rarely used as a diagnosis; (2) the decision about whether a patient's condition is psychophysiologic or organic was arbitrary; (3) the term was believed to decrease collaboration between specialists; (4) the term perpetuated simplistic ideas about causes of diseases; (5) the term was often used as a last resort when previous efforts at medical diagnosis and treatment have failed; (6) the term referred only to causation and did not address the issue of how psychosocial factors may perpetuate or exacerbate illness; (7) no clear operational criteria were defined; and (8) the DSM-II classification of psychophysiologic disorders was inadequate for research purposes.

The DSM-III category was believed to offer advantages over the DSM-II terminology because it integrated psychological contributions to medical illness into a multiaxial diagnostic system. However, psychological factors affecting physical conditions was considered a category, not a specific diagnosis per se. By enlarging the scope of DSM-II psychophysiologic disorders, the framers of DSM-III hoped the category and multiaxial system would broaden the range of psychological factors considered to contribute to the onset or exacerbation of physical illnesses.

The DSM-III category was reevaluated in the process of developing the fourth edition of DSM (DSM-IV). To make the category more clinically useful, DSM-IV contains a subcategorization format that allows clinicians to specify the type of psychological or behavioral factor that affects the patient's medical condition; the factors so designated include the broad range of psychological and behavioral phenomena that appear to affect physical health (Table 25.1-1).

A. A general medical condition (coded on Axis III) is present.
B. Psychological factors adversely affect the general medical condition in one of the following ways:
(1) the factors have influenced the course of the general medical condition as shown by a close temporal association between the psychological factors and the development or exacerbation of, or delayed recovery from, the general medical condition.
(2) the factors interfere with the treatment of the general medical condition.
(3) the factors constitute additional health risks for the individual.
(4) stress-related physiological responses precipitate or exacerbate symptoms of a general medical condition.
Choose name based on the nature of the psychological factors (if more than one factor is present, indicate the most prominent):
Mental disorder affecting medical condition (e.g., an Axis I disorder such as major depressive disorder delaying recovery from a myocardial infarction)
Psychological symptoms affecting medical condition (e.g., depressive symptoms delaying recovery from surgery; anxiety exacerbating asthma)
Personality traits or coping style affecting medical condition (e.g., pathologic denial of the need for surgery in a patient with cancer; hostile, pressured behavior contributing to cardiovascular disease)
Maladaptive health behaviors affecting medical condition (e.g., lack of exercise, smoke ses, overeating)
Stress-related physiological response affecting general medical condition (e.g., stress-related exacerbations of ulcer, hypertension, arrhythmia, or tension headache)
Other unspecified psychological factors affecting medical condition (e.g., interpersonal, cultural, or religious factors)

Table 25.1-1 DSM-IV Diagnostic Criteria for Psychological Factors Affecting Medical Condition

The DSM-IV strategy continues to allow the designation of comorbidity between Axes I and II and Axis III conditions and specific subtyping of multiple factors that can affect the onset, exacerbation, and outcome of physical disorders. The revised category attempts to embrace the basic concepts involved in such terms as “psychosomatic,” “psychophysiological,” “psychobiological,” “integrative,” “holistic,” and “biopsychosocial.”

The 10th revision of *International Statistical Classification of Diseases and Related Health Problems*, published in 1992, classifies psychosomatic disorders as “psychological and behavioural factors associated with disorders or diseases classified elsewhere,” referring to factors that influence the manifestation or alter the course of physical illnesses. Additional codes are used in this system to identify specific disorders, including asthma, dermatitis, gastric ulcer, mucous colitis, ulcerative colitis, and urticaria. This system, which complements the DSM-IV classification of psychosomatic disorders, may become increasingly important in the future if is adopted worldwide (Table 25.1-2).

This category should be used to record the presence of psychological or behavioral factors thought to have influenced the manifestation, or affected the course, of physical disorders that can be classified using other chapters of ICD-10. Any resulting mental disturbances are usually mild and often prolonged (such as worry, emotional conflict, apprehension) and do not of themselves justify the use of any of the categories described in the rest of the book. An additional code should be used to identify the physical disorder. (In rare instances in which an overt psychiatric disorder is thought to have caused a physical disorder, a second additional code should be used to record the psychiatric disorder.)

Table 25.1-2 ICD-10 Diagnostic Criteria for Research (DCR-10) for Psychological and Behavioral Factors Associated With Disorders or Diseases Classified Elsewhere

HISTORY

Early Theories Mind-body concepts date to ancient beliefs that the body can be affected by external forces. In prehistoric times, disease was understood to be caused by evil spirits or forces, and the concept of disease as a result of divine intervention to test or punish the guilty or ungodly is well entrenched in Judeo-Christian religion as reflected in the Book of Job and the exorcisms practiced by Jesus in the *New Testament*. What are now understood to be mental disorders were believed to result from possession by evil spirits or demons that could be cast out by exorcistic rites or destroyed by killing the possessed persons. Alternatively, one could be cured or cleaned of illness by supplication, sacrifice, prayer, or ritualistic appeasement of the gods. Belief in the power of prayer and other religious and spiritual rituals to invoke divine intervention to alter the forces of disease remain a component of most religious belief systems.

The roots of intellectual approaches to psychosomatic theory date to the ancient Greeks. Mind-body relations were noted by Hippocrates, Aristotle, Plato, and Socrates. Theodore Brown noted that the doctrine of the passions was a basic component of both classical and neoclassical medical theory; it held that relations exist between emotional states (anger, fear, joy, love) and physical states. Hippocrates established ancient psychosomatic concepts based on the humoral theory, and Galen subsequently validated emotions as important in the pathogenesis of disease.

Although psychosomatic scholars have incriminated René Descartes for creating the mind-body dualism that prevented the development of integrated models of psychosomatic relations in the evolution of modern medicine, that conclusion may be a misunderstanding of Cartesian theory. Careful analysis of Descartes' ideas reveals that he did not rigidly split the mind from the body, but regarded mental forces as interacting with the physical. Brown proposed that rather than denying theoretical mind-body interactions, Descartes actually facilitated them. He specified a location, the pineal gland, where mind and body regularly and readily interact, and he provided a logical basis for the extensive interaction of affective states with bodily conditions by explaining that most aspects of affective states are primarily somatic. Descartes' views provided the impetus for the replacement of the passion-based neoclassical understanding of mind-body relations by more scientific views of illness (Table 25.1-3).

Table 25.1-3 History of Psychosomatic Medicine

Psychoanalytic Theories Many psychosomatic concepts in modern medicine and psychiatry can be traced to Sigmund Freud, whose psychoanalytic formulations and theories seemed to confirm the role of psychological factors in causing and determining the manifestations of such conversion reactions as paralysis and blindness (Table 25.1-4). Neo-Freudians elaborated and extrapolated his basic theory, perhaps prototypically represented by Sandor Ferenczi, who applied the notion of conversion phenomenon to the autonomic nervous system and used the theory to explain such diseases as ulcerative colitis.

Table 25.1-4 Major Conceptual Trends in 20th-Century Psychosomatic Medicine

The psychoanalytic tradition in psychosomatic theory culminated in the work of Franz Alexander. He conceptualized hysterical conversion as caused by unconscious conflicts between aggressive or dependent wishes and opposing effects of the ego and superego, leading to chronic emotional distress. Specific types of psychodynamic conflicts were purported to cause specific types of diseases from stress-induced autonomic and physiological distress. Alexander applied the theory to seven illnesses: essential hypertension, rheumatoid arthritis, thyrotoxicosis, peptic ulcer, ulcerative colitis, bronchial asthma, and neurodermatitis.

Although Alexander's psychosomatic specificity theory has been largely discarded, his specificity theory was but one component of his overall approach. Careful analysis of his work reveals that Alexander believed that psychosomatic illness always occurred in the context of multiple interacting variables, such as biogenetic vulnerabilities and social environmental influences. Alexander developed a biopsychosocial model that was overshadowed by psychoanalytic emphasis on the “specificity” aspect of his model.

Recent Theoretical Approaches A parallel theory was developed by Adolph Meyer, whose work continues to influence mainstream psychiatry and psychosomatic theory. Meyer's psychobiology was an inherently multifactorial approach to the cause and the treatment of mental illness. His psychobiological approach attempted to integrate mind and body into a psychobiological unit; he proposed studying psychological and biological processes as dynamic interacting systems. Meyer's approach was eclectic and encouraged evaluating each aspect of the patient's life—developmental, psychological, social, environmental, and physiological.

One of Meyer's followers, Dunbar, in 1935 coalesced the literature and compiled reports of psychosomatic reactions observed by clinicians over a 23-year period. In 1943 she postulated the first formulation of what is now known as the type A personality theory and theorized other personality profiles associated with psychosomatic illnesses. Dunbar established the American Psychosomatic Society and is acknowledged as the founder of modern psychosomatic medicine. The continued efforts of many researchers to identify specific personality attributes that cause or predispose to physical illness directly relates to her original contributions.

The psychophysiological approach in psychosomatic theory dates to Pavlovian studies of conditioned physiological responses in animals and has continued through current biofeedback and behavioral physiological research. Cannon was among the first scientists to demonstrate the physiological sequelae of emotional states and to study the influence of the autonomic nervous system in modulating such responses. The classic study by William Beaumont examining the variations in gastric fluid

induced by emotional states in a patient with a gastric fistula, formed the basis for such later observations as those by the internist and psychoanalyst George Engel, who coined the term “biopsychosocial.”

Stress Theory The concept of stress has been central in the development of psychosomatic theory. Cannon conducted the first systematic study involving stress paradigms relevant to psychosomatic medicine. His model of stress was derived from physics: under certain circumstances, physical or emotional stimuli can strain an animal beyond its ability to adapt successfully.

The research of Harold Wolff and Stewart Wolf continues to serve as a model for scientific investigations of stress. One of Wolff's fundamental premises was that disease is a failure or inability to adapt to life stress. Wolff's theory heralded the concept that the way in which a person copes with a stressful event is critical in determining the magnitude of subsequent physiological effects. Events are deemed stressful only if the person perceives the stress as threatening to life, well-being, or emotional security.

Wolff and Wolf also observed that the physiological states of the gastrointestinal tract appear to correlate with specific emotional states (hyperfunction with hostility and hypofunction with sadness). Nevertheless, they regarded such reactions as relatively nonspecific, believing that the patient's reaction is determined by the general life situation and perceptual appraisal of the stressful event. Wolff also emphasized that the capacity to adapt to a threatening event (e.g., familial discord, emotional deprivation, goal frustration, object loss, separation, and unemployment) determines the nature and severity of psychophysiological response patterns.

Hans Selye's model of stress was based on experiments in which toxic substances were injected into animals and the subsequent reactions observed. Selye outlined the general adaptation syndrome as consisting of three phases: (1) the alarm reaction; (2) the stage of resistance, in which adaptation is ideally achieved; and (3) the stage of exhaustion, in which acquired adaptation or resistance may be lost. Selye's concept of stress was originally used to describe the effects of a force acting against an organism's innate resistance. He considered stress a nonspecific bodily response to any demand caused by either pleasant or unpleasant conditions. Selye's basic theory that physical and emotional stressful stimuli can produce relatively predictable responses formed a fundamental model for much of the behaviorally oriented stress experimentation in psychosomatic research that followed.

Selye's concept of a single nonspecific physiological response to stressors was superseded by experiments demonstrating complex adaptational reactions to stress. For example, John Mason performed elegant research in psychoendocrinology demonstrating that in experimental stress situations, physiological reactions are largely influenced by the emotional response to the stimuli—that is, not determined just by the nature of the stimulus itself. Mason focused on intervening psychological variables that determine both acute hormonal reactions to stressful stimuli and the effects of psychological variables on long-term adaptational responses.

Richard Lazarus elaborated the concept of individualized stress responses, which are determined by cognitive factors. He proposed that responses are determined by the manner in which a person cognitively appraises and copes with stressful events. Hence, persons' reactions to stress depend on their appraisal of the event and their belief in their ability to cope with the stress; their attitude regarding the significance of the outcome of the event is also considered important. The reality of the stress is of less importance than an individual's subjective cognitive assessment of it in determining the subsequent emotional and physiological reactions.

MEASURES OF STRESS A major area of psychosomatic research involving social stress is based on the work of Thomas Holmes and Richard Rahe, using the Schedule of Recent Experience (SRE). Recent life events (e.g., the death of a close relative, a job change, or a divorce) are assigned life change units. An expanded and revised version of the SRE, the Recent Life Change Questionnaire, also asks subjects to score recent life changes on the degree of perceived adjustment. Both instruments are designed to measure recent life stress and to correlate the degree of life stress with subsequent illness. The basic hypothesis is that stressful life occurrences are risk factors for the development of physical illness. Numerous studies demonstrate a probability relation between stressful life events and one's chances of having a physical illness. Epidemiological research involving other types of stressful life events (e.g., natural disasters, social disruption, social changes, poor social support, and work-related stress) has shown similar trends toward an increased probability of physical illness and relatively poor medical outcome. Current models of psychosomatic research integrate the interaction of psychological variables, stressful social situations, and biological vulnerability with latent physical disease.

X-Y-Z Model. The National Academy of Sciences' Institute of Medicine set forth a definition of stress in an attempt to present a scientifically integrated model to aid in mind-body research. The three major elements of environmental stress are identified as the environmental activator, the reaction to the activator (stress reaction), and the resulting consequences. The series is called the x-y-z sequence.

An *activator* is defined as any internal or external event or condition that can alter a person's physical or psychological state. Activators can be quantified and qualified on the basis of intensity, duration, frequency, and the part of the body they act on (i.e., globally or molecularly). If an activator becomes a stressor, its effect is considered sufficient to cause a significant physical or psychological reaction. A *reaction* to the activator (stress reaction) can also be quantified and described physiologically and psychologically. Reactions can also be characterized as transient responses to specific activators. *Consequences* are the prolonged effects of the reactions. Consequences may be biological, psychological, and sociological. *Mediators* are qualities and characteristics of the person that account for the variability in the psychological and physiological reaction-consequences sequence. Mediators may be qualities (physical or psychological) of the person, the environment, or the social milieu that provide buffering (protective effects) or that impart vulnerability.

An essential aspect of the x-y-z model that has proved helpful in conceptualizing stress paradigms is the concept of *dynamic interaction* between the various components of the stress-response system. Each part of the system interacts with and modifies the other parts. For example, mediators may facilitate each aspect of the x-y-z sequence, but change and modification may result because of past responses and the success or failure of efforts to adapt.

The main value of the x-y-z model derives from the possibility of identifying *risk factors*, characteristics that appear to predispose a person to an illness. Risk-factor research is in many respects basic probability assessment. In general, because of difficulties in the definition and measurement of stress and because of individual variability in responsiveness, the association between stress-related variables and physical illness has remained statistically weak.

DEVELOPMENTAL PSYCHOBIOLOGY

Although not traditionally considered part of mainstream psychosomatic medicine, basic science research examining the biological effects of attachment and traumatic separation on developing animals and humans forms a strong scientific underpinning for the validity of many traditional psychosomatic concepts. For example, a long tradition in psychosomatic medicine has associated the onset of physical illness with the stressful effects of bereavement and loss. From his anecdotal clinical experience, Engel popularized the notion of the “giving up–given up syndrome.” Psychosomatic theory has long held that losses that are poorly coped with or that otherwise overwhelm a person's adaptive capabilities may cause a breakdown in resistance to illness and precipitate the onset or the exacerbation of illnesses ranging from diabetes to cancer. Epidemiological data also indicate increased rates of mortality among the bereaved.

As far back as Richard Burton's *Anatomy of Melancholy*, published in 1621, traumatic separations and losses first described by Reneé Spitz have been deemed the cause of psychiatric illness. Anaclitic depression in infants deprived of maternal nurturing leads to failure to thrive and death. In a similar phenomenon described in infant primates, a period of frantic searching for the mother is followed by a depressive response characterized by sad facial expressions, slouched posture, cessation of play, withdrawal, and other social changes. These observations, including the classic primate-separation experiments by Harry Harlow, have led to research examining the behavioral, social, and biological effects of separation and loss.

Physical Correlates. Through studying traumatic separation in primates, investigators have found that agitated states of loss are associated with elevations in heart rate and body temperature. The agitation phase of the separation response is marked predominantly by activation of the sympathetic adrenergic system and adrenocortical response with increased serum cortisol concentration. Almost opposite effects are observed in the bereavement period, which is associated with diminished central b-adrenergic tone and a net decrease in central b-adrenergic activity. The depressed state is typified by fragmented circadian rhythms and sleep, increased cardiac arrhythmias, and decreased immune responsiveness. The reaction has been described as a compensatory homeostatic response to adrenergic activation in the agitated-protest phase of a separation experience.

The involvement of biogenic amine systems in such reactions is further suggested by the observation that behavioral responses to separation can be modified by treatment with pharmaceutical agents. For example, in separation experiments infant rhesus monkeys given imipramine (Tofranil) display less passivity and more interest in the environment than do placebo-treated animals. Similar studies have been performed in rodent models.

Data from a variety of psychobiological investigations confirm the effects that early experience can have on the neurophysiology of the developing organism. Experiments have shown that postnatal handling changes subsequent behavioral and neuroendocrine responses to stress. Research showing that rats previously subjected to stressful handling experiences show attenuation of fear reactions in strange or new environments and less-pronounced increases in the secretion of adrenal glucocorticoids has led to research examining how early handling experiences may influence the development of certain brain regions that regulate glucocorticoid negative-feedback inhibition of hypothalamic-pituitary-adrenal axis activity. Handling increases glucocorticoid receptor density in the hippocampus and the frontal cortex, increasing the sensitivity of these neuronal structures to the negative-feedback effects of higher glucocorticoid concentrations, thereby increasing the efficiency of neuronal inhibition of adrenocorticotropic hormone (ACTH) secretion. It is well established that children who are physically or sexually abused develop enduring dysfunction of their neuroendocrine and immune systems.

Current Advances in Psychosomatic Medicine Historically and in current research, the essential challenge in psychosomatic-psychobiological research is to delineate the mechanisms by which experiences cause certain types of physiological reactions that result in disease states. In addition, the mechanisms of neurobiological modulating systems must be understood in molecular and genetic terms. A host of research advances in psychosomatic medicine have delineated the role of stress in psychological states, the role of behavior in immunity, and the complex interactions of psychological conditions and various disease conditions.

Psychocardiology Psychocardiology encompasses the spectrum of interactions of psychiatric disorders, cardiac symptoms, and cardiac disease, including associated complicating health behaviors. For the past several decades attention to the psychosocial and behavioral factors in cardiovascular disease has increased significantly. The research has taken two primary pathways: one has examined hypertension and the other has looked generally at coronary artery disease, including myocardial infarction and sudden cardiac death.

Hypertension Hypertension, one of the originally hypothesized psychosomatic illnesses, is a major risk factor for coronary artery disease and cerebral vascular disease. Psychological factors have been closely studied as part of the pathogenesis of the condition; these factors have been categorized as pressure reactivity and personality and behavioral factors. Physiological hyperreactivity to environmental stimuli (pressure reactivity) has been studied many times, and although results are contradictory, some specific commonalties appear. Relatively strong evidence indicates that some persons have greater blood pressure reactivity than do others to a variety of stressors, ranging from experimental stress induced in the laboratory to such social and societal stressful conditions as racism. However, the evidence linking reactivity in normotensive persons with hypertension is equivocal. Perhaps most important, pressure reactivity in hypertensive individuals may exacerbate and even accelerate the disease process.

Other research examining psychological aspects of hypertension has focused on personality traits or coping styles. Traits such as submissiveness and distorted expression of anger have emerged as correlates of hypertension. The most consistent correlates have involved anger-coping styles, both inhibited anger expression and excessive anger expression. Epidemiological researchers have noted that persons using an active coping style under environmental conditions that are not conducive to success (e.g., low education and socioeconomic status) may be predisposed to hypertension.

As evidence has clarified how psychological factors affect hypertension, investigators have focused on treatment interventions. Various behavioral procedures including biofeedback, relaxation training, and psychotherapy have been used as interventions. Some investigators have reported clinically significant success in controlled studies. For example, studies that used 24-hour monitoring of blood pressure to examine the effects of combined relaxation therapy and medication found the combination to be more effective in controlling blood pressure than medication alone.

Coronary Artery Disease

STRESS Stress causes a sympathicoadrenal medullary alarm reaction characterized by excess catecholamine secretion. Specifically, excess epinephrine is secreted under what the body interprets as stressful conditions. The outpouring of epinephrine raises blood pressure and heart and respiratory rates, enhances neuromuscular transmission, elevates the concentration of blood sugar by glycogenolysis, mobilizes fat, redirects hemodynamic patterns to suit muscular activity, and while increasing blood oxygenation, increases oxygen consumption. More-specific b-adrenergically mediated cardiac effects include increased heart rate, contractility, and conduction velocity and a short arteriovenous refractory period. These catecholamine-mediated cardiac effects are thought to be pathogenically related to adverse cardiac events.

Studies of stress-induced cardiac changes and studies examining stress, arrhythmias, and sudden cardiac death suggest a significant relation in the pathophysiology of coronary artery disease. Early researchers examined temporally related stressful life experiences including stressful states described among patients who had experienced sudden death attributed to arrhythmias. One study found that the cardiac surgery patients at greatest risk for complications, including arrhythmias and sudden death, were depressed, anxious and in denial of their anxiety, or both.

Recent research has examined the direct cardiac effect of controlled stress. For example, in a study of the effects of psychological stress on patients with ventricular arrhythmias, the stress of mental arithmetic and recalling past traumatic events increased the ventricular premature beat frequency in most patients. Other studies have documented diminished cardiac perfusion during mental stress via positron emission tomography and radionucleotide ventriculography in patients with coronary artery disease. One group of investigators who also used 48-hour Holter monitoring examined mental stress–induced myocardial changes in patients with coronary artery disease and found that ischemia was associated with significantly higher rates of subsequent fatal and nonfatal cardiac events independent of age, baseline left ventricular ejection fraction, and previous myocardial infarction.

TYPE A BEHAVIOR Most of the studies examining the influence of psychosocial and behavioral risk factors in the etiology of coronary artery disease have focused on type A behavior (Fig. 25.1-1). Individuals with type A behavior exhibit enhanced aggressiveness, ambitiousness, competitive drive, impatience, and a chronic sense of time urgency. Associated speech and motor characteristics are rapid body movements, tense facial and body musculature, explosive conversational speech, and hand or teeth clenching. Three major prospective studies have found the type A behavior pattern to be a risk factor for clinical coronary artery disease; however, once the disease is present, type A behavior does not appear to increase the risk of subsequent cardiac morbidity.

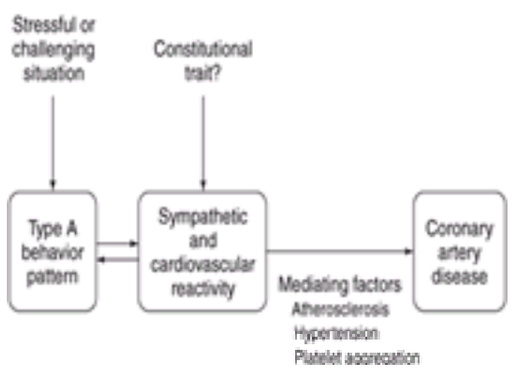

FIGURE 25.1-1 Conceptual model of type A behavior and the development of coronary artery disease. (Adapted from Goldstein MG, Niaura R: Cardiovascular disease, Part I: Coronary artery disease and sudden death. In *Psychological Factors Affecting Medical Conditions,* A Stoudemire, editor. American Psychiatric Press, Washington, DC, 1995.)

The initial enthusiasm for the global type A concept waned in the middle 1980s, as hostility was found to be the more toxic element of the syndrome. Whereas global type A behavior does not always predict risk of coronary artery disease, hostility is consistently linked to coronary artery diseases and appears to be pathophysiologically related to the disease by numerous mechanisms. Expressive hostility and antagonistic interactions appear to be the subcomponents of type A behavior that are most strongly related to the risk of coronary artery disease, especially among female patients and middle-aged male patients.

Physiological correlates of type A behavior have also been studied with regard to cardiac morbidity. Type A behavior is believed to be part of a stress paradigm. Numerous studies report that persons with type A behavior patterns display large, episodic increases in blood pressure, heart rate, and catecholamine concentrations

when confronted by stressful tasks. Interestingly, evidence from primate studies links atherosclerosis in coronary disease and sympathetic nervous system activation. Findings suggest a link between psychological states, physiological activity, and subsequent cardiovascular disease.

A meta-analysis of 18 controlled studies examining effects of psychological treatment on type A behavior concluded that psychological treatment aimed at reducing the behavior had a positive outcome. When type A behavior decreased, treatment had a significant improved effect on coronary events and mortality at 1-year follow-up.

A recent study by Dean Ornish revealed that lifestyle modification (e.g., aerobic exercise, stress management, group therapy) actually promoted revascularization, and improved the prognosis of patients with cardiac disease.

MOOD STATES A number of mood states have been linked with cardiovascular disease, and an increasing body of literature links major depression to increased morbidity and mortality in individuals with coronary artery disease. Recent investigations using standardized instruments and current diagnostic categories have found the point prevalence of major depression in patients with coronary artery disease to be between 17 and 22 percent—approximately twice that in primary care patients and three to four times the 30-day point prevalence in the general population. One study showed that a major depressive episode was the best predictor of major cardiac events during the 12 months after cardiac catheterization; the events were independent of such variables as severity of cardiac disease, left ventricular function, and smoking. In a recent prospective study of patients hospitalized following a myocardial infarction, major depressive disorder was found to be an independent risk factor for mortality at 6 months. The risk was at least equivalent to that of left ventricular dysfunction and previous myocardial infarction. When these patients were studied 18 months after their hospitalization for myocardial infarction, depression was a significant predictor of cardiac mortality, particularly among patients with 10 or more premature ventricular contractions per hour.

Increasing evidence of an association between depressive disorders and coronary artery disease makes it important to ascertain the strength of this association because of the important practical health implications. Therefore, researchers have assessed both the persistence of this relation over time and its magnitude. In most patients with coronary artery disease, depressive disorders do not appear to be a transient adjustment to a major illness, but rather a clinically significant comorbid disorder that is often chronic. Moreover, recent studies have shown that among individuals with coronary artery disease, women appear to have a higher prevalence of depressive disorders than men. The impact of depressive disorders on poor outcome of coronary artery disease appears to equal or exceed that of other well-known cardiovascular risk factors. Current explanations for this relation include biological correlates related to sympathetic activity and autonomic dysregulation, neuroendocrine-immunological interactions producing cytokine-mediated coronary artery occlusion including serotonin-mediated platelet aggregation, and behavioral factors related to the effect of depression on cardiac treatment adherence. The importance of aggressive treatment of depression in coronary artery disease is clear, and research examining treatment benefits and prevention strategies is under way.

A convincing body of literature focuses on the mood states related to acute situational disturbances. A number of studies have demonstrated a connection between sudden death and acutely disturbing life events. One study found that the onset of malignant ventricular arrhythmia was associated with identifiable emotional triggers in 21 percent of patients referred for antiarrhythmic treatment. Finally, such sociological factors as work overload and life stress in the face of a lack of social support enhance general coronary risk (Table 25.1-5). Research is increasing into the possibility that central or autonomic nervous system events or both mediate the increase in cardiovascular morbidity and mortality.

Risk Factor	Cardiac Effects
Stressful life experiences	Sudden death, myocardial ischemia, arrhythmias
Type A behavior pattern	
Expressive hostility	
Antagonistic interactions	Risk of coronary artery disease; episodic increases in blood pressure, heart rate, and catecholamine levels (linked to atherosclerosis in primates)
Cynicism	
Hostile affect	
Aggressive responding	Significant relationships to cardiac mortality
Psychiatric diagnosis	
Major depression	Significant predictor of morbidity after cardiac catheterization; significant predictor of cardiac mortality up to 18 months following myocardial infarction may increase platelet aggregation and thrombus formation
Anxiety	Enhanced risk of cardiac morbidity
Sociocultural factors	
Work overload and life stress	
Lack of social support	Enhanced risk of cardiac morbidity

Table 25.1-5 Psychological Factors Related to Coronary Artery Disease

Gastrointestinal Conditions Historically, the interactions of emotions and the gastrointestinal system have been predominant in psychosomatic theory and research. Alexander identified emotional factors believed to be affect disturbances of appetite and eating, swallowing, digestive functions, and eliminative disorders. Although most studies examining psychological factors and the gastrointestinal tract have been methodologically flawed, a few have important historical significance. For example, in 1957, a double-blind prospective study of military inductees measured serum pepsinogen concentrations and psychological profiles to examine the role of psychological factors in causing peptic ulcer disease. A profile characterized by unresolved conflicts about dependency and oral gratification and relatively high pepsinogen secretion reliably predicted a risk for subsequent development of peptic ulcers; only high secretors developed ulcers, and combined measures were the best predictors. Persons with a genetic predisposition to secrete high levels of pepsinogen were considered at risk for peptic ulcer if they were psychologically vulnerable and were placed in situations that activated the conflict.

Peptic ulcer disease, a condition now etiologically linked to heterogeneous factors affecting mucosal integrity, including *Helicobacter pylori* infection, continues to be a primary focus of psychosomatic investigation. The corrosive action of gastric acid was once widely accepted as a complicating factor in peptic ulcer disease, as affecting illness course and outcome. Recent studies have shown that personality features of hostility, irritability, hypersensitivity, and impaired coping ability correlate significantly with serum pepsinogen concentration in peptic ulcer disease patients. The incidence of cigarette smoking, alcohol intake, and aspirin ingestion is also higher in peptic ulcer disease patients but is not related to coexistent psychopathology. The fact that antibiotic treatment of *H. pylori* is effective in gastric and peptic ulcer disease brings into serious question previous theories and studies linking psychological factors, acid secretion, and ulcerative stomach disease. However, there remains evidence for other mediators, such as stress, given the fact that more than 80 percent of *H. pylori*-infected people never develop an ulcer.

Although the relation between psychological factors and inflammatory bowel disease (ulcerative colitis and regional enteritis) remains unclear, irritable bowel syndrome, first described in 1820, is the most frequently documented gastroenterological syndrome that has been related to psychiatric influences. Irritable bowel syndrome is defined by a cluster of bowel syndromes, which make classification of the disorder difficult; predominant symptoms are abdominal pain and change in bowel habit. If irritable bowel syndrome is conceptualized as a condition in which the gut is hypersensitive and hyperactive to mechanical and chemical stimuli, it may be comparable with asthma in the respiratory system. The psychophysiological disturbances found with irritable bowel syndrome suggest an underlying biological predisposition toward abnormal electrical rhythms in the smooth muscle of the rectum and rectosigmoid colon. Irritable bowel syndrome is presumed then to be associated with disturbances in motility and be influenced by psychological factors in individuals whose symptoms tend to recur in a chronic, relapsing, and remitting course. Individuals with irritable bowel syndrome have significantly greater reactivity to stress than matched controls with abdominal pain without irritable bowel syndrome. Moreover, environmental stress, life events, and psychological factors are now known to be associated with colonic physiology.

A strong, consistent association between functional gastrointestinal disorders and psychological factors suggests the need for well-controlled psychological interventions other than prescribing drugs or diets. To date, intervention studies have shown benefit from supportive psychotherapy, behavioral interventions (e.g., hypnotherapy, stress management) and education. However, the long-term efficacy of these interventions needs further study. Low dosages of tricyclic antidepressants have also resulted in symptom improvement. Nonetheless, the interrelatedness of behavioral factors and gastrointestinal conditions continues to offer insight into the complex interactions of the mind and body.

Psychoneuroimmunology In 1964 the term “psychoimmunology,” later amended to *psychoneuroimmunology*, was coined to identify the field of investigation directed at understanding how behavior and mental states affect immune function. Robert Ader's landmark studies of classical conditioning laid much of the foundation for this area of specialty. His research paired specific hemagglutinating antibody titers with nausea induced by an immunosuppressant agent. By carefully controlling all possible alternative explanations, Ader demonstrated a brain–immune system influence, an effect now replicated in humans.

In recent years major advances have been made in establishing direct evidence for a bidirectional brain–immune system relation. Evidence for such a communication system ranges from anatomical confirmation of central nervous system (CNS) innervation of immune organs to reports documenting behavioral effects on immune response and tumor acquisition in experimental animals. A number of studies involving experimental animals and human autopsy specimens have shown direct sympathetic nervous system innervation of the spleen, thymus, and lymph nodes. Cholinergic innervation of the thymus gland has been documented, and investigators have described noradrenergic innervation of lymphoid tissue in a variety of mammalian species, including humans. Lending further evidence is the presence of receptors for various neurotransmitters, neurohormones, and neuropeptides on cells of the immune system. Recent evidence indicates that lymphocytes may synthesize some neurohormones de novo.

Lymphokines Studies in both humans and animals indicate that activation of the hypothalamic-pituitary-adrenal axis is associated with immune activation. Just as cells of the peripheral immune system are influenced by circulating factors of CNS origin, a reciprocal relation is demonstrated by the brain's susceptibility to lymphokines (substances produced by lymphocytes). Interleukin-1, a widely studied lymphokine, plays a major role in the initiation of events leading to T-cell responses. Interleukin-1 (IL-1) directly stimulates the hypothalamus to produce corticotropin-releasing factor (CRF). Stimulation of CRF is a physiologically important part of an inhibitory feedback loop that regulates the immune response. CRF increases ACTH secretion, which in turn increases cortisol secretion by the adrenal glands, which then inhibits immune function. Glucocorticoids have well-known immunosuppressive effects, including the reduction of circulating T-cell subsets. The inhibitory feedback loop is of particular interest to researchers studying mood disorders who have documented increased hypothalamic CRF production among some populations of depressed patients. Aldesleuken, a human IL-2 derivative, has proven to be an important component of immunotherapy for certain cancers such as malignant melanoma. Hence, augmentation of immunity shows promise as an effective strategy for cancer treatment.

Behavioral States Considerable psychoneuroimmunology research has examined behavioral states and associated in vitro immune suppression; however, these studies are correlational and do not imply direction of causality. Investigators have examined various forms of life stress to ascertain associated changes in immunity, and although most have examined depressed states, researchers have examined a variety of stressful conditions, including laboratory stress, examination stress, loneliness, divorce, caregiver stress, and bereavement. All of these behavioral states have been associated with suppression of markers of immune function, usually measured by lymphocyte responses to antigens and natural killer (NK) cell activity (Table 25.1-6).

Disturbed sleep function
Examination stress
Loneliness
Unemployment
Marital discord
Divorce
Alzheimer's disease–caregivers' stress
Bereaved spouses (including anticipatory bereavement)
Clinical anxiety
Major depressive disorder

Table 25.1-6 Behavioral States Associated With In Vitro Immune Suppression

A growing number of reports have provided data on depression and the immune system, a topic of considerable public interest in recent years. However, the studies have led to disagreement and confusion regarding conceptualizations, methods, experimental designs, and results. Alterations in the immune system in major depressive disorders do not appear to be specific biological correlates of depression but occur in association with other variables that characterize depressed patients, including age and symptom severity. A recent study found significant age-related differences between depressed patients and controls. Specifically, the depressed patients did not show increases in lymphocyte function or in the number of T-helper lymphocytes with advancing age, as did the controls, suggesting diminished immune functioning.

Psycho-Oncology The growing interface between the social sciences and oncology between the 1930s and 1950s was the foundation for emergence of the subspecialty called psychosocial oncology or psycho-oncology. This area, which has become a major contender in psychosomatic medicine research, seeks to study both the impact of cancer on psychological functioning and the role that psychological and behavioral variables may play in cancer risk and survival. A hallmark of psycho-oncology research has been intervention studies that attempt to influence the course of illness in patients with cancer. While most psychosocial interventions are aimed at providing psychological support rather than direct treatment of comorbid conditions such as major depressive disorder, important clinical observations have emerged that focus on such variables as cancer outcome and psychoneuroimmunology. For example, one landmark study demonstrated that women with metastatic breast cancer who received weekly group psychotherapy survived an average of 18 months longer than control patients randomly assigned to routine care. In their study of patients with malignant melanoma, one group of investigators found that control patients who did not receive a structured group intervention had a statistically significant recurrence of cancer and a greater mortality rate than patients who did receive such therapy. The malignant melanoma patients who received the group intervention also exhibited a significant increase in the number of large granular lymphocytes and NK cells as well as indications of increased NK cell activity. Another group of investigators used a group behavioral intervention (relaxation, guided imagery, and biofeedback training) in patients with breast cancer to demonstrate increased NK cell activity and lymphocyte mitogen responses in patients receiving treatment compared with controls.

Increasingly, intervention studies in psycho-oncology are focusing on complex variables of disease outcome including neuroendocrine and immune parameters. Investigators have found that psychosocial variables such as lack of social support and depressive symptoms may be linked to reduced NK cell activity in women with breast cancer and that more metastatic nodes and decreased NK cell activity are associated with depressive symptoms, emphasizing the need for more research in the area. Addressing psychoneuroimmunological aspects of depression in patients with cancer may have important treatment implications, particularly regarding hypothalamic-pituitary-adrenal axis hyperactivity associated with depression. In fact, hypothalamic-pituitary-adrenal hyperactivity in depressed cancer patients may have important prognostic implications, particularly since hypothalamic-pituitary-adrenal hyperactivity induced by exposure of rats to stress is associated with increased tumor growth, especially in older rats. Psychosocial treatment of patients with malignant melanoma has been shown by Fawzy Fawzy to improve prognoses and enhance certain immune parameters.

Psychoneuroendocrinology Selye first described the adaptation syndrome in rats exposed to chronic stress, a response characterized by adrenal hypertrophy, gastric ulcers, and thymus and lymph node involution. Since then, psychoneuroendocrinology, the subspecialty that addresses the relation between hormones and behavior, has continued as an area of study. While earlier researchers in psychosomatic medicine were more interested in endocrine disturbances that produce psychiatric syndromes (Cushing's syndrome, hyperthyroidism, hypothyroidism), exogenous hormone–induced syndromes (glucocorticoid administration), and psychiatric aspects of other endocrine abnormalities (diabetes mellitus), more-recent research has focused on the multifaceted role of neuroendocrine modulation and its relation to behavioral disturbances and psychiatric symptomatology.

For example, exposure of rats to stress reliably increases plasma concentrations of ACTH and corticosterone and decreases secretion of growth hormone and gonadotropins. Increased secretion of CRF from the hypothalamic-hypophysial portal system mediates a complex cascade. Within the CNS, CRF activates the sympathetic nervous system, raising plasma concentrations of epinephrine and norepinephrine, thereby increasing heart rate, blood pressure, and plasma glucose concentrations. Stress-induced alterations in immune function may also be mediated by increased CRF secretion. The CRF concentration in the locus ceruleus increases markedly after acute stress.

When administered directly into the CNS of laboratory animals, CRF produces a number of physiological and behavioral changes similar to the physiological changes observed in stressed animals, which resemble signs and symptoms of depression and anxiety disorders. Centrally administered CRF increases mean arterial pressure, heart rate, oxygen consumption, and plasma glucose and catecholamine concentrations. It also alters locomotor activity, decreases sexual activity, diminishes food consumption, increases emotionality, and induces sleep disturbances.

Depression Much recent psychoendocrinology research has focused on neuroendocrine alterations in psychiatric disorders. Some of the most reproducible findings

were observed in depressed patients. Disorders of both the hypothalamic-pituitary-thyroid axis and the hypothalamic-pituitary-adrenal axis have been documented.

One of the most reproducible findings in biological psychiatry is the hyperactivity of the hypothalamic-pituitary-adrenal axis in some patients with major depressive disorder. Early studies measured glucocorticosteroid concentrations in plasma, urine, or cerebrospinal fluid (CSF) of depressed patients and matched controls. Those early findings led to development of the dexamethasone (Decadron)-suppression test (DST), which received considerable attention. The sensitivity and specificity of the test have prevented it from performing as a reliable diagnostic probe.

Considerable research has explored the locus of the hypothalamic-pituitary-adrenal axis abnormality in depression. Some research has focused on the role of ACTH and the possibility of adrenal supersensitivity to ACTH. Results are supported by postmortem and computerized tomographic studies that have provided evidence for adrenal gland enlargement in some depressed patients. Further, studies using the steroid hormonal receptor antagonist RU486, which blocks cortisol receptors and stimulates pituitary secretion of ACTH and beta-endorphin, have provided evidence for ACTH hypersecretion in a percentage of depressed patients.

Much recent research pertaining to hypercortisolism has focused on the role of CRF in hypothalamic-pituitary-adrenal–axis hyperactivity. For example, markedly higher CRF concentrations were found in CSF samples from suicide victims than in similar samples from sudden-death controls. In a study of CSF-CRF concentrations in drug-free depressed patients before and after a series of electroconvulsive shock treatments, the values at baseline were significantly elevated, but the values normalized after the patients had undergone electroconvulsive therapy and showed improvement in their condition. Increased CSF-CRF concentrations have now been found in other settings, including patients with anorexia nervosa and comorbid depression, as well as depressed patients with Huntington's disease. These findings illuminate earlier animal research examining the role of intracerebral administration of CRF in the production of a peripheral behavioral response resembling neurovegetative symptoms of depression. A confounding factor in these studies is that the stress of lumbar puncture itself may elevate CSF-CRH concentrations.

FUTURE DIRECTIONS

When psychological factors influence the onset, course, exacerbation, or outcome of illness, they do so in a complex interaction that depends on preexisting biogenetic factors predisposing the person to disease. Current psychosomatic theory emphasizes psychological factors as interacting dynamically with other biological and social factors in influencing disease processes. In fact, Leon Eisenberg has reviewed the spectrum of psychiatric disorders to emphasize how psychopathology arises at the interface between the brain and social experience. He has clarified the concept that contemporary psychiatric research has demonstrated that the brain responds to biological and social vectors and is jointly constructed by both. Such reasoning further delineates current views of the interrelatedness of psychological and somatic systems.

Emphasis in psychosomatic research will continue to focus on basic biological mediating mechanisms—derived from neuroimmunological, neurophysiological, and psychoneuroimmunological investigations—to identify more clearly the processes by which behavioral factors and psychological responses affect physiological activity and disease vulnerability. Simultaneously, this research must focus on the importance of psychosocial stressors, psychological influences of well-being, and modifiers of outcome in therapeutic interventions. Important research is continuing on the psychobiological effects of developmental trauma, such as that by Bessal van der Kolk, who has related such trauma to the development of posttraumatic stress disorder and borderline personality disorder.

SUGGESTED CROSS-REFERENCES

A general history of psychiatry appears in Section 55.1. Psychoneuroendocrinology is discussed in depth in Section 1.11, and endocrine and metabolic disorders in Section 25.6. Neurotransmitters are discussed in Section 1.4 and Section 1.5, cardiovascular disorders and psychosomatic medicine are reviewed in Section 25.4, stress in Section 25.9, behavior and immunity in Section 25.10, gastrointestinal conditions in 25.2, psycho-oncology in Section 25.11, and consultation-liaison psychiatry in Section 25.12.

25.2 GASTROINTESTINAL DISORDERS

WILLIAM R. YATES, M.D.

The psychiatric and psychological connections to gastrointestinal diseases have a rich history that continues to evolve as knowledge accumulates about both medical and psychiatric contributions to disease. Peptic ulcer disease and ulcerative colitis emerged as two of the earliest proposed examples of psychosomatic illnesses. Psychological factors such as personality characteristics were felt to be of primary importance in the development of both peptic ulcer and ulcerative colitis. Some early psychosomatic theories have not been confirmed, as medical knowledge of the causes of gastrointestinal diseases advanced. Recent understanding of the role of *Helicobacter pylori* in peptic ulcer disease now supports a primary medical mechanism for this gastrointestinal disease. However, this does not eliminate the need to examine biopsychosocial factors in the disease management of peptic ulcer. Gastrointestinal disorders underscore the importance of a biopsychosocial model of illness management.

The term *psychosomatic* indicates simply a mind-body relationship. At times, *psychosomatic* has inaccurately been used to mean that a physical disorder was caused by a mental disorder or process. More accurately, psychosomatic syndromes or disorders are physical disorders in which emotional processes play a role in some individuals.

Understanding psychiatric contributions and their importance to gastrointestinal disorders is growing. This is particularly true for the importance of psychological factors in the functional gastrointestinal disorders. Psychiatric illnesses frequently produce somatic symptoms including gastrointestinal symptoms. Patients frequently consult medical physicians for the gastrointestinal symptoms produced by psychiatric disorders. Medications used for gastrointestinal disorders can induce psychiatric symptoms, and medications used for psychiatric disorder can induce gastrointestinal symptoms. Understanding the interaction between gastrointestinal disorders and psychiatric disorders is important for primary care physicians, gastroenterologists, general psychiatrists, and consultation-liaison psychiatrists.

HISTORY

In the mid–nineteenth century, William Beaumont conducted longitudinal observational studies of the stomach of a man who had accidently shot himself in the abdomen. This accident resulted in the opportunity to directly observe the gastric mucosa while modifying external factors such as sight, taste, smell, and emotional arousal. Beaumont noted that emotional factors directly influence the appearance and function of the stomach.

Ivan Pavlov used a direct observational model in studying the principles of behavior. Pavlov studied gastrointestinal function, including digestion, in the dog by developing a surgical technique that allowed observation and sampling of the stomach. He found that the sight of food elicited the salivation response. Other cues could also be linked to the salivation response by pairing them with the sight of food. For example, if a tone accompanied the sight of food or feeding, the tone itself would eventually elicit a salivation response when presented without food. This finding led to the development of the concept of a conditioned stimulus and conditioned response. Pavlov developed a model for behavioral therapy using the results of his studies on the link between the gastrointestinal tract and the brain.

In the twentieth century, George Engel and others continued the study of the gastrointestinal tract and emotions. Engel was able to study the role of developmental factors on gastrointestinal function in a girl with a gastric fistula whom he observed from infancy to adulthood. Engel noted that developmental factors, interpersonal events, and emotional state all affect gastrointestinal function. Changes in gastrointestinal secretion, motility, and color were linked to specific emotions of anxiety, depression, and anger. Disruption in interpersonal function adversely affected gastrointestinal function.

Today, the study of the link between gastrointestinal function and emotional state involves analysis of the interaction between the cortex, hypothalamic axis, neurotransmitter function, and the gastrointestinal tract. Many gastrointestinal hormones and transmitters are also found in the brain and appear to mediate some of the complex interactions between the brain and gut. Emotional factors continue to appear to influence the function of the gastrointestinal tract and hence the gastrointestinal symptoms humans experience.

DEFINITION AND COMPARATIVE NOSOLOGY

It is important to understand the distinction between the terms *gastrointestinal disease* and *functional gastrointestinal disorders*. Gastrointestinal disease indicates a medical condition that can be documented by changes in pathophysiology, for example, peptic ulcer disease. Peptic ulcer disease can be diagnosed by direct examination of the anatomical features by endoscopy or radiography. Additionally, blood and breath tests confirm the presence of *H. pylori*, a bacterial agent that frequently causes peptic ulcer. The term *functional gastrointestinal disorders* indicates clinically significant distress producing a symptom related to the gastrointestinal tract (e.g., heartburn, dyspepsia, diarrhea) that does not demonstrate a pathophysiological mechanism. The term *functional* implies a disturbance of function without a disturbance of structure.

Functional Gastrointestinal Disorders Functional gastrointestinal disorders are common syndromes associated with significant subjective distress, abnormalities of bowel function, without evidence of structural abnormalities. Functional gastrointestinal disorders frequently have high rates of psychiatric comorbidity. Psychological factors can contribute significantly to the level of subjective gastrointestinal distress, use of medical resources, and the course and outcome of the functional gastrointestinal distress. Successful treatment of comorbid psychiatric conditions appears to reduce the severity of many functional gastrointestinal symptoms. Psychotropic drugs are commonly used by primary care physicians and subspecialists who treat functional bowel syndromes.

Table 25.2-1 outlines the spectrum of functional gastrointestinal disorders. Functional gastrointestinal disorders can include symptoms identified throughout the gastrointestinal tract. Individual functional gastrointestinal disorders with the highest prevalence rates and clinical importance are reviewed below.

Table 25.2-1 Functional Gastrointestinal Disorders

Globus and Fear of Choking *Globus*, the Latin word for lump, indicates a sensation of having a lump in the throat. Alternate terms for globus include *globus pharyngeus, globus hystericus*, and *globus syndrome*. Globus must be distinguished from *dysphagia*, or difficulty swallowing. Patients complaining of globus may also report dysphagia and fear of choking, but most patients with globus endorse neither of these other symptoms. Historically, globus constituted one of the symptoms of hysteria and was described by Hippocrates as a symptom related to the wandering uterus putting pressure on the neck. Approximately half of patients complaining of globus have no medical diagnosis after extensive testing. Acid reflux can produce globus and is the most common medical cause of the sensation. Other pharyngeal disorders including pharyngeal cancer can also produce globus.

Functional Heartburn Functional heartburn is the most common functional gastrointestinal disorder. Functional heartburn needs to be distinguished from gastroesophageal reflux disease. In functional heartburn, symptoms of acid reflux are present (i.e., heartburn, regurgitation of food), but there is no evidence of anatomical abnormality or esophagitis on endoscopy or radiography.

Functional Abdominal Bloating and Aerophagia Emotional distress and anxiety disorders can result in abnormal respiration and air swallowing or aerophagia. Swallowed air produces distension of the stomach and feelings of abdominal fullness or bloating along with belching.

Functional Chest Pain Chest pain frequently prompts attention for potential cardiac causes. However, functional esophageal motility disorders can produce chest pain and need to be considered in patients with chest pain and no evidence of cardiac abnormalities. Pain related to esophageal motility disturbances can be described as angina-like in location and character. High-amplitude esophageal contractions in the distal esophagus, “nutcracker esophagus,” can produce significant pain.

Referral to gastroenterology for evaluation of gastrointestinal causes of chest pain frequently occurs after cardiac causes have been ruled out. It is not unusual for several specialists to see the chest pain patient prior to appropriate psychiatric referral. However, at times psychiatrists may be involved before a comprehensive medical evaluation has been completed. Psychiatrists need to be aware of the possible gastrointestinal causes for chest pain, particularly when there is limited evidence for a psychiatric disorder in an unexplained chest pain presentation.

Irritable Bowel Syndrome Irritable bowel syndrome is the prototypical functional gastrointestinal disorder characterized by abdominal pain and diarrhea or constipation. The International Congress of Gastroenterology has developed a standardized set of criteria for irritable bowel syndrome.

1. Abdominal pain relieved by defecation or associated with change in frequency or consistency of stool.
2. Disturbed defecation involving two or more of the following:
   altered stool frequency
   altered stool form (hard or loose and watery)
   altered stool passage (straining or urgency, feeling of incomplete evacuation)
   passage of mucus

Irritable bowel syndrome can often be categorized into diarrhea-predominant, constipation-predominant, and mixed subtypes. Medical treatment often targets the predominant symptom. Some studies suggest that irritable bowel syndrome accounts for up to 50 percent of all outpatient evaluations done by gastroenterologists. Comorbid psychiatric disorders appear to increase the likelihood of health-care-seeking behavior for people with symptoms of irritable bowel syndrome.

Some patients with irritable bowel syndrome may demonstrate physiological abnormalities including abnormal intestinal myoelectric activity, gastrointestinal hormonal abnormalities, or allergic responses to some foods. Most clinicians agree that both physiological and psychological factors contribute to the clinical picture of irritable bowel syndrome in most patients.

Dyschezia and Functional Anorectal Pain Dyschezia (difficulty with evacuation of rectal contents) and functional anorectal pain appear commonly in the general population. Two types of functional anorectal pain have been described: one is associated with constant rectal pain (levator syndrome) and the other is characterized by intermittent sharp pain that often disappears completely (proctalgia fugax).

Classification of Functional Gastrointestinal Disturbances The 10th revision of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) classification system shares and differs in some ways from the diagnoses and categories of the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV). ICD-10 recognizes a category of somatoform disorders with somatization disorders and hypochondriacal disorders similar to their DSM-IV counterparts. However, ICD-10 also includes a diagnosis called somatoform autonomic dysfunction. Two subtypes are noted in this category relevant to gastrointestinal disorders: upper gastrointestinal tract and lower gastrointestinal tract. Such diagnoses may be appropriate in patients with functional gastrointestinal disorders where the ICD-10 system is used.

Functional Gastrointestinal Disorders and Somatothymia Somatothymia has been proposed by Alan Stoudemire as a way to understand the mechanism of unexplained somatic symptoms in some patients. Somatothymia is the tendency to communicate psychological distress (i.e., affective distress) to others through somatic symptoms. Patients who tend to somatize may be using their own culturally determined communication strategies to acknowledge psychological distress. Some functional gastrointestinal disorders may be elicited through this mechanism. Patients from lower socioeconomic classes and third-world countries may be more likely to have somatothymia.

Somatization Somatization indicates the presentation of somatic symptoms in the absence of disease or tissue damage. Often somatization increases during periods of stress or during conflict. Functional somatic symptoms including functional gastrointestinal disorders are more likely to be endorsed by patients with somatization. Somatization occurs in a variety of psychiatric disorders including major depressive disorder, anxiety disorders, and somatoform disorders. The term *functional* does not imply that the symptoms serve some function for the patient, only that a medical disease cannot be confirmed as the direct cause of the patient's symptoms.

Psychological Factors Affecting Medical Conditions Psychiatric disorders can influence gastrointestinal diseases and functional gastrointestinal disorders in a variety of ways. DSM-IV defines psychological factors affecting physical conditions to address the spectrum of ways that psychiatric disorders and psychological mechanisms influence medical conditions. Psychological factors affecting medical conditions include the following subtypes: (1) mental disorder affecting a medical condition, (2) psychological symptoms affecting a medical condition, (3) personality traits or coping style affecting a medical condition, (4) maladaptive health behaviors affecting a medical condition, and (5) stress-related physiologic response affecting a medical condition. The corresponding classification category in ICD-10 is F54 psychological and behavioral factors associated with disorders or diseases classified elsewhere. All of the psychological factors affecting medical condition categories can be found with gastrointestinal diseases and disorders.

EPIDEMIOLOGY

Gastrointestinal diseases occur frequently in the general population. Primary care physicians commonly encounter and manage many of the common gastrointestinal disorders. Gastroenterologists provide specialized care for more serious or complicated gastrointestinal disorders.

Table 25.2-2 lists the common gastrointestinal diseases by anatomical region. Diseases of the esophagus, stomach, intestines, anorectum, pancreas, liver, and gallbladder constitute the spectrum of gastroenterology. Consultation psychiatrists are likely to be involved in assessment and psychiatric treatment for patients who have one of these gastrointestinal diseases.

Disorders of the esophagus
Reflux esophagitis (GERD)
Infectious esophagitis
Esophageal motility disorders
Disorders of the stomach and intestines
Peptic ulcer disease
Gastroparesis
Malabsorption and maldigestion
Inflammatory bowel disease
Crohn's disease
Ulcerative colitis
Diverticular disease
Diseases of the anorectum
Hemorrhoids
Anal fissures
Perirectal abscess
Diseases of the pancreas
Acute pancreatitis
Chronic pancreatitis
Diseases of the liver and gallbladder
Infectious hepatitis
Toxic and drug-induced hepatitis
Primary biliary cirrhosis
Primary sclerosing cholangitis
Metabolic liver disease
Gallstones and cholecystitis
Cancer of the gastrointestinal tract
Colon and rectal cancer
Pancreatic cancer
Esophageal cancer
Stomach cancer
Liver cancer

Table 25.2-2 Common Gastrointestinal Diseases

Cancer of the gastrointestinal tract represents a major cause of cancer mortality in the United States and throughout the world. Colon and rectal cancer is estimated to be the third leading cause of death in men (following lung and prostate cancer) and the second leading cause of death in women (following breast cancer). Pancreas, stomach, and esophageal cancer rank in the top ten leading sites of cancer in men. Pancreas and stomach cancer rank in the top ten leading sites of cancer in women. The reader is directed to the chapter on oncology for further discussion of psychiatric issues related to cancer.

Prevalence Rates and Correlates Drossman and his colleagues examined the prevalence and correlates of functional gastrointestinal disorders in a community survey of U.S. households. Sixty-nine percent of this sample reported at least one of 20 functional gastrointestinal symptoms in the 3 months prior to the survey. The prevalence rates for various functional gastrointestinal syndromes are noted in Table 25.2-3. Most individuals who experience functional gastrointestinal symptoms do not seek medical attention. Severity of symptoms and psychiatric comorbidity increase the likelihood of seeking medical attention.

Disorder	Prevalence (%)
Functional heartburn	32.6
Functional abdominal bloating	30.8
Aerophagia	23.4
Dyschezia	13.8
Functional chest pain	13.6
Globus	12.5
Functional anorectal pain	11.6
Irritable bowel syndrome	11.6
Rumination syndrome	10.9
Functional incontinence	7.8
Functional dysphagia	7.5
Functional constipation	3.6
Functional dyspepsia	2.9
Chronic abdominal pain	2.2
Functional diarrhea	1.8
Sphincter of Oddi dyskinesia	1.5

Adapted from Drossman DA, Li Z, Andruzzi E, Temple RD, Talley NJ, Thompson WG, Whitehead WE, Janssens J, Funch-Jensen P, Corazziari E: U.S. householder survey of functional gastrointestinal disorders. Dig Dis Sci 38:1569, 1993.

Table 25.2-3 Prevalence of Functional Gastrointestinal Disorders in the Community

Functional heartburn ranked as the most frequent functional gastrointestinal disorder, experienced by nearly one-third of the sample in this community survey. Functional abdominal bloating and aerophagia were reported by 31 percent and 23 percent of the sample, respectively. A variety of other functional gastrointestinal disorders of the esophagus, stomach, intestine, and anorectal areas were endorsed by 10 percent or more of the population.

Risk Factors Women are more likely to report globus, functional dysphagia, irritable bowel syndrome, functional constipation, functional abdominal pain, functional biliary pain, and dyschezia. Men are more likely to report aerophagia and functional bloating. Functional gastrointestinal syndromes increase the rate of absenteeism at work or school. Occupational impairment appears to be specifically associated with chronic abdominal pain, functional biliary pain, functional dyspepsia, and irritable bowel syndrome.

Psychiatric disorders and the behaviors associated with them can increase the risk of gastrointestinal disease. A good example of this is alcohol abuse or dependence. Chronic alcohol consumption is associated with a variety of gastrointestinal disorders including esophageal reflux, gastritis, pancreatitis, and several of the gastrointestinal cancers. Intravenous drug abuse or dependence increases the risk for hepatitis B and hepatitis C. Sexual promiscuity associated with antisocial personality disorder may also increase the risk for viral hepatitis.

Nicotine and caffeine produce direct physiological changes in gastrointestinal function. Both compounds can increase gastric acid secretion and exacerbate gastritis, esophagitis, or peptic ulcer disease. Patients with psychiatric disorders have higher rates of nicotine dependence and caffeine dependence than the general population. Modification of smoking behaviors may be more difficult in patients with depressive and other concurrent psychiatric disorders than in those with nicotine dependence alone.

PSYCHIATRIC COMORBIDITY IN FUNCTIONAL GASTROINTESTINAL DISORDER

A large part of the literature reports the link between stress, anxiety, and physiologic responsivity of the gastrointestinal system. Anxiety can produce disturbances in gastrointestinal function through a central control mechanism or via humoral effects such as the release of catecholamines. Electrical stimulation studies suggest that sympathetic autonomic responses can be generated in the lateral hypothalamus, a region with neural interactions within the limbic forebrain. Parasympathetic autonomic responses also influence gastrointestinal function. Parasympathetic impulses originate in the periventricular and lateral hypothalamus and travel to the dorsal motor nucleus of the vagus, the main parasympathetic output pathway. The vagus is also modulated by the limbic brain, producing an emotional-gut pathway of response.

Acute stress can induce physiological responses in several gastrointestinal target organs. In the esophagus, acute stress increases resting tone of the upper esophageal sphincter and increases contraction amplitude in the distal esophagus. Such physiological responses may result in symptoms consistent with globus or esophageal spasm syndrome. In the stomach acute stress induces decreased antral motor activity, potentially producing functional nausea and vomiting. Reduced migrating motor function can occur in the small intestine while in the large intestine there can be increased myoelectrical and motility activity under acute stress. These effects in the small and large intestine may be responsible for bowel symptoms associated with irritable bowel syndrome.

Patients with contraction abnormalities and functional esophageal syndromes demonstrate high rates of psychiatric comorbidity. Functional esophageal symptoms include globus, dysphagia, chest pain, and regurgitation. Such symptoms can occur in conjunction with esophageal smooth muscle contraction abnormalities. Not all patients with functional esophageal symptoms display contraction abnormalities. Anxiety disorders ranked highest in a study of psychiatric comorbidity in functional esophageal spasm, being present in 67 percent of subjects referred to a gastrointestinal motility laboratory for testing. Generalized anxiety disorder topped the list of anxiety disorder diagnoses in this series. Many patients in this study had anxiety disorder symptoms prior to the onset of esophageal symptoms. This suggests that anxiety disorder may induce physiological changes in the esophagus that can produce functional esophageal symptoms.

One of the earliest studies of psychiatric comorbidity that used structured psychiatric interviews focused on patients with esophageal motility disorders. A nonspecific esophageal motility group (the functional group) was compared with a group of patients with organic esophageal disorders (i.e., achalasia) and a group of healthy controls. The functional esophageal motility group ranked highest in rate of psychiatric comorbidity, with 84 percent of the group receiving at least one psychiatric diagnosis. The organic esophageal motility group and healthy control groups had psychiatric comorbidity rates of 33 and 31 percent, respectively. The psychiatric disorders noted in the functional motility group included depressive disorders, anxiety disorders, somatization disorder, and phobias.

Gastroesophageal Reflux Disease Gastrointestinal reflux disease is the most common disorder of the esophagus and accounts for most over-the-counter antacid

consumption. The predominant symptom is heartburn, which may be accompanied by regurgitation and pain with swallowing. Multiple factors appear to be important in the generation of reflux and heartburn: (1) presence of a hiatal hernia, (2) effectiveness of the lower esophageal sphincter in blocking the reflux of stomach acid, (3) effectiveness of the esophagus in clearing and neutralizing reflux, (4) ability of the esophagus to protect itself against acid and pepsin, and (5) delayed gastric emptying and acid hypersecretion. Up to 80 percent of patients with gastrointestinal reflux disease have a hiatal hernia. However, 50 percent of patients with a hiatal hernia do not have gastrointestinal reflux disease.

Many patients with gastrointestinal reflux disease along with many clinical gastroenterologists believe that psychological distress increases symptom severity in those prone to this disease. In a survey of gastrointestinal reflux disease sufferers, excessive stress, too much excitement, family arguments, and temporary depression were felt to trigger heartburn.

Irritable Bowel Syndrome Psychiatric disorders complicate the diagnosis and management of many patients with irritable bowel syndrome. Because many studies of psychiatric comorbidity have focused on clinical and hospitalized patients, a potential sample bias effect could explain this association. However, recent studies of general population samples found evidence of increased psychiatric comorbidity in community subjects with unexplained gastrointestinal symptoms. In the National Institute of Mental Health (NIMH) Epidemiologic Catchment Area (ECA) Study, over 18,000 adults in the United States received a direct interview for psychiatric illness. Six gastrointestinal symptoms from the somatization disorder section were reviewed with the participants (abdominal pain, diarrhea, gas and bloating, constipation, and nausea and vomiting). Subjects who experienced multiple gastrointestinal symptoms were compared with those without gastrointestinal symptoms.

One gastrointestinal symptom increased the rate of lifetime major depressive disorder (7.5 versus 2.9 percent), panic disorder (2.5 versus 0.7 percent), and agoraphobia (10.0 versus 3.6 percent). Community subjects with two gastrointestinal symptoms had even higher rates of major depressive disorder (13.4 percent), panic disorder (5.2 percent), and agoraphobia (17.8 percent). These rates of psychiatric disorders are lower than those in referred tertiary-care populations with functional bowel syndromes. However, the increased rates compared with controls in this community population suggests a true link between psychiatric illness and functional gastrointestinal disorders and cannot be simply explained by sample selection bias.

Other studies of psychiatric comorbidity in irritable bowel syndrome estimate comorbidity rates of 42 to 64 percent of all irritable bowel syndrome patients. Control comorbidity rates in these populations generally range from 15 to 20 percent. The exact mechanism for high rates of psychiatric comorbidity in irritable bowel syndrome is unknown.

Four models have been proposed to explain the relation between irritable bowel syndrome and high rates of psychiatric comorbidity. The first model is the somatization disorder hypothesis, which proposes that some people display anxious and depressed mood with multiple nonspecific somatic symptoms. This model classifies irritable bowel syndrome as one of a group of diagnoses that can be made from a primary somatization disorder or other somatoform disorder. Other similar functional medical disorders that could occur in these patients include fibromyalgia. Although somatization disorder and other somatoform disorders occur with irritable bowel syndrome, they do not occur in all patients.

A second model to explain the role of psychiatric comorbidity in irritable bowel syndrome is the somatopsychic hypothesis. This hypothesis states that psychological symptoms are the result of chronic gastrointestinal distress and unsatisfactory interaction with health care providers who do not accurately diagnose and treat irritable bowel syndrome. One argument against the somatopsychic hypothesis is the relatively lower rates of psychiatric disorder in more severe and chronic gastrointestinal disorders such as inflammatory bowel disease and lactose intolerance. These disorders would be expected to have higher rates of psychiatric comorbidity than irritable bowel syndrome if the somatopsychic hypothesis explained the psychological manifestation of symptoms in irritable bowel syndrome.

A third explanatory model, the psychogenic hypothesis, states that specific psychiatric disorders cause irritable bowel syndrome in a significant proportion of patients. Panic disorder in particular is proposed to cause secondary irritable bowel syndrome. Although a significant percentage of irritable bowel syndrome patients have panic disorder, most do not, so this third model is unlikely to be a sole explanation for the psychological manifestation of irritable bowel syndrome.

The final model is the self-selection model. This model proposes that psychiatric comorbidity increases the rate of treatment seeking by patients who have irritable bowel syndrome. Under this model, irritable bowel syndrome without psychiatric comorbidity would be accompanied by the lowest rate of health care use, while irritable bowel syndrome with psychiatric comorbidity would be associated with the highest rate. There is some support for this model in the medical clinic setting; psychiatric comorbidity does seem to be more prevalent in clinic samples than in community samples. However, population studies (including the NIMH ECA study) suggest that this model cannot fully explain the relation. A significant number of community subjects with irritable bowel syndrome who do not seek medical attention suffer from significant psychiatric comorbidity. Possibly several of the proposed models contribute to the overlap between irritable bowel syndrome and psychiatric illness.

One method of sorting out the relation between irritable bowel syndrome and psychiatric illness is the family study method. If psychiatric disorders simply follow the distress of irritable bowel syndrome, one would not expect a higher rate of psychiatric illness in the relatives of patients with the syndrome. Twenty patients with irritable bowel syndrome and 20 patients undergoing laparoscopic cholecystectomy were compared. Family rates of depressive disorders and anxiety disorder were higher in family members of the irritable bowel syndrome probands than in control probands. This study supports the psychogenic hypothesis for irritable bowel syndrome, although the association could be due to a treatment selection bias since probands in this study were identified in a tertiary-care center.

Physiological abnormalities also appear to contribute to the symptom profile of irritable bowel syndrome. Autonomic nervous system abnormalities in irritable bowel syndrome may vary by the predominant symptom noted by individual patients; one study found separate physiological abnormalities in diarrhea- and constipation-predominant patients. Diarrhea-predominant patients exhibited abnormalities in adrenergic function as measured by blood flow in the hand in various postures. Constipation-predominant patients exhibited vagal cholinergic function abnormalities as measured by R-R interval changes during deep breathing. Constipation-predominant patients exhibited higher levels of psychological distress (i.e., anxiety and depression) than the diarrhea-predominant group.

Peptic Ulcer Disease Peptic ulcer refers to mucosal ulceration involving the distal stomach or proximal duodenum. Symptoms of peptic ulcer disease include a gnawing or burning epigastric pain that occurs 1 to 3 hours after meals and is relieved by food or antacids. Accompanying symptoms can include nausea, vomiting, dyspepsia, or signs of gastrointestinal bleeding such as hematemesis or melena. Lesions are generally small, one centimeter or less in diameter.

Early theories identified excess gastric acid secretion as the most important etiologic factor, but the importance of infection with *H. pylori* is becoming more acknowledged. *H. pylori* is associated with 95 to 99 percent of duodenal ulcers and 70 to 90 percent of gastric ulcers. Antibiotic therapy that targets *H. pylori* results in much higher healing and cure rates than antacid and histamine inhibitor therapy. Standard regimens for the treatment of *H. pylori* infection often include combinations of two or three antibiotic agents. Commonly used antibiotic agents with efficacy against *H. pylori* include amoxacillin (Amoxil), metronidazole (Flagyl), tetracycline (Achromycin), and clarithromycin (Biaxin).

Early studies of peptic ulcer disease suggested a role of psychological factors in the production of ulcer vulnerability. This effect was felt to be mediated through the increased gastric acid excretion associated with psychological stress. Studies of prisoners of war during World War II documented rates of peptic ulcer formation twice as high as controls. Recent evidence for a primary role of *H. pylori* in peptic ulcer initiation, suggests that psychosocial factors are primarily involved in the clinical expression of symptoms. Stressful life events may also reduce immune responses, resulting in higher vulnerability to *H. pylori* infection. There is no consensus on whether specific psychiatric disorders are related to peptic ulcer disease.

Ulcerative Colitis Ulcerative colitis is an inflammatory bowel disease affecting primarily the large intestine. The cause of ulcerative colitis is unknown, but it must be differentiated from forms of infectious colitis such as campylobacteriosis, amebiasis, and shigellosis and pseudomembranous enterocolitis and ischemic colitis. The yearly incidence of ulcerative colitis is about 10 per 100,000. Risk factors for ulcerative colitis include Jewish ethnicity. The predominant symptom of ulcerative colitis is bloody diarrhea. Extracolonic manifestations can include uveitis, iritis, skin diseases, and primary sclerosing cholangitis. Diagnosis is made mainly by colonoscopy or protoscopy. Surgical resection of portions of the large bowel or entire bowel can result in cure for some patients.

Over 100 studies of ulcerative colitis have examined associated psychiatric factors. A review of these studies found serious flaws in research design, including lack of control subjects, unspecific data collection methodology, and failure to use standardized diagnostic criteria. Studies without adequate controls were more likely to suggest an association of life events, abnormal personality, and psychiatric disorders. When the seven studies with the best methodological design were examined, no association between ulcerative colitis and psychiatric factors was found. This review emphasizes the need for caution in interpreting psychiatric factors associated with organic gastrointestinal disease. Undoubtedly, for individual patients, psychiatric factors may play a key role in the manifestations and complexity of disorders

such as ulcerative colitis. However, generalizations about psychological mechanisms for ulcerative colitis must be considered unproved.

Crohn's Disease Crohn's disease is an inflammatory bowel disease affecting primarily the small intestine and colon. Common symptoms in Crohn's disease include diarrhea, abdominal pain, and weight loss. The yearly incidence of Crohn's disease is about half that of ulcerative colitis, about 5 per 100,000 population. The course is chronic, often with periods of remission followed by periods of acute symptoms. Treatment consists of the use of antibiotic agents such as metronidazole, sulfasalazine (Azulfidine) or mesalamine (Asacol). Immunosuppressive drugs also are commonly used to control flare-ups. Prednisone is the most frequently used corticosteroid, and azathioprine (Imuran) a commonly used immunosuppressive agent.

Because Crohn's disease is a chronic illness, most studies of psychiatric comorbidity focus on psychiatric disorders occurring after the onset of the disorder. A study of psychiatric symptoms in Crohn's disease prior to the onset of physical symptoms found high rates (23 percent) of preexisting panic disorder compared with control subjects and subjects with ulcerative colitis. No statistically significant preexisting psychiatric comorbidity in ulcerative colitis occurred in this study. Longitudinal studies and careful retrospective studies in gastrointestinal chronic gastrointestinal disorders can be helpful in sorting out psychiatric disorder as a risk factor, consequence, or chance association with specific gastrointestinal disorder.

A young woman from a small Midwestern town developed Crohn's disease while in high school. Her symptoms included intermittent abdominal pain and diarrhea. Prior to the onset of her inflammatory bowel disease, she had been obese, with a maximum weight of 225 lbs. She had no history of psychiatric illness prior to the development of Crohn's disease but had been a somewhat shy individual. Her family became quite distressed by the development of her medical illness. They developed a protective style of interacting with her, and she continued to live at home following completion of high school.

Her Crohn's disease became chronic, with intermittent periods of flare-up and remission. Over time her gastroenterologist noted that her complaints of abdominal pain did not always correspond with periods of inflammatory disease activity. She developed a fear of eating and drinking and associated oral intake with abdominal pain. She became preoccupied with her weight and began vigorous dieting and restricting her oral fluid intake. By age 24 her weight began to drop, and over 6 months, she lost 100 pounds, down to a weight of 125. Her gastroenterologist suspected she might be developing an eating disorder, and she was referred for a psychiatric consultation.

The psychiatric consultant evaluated the patient and noted chronic low mood consistent with a diagnosis of dysthymia. She was preoccupied with concerns about her weight and had rigid rules about eating. Dieting complicated the medical management of her Crohn's disease. A diagnosis of eating disorder not otherwise specified along with dysthymic disorder was made, therapy with a selective serotonin reuptake inhibitor (SSRI) was started, and she was referred to an eating disorder partial hospitalization program. In the partial program her compliance was poor, and one day she collapsed in group therapy. Medical evaluation revealed orthostatic hypotension that resolved with hospitalization and intravenous fluid and electrolyte replacement. She was transferred to an inpatient eating disorder program. However, her family checked her out of the program against medical advice. The patient and family complained that a psychiatric disorder was not her problem and that the psychiatric treatment team did not understand her Crohn's disease and proper medical management.

This case illustrates the effect that chronic gastrointestinal disorders can have on individuals vulnerable to psychiatric illness. Chronic gastrointestinal illness can worsen abnormal family dynamics and stimulate development of psychiatric illnesses such as mood and eating disorders. When both a gastrointestinal illness and a psychiatric illness are present, the outcome and prognosis for each individual condition becomes complicated. Coordination of medical and psychiatric services is necessary to maximize the likelihood of a successful outcome.

Hepatitis and Liver Failure Hepatitis can be caused by viral agents, drugs, or poisons that cause hepatotoxicity. Viral agents associated with hepatitis include hepatitis A, hepatitis B, hepatitis C, hepatitis D, hepatitis E viruses, cytomegalovirus, and Epstein-Barr virus. Intravenous drug use increases risk for hepatitis B and C. Hepatitis C is most commonly due to transfusions that occurred prior to blood bank screening for this agent. Hepatitis C can become a chronic infection taking decades to progress to the symptomatic phase. Hepatitis C is becoming increasingly prevalent because chronic transfusion-associated infections are now moving into symptomatic and cirrhotic phases.

Alcohol is a hepatotoxic agent that causes alcoholic hepatitis and cirrhosis. Typically, long periods of heavy drinking are required for development of cirrhosis—estimates of 12 standard drinks a day for 20 years have been made for the alcohol burden necessary to cause cirrhosis. Concurrent hepatitis C infection may increase the risk of alcohol-related liver disease. Women appear to be more susceptible to alcoholic cirrhosis than men.

The symptoms of hepatitis include malaise, nausea, anorexia, fatigue, vomiting, diarrhea, and weight loss. Treatment for hepatitis differs by specific agent. Antiviral therapies continue to evolve and become more widely used. Interferon therapy for hepatitis C carries neuropsychiatric risks, including an increased risk of depression and suicide.

Psychiatric comorbidity is common with infectious and toxic hepatitis. Acetaminophen overdose can produce acute toxic hepatitis. This drug is commonly ingested in overdose by patients with psychiatric disorders such as mood disorders, personality disorders, alcohol and other substance abuse, and adjustment disorders. The management of alcoholic hepatitis requires attention to the alcohol abuse and dependence issues common in this patient population. Liver transplantation for alcohol-related end-stage liver disease commonly requires psychiatric consultation. Consultation-liaison services increase the likelihood of successful transplant outcomes.

PSYCHIATRIC CONSULTATION IN GASTROINTESTINAL DISEASE

Patients with gastrointestinal disorders frequently require psychiatric consultation. In a series of 1250 patients referred for psychiatric consultation over a 1-year period, 103 (8 percent) had gastrointestinal disorder as their primary medical diagnosis (Table 25.2-4). This series of psychiatric consultations occurred in a tertiary-care university hospital setting. Consultation requests originated from medical inpatients (55 percent) and medical outpatients (45 percent) referred from primary care internists and gastroenterologists. Most patients were female (56 percent). All patients were diagnosed by a faculty psychiatrist using DSM-IV criteria. A database of primary medical and psychiatric disorders coded for the ninth revision of *International Statistical Classification of Diseases* (ICD-9) and DSM-IV diagnoses for these consultation patients provides some insight into the epidemiology of psychiatric illness in the gastrointestinal disorders.

Medical Disorder	Frequency (%)	Psychiatric Diagnosis	Frequency (%)
Hepatitis	25	Major depressive disorder or dysthymic disorder	30
Abdominal pain	12	Alcohol or other substance dependence	17
Pancreatitis	12	Somatoform disorder	10
Crohn's disease or ulcerative colitis	10	Anxiety disorder	7
Peptic ulcer or gastritis	8	Personality disorder	7
Cirrhosis	7	Adjustment disorder	6
Gastroesophageal reflux	6	Bipolar I disorder	5
Diarrhea or constipation	6	Psychotic disorder	5
Esophageal disorder	5	Factitious disorder	4
Gastroparesis	5	No psychiatric diagnosis	4

* Rankings and frequencies in series of 103 patients referred from internal medicine for psychiatric consultation. Patients had a primary diagnosis of a gastrointestinal disorder in a university hospital setting.

Table 25.2-4 Frequency of Medical and Psychiatric Disorders in Psychiatric Consultation for Gastrointestinal Disease*

Specific gastrointestinal disorders encountered in this recent series are ranked in Table 25.2-4. Hepatitis ranked first in this series. Most hepatitis patients presented with hepatitis C and were seen with mood disorders or referred for consultation prior to interferon therapy. Undiagnosed gastrointestinal symptoms of abdominal pain, diarrhea, and constipation were common, with many representing functional gastrointestinal disorders. Pancreatitis presented primarily in the inpatient setting, with alcohol dependence as the primary psychiatric comorbid condition. Inflammatory bowel disease, peptic ulcer, gastritis, gastroesophageal reflux disease, esophageal disorders, and gastroparesis all represented at least 5 percent of the series total. The type of gastrointestinal disorders seen in consultation can vary by the site of

practice, and tertiary-care-center distributions may not reflect the patient profiles seen in other practice settings.

Major depressive disorder and dysthymic disorder ranked first in the psychiatric diagnosis category for this series. This is consistent with the most prevalent diagnoses seen overall in internal medicine referrals. Substance dependence and somatoform disorders both occurred in 10 percent or more of consultations. Anxiety disorders, personality disorders, adjustment disorders, bipolar I disorder, and psychotic disorders occurred in at least 5 percent of the diagnoses. Factitious disorder, a very rare psychiatric disorder, also made the top 10 ranking for this series of patients. Many patients in this series also met criteria for psychological factors affecting a medical condition, a diagnosis that would have been made in addition to the primary psychiatric disorder but not coded in the series database.

DIAGNOSIS AND CLINICAL FEATURES

Gastrointestinal Symptoms in Psychiatric Disorders Gastrointestinal symptoms occur commonly in a variety of psychiatric disorders. This association is so well known that many of the diagnostic criteria for some mental disorders include the presence of specific gastrointestinal symptoms and behaviors. Table 25.2-5 shows some relations between specific psychiatric disorders and gastrointestinal symptoms. Somatization disorder and the associated somatoform disorders commonly present with gastrointestinal complaints. In DSM-IV abdominal and rectal pain are two possible symptoms for meeting the criteria for medically unexplained pain in four separate sites. In addition, somatization disorder requires two additional gastrointestinal symptoms. Examples given to meet these criteria include nausea, bloating, vomiting other than during pregnancy, diarrhea, or intolerance to several varieties of food.

Symptom	Somatization Disorder	Major Depressive Disorder	Panic Disorder	Social Phobia	Eating Disorders	Substance Withdrawal	Substance Intoxication
Nausea	•		•			†	†
Vomiting	•				•	†	†
Abdominal pain	•		•				†
Diarrhea	•			†	†	†	†
Appetite disturbance		•			•	†	†
Food intolerance	•						

• = "A diagnostic criteria," † = disorder description.

Table 25.2-5 Gastrointestinal Symptoms Noted in DSM-IV

Changes in appetite are a hallmark feature of major depressive disorders. Nausea frequently accompanies a panic attack, as does abdominal distress. Diarrhea or fear of uncontrollable diarrhea in a social situation can be present in social phobia. Eating disorders usually include a disturbance of appetite, and self-induced vomiting is the most common cause of purging behavior in bulimia. A variety of substances produce gastrointestinal disturbances during the intoxication and withdrawal phases. Physicians need to keep these psychiatric disorders in mind when considering the differential diagnosis of patients presenting with gastrointestinal symptoms.

Psychotropic Drug Adverse Effects on Gastrointestinal Function Another potential link between psychiatric illness and gastrointestinal symptoms is the potential for psychotropic drugs to influence gastrointestinal function adversely. These drug-induced effects can produce several clinical challenges. First, patients may elect to discontinue necessary treatment because of the gastrointestinal adverse effects. Second, prescribers may need to consider the possibility of serious gastrointestinal disease or exacerbation of functional gastrointestinal disturbances when drug-induced symptoms develop. Clinicians may need to carefully consider the side-effect profile of specific psychotropic drugs when treating patients with gastrointestinal disorders.

The SSRIs can produce significant gastrointestinal symptoms. These gastrointestinal adverse effects tend to be noted at the initiation of therapy and to be dose related, with higher dosages producing higher rates of adverse effects. Nausea is a significant adverse effect in the profile of the SSRIs. In placebo-controlled trials of SSRIs for depression, rates of nausea attributed to SSRIs were 11 to 26 percent above the rates of nausea related to placebo. Fluvoxamine (Luvox) appears to have higher rates of nausea. Fluoxetine (Prozac) and Sertraline (Zoloft) studies indicate relatively lower rates of nausea. Additional gastrointestinal adverse effects noted in the placebo-controlled studies of SSRI include diarrhea (0 to 8 percent), anorexia (1 to 9 percent), and dyspepsia (1 to 3 percent). All these rates are adjusted for placebo rates and are statistically significant.

It is not suprising that drugs affecting serotonin induce changes in gastrointestinal function. Serotonin-rich areas of the brain are located in the brainstem and spinal cord. Efferent tracts from these areas innervate multiple areas throughout the brain that regulate many bodily functions including sleep, appetite, gastrointestinal motility, and reproductive function.

Standard tricyclic antidepressant drugs can also produce gastrointestinal effects, specifically dry mouth and constipation. These effects appear primarily related to the anticholinergic effect of tricyclic compounds. Tricyclic drugs with lower gastrointestinal adverse-effect profiles include desipramine (Norpramin) and nortriptyline (Pamelor), compounds with lower anticholinergic potencies. Higher rates of gastrointestinal adverse effects are noted in amitriptyline (Elavil) and imipramine (Tofranil). With imipramine nearly 50 percent experience dry mouth, and constipation is noted in nearly 20 percent. Tricyclic drugs can reduce gastric motility and need careful consideration for patients with gastrointestinal reflux or gastric hypomotility syndromes such as gastroparesis and for geriatric patients prone to problems related to constipation. Low-potency antipsychotic agents such as chlorpromazine (Thorazine) and thioridazine (Mellanil) share anticholinergic properties with the tricyclic drugs.

Use of nortriptyline rather than amitriptyline as the standard tricyclic drug has several advantages. Because of the lower anticholinergic effect, nortriptyline is better tolerated by most patients and is likely to induce fewer gastrointestinal adverse effects. Amitriptyline has a much higher discontinuation rate than nortriptyline for gastrointestinal effects. Patients who are prescribed amitriptyline as a first-line agent may discontinue the drug and psychiatric treatment because of adverse effects. If a tricyclic drug is used to treat depression, a less anticholinergic agent such as nortriptyline is likely to be tolerated well enough for an adequate therapeutic trial.

Psychiatric Adverse Effects Associated With Commonly Prescribed Drugs for Gastrointestinal Conditions Gastrointestinal prescription drugs represent a significant percentage of all prescriptions. Several of these agents can produce psychiatric symptoms. Additionally, several of the gastrointestinal drugs can interact with common psychiatric prescription drugs. Table 25.2-6 summarizes some of the important potential adverse psychiatric effects and drug interactions with common prescription drugs.

Generic	Brand	Indications	Adverse Psychiatric Effects and Drug Interactions
Histamine receptor antagonists		Peptic ulcer disease	
Nizatidine	Axid		Cimetidine can cause delirium especially in severely ill and hospitalized patients; cimetidine can increase blood levels of tricyclic drugs, carbamazepine, valproate, SSRI compounds; fewer CNS effects and metabolic disturbances are noted with other histamine receptor agonists
Famotidine	Pepcid		
Cimetidine	Tagamet		
Ranitidine	Zantac		
Proton pump inhibitor		Peptic ulcer disease	
Omeprazole	Prilosec		Can increase carbamazepine concentrations
Gastrointestinal stimulants		Cosmogenics	
Cisapride	Propulsid		
Metoclopramide	Reglan		Can cause depression and less frequently dystonic reactions and parkinsonism
Antiemetics		Nausea	
Prochlorperazine	Compazine		Prochlorperazine is an phenothiazine and like others can increase tricyclic drug levels
Dronabinol	Marinol		A cannabinoid found in marijuana; can cause drowsiness, dizziness, euphoria
Ondansetron	Zofran		A selective serotonin (5-hydroxytryptamine [5-HT]) type 3 receptor antagonist; interactions with SSRIs unclear
Antidiarrheal Agents			
Interferon alpha	Intron A	Hepatitis C	Depression in up to 10%, also insomnia, anxiety, constipation
Metronidazole	Flagyl	Giardiasis, Helicobacter	Potential nephrotoxic effect when used with lithium, interacts with disulfiram

Table 25.2-6 Common Drugs Used for Gastrointestinal Disorders—Psychiatric Effects and Interactions With Psychiatric Drugs

Cimetidine (Tagamet) has been available for over 20 years as a histamine receptor antagonist blocking gastric acid secretion. Cimetidine appears to have some anticholinergic effect and can produce delirium, especially in hospitalized patients with severe medical or surgical illness. The newer histamine receptor antagonists (ranitidine [Zantac], nizatidine [Axid], and famotidine [Pepcid]) have fewer adverse central nervous system (CNS) effects and drug interaction problems with psychotropic drugs. Cimetidine use has increased in many hospitals to reduce hospital costs and is a preferred drug in some managed care settings. This change has resulted in a risk for more adverse CNS and drug interaction problems. Omeprazole (Prilosec) is a blocker of acid secretion that works by inhibiting the proton pump in gastric cells. A possible drug interaction with carbamazepine (Tegretol) that increases carbamazepine concentrations has been reported.

Gastrointestinal stimulants target delayed gastric emptying associated with diabetes and advanced age. Two drugs in this class include cisapride (Propulsid) and metoclopramide. Metoclopramide (Reglan) appears to induce a depressive state in some individuals and can also occasionally cause neuroleptic-induced adverse effects. Parkinsonian symptoms noted with metoclopraminde include dystonic reactions, akathisia, and muscular rigidity. Dystonia associated with metoclopramide has been noted in up to 25 percent of children and young adults treated for chemotherapy-associated nausea. Prophylactic diphenhydramine (Benadryl) is used commonly to reduce the incidence of metoclopramide-associated dystonia. Metoclopramide doses may need to be reduced with renal compromise to avoid adverse effects.

Akathisia related to metoclopramide appears commonly in elderly patients receiving the drug. This may be related to reduced renal function and reduced clearance of standard doses in the geriatric age group. Renal impairment may result in high blood concentrations of metoclopramide and higher rates of adverse effects in this age group.

Antipsychotic drugs reduce nausea and vomiting. Some common antipsychotic drugs like haloperidol (Haldol) and chlorpromazine are used in the medical setting for their antiemetic effect. The antipsychotic prochlorperzine (Compazine) can produce the adverse effects of other phenothiazines and potentiate the sedative effects of some psychotropics. Like other phenothiazines, concurrent tricyclic drug administration results in higher blood concentrations of the tricyclic agents. As interferon therapy for hepatitis C carries a risk of depression with reports of suicide attempts and completed suicide in several cases, some centers recommend psychiatric consultation prior to the institution of interferon therapy.

Metronidazole is commonly prescribed for giardiasis and peptic ulcer due to *Helicobacter* infection. This agent may increase risk for nephrogenic toxicity associated with lithium (Eskalith) and also can produce a disulfiram (Antabuse)-like reaction when alcohol is consumed.

Psychiatrists and other physicians prescribing psychotropic agents need to consider these potential interactions when treating patients with gastrointestinal diseases. Collaboration between psychiatrists and physicians treating gastrointestinal disorders is frequently necessary for patients with combined illnesses. This collaboration is often also necessary for separating out gastrointestinal and psychiatric causes in the differential diagnosis of complex cases.

A 30-year-old woman developed fatigue and consulted her family physician. During her teenage years, she had a period of experimentation with alcohol and drug use. For a brief period, she used intravenous methamphetamine. After several years of intermittent drug use she stopped all drug use at her boyfriend's insistence. They later married, and she had two children without obstetrical complications.

Her family physician completed a medical workup. Blood tests revealed elevated liver transaminase levels. She was referred to a gastroenterologist for further diagnostic workup and treatment. Serum tests and a liver biopsy confirmed a diagnosis of hepatitis C. Interferon therapy was recommended, and she was referred for psychiatric consultation prior to initiating interferon to rule out psychiatric contraindications to interferon therapy. Psychiatric consultation identified her previous drug use but showed no evidence for a history of depression or active depression. No contraindications to interferon therapy were found.

Interferon therapy began, and she did well for several weeks. However, she began to notice mood lability, irritability, and sleep disturbance. Her symptoms distressed her a great deal, and she began to have difficulty with occupational and social functioning. She denied suicidal ideation. Psychiatric reevaluation resulted in a diagnosis of mood disorder due to interferon. Her initial liver response to interferon was excellent, with liver transaminase levels reduced to normal. Since her response to interferon had been very positive, her gastroenterologist and psychiatrist elected to continue the interferon therapy while treatment with an SSRI was initiated.

Following 3 weeks of antidepressant therapy, her mood symptoms improved, including a return to normal sleep patterns. She continued antidepressant therapy during the year of interferon therapy. Her mood remained normal during interferon therapy. Following completion of interferon therapy, her antidepressant medication was tapered without recurrence of depression.

Discussion This case illustrates the potential psychiatric effects of drugs used for gastrointestinal disorders. Interferon can produce a significant mood disorder in some individuals. Since suicide has been reported during interferon therapy, mood symptoms should not be ignored. The *Physician's Desk Reference* (PDR) includes risk for suicide and suicidal ideation in the warning section for interferon with a note that depression may occur in up to 15 percent of patients treated with interferon alpha. Additionally, it notes that if depression occurs during the course of interferon, discontinuation of the drug does not guarantee clinical remission of the depressive disorder. The PDR goes on to note that suicide has occurred following the discontinuation of interferon. Early consultation with a psychiatrist can facilitate coordinated care. Active psychiatric treatment can allow successful completion of medical therapy.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of gastrointestinal complaints requires careful attention to the medical and psychiatric history as well as the pattern of the patient's symptoms. A psychiatric cause is more likely when the symptoms are chronic, occur in the context of multiple somatic symptoms, and occur in a patient with a psychiatric comorbid Axis I or Axis II diagnosis or multiple psychosocial stressors. A medical cause is more likely when these factors are absent and the patient has a physical examination (e.g., fever or abnormalities on laboratory testing).

A 45-year-old woman presented to her primary care physician with complaints of chronic intermittent abdominal pain and diarrhea. Medical workup did not reveal a cause for her symptoms, and a diagnosis of irritable bowel syndrome was made. The patient received treatment with fiber supplementation and bulking agents without relief. Various antidiarrheal medications did not improve her complaints of frequent loose stools. In an attempt to provide relief, her primary care physician prescribed acetaminophen with codeine. The patient reported some improvement in her symptoms with this medication.

Over time the patient's symptoms worsened, despite the acetaminophen with codeine. She requested larger doses than she was given and refilled prescriptions before they were scheduled to expire. She started to make desperate claims to her physician that she didn't know if she could go on if there was no improvement in her pain. Her physician referred her for psychiatric consultation to assess for somatization, depression, and possible prescription drug abuse.

On psychiatric evaluation, the patient denied any psychiatric problems, claiming she had only a physical problem. She had a history of recurrent pain complaints dating back to age 22. These pain complaints involved multiple sites and had often lacked evidence of a medical cause. On further questioning, it became apparent she was receiving narcotic pain prescriptions from several physicians. Her physicians were unaware that she had other sources of prescription drug supply. Her family history was positive for alcohol dependence in her father and alcohol and drug dependence in her brother. A diagnosis of somatization disorder and prescription drug abuse was made.

Discussion The case demonstrates the relation of somatization disorder to a functional gastrointestinal disorder. Patients with functional gastrointestinal disease who do not unrespond to treatment may have psychiatric comorbidity that affects the medical long-term prognosis. Patients with multiple functional complaints need careful coordination of care. Prescription drug abuse and misuse by these individuals is common and requires careful management.

COURSE AND PROGNOSIS

The course and prognosis of many of the functional somatic syndromes are often favorable, given time and reassurance. One group of patients presenting to a

physician with globus followed and interviewed after 15 years showed only 10 percent with continued symptoms, 43 percent had no symptoms in the interval and a similar number had minor recurrences during the follow-up period.

Similarly, studies of irritable bowel patients suggest an overall favorable course for most patients. Studies 2 and 5 years after diagnosis report that 70 to 80 percent of patients were improved. Compliance with a high-fiber diet and bulking agents appears to improve the prognosis. The longest outcome study of irritable bowel syndrome covered an average of 29 years following the index evaluation. An organic gastrointestinal disorder was detected in the follow-up in only 10 of 112 patients. Survival in irritable bowel syndrome was identical to expected survival, and most patients demonstrated improvement with time.

Some evidence indicates that men with irritable bowel syndrome may respond better to treatment than women and that those with constipation-predominant symptoms do better than those with diarrhea-predominant symptoms. Those with a shorter duration of illness have a more favorable prognosis. Irritable bowel syndrome patients with high anxiety measures or other psychiatric comorbidity have a poorer prognosis than those without anxiety. More-recent treatment studies suggest a better prognosis with completion of psychotherapy.

Follow-up studies of functional dyspepsia also appear to support an overall favorable prognosis. In a series of 102 patients followed 6 years, 76 percent reported no symptoms of dyspepsia, and only 3 percent developed a peptic ulcer. Not all studies of dyspepsia support a favorable prognosis. Case selection factors may influence the likelihood of improvement.

Successful attention to psychological factors and the development of a strong patient relationship can contribute to an improved prognosis for functional gastrointestinal disorders. In a series of patients with irritable bowel syndrome, a strong patient-physician relationship appeared to decrease the frequency of return visits needed for the management of the syndrome. Some physician behaviors increase the likelihood of successful management of irritable bowel syndrome patients. Primary care physicians who attend to important factors in the psychosocial history and to symptom precipitants appear to increase the rate of successful outcome. Providing reassurance and discussing psychologic issues in irritable bowel syndrome also appear to favorably influence outcome.

TREATMENT

Psychotropic Treatment Psychotropic drug use is common in the treatment of a variety of gastrointestinal disorders and is complicated by disturbances in gastric motility, absorption, and metabolism related to the underlying gastrointestinal disorder. Many gastrointestinal effects of psychotropic drugs can be used therapeutically in functional gastrointestinal disorders. For example, tricyclic antidepressant agent can be used to reduce gastric motility in patients with irritable bowel syndrome with diarrhea. However, pscychotropic gastrointestinal side effects can exacerbate a gastrointestinal disorder (e.g., prescribing a tricyclic drug to treat a depressed patient with gastroesophageal reflux).

Psychopharmacological agents provide one step in a stepped-care approach to the management of irritable bowel syndrome. For milder cases of irritable bowel syndrome, education, reassurance, and avoidance of foods that increase symptoms forms the base of treatment. Moderate cases of irritable bowel frequently respond to nonpsychopharmacological drug treatment targeted at the patient's primary symptom. Dicyclomine (Bentyl) can be helpful for abdominal pain, and loperamide (Imodium) frequently provides relief for diarrhea associated with irritable bowel syndrome.

Tricyclic antidepressants can significantly reduce irritable bowel symptoms for many more-severe cases of irritable bowel syndrome and usually are reserved for more severe cases. The exact mechanism for tricyclic drug efficacy is unknown but may include controlling pain through central analgesia, reduced colonic motility because of a direct anticholinergic action on the gut, or reduction in comorbid depression. Retrospective studies of outpatients with irritable bowel syndrome found that 89 percent of patients had improvement in bowel symptoms with use of tricyclics or anxiolytics. Sixty-one percent of patients reported complete remission of symptoms. The most frequently used tricyclic drugs in this series were amitriptyline (about 50 mg a day) and doxepin (Adapin) (about 25 to 50 mg daily). These response rates to relatively low doses of tricyclic drugs suggest that the mechanism is not likely to involve remission of a comorbid depressive disorder.

Antidepressant treatment can also reduce symptoms in other functional disorders. In a placebo-controlled trial, trazodone (Desyrel) (100 to 150 mg daily) significantly reduced esophageal symptoms in a series of patients. Improvement in this series of patients did not correlate with reduction in esophageal contraction abnormalities, presence of psychiatric illness at entry, or changes in measures of anxiety or depression. Reduction of functional esophageal symptoms by antidepressants does not appear to depend on psychiatric comorbidity, suggesting that all patients with the gastrointestinal symptoms should be considered for treatment. Tricyclic drugs appear effective for the management of functional nausea and vomiting. An open-label study documented moderate reduction in symptoms of functional nausea and vomiting in 84 percent of patients taking an average dosage of 50 mg a day.

Gastrointestinal diseases can complicate the administration of psychotropic agents. Patients unable to take oral agents because of acute or chronic gastrointestinal diseases may need to use available parenteral forms of psychotropic agents. Lorazepam (Ativan) can be administered by the sublingual, intravenous, or intramuscular route. Many antipsychotic agents have parenteral forms including haloperidol, fluphenazine (Prolixin), trifluoperazine (Stelazine), thiothixene (Navane), perphenazine (Tritofon), and loxapine (Loxitane). Haloperidol has been commonly used by the intravenous route although this route is not approved by the Food and Drug Administration (FDA). Intensive care unit management of agitation associated with delirium often includes intravenous haloperidol as one treatment option, particularly for patients without evidence of rhythm abnormalities or other cardiac conditions.

Psychotropic drug treatment is complicated by acute and chronic liver disease. Most psychotropic agents are metabolized by the liver, and many of them can be associated with hepatoxicity. When acute changes in liver function tests occur with tricylic drugs, carbamazepine, or antipsychotic agents, it may be necessary to discontinue the drugs. During periods of discontinuation, lorazepam or lithium can be used, because they are excreted by the kidney. Electroconvulsive therapy (ECT) can also be used in the patient with liver disease, although the anesthesiologist must carefully select anesthetic agents that carry a minimal risk for hepatotoxicity.

Antidepressant treatment for patients on total parenteral nutrition can be a significant clinical challenge. Common antidepressant agents do not have parenteral forms. Fluoxetine is available in a liquid form that may be used for some patients who can tolerate and absorb some oral intake. ECT can be accomplished for patients without the option for oral antidepressant agents. For some patients with gastrointestinal diseases and disorders, aggressive use of psychotherapy may be the most appropriate choice in providing psychiatric treatment.

Psychotherapy Psychotherapy can be a key component in the stepped-care approach to the treatment of irritable bowel syndrome and other functional gastrointestinal disorders. Multiple different models of psychotherapy have been applied to clinical samples of patients with irritable bowel syndrome, including short-term, dynamically oriented individual psychotherapy, supportive psychotherapy, hypnotherapy, relaxation techniques, and cognitive therapy. There appears to be a significant placebo effect for psychotherapy in this population for both pharmacological and psychological treatment approaches. At least one study found the response to psychological treatment alone for irritable bowel syndrome to be comparable to that of pharmacological treatment. Patients with significant Axis I psychopathology appear to be less responsive to psychological intervention than those without. This may be related to the increased severity of irritable bowel syndrome symptoms associated with psychiatric comorbidity.

Most studies of psychotherapeutic approaches to the treatment of irritable bowel syndrome have been case series, not controlled trials. Some well-controlled studies are beginning to be published that use various models of psychotherapy. A cognitive therapy model for the treatment of irritable bowel syndrome has been developed that considers irritable bowel syndrome to be autonomic nervous system response to stress, with three components: cognitions, behaviors, and physiological response. Cognitions form the key element in this therapy. Therapy focuses on identifying life stressors and the thoughts associated with these stressors. Subjects are taught to identify threatening stimuli and modify their appraisals and interpretations of such stimuli. Subjects record automatic thoughts in their daily lives, and the therapist focuses on identifying central themes. Therapeutic work centers around three processes: rational self-analysis, decentering, and experimental disconfirmation.

Using this model, a study of 20 patients compared gastrointestinal symptom response of 10 subjects receiving cognitive therapy with that of 10 subjects who simply monitored their gastrointestinal symptoms; 80 percent of the cognitive therapy group showed clinically significant improvement compared with only 10 percent of the control. These small, early studies suggest that specific psychotherapy approaches may become a key intervention in irritable bowel syndrome and other functional gastrointestinal syndromes.

Because of the lack of controlled studies, it is not possible to recommend a specific model of psychotherapy for irritable bowel syndrome. Controlled comparison studies with rigorous selection criteria are needed before conclusions about the relative efficacy of different psychotherapeutic models can be made. Despite this lack

of information, psychological treatments appear promising and can be a legitimate part of a comprehensive treatment plan for irritable bowel syndrome.

25.3 OBESITY

KELLY D. BROWNELL, PH.D., AND THOMAS A. WADDEN, PH.D.

Obesity is a problem as mysterious as it is pervasive. At first glance the cause is apparent—an individual consumes more energy than the body expends. The more complex question is why this occurs. Society's view that overweight individuals are responsible for their problem and that an overweight body reflects a troubled personality is at odds with a robust literature yet persists to the point that severe bias and discrimination against overweight persons are widespread. Health professionals are not immune from this bias. Overweight persons often feel blamed, scolded, and overtly criticized by professionals to the point they are much less likely to seek medical help for a given disease than are persons of normal weight.

What has been missing but is becoming more common is a social and scientific climate where the causes of obesity can be evaluated in the absence of social bias, the disease gets the needed attention given its toll on the public health and the lives of those affected, prevention can become a priority, the resources necessary to develop safe and effective treatments will be forthcoming, health care professionals skilled in the management of obesity and its complications are more abundant, and compassionate treatment is the norm.

DEFINITION

Obesity refers to an excess of body fat. In healthy individuals body fat accounts for approximately 25 percent of body weight in women and 18 percent in men. Estimating body fat accurately is expensive, although advances in the assessment of body composition may change this picture. *Overweight* refers to elevated weight above some reference norm, typically standards derived from actuarial or epidemiological data. In most cases increasing weight reflects increasing obesity, but not always. Muscular individuals might be overweight (weight might be elevated given height) but not be obese, and a person might have normal weight but have elevated body fat.

Indexes have been developed using height and weight to estimate level of obesity. The most common of these is the body mass index (BMI). BMI is calculated by dividing weight in kilograms by height squared in meters. Although there is debate about the ideal BMI, it is generally thought that a BMI of 20 to 25 kg/m ^{2} represents healthy weight, a BMI of 25 to 27 kg/m^2 is associated with somewhat elevated risk, a BMI of above 27 kg/m^2 is where the increase in risk is clear, and a BMI above 30 kg/m^2 is where there is greatly increased risk. Figure 25.3-1 presents a nomogram for calculating BMI from height and weight.

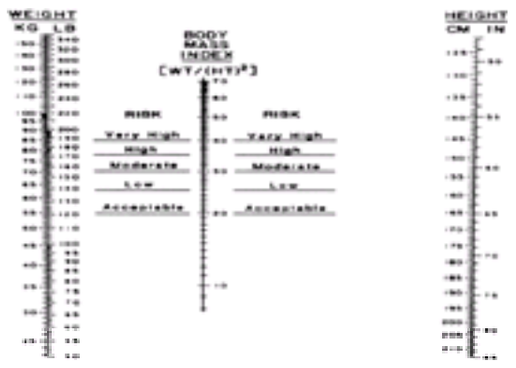

FIGURE 25.3-1 Nomogram for calculating body mass index (BMI) from height and weight. To determine BMI, place a ruler or other straight edge between the body weight column on the left and the height column on the right and read the BMI from the point where it crosses the center. (Reprinted with permission from GA Bray: Definition, measurement, and classification of the syndromes of obesity. Int J Obesity *2:*99, 1978.)

There has been a move in the obesity field to embrace BMI as an index of obesity. This is positive because BMI better estimates level of obesity than does weight per se, but there is the illusion that BMI avoids the problem of people focusing on “ideal” weight. However, ideal BMI levels do exist; it is only a matter of time before these are in wide use and the problems of overemphasis on ideal weights are still an issue, only using a different metric.

EPIDEMIOLOGY

The prevalence of obesity varies greatly by nation, by social groups within nations, and in some cases, within a given nation over time. In the United States approximately 35 percent of women and 31 percent of men are significantly overweight (BMI 27 or above—about 20 percent overweight). If one defines obesity as BMI over 25, there are now more obese than nonobese Americans. Using BMI over 31 (approximately 40 percent overweight), 11 percent of women and 8 percent of men are severely overweight. The prevalence of obesity in America has tripled since the early 1900s. Through the 1960s, 1970s, and early 1980s there was a steady rise in prevalence, but the dramatic changes occurred in subsequent years; there has been a 25 percent increase since the 1980s alone.

The prevalence of obesity is highest in minority populations, particularly among women. Fully 60 percent of African-American women ages 45 years and older are overweight, as defined by a BMI of 27 or greater. The high prevalence of obesity among minorities appears attributable primarily to lower income and educational attainment rather than race. Obesity is six times more prevalent in women of low socioeconomic status as compared with women of high socioeconomic status.

Weight gain is most pronounced in both sexes between the ages of 25 and 44. During this time, men gain an average of 4 kg and women 7 kg. Pregnancy probably contributes to the greater increase in women, who on average, begin each successive pregnancy approximately 2.5 kg heavier than at the last. After age 50, weights of men stabilize, and even decline slightly between ages 60 and 74. Women, in contrast, continue to increase in weight until age 60, at which time weight begins to decline.

Obesity is a massive public health problem by any standard. The prevalence is extreme, is increasing rather than decreasing, and in what speaks to a bleak future, is especially high and growing in children. Obesity rivals the most serious illnesses in the public health toll it takes.

COURSE AND PROGNOSIS

Recent developments in treatment offer new hope for overweight individuals, but obesity remains one of the most refractory conditions confronted by health professionals. There is little evidence of spontaneous remission, and the natural history of obese individuals left untreated is weight gain over time. As people age, the likelihood of chronic diseases such as diabetes, hypertension, cardiovascular disease, and cancer increases, due in part to the contribution of weight and the

behaviors that affect weight (poor diet and sedentary life-style).

Medical Complications There is a clear association of obesity with serious diseases and with mortality. Figure 25.3-2, from a study of 750,000 men and women from the general population by the American Cancer Society (ACS), shows a curve that has been replicated a number of times. An orderly relationship is seen between increasing weight and the risk of premature death. The major contribution to mortality in overweight persons in the ACS study was from coronary heart disease. At the low end of the weight curve, there was an increase in mortality attributable to low weight and excess mortality occurring in smokers. When smokers are excluded from such analyses, the relationship between weight and mortality falls nearly on a straight line. The minimum mortality ratio in the ACS study occurred at a BMI of approximately 22, but there was no substantial increase in mortality until BMI exceeded 27.

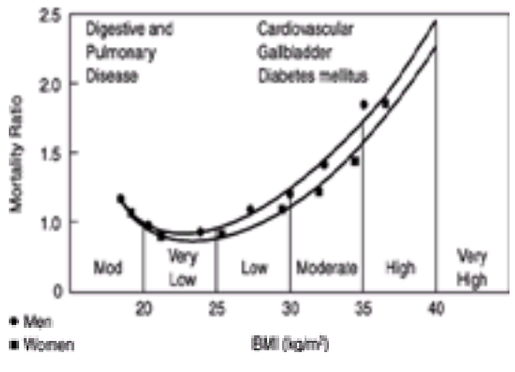

FIGURE 25.3-2 Obesity and mortality risk in the American Cancer Society Study of 750,000 men and women from the general population. Mortality rates were calculated as a ratio of observed deaths to expected deaths. Increased mortality in those at the lowest weights is attributable primarily to both low weights and elevated mortality occurring in smokers. (Data abstracted from Lew EA, Garfinkel L: Variations in mortality by weight among 750,000 men and women. J Chron Dis *32:*563, 1979.)

Table 25.3-1 lists the medical conditions most often associated with obesity. Nearly every organ system and part of the body can be affected, although this varies from person to person and depends in part on the extent of the obesity. Some weight-sensitive people will have comorbid problems such as hypertension and diabetes with only a small degree of overweight whereas others may gain large amounts of weight and have little or no evidence of medical problems.

Cardiovascular disease	Degenerative joint disease
Type II diabetes	Some cancers
Hypertension	Gallstones
Dyslipidemia	Gynecological irregularities
Sleep apnea	

Table 25.3-1 Major Health Consequences of Obesity

At one point there was lively debate in the obesity field about whether excess weight is a risk factor for morbidity and mortality independent of its influence on other disease processes (e.g., hypertension, diabetes, dyslipidemia). This question has been put to rest, not only because obesity does cause these comorbid problems in many people, and because the poor diet and inactive life-style that lead to obesity are themselves dangerous, but because studies have shown an independent contribution of obesity beyond its effect on risk factors. As shown in Table 25.3-2, the risk for a number of serious diseases increases with rising weight.

	20–25 kg/m²	25–30 kg/m²	30–35 kg/m²	>35 kg/m²
Diabetes	3.7	7.4	12.2	15.3
Hypertension	17.7	29.4	36.7	39.4
Elevated cholesterol	12.6	18.6	19.5	14.0
Coronary heart disease	9.9	14.8	16.8	16.9
Depression	12.8	13.5	16.4	22.4
Musculoskeletal pain	21.2	24.1	28.3	30.6

Data abstracted from Queseberry CF Jr, Caan B, Jacobson A: Obesity, health services use, and health care costs among members of a health maintenance organization. *Arch Int Med* 158:466, 1998.

Table 25.3-2 Percentage of Patients With Medical Conditions by Increasing Levels of Body Mass Index (BMI)

The most common diseases associated with obesity are coronary heart disease, diabetes, hypertension, gallbladder disease, sleep apnea, and some cancers. For many people, joint problems, difficulty breathing, and the psychosocial consequences of obesity are of greatest personal concern because of their effect on the quality of life.

There has been strident debate about the exact weight at which risk begins to increase, with some estimates being as low as 5 percent overweight and others being six times or more that figure. In addition, some have argued that tables of ideal weights need to vary by age and that some weight gain with age is healthy. Prevailing sentiment is that risk increases when BMI exceeds 27, which is approximately 20 percent overweight.

Body Fat Distribution Body fat distribution is a better predictor of cardiovascular morbidity and mortality than is weight, total body fat, or BMI. Persons whose fat is confined primarily to the upper body (more common in males) are at greater risk of type II diabetes and cardiovascular morbidity and mortality than are persons whose adiposity is carried primarily in the lower body. Within the upper body, increased visceral fat is more damaging to health than is subcutaneous fat. The mechanisms by which visceral fat leads to increased metabolic abnormalities are not well understood but appear to be related to an increase in portal free fatty acid concentrations, which are associated with elevated hepatic gluconeogenesis and very–low-density lipoprotein secretion as well as decreased hepatic insulin clearance.

Findings for fat distribution have important implications. Such data suggest possible factors that would argue in favor of targeting the most aggressive treatments at those at greatest risk. For example, women are much more likely than men to diet and to enroll in weight loss programs, yet men may have a more compelling reason to do so, given their greater likelihood of having upper body fat distribution.

Social and Psychological Consequences It is a clear social disadvantage to be obese, and in some cases, even to be mildly overweight, particularly for women. In

a culture where beauty ideals are pathologically thin and highly unrealistic, overweight people are blamed for their condition and are the subject of teasing, bias, discrimination, and torment. Income and earning power are lower in overweight people, and untoward social conditions such as absence of romantic relationships are more common.

The bias against overweight people begins at early ages, and both the general public and health care professionals are involved. Children as young as age 6 describe obese children shown in silhouettes as “lazy,” “dirty,” “stupid,” “cheats,” and “lies.” When shown drawings of an obese child and children with various handicaps, including facial disfigurement, both children and adults pick the obese child as the one they would least like to play with.

Health care providers appear to share this prejudice. Some research finds physicians describing their obese patients as “weak-willed, ugly, and awkward.” Patients appear to be conscious of such attitudes, as indicated by the results of a recent study of individuals who underwent surgery for their obesity. Approximately 80 percent of respondents indicated that they had “been treated disrespectfully by the medical profession” because of their weight. The finding from a study in the family practice literature that overweight people are less likely to seek medical help for a given condition than are people without weight problems reflects embarrassment, shame, and fear of being criticized.

The literature on the psychological consequences of obesity has been mixed. Several studies report no differences in psychological function (using general measures of psychopathology such as depression and anxiety) between overweight and nonoverweight individuals. This seems counterintuitive given the strong social bias and the recurrent clinical observation that many overweight individuals internalize the negative messages and make very negative attributions for their problem. More recent papers have noted the methodological shortcomings of earlier work and propose that obesity does increase risk for psychological problems, particularly in the presence of possible risk factors such as binge eating.

Health Care Costs Its massive prevalence and serious effects on health make obesity a major contributor to health care costs. In the early 1990s the health care costs of obesity were estimated at $40 billion annually. More sophisticated and recent data show even more disturbing figures. The estimated annual cost of obesity, including direct costs (costs of preventive, diagnostic, and treatment services related to disease) and indirect costs (value of lost wages, value of future earnings lost due to premature mortality) is $51.64 billion annually, which is 5.7 percent of the national health care expenditure.

On a more local level, a study of 17,118 patients in the Kaiser Permanente Medical Care Program in northern California examined health care costs across different levels of weight. Compared to patients at normal weight, patients with a BMI between 30 to 35 kg/m^2 had 25 percent higher annual costs. The costs were 44 percent higher for those with BMI greater than 35 kb/m^2. These incremental costs attributable to obesity accounted for 6 percent of the total healthcare costs in the Kaiser health plan.

Quality of Life The toll of obesity to individuals can be seen in discrete medical conditions, psychological disturbances, and social disadvantages. Recent attempts have been made to quantify the overall impact on quality of life. Table 25.3-3 shows a comparison of individuals in different weight groups in various quality-of-life domains. These figures show clearly increased problems in living with elevated weight. The problems are in areas of disease and general health, and also in mental health and social and emotional functioning. Excess weight can have a profound effect on the quality of an individual's life.

SF-36 Item	Mildly Obese	Moderately Obese	Morbidly Obese
Physical functioning	85.6	79.4	51.9
Role—physical	85.0	77.8	46.3
Bodily pain	66.4	54.5	43.2
General health	72.0	65.7	54.3
Vitality	49.5	48.1	38.0
Social functioning	84.9	79.3	67.9
Role—emotional	85.4	75.3	69.3
Mental health	74.3	68.6	65.6

*In 278 mildly, moderately, and morbidly obese individuals using the SF-36. Figures represent mean SF-36 scores. Lower scores represent lower satisfaction with quality of life.

Table 25.3-3 Comparison of Quality-of-Life Scores*

ETIOLOGY

Obesity is a heterogeneous disorder with causes in the environment and in the individual's psychology and biology. The field has progressed from ideas that a single cause might exist and that obesity is a singular entity, to recognition that multiple causes are necessary to explain obesity across individuals, within the same individual at a given time, and even within a given individual over time.

Fat storage remains the end product of consuming more energy than the body requires, but a variety of factors may contribute to positive energy balance. The etiology of obesity can be examined in terms of risks to the population as a whole, and of genetic and behavioral factors that place individuals in the population at even greater risk. Illnesses that give rise to obesity are also discussed.

Risks to the Population Merely by residing in the United States a person has a greatly increased risk of obesity. With the highest prevalence in the world and climbing, it is important to examine the American environment in the search for causes; epidemiological data from other countries can also be informative in this context.

There are data from country after country showing increased prevalence of obesity as cultures become more like that of the United States. Prevalence is increasing in nearly every such country as development and modernization occur. The rate of increase in the United Kingdom, for example, is much the same as that in the United States, but at a lower starting point. In peoples as diverse as inhabitants of Mauritius (an island in the Indian Ocean), Alaskan Eskimos, natives of Samoa, Pima Indians living in the United States and Mexico, and immigrants from countries like India and Japan moving to countries like the United Kingdom and the United States, the risk of obesity increases dramatically as individuals are exposed to a changed environment.

Energy balance in the U.S. population is affected in negative ways by the food supply and diminishing need to be physically active. Both have changed in dramatic fashion in recent years.

High-Fat, High-Calorie, Palatable Diet From 1910 to 1985 the percentage of calories in the U.S. diet derived from fat increased from 32 to 43 percent, whereas that from carbohydrate declined from 57 to 46 percent. Protein remained relatively constant at about 11 percent. An extensive body of literature shows that both animals and humans gain weight when fat in the diet is high. Weight gain results from increased caloric intake, attributable to the high energy value of fat (9 kcal/g for fat versus 4 kcal for protein and carbohydrate), and to fat's palatable flavor and texture. In addition, dietary fat is converted to body fat with approximately 25 percent greater efficiency than is carbohydrate, such that a person in positive energy balance will gain more weight when consuming fat than when consuming the same number of calories from carbohydrate. Premium ice creams and a host of sweet and salty foods derive 50 percent or more of their calories from fat.

High-calorie, high-fat, and highly palatable foods are ubiquitous. Fast-food restaurants have exploded in number, most now with drive-through windows, breakfast, packaged meals, and massive serving sizes. Most gas stations have been remodeled to have convenience food markets. Malls have food courts, airports and train stations have fast-food franchises, and there are even cases of fast-food restaurants in the lobbies of children's hospitals and in schools. In no country on earth is food more available, promoted, and inexpensive. Some experts have labeled this a “toxic environment” and claim that the outcome is entirely predictable—climbing rates of obesity.

The American lifestyle also contributes. Americans are eating out in record numbers, with the greatest expenditures occuring at fast-food restaurants. Fully 7 percent of the U.S. population eats at McDonald's on any given day. More processed foods are available. In the late 1990s the majority of the best-selling new food products were snack foods and beer. With single-parent families and a stressful lifestyle, less and less cooking is done at home, and good nutrition becomes more difficult to

achieve.

Declining Physical Activity Decreased physical activity is also a major threat to the nation's weight control. Daily energy expenditure decreased substantially as this nation changed from an agricultural to an industrial economy and, more recently, from a service to an information economy. From 1965 to 1977 alone, energy expenditure was thought to decrease by approximately 200 kcal per day. The increasing reliance upon automobiles, elevators, escalators, extension telephones, computers, and remote control devices all contribute to increasing obesity.

GENETIC RISKS

Although all Americans, as a result of national life-style changes, are at risk of weight gain, persons at greatest risk are those with a genetic predisposition to obesity. Studies of twins and adoptees have shown that body weight is under substantial genetic control. Current estimates are that 35 to 40 percent of the variance in BMI is attributable to genes and the remainder to environmental influences or gene-environment interactions.

Recent studies have identified five separate genes that cause obesity in laboratory animals. The best-known animal model is the *ob*/*ob* mouse. This animal grows markedly obese because of a deficiency in leptin, a protein that is synthesized in adipose tissue and acts on central neural networks that control ingestive behavior and energy expenditure. Under normal conditions leptin inhibits food intake and increases energy expenditure. As an animal's adipose mass increases, leptin secretion increases proportionately, thus reducing food intake and eventually body fat. The *ob*/*ob* mouse, because of a mutation in the ob gene, produces no leptin. As a result the animal is hyperphagic and extremely sedentary, producing its marked obesity. Peripheral or central administration of recombinant leptin in the *ob*/*ob* mouse results in rapid normalization of food intake, activity, and body weight.

With the discovery of the *ob* gene, investigators expected to find low leptin concentrations in obese humans. To date, only a handful of individuals have been identified who produce little or no leptin (comparable to the *ob*/*ob* mouse). Instead, the overwhelming majority of obese individuals have high circulating leptin levels; the higher the body fat, the higher the leptin excretion. Attention has now shifted to whether some obese individuals are leptin insensitive, in the same manner that many overweight individuals develop insulin insensitivity. Clinical trials are currently investigating whether leptin administration in humans reduces body weight.

Energy Expenditure With a few exceptions, such as Prader-Willi syndrome, researchers have not identified the specific gene(s) responsible for human obesity or the mechanisms of transmission. However, inherited differences have been shown not only in body fat but also in body fat distribution (i.e., upper- versus lower-body obesity), level of spontaneous physical activity, resting metabolic rate, and the thermic effect of food (i.e., energy expended in the digestion and absorption of food). Of these, resting metabolic rate (RMR), which accounts for approximately 60 to 75 percent of daily energy expenditure in sedentary individuals, appears the most significant. Longitudinal investigations of infants and adults have shown that those with low metabolic rates are more likely to become obese than are those with normal or elevated rates. Recent studies have also suggested that African-American women have lower resting energy requirements than Caucasian women, a factor that could contribute to the higher rates of obesity in black women.

Discovery of the leptin protein has greatly advanced the understanding of the complex neurohumoral regulation of body weight. Using the techniques of molecular biology, future research is likely to reveal that obese individuals differ from lean individuals in the mechanisms that regulate food intake (such as neuropeptide Y) or energy expenditure (such as uncoupling proteins). The identification of these mechanisms should provide specific targets for therapeutic intervention, whether by pharmacotherapy or gene therapy.

Behavioral Risks Behavioral and psychological factors also play a major role in the etiology of obesity. People makes choices about their eating and physical activity. A person's psychological well-being can influence weight and vice versa.

Energy Intake and Food Choices Investigators sought for years to determine whether obese individuals eat more than their average-weight peers; almost two dozen studies that relied upon self-reports of caloric intake concluded that they did not.

Recent studies have used doubly labeled water to assess 24-hour energy expenditure, and find that obese individuals typically underestimate their caloric intake by 30 to 40 percent, as compared with only 5 to 20 percent for average-weight controls. Hence, obese individuals generally do have higher caloric intakes than the nonobese, although the excess energy consumed is generally limited to that required to support the extra fat-free mass associated with obesity (approximately 25 to 30 percent of excess weight in significantly obese individuals consists of fat-free mass). These findings suggest that although practitioners should take seriously a patient's report of low caloric requirements, they must stress to the patient the need to keep very precise records of food intake.

Patients also make choices about the type of food they eat. This is influenced by family upbringing and by the general culture the individual is exposed to. Risk for obesity is increased in individuals who have preferences for high-fat, high-calorie food and in those who use food as a source of emotional comfort.

Binge Eating Approximately 20 to 30 percent of individuals who seek professional treatment of their obesity suffer from binge eating—episodes of uncontrolled eating in which they consume large quantities of food. Persons diagnosed with binge-eating disorder do not purge following overeating episodes, which distinguishes them from individuals with bulimia nervosa.

The absence of purging may contribute to the development of obesity, although there are few data on this topic. Little also is known about the etiology of binge eating. Early theorists proposed that binge eating resulted from severe caloric restriction (i.e., dieting), but more recent reports suggest that binge eating can precede dieting or may occur in the absence of dieting. This suggests the presence of serious psychological disturbance, created perhaps by interpersonal distress, leading the person to use food as a means of escaping from unpleasant life circumstances. It is common for binge eaters to report being “numb” during these episodes and using food as a means for blocking out the world.

Psychological Status With the possible exception of binge eating, there is little evidence to support popular notions that obesity results from overeating in response to feelings of anxiety or depression. Longitudinal investigations have not found psychological status to predict the development of obesity in children, and in cases in which psychopathology is observed in overweight adults, it is probably a consequence rather than cause of the obesity. A minority of obese individuals will present with significant psychological distress, but these must be addressed in treatment. However, practitioners should not expect that resolution of such distress will automatically result in weight loss.

A consistent finding in binge eaters is that of increased depression and psychopathology. As many as 50 percent of obese binge eaters present with clinically significant depression, as compared with only 5 percent of obese nonbingers, whose scores on depression scales typically fall within the normal range. It is not clear whether depression results from binge eating or causes it. Alternatively, the two disorders may be linked to a common neurotransmitter deficiency, given the favorable response of each to serotonergic agents such as fluoxetine (Prozac).

The psychological meaning of food to individuals who struggle with weight is an important topic that has been studied far too little. From clinical experience it is clear that some individuals use food to escape and food may become their best friend in many ways. They look forward to times when they can be alone with food and use food in the way others may use close personal relationships. This is generated by intense personal needs, but no research has occurred on the personality or situational factors that predispose an individual to this phenomenon, how exactly this contributes to weight gain, and how such individuals might be treated.

Illness Risks In only a small number of cases is obesity the consequence of identifiable illness. Such cases include a variety of rare genetic disorders, as well as the neuroendocrine abnormalities shown in Table 25.3-4. Hypothalamic obesity results from damage to the ventromedial region of the hypothalamus, which has been studied extensively in laboratory animals and is a known center of appetite and weight regulation. In humans, damage to the ventromedial region of the hypothalamus may result from trauma, surgery, malignancy, or inflammatory disease. If the patient has had a recent physical examination and laboratory tests, with satisfactory results, the disorders in Table 25.3-4 generally can be ruled out.

Genetic (dysmorphic) obesities
Autosomal recessive
X-linked
Chromosomal
Neuroendocrine obesities
Hypothalamic syndrome
Cushing's syndrome
Hypothyroidism
Polycystic ovary (Stein-Leventhal) syndrome
Pseudohypoparathyroidism
Hypogonadism
Growth hormone deficiency
Insulinoma and hyperinsulinism
Iatrogenic obesities
Drugs (psychiatric)
Hypothalamic surgery (neuroendocrine)

Adapted from Bray GA: An approach to the classification and evaluation of obesity. In Obesity, P Björntorp, BN Brodoff, editors. Lippincott, Philadelphia, 1992.

Table 25.3-4 Illnesses That Can Explain Some Cases of Obesity

Some forms of depression, particularly mood disorder with seasonal pattern, are associated with weight gain. Most persons who live in seasonal climates report increases in appetite and weight during the fall and winter months, with decreases in the spring and summer. These variations, however, are usually more marked in persons diagnosed with mood disorder with seasonal pattern (seasonal affective disorder). One study found that 67 percent of patients gained 4 kg or more during the winter and that many had trouble losing the weight over the summer; only 33 percent of normals gained a comparable amount. It has been reported that 38 percent of patients diagnosed with major depressive disorder gained a significant amount of weight, as compared with 51 percent who lost weight. Thus, weight change may prove to be a marker for subtypes of depressive disorder.

PSYCHIATRIC MEDICATIONS

Long-term use of steroid medications is associated with significant weight gain, as is the use of several psychiatric agents. Patients treated for major depressive disorder, psychotic disturbances, and bipolar I disorder typically gain 3 to 10 kg, with even larger gains with long-term care. Table 25.3-5 shows the antidepressant and antipsychotic medications that are most and least likely to produce significant weight gain.

Tendency to Increase Appetite and Body Weight		
Greatest	**Intermediate**	**Least**
Antidepressant Drugs		
Amitriptyline (Elavil)	Imipramine (Tofranil) Trimipramine (Surmontil) Nortriptyline (Pamelor) Doxepin (Adapin, Sinequan) Phenelzine (Nardil)	Amoxapine (Asendin) Desipramine (Norpramin) Trazodone (Desyrel) Tranylcypromine (Parnate) Fluoxetine (Prozac)* Bupropion (Wellbutrin)*
Antipsychotic Drugs		
Chlorpromazine (Thorazine) Thioridazine (Mellaril) Mesoridazine (Serentil)	Trifluoperazine (Stellazine) Perphenazine (Trilafon) Thiothixene (Navane)	Haloperidol (Haldol) Loxapine (Loxitane) Molindone (Moban)*

*May decrease appetite and facilitate weight loss.

Table 25.3-5 Psychiatric Medications and Changes in Body Weight

The tricyclic and heterocyclic antidepressant drugs are associated with increased appetite and cravings for carbohydrates and sweets. In addition, anticholinergic effects produce dry mouth and increased thirst, which may lead to the consumption of high-caloric beverages and candy to freshen the mouth. By contrast, fluoxetine, sertraline (Zoloft), and other selective serotonin reuptake inhibitors are usually associated with reduced appetite and food cravings and may initially induce small weight losses (0.5 kg a week) in depressed and obese individuals. Similarly, bupropion (Wellbutrin), a weak reuptake inhibitor of dopamine reuptake, appears to be associated with modest weight loss rather than gain.

Of the antipsychotic agents, chlorpromazine (Thorazine) is generally associated with the greatest weight gain and molindone (Moban) with the least (and sometimes even with weight loss). Weight gain on antipsychotic agents appears to result from their antiserotonergic and anticholinergic effects; patients should be encouraged to drink water rather than high-calorie beverages when trying to reduce thirst and dry mouth.

In many cases patients with bipolar I disorder can be maintained atisfactorily on carbamazepine (Tegretol) or valproic acid (Depakene) without the significant weight gain typically associated with lithium (Eskalith). Like those treated by antidepressant and antipsychotic agents, these individuals should be provided dietary counseling to ensure that they select foods and beverages that are low in fat and sugar.

DIAGNOSIS

The diagnosis of obesity, if done in a sophisticated way, would involve assessment of body fat. This is rarely practical, so use of height and weight to calculate body mass index is recommended (Fig. 25.3-2).

Binge eating disorder may accompany and complicate obesity. Binge eaters are more likely than obese non–binge-eaters to suffer significant psychiatric complications that may require pharmacological or other treatment to regulate mood and appetite. Binge eating disorder, in turn, must be differentiated from bulimia nervosa. The management of binge eating disorder is discussed below.

In most cases of obesity it is not possible to identify its precise etiology, given the multitude of possible causes and their interactions. Instances of secondary obesity (described in Table 25.3-4) are rare but should not be overlooked. In Cushing's disease, for example, a distinct weight pattern is seen (Fig. 25.3-3).

FIGURE 25.3-3 Cushing's syndrome. Obesity and round face are evident. Hirsutism and abdominal striae are noted. (Reprinted with permission from Spillane JD, Spillane JA: *An Atlas of Clinical Neurology*, ed 3. Oxford University Press, New York, 1982.)

TREATMENT

Many treatments are available for obesity and different approaches are likely to be effective for different people. The most thoroughly evaluated approaches, behavior therapy, pharmacotherapy, very–low-calorie diets, and surgery, represent only a fraction of the means people use to lose weight. Self-help books, commercial and self-help programs, input from a variety of health professionals, and just doing it entirely on one's own have not been evaluated to the extent that firm conclusions can be drawn.

It is generally accepted that life-style change is necessary no matter what approach to weight control is used. Behavior therapy is the means for altering life-style and hence could be considered sufficient by itself for some individuals or a necessary adjunct for people needing additional assistance.

Preparing for Treatment More thought has been given in recent years to whether treatment is more important or more likely to be successful in some obese individuals than others. Having upper body fat distribution confers greater risk than does lower body obesity, but this is not widely used as a criteria for aggressive intervention. The field has not yet accepted a scheme by which treatment might be targeted to certain individuals. This is an important area of inquiry because some individuals will have more medical and psychological complications from their weight and some will have a better prognosis for treatment.

Matching Individuals to Treatments Some experts in the obesity field believe that a search for a single best treatment will not be fruitful and that finding the best fit between individuals and different treatments is a more productive way to proceed. This is based on the fact that most treatments are effective for at least some people, and obesity has multiple etiologies.

There has been some speculation of how patients might be matched, but there is little in the way of validated criteria to undertake a matching process. An example of this speculation is that Overeaters Anonymous might be especially helpful for binge eaters, given its focus on “compulsive overeating.”

In the absence of criteria for matching, several steps are still possible. First, speaking with patients about weight loss resources in the community is useful. It can be helpful to develop a list of local weight control programs (commercial, self-help, professionally directed), relevant facilities such as health clubs, and professionals who may be valuable (dietitians, exercise specialists, etc.). Patients can be told that a variety of approaches are available and that they should think about what might be most effective for them as individuals. Second, patients can be encouraged to combine or sequence programs in creative ways. Seeing a professional once each week and attending a self-help group on alternate days might be a helpful combination for some individuals. Finally, patients can think of various resources as means of maintaining weight loss. Re-entering a program if weight begins to increase might be used as crisis intervention. Periodic attendance at a program might be viewed as a booster to strengthen defenses.

Treatment Provider It is important for practitioners to clarify the role that they will play in the treatment of a patient's obesity. Psychiatrists and other mental health professionals certainly can assume primary responsibility for the patient's weight loss efforts and will probably achieve the most successful weight loss outcome by using a structured treatment manual, in some cases accompanied by pharmacotherapy.

Psychiatrists, however, may choose not to direct the patient's weight loss effort when obesity is not the primary presenting problem. Treatment time devoted to weight loss reduces time available for other problems and may confuse the therapeutic agenda. Specifically, the treatment of obesity is usually goal-directed and includes homework assignments that the patient must complete and turn in to the therapist. This approach contrasts with more open-ended models of traditional psychotherapy. In addition, patients may attempt to avoid the discussion of difficult topics in psychotherapy by indicating that they want to “work on their weight.” Alternatively, when it is time to discuss weight-related tasks (such as keeping a diet diary) that were not completed, patients often object that they want to discuss the “real things that are troubling me.”

Obesity is not a principal complaint in the majority of cases referred to psychiatrists or other mental health professionals, perhaps because obesity is not recognized as a psychiatric disorder except when it is accompanied by an eating disorder. In cases in which weight loss is raised as a secondary goal in ongoing therapy, the most favorable outcome is usually obtained by referring the patient to a weight loss program or specialist. This allows the mental health professional to discuss the significance of weight-related issues and to support the patient's efforts to lose weight without losing sight of the original presenting problem.

Setting Weight Loss Goals Individuals begin with an image of what they will accomplish. It may be a picture of how the new body will look, or may be a goal weight, and is shaped by multiple factors, including media portrayals of beauty, messages from the general culture about how people can and should look, family, health ideals (e.g., height-weight charts), and personal experience. What is common is the highly unrealistic nature of these ideas.

One study examined goals in 60 women beginning a weight loss program at an average weight of 218 pounds. The women were asked to list weights at which they would be successful, including a dream weight, happy weight (less than the dream but still satisfying), acceptable weight (not satisfying, but reasonable), and disappoint weight (better than nothing, but clearly disappointing). The weight losses needed to attain these weights, expressed as percent of initial body weight, are shown in Figure 25.3-4.

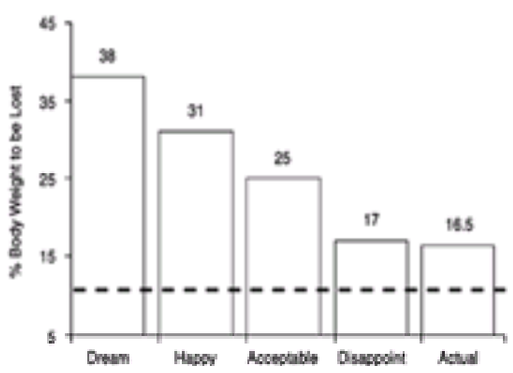

FIGURE 25.3-4 Amount of weight patients said they needed to lose to attain a dream weight, weight at which they would be happy, acceptable weight, and weight at which they would feel disappointed, and finally, their actual weight loss. The dashed line represents a weight loss of 10 percent of initial body weight. This is the approximate magnitude of weight loss produced by most approaches to obesity except for larger losses produced by very aggressive diets or surgery. The data show that actual weight loss in a program with quite good results is far below what patients feel they need to lose to feel at all satisfied with their effort. (Data from Foster GD, Wadden TA, Vogt RA, Brewer G: What is a reasonable weight loss? Patients' expectations and evaluations of obesity treatment outcomes. J Consult Clin Psychol *65:*79, 1997.)

The average weight loss needed to attain the dream weight was 38 percent of initial body weight. The weight at which the subjects felt they would be disappointed was a 17 percent loss, far above the 10 percent loss in body weight that most programs produce. In this study the average loss was 16.5 percent, far above average for most studies but still below the disappoint weight. It is clear from these data that unrealistic goals and expectations are the norm.

Unrealistic goals create a discrepancy between expected and actual performance. This can lead to mood changes, cognitive distortions, and a series of mental events that create disappointment, frustration, self-blame, and poor self-esteem. People feel that failure is inevitable and dismiss as inconsequential weight losses that their physicians might feel are beneficial.

Helping people develop reasonable expectations for their rate of weight loss, the ease with which weight loss will occur, and the ultimate magnitude of weight loss is crucial. However, this requires more than a single admonition to accept modest losses. A 200-pound woman making a 10 percent loss in body weight will weigh 180 pounds. It will not be easy for her to accept this weight, and in order to do so she must uncouple weight from self-esteem and challenge a number of fundamental body image assumptions. Current thinking is that a 10 percent loss in initial body weight is likely to be beneficial from a health perspective; some experts feel the number may be as low as 5 percent. Certainly greater weight loss is desirable, but not always possible, so thinking of moving a person toward a healthier weight

rather than an ideal weight offers a greater chance of having goals attained. This brings goals more in line with what modern treatments can deliver.

Behavior Therapy Behavior therapy became a presence in the field in the late 1960s and 1970s and has become the cornerstone of a great many treatment approaches for obesity. This approach, as the foundation of many commercial programs such as Weight Watchers and Jenny Craig, is used in some form in most obesity centers, and is the primary feature of lifestyle change that is thought to be essential even when treatments such as pharmacotherapy are used. It is based in theory, provides a conceptual scheme for encouraging behavior change, offers a multitude of techniques for initiating change, is the most thoroughly evaluated approach, and is designed to promote long-term changes in important aspects of lifestyle (diet, physical activity, and attitudes).

Behavioral treatment is designed to help patients make gradual habit changes to produce slow but steady weight loss. This approach has several distinguishing features. Its hallmark is in being goal-oriented. The objectives of treatment are clearly specified in weekly homework assignments that patients complete and discuss with the therapist the following week. Patients might be asked to limit eating to two rooms of the home, to walk after dinner three times weekly, or to record self-critical statements following overeating episodes.

Treatment is designed to change behavior and to help the individual establish new skills. It differs from traditional psychodynamic therapy, which would focus on unconscious motives thought to control overeating. Treatment is also process-oriented; it offers patients a method of analyzing eating and exercise habits to determine the behaviors to be modified and the best strategies for changing them. When the patient fails to acquire new behaviors, treatment examines emotional conflicts in a manner similar to more traditional psychotherapy. This step is taken, however, only after more direct methods of behavior change have proven ineffective.

The key elements to behavioral approaches are structured lifestyle change, methods to increase physical activity, cognitive techniques for attitude change, strategies for increasing social support, and methods for dietary change.

Record Keeping Patients keep extensive records of food intake throughout treatment. In the initial weeks they record the types and amounts of foods eaten and their caloric value. They are asked to reduce consumption of high-fat and high-calorie foods as a means of decreasing caloric intake by approximately 500 kcal a day. Record keeping is increased over time to include information about times, places, and feelings associated with eating, along with exercise habits. In the latter stages of treatment the records help identify high-risk situations that are associated with dietary lapses and the thoughts and feelings that occur in response to these situations.

Physical Activity Patients increase their life-style activity by walking more, using stairs rather than escalators, and reducing their dependence on energy-saving devices such as extension phones and remote control devices. Most patients also adopt a structured exercise program, such as walking or swimming, but not until they understand that the activity need not be heroic or punishing. Because there are psychological advantages to exercise (effects on body image, self-esteem, and mood), patients are encouraged to be active as often as possible, in ways that can be sustained, and to be certain that every activity they engage in, no matter how small, “counts” as exercise in their minds.

Cognitive Change People often have attitudes that are significant barriers to weight control. Body image disparagement is an example, but others include issues with self-concept, the tendency for small slips to become grounds for relapse, rigid rules about what constitutes adherence to or breaking a diet, and highly unrealistic goals about how rapidly weight loss will occur and how much weight will ultimately be lost. Behavioral approaches, now more often called *cognitive-behavioral treatments*, provide a systematic way for identifying problem attitudes and for replacing them with thoughts that are more constructive.

Relapse Prevention Based in large part on the pioneering work on relapse by G. Alan Marlatt and Judith Gordon, behavioral treatments have a strong focus on the maintenance of weight loss. Relapse-prevention strategies involve identifying high-risk situations (e.g., negative moods, interpersonal difficulties), planning to prevent initial mistakes (lapses), and building cognitive and behavioral methods for preventing lapses from becoming relapse.

Treatment Mechanics Treatment appears to be most cost effective when delivered in small groups (of 10 to 12 persons) in which participants discuss weekly homework assignments and related issues. Individual treatment may also result in adequate weight loss although usually not the emotional support associated with group care. The most favorable outcome is likely to be facilitated in either case by the use of a structured treatment manual, such as *The LEARN Program for Weight Control*.

Patients treated by group behavioral therapy lose an average of 8 kg in 15 to 20 weeks, approximating a weekly loss of 0.5 kg (1 lb) a week. Longer therapy is associated with greater losses but the average rarely exceeds 15 kg, even in treatment of 40 to 52 weeks. Patients regain approximately one-third of their weight loss in the year following therapy, although better maintenance has been reported in some studies, with increasing regain over time.

Maintenance of Weight Loss Weight regain can be minimized and even prevented. Persons in one research study, who following weight reduction attended every-other week meetings for 1 year maintained their full weight loss during this time whereas those without the benefit of such care regained almost half the weight they had lost. Regular therapist-patient contact by telephone or mail also helps to keep the weight off.

Physical activity is a key issue in considering maintenance. Correlational studies as well as controlled trials show consistently that persons who engage in regular physical activity are the ones most likely to maintain a reduced weight. The exercise need not be punishing as revealed by favorable findings for lifestyle changes such as walking and using stairs. The mechanisms by which exercise controls weight are not well understood. Physical activity clearly burns calories but may also have favorable effects on mood, metabolic rate, and appetite.

That the issue of maintenance is complicated is an understatement. Most overweight people have lost weight, but many have regained it. There are a number of methods for producing weight loss, but long-term maintenance of the loss is far too rare. The future looks hopeful, however, because fundamental changes are occurring in the conceptualization of obesity and its treatment. The view of obesity as a chronic disease that requires long-term treatment should lead to new approaches to therapy (e.g., sustained pharmacotherapy), may open the door to better coverage of the costs of obesity treatment, and should enhance attention among researchers to the issues that govern maintenance and methods for improving it.

Very-Low-Calorie Diets Very-low-calorie diets, which provide 400 to 800 kcal daily, are not as popular today as they were in the 1980s, but remain an important treatment option for patients with a BMI >30 kg/$m^{2.}$ The popularity of liquid diets, in particular, lay in their ease of preparation and to their induction of large, rapid weight losses—as great as 20 kg in 12 weeks. Findings, however, that patients regained 35 to 50 percent of their weight loss in the year following treatment decreased the attractiveness of this approach, as did concerns that the diets were associated with an increased risk of gallstones and binge eating.

The most appropriate candidates for very-low-calorie diets are individuals who need to lose weight quickly in order to undergo surgery, as well as those who are unable to lose weight on a conventional diet. Even with these individuals, severe caloric restriction is not necessary. Recent studies have shown excellent weight losses (i.e., 15 kg) with diets that provide 900 to 1000 kcal a day and that include a daily meal of conventional foods, usually in the form of a frozen-food entree. These dietary changes reduce patients' anxiety and problem eating during the refeeding period, during which patients terminate the liquid diet and resume consumption of conventional foods. As compared with traditional very-low-calorie diets low-calorie mixed diets (i.e., liquid diet plus conventional foods) also require less intensive medical monitoring, which can reduce the cost of treatment substantially.

The best long-term results are likely to be obtained with very-low-calorie diets (and low-calorie diets) when they are combined with a comprehensive program of life-style modification that focuses, in particular, on increasing physical activity. Promising results have also been reported by using anorectic agents, such as sibutramine (Meridia), to facilitate maintenance of weight loss following discontinuation of the very-low-calorie diet. Patients interested in this approach should be referred to multidisciplinary programs that specialize in such care.

Pharmacotherapy Weight loss medications will play an increasingly important role in the treatment of obesity in years to come, based on the discovery of new agents growing out of research on the regulation of body weight. The identification of safe and effective medications will allow practitioners to use long-term pharmacotherapy to manage obesity (and its health complications) in the same manner that medications are used to control long-term conditions including depressive disorder, diabetes, and hypertension.

The pharmacological treatment of obesity suffered a setback in September, 1997 when fenfluramine and dexfenfluramine, both serotonin releasers and reuptake inhibitors, were withdrawn from the market because of concerns that they were associated with valvular heart disease. The Food and Drug Administration (FDA)

received reports that approximately 30 percent of individuals who used these medications for 6 months or more experienced aortic regurgitation of mild or greater severity and mitral regurgitation of moderate or greater severity. These findings abruptly halted use of the popular fenfluramine-phentermine combination ("Fen-Phen") that had been tried by millions of Americans, following demonstration that it reduced weight by approximately 15 percent in only 34 weeks.

Current weight-loss medications can be divided into those that (1) increase energy expenditure, (2) reduce food intake, or (3) affect nutrient absorption. Historically, drugs in the second class have been prescribed most widely and consist primarily of noradrenergic agents (including diethylpropion [Tenuate], mazindol [Sanorex], and phentermine [Ionamin, Eastin]), which were approved by the FDA for only short-term use (i.e., £3 months). This restriction severely limits their usefulness; weight is likely to be regained rapidly when medication is terminated.

Sibutramine is a B-phenylethylamine that inhibits the reuptake of serotonin and norepinephrine (and dopamine to a very limited extent). It was approved by the FDA in 1997 for weight loss and the maintenance of weight loss (i.e., long-term use) in patients with a BMI £30 kg/m ^{2} (or a BMI £27 kg/m^2 in the presence of comorbidities). Clinical trials showed that sibutramine (10 to 15 mg a day) in combination with a 1200 to 1500 kcal-a-day diet, reduced initial weight by approximately to 9 percent in the first 6 months and maintained this loss at 12 months while patients remained on medication. In contrast to the fenfluramine and dexfenfluramine, sibutramine has not been linked to valvular heart disease. Its apparent safety resembles that of other agents that are serotonin or norepinephrine reuptake inhibitors but not releasers (e.g., selective serotonin reuptake inhibitors). No cases of primary pulmonary hypertension, another complication linked to the fenfluramines, have been reported in the more than 6000 patients treated by sibutramine. More patients, however, must be studied because only 1 case of primary pulmonary hypertension is expected in every 25,000 to 50,000 treated patients.

Sibutramine is contraindicated with the use of monoamine oxidase inhibitors (MAOIs), as well as with centrally acting appetite-suppressant medications. It also should not be used in combination with SSRIs and migraine medications (i.e., sumatriptin [Imitrex] and dihydroergotamine [D.H.E]). Such use could precipitate a *serotonin syndrome*, characterized by excitability, agitation, and even psychosis. Sibutramine also substantially increases blood pressure in some patients and should not be used in those with uncontrolled hypertension.

The other weight-loss medication approved by the FDA (in 1999) for long-term use is orlistat (Xenical), which is a selective gastric and pancreatic lipase inhibitor that reduces the absorption of dietary fat (which is then excreted in stool). In clinical trials orlistat (120 mg, three times a day), in combination with a low-calorie diet, induced losses of approximately to 10 percent of initial weight in the first 6 months, which were generally well maintained for periods up to 24 months. Because of its peripheral mechanism of action, orlistat is generally free of the central nervous system effects (i.e., increased pulse, dry mouth, insomnia, etc.) that are associated with most weight-loss medications. Thus, orlistat may be preferable to sibutramine in managing obese patients with hypertension or other cardiovascular complications, as well as patients who are treated by serotonergic medications for depression or migraine headache. The principal adverse effects of orlistat are gastrointestinal; patients must consume 30 percent or fewer calories from fat in order to prevent adverse events that include oily stool, flatulence with discharge, and fecal urgency.

The practitioner should emphasize three points in treating patients with weight-loss medications. First, the best results are likely to be obtained if medication is combined with the patient's own efforts to change eating and activity habits. Patients should not assume that they can eat whatever they wish simply because they are taking medication. Second, patients should be prepared for weight loss to slow and eventually stop after the first 4 to 6 months. Most will lose about 10 percent of their initial weight, which will leave them far short of ideal weight. Patients will need support in accepting that a 10 percent loss is a therapeutic success. Third, serious consideration should be given to using weight-loss medications for the long term (i.e., indefinitely). Pharmacotherapy effectively maintains weight loss and improvements in health complications. These benefits are likely to be lost if medication is discontinued, just as blood pressure is likely to increase if antihypertensive medications are withdrawn.

Surgery Surgery is an option for persons 100 percent or more overweight (i.e., BMI >40 kg/m ^{2}) who have failed to lose weight using more conservative measures. There are two principal procedures. With *vertical-banded gastroplasty*, a staple line is used just below the gastroesophogeal junction to create a small vertical pouch (15–30 mL) with a narrow opening (10 mm) to the remaining stomach. The intestines are not altered in any fashion. The pouch drastically reduces the amount of food that can be eaten at a given meal, thus inducing weight loss. Patients vomit frequently during the first few months until they learn to reduce their portion sizes. Weight losses of 50 kg are common in the first year, although patients can circumvent the operation by consuming high-calorie liquids or easily dissolvable foods such as chocolate or potato chips.

In the *gastric bypass*, a staple line is used just below the gastroesophogeal junction to create a horizontal pouch, which is attached to a loop of the small bowel. Thus, nutrients bypass the remainder of the stomach and the duodenum. The procedure is frequently associated with diarrhea (which can be managed by dietary modification and medication) and with *dumping*—a syndrome characterized by palpitations, weakness, and possible diaphoresis resulting from excessive intake of carbohydrate.

Patients typically reduce their pretreatment weight by 25 to 35 percent in the first 1 to 2 years following surgery. Gastric bypass is associated with greater weight loss than is gastroplasty, although patients treated by both procedures frequently remain as much as 50 percent over their desired weight because of their cell hyperplasia. Both interventions are associated with generally good maintenance of weight loss 5 years postsurgery. Moreover, there is a marked reduction in both physical and psychological complications of obesity. The most striking indication of success is the improved life expectancy of operated patients, which approaches actuarial standards of the general population.

It is imperative that patients who are candidates for surgery be referred to centers that specialize in the procedures and perform a large series annually. Under such conditions, operative mortality is as low as 0.5 percent. It may increase, however, to 1 to 5 percent at centers that perform only an occasional gastric procedure.

Role of the Psychiatrist Patients with chronic psychotic illness are inappropriate for surgery, as may be those with a history of alcohol or other substance abuse. Psychiatrists can play an important role in screening such individuals and in identifying potential psychosocial complications of marked weight loss. Although surgery is usually accompanied by improvements in mood, self-esteem, and body image, patients should anticipate changes in their personal relationships as family and friends adjust to the patient's reduced weight and more active life-style. Many patients, for example, leave unsatisfactory marriages following surgery—an action that is potentially positive but also stressful. Finally, some reports suggest that persons with personality disorders (particularly borderline personality) decompensate following surgery, although studies have failed to find that psychopathology consistently predicts weight loss or psychological response to surgery.

Management of Binge Eating Binge eating was treated initially by researchers working in the eating disorders field. Based on a classic study by Christopher Fairburn with bulimia nervosa showing equivalent results using interpersonal psychotherapy and cognitive-behavioral therapy, these two treatments were applied in randomized research to binge eating and once again showing equivalent results. This led some in the field to believe that binge eating was a disorder distinct from obesity and that eating disorders treatment for the binge eating was necessary before the issue of weight loss could be addressed.

Some recent preliminary research suggests that binge eating responds as well to traditional cognitive behavioral treatment for obesity as it does to eating disorders treatment. Furthermore, patients receiving weight loss treatment lose weight whereas obese binge eaters receiving eating disorders treatment do not—this is a robust finding. This would suggest that treating binge eating as an eating disorder may help to remedy the disorder, but will not influence weight. Hence, priorities of treatment (weight or the binge eating) must be defined before intervention should proceed.

Comprehensive, Compassionate Approach A truly comprehensive approach for managing obesity would require facilities (e.g., metabolic measurement rooms) and personnel (e.g., dietitians and exercise physiologists) that are rarely available. High-quality help can still be provided by use of readily available resources (e.g., treatment manuals) and the judicious use of referral. Deciding on the need for psychotherapy or weight management alone is an important task, and then deciding with the patient which combination of resources for weight control would be most suitable is the next logical step.

Overweight individuals too seldom receive compassionate treatment. The suffering experienced by such people can be considerable. The blame assessed by society is often internalized as self-blame, and it often comes to pass that people hate their bodies and hate themselves. To help reverse this, health professionals must be sensitive to the suffering, resist the cultural bias about assigning blame, recognize that the patient faces a long-term illness, and be persistent and understanding in providing help. When this occurs, there can be striking effects on the health and well-being of people who struggle with their weight.

SUGGESTED CROSS-REFERENCES

Eating disorders, including binge eating disorder, are discussed in Chapter 20. Learning theory is discussed in Section 3.3, behavior therapy in Section 30.2, and

cognitive therapy in Section 30.6. Group psychotherapy is discussed in Section 30.4.

25.4 CARDIOVASCULAR DISORDERS

PETER A. SHAPIRO, M.D.

Cardiovascular disease is the leading cause of death in the United States and in most of the industrialized world. About one-third of all adults over age 35 will ultimately die of cardiovascular disease, most often of complications of atherosclerotic coronary artery disease. In the United States, the incidence of coronary artery disease is over 5,000,000 cases per year, and 500,000 persons per year have a myocardial infarction; 20 percent of survivors of the acute infarction will die within a year. Some 400,000 persons develop congestive heart failure each year, and heart failure is cited as the principal cause in 40,000 deaths and as a contributing factor in 250,000 deaths annually. Although rapid advances in cardiovascular therapeutics have reduced mortality for patients admitted to the hospital with acute myocardial infarction, about one-third of cardiac deaths occur within the first hour of the patient's first heart attack, before any opportunity for medical intervention exists. This fact underscores the importance of primary prevention, efforts to reduce the risk of coronary artery disease before its clinical presentation. Behavioral risk factors for coronary heart disease, such as smoking, overeating, physical inactivity, and poor compliance with management of diabetes, hypercholesterolemia, and hypertension, are the main targets for primary prevention interventions. Achieving behavioral change with respect to these risk factors poses a considerable challenge for medicine and psychiatry. In addition, certain psychiatric disorders, acute mental stress, and psychological traits are risk factors for development and clinical progression of cardiovascular disease.

Psychiatric disorders frequently occur as complications or comorbid conditions in individuals with cardiovascular disease. Depression, anxiety, delirium, and cognitive disorders are especially prevalent problems. Surveys of ambulatory cardiology patients with documented heart disease indicate a point prevalence of 5 to 10 percent with anxiety disorders (predominantly panic attacks and phobias) and 10 to 15 percent with mood disorders (predominantly depressive episodes and minor depression or dysthymia). Major depressive disorder occurs in 15 to 20 percent of patients following myocardial infarction.

DEPRESSION, ANXIETY, AND OTHER RISK FACTORS

Depression In overwhelming support of long-held popular views, numerous recent investigations strongly support the hypothesis that depression increases the risk of development and progression of coronary artery disease. Over the past 60 years, several studies of institutionalized or treated mentally ill patients suggested an excess of cardiovascular mortality in those with depression compared with the general population, but these studies were potentially confounded by effects of the setting or treatment that defined the population. More recently, numerous large-scale, prospective epidemiological studies of community-dwelling subjects who were not psychiatric patients have yielded converging estimates of increased relative risks of incident myocardial infarction and cardiac related mortality of about 1.6-2.2 to 1 in association with depression. This finding holds even after controlling for smoking, a potent risk factor for cardiovascular morbidity and mortality, which is far more prevalent in those with depression than in the population at large, and the effect of depression persists, even in long-term follow-up over 10 to 20 years. Furthermore, studies of patients with preexisting coronary artery disease also demonstrate a near doubling of risk for adverse coronary disease–related outcomes, including myocardial infarction, revascularization procedures for unstable angina, and death, in association with depression. Symptoms of depression and the diagnosis of major depressive disorder carry a 3.5 to 6.6-fold increased adjusted relative risk of death in 6- and 18-month follow-up of myocardial infarction patients. In these patients the predominant mode of death is sudden cardiac death. Cooccurrence of depression and frequent premature ventricular contractions after myocardial infarction appears to increase mortality risk substantially, suggesting arrhythmia as the mechanism of death. Whether this risk can be reduced by treatment of depression is currently under investigation. One recent study of psychosocial intervention for postmyocardial infarction patients with depression or social isolation used monthly telephone contact, followed by a nurse's home visit to patients who expressed distress, and variable subsequent contacts. Although a preliminary study in men had suggested a beneficial effect of this program on recurrent cardiac event and mortality rates, replication in a cohort of both men and women failed to demonstrate an overall benefit, and women receiving the intervention had a poorer outcome than a control group receiving usual care. Further psychosocial intervention and pharmacotherapy trials are ongoing.

Possible Mechanisms Mechanisms by which depression may increase coronary disease risk are uncertain. Autonomic dysregulation with diminished cardiac vagal modulation occurs in depression and may provide a substrate for increased arrhythmic activity and sudden death. Disordered platelet aggregation leading to increased thrombus formation may also play a role in increasing risk of coronary events in depression. Measures of in vivo platelet activation and aggregation after overnight bed rest and following orthostatic challenge in medication-free, otherwise healthy depressed patients and normal control subjects show that depressed patients exhibit greater procoagulant activity at baseline and greater platelet activation on orthostatic challenge. The findings suggest that increased concentrations of plasma neuroregulators that can induce platelet activation (e.g., epinephrine or serotonin), intrinsic platelet factors, intraplatelet catecholamine or monoamine concentration changes, or a combination of these increase platelet reactivity in depressed patients. Patients with ischemic heart disease and depression have significantly elevated concentrations of circulating platelet factor 4 and b-thromboglobulin, factors associated with platelet activation; patients with ischemic heart disease alone also have elevated levels of these factors, but to a much lesser extent than patients with depression. Treatment with the serotonergic antidepressant paroxetine, but not with the tricyclic antidepressant nortriptyline, was associated with reduced levels of these indexes of platelet activation in one small study.

Anxiety, Depression, and Arrhythmias Malignant ventricular arrhythmias may occur as an “electrical accident” in individuals with no structural heart disease but are more frequent in those with underlying heart disease. Because conduction of myocardial depolarization may be delayed in regions of myocardial tissue damage, regions distal to the affected area may be stimulated to depolarization while adjacent tissue is undergoing repolarization, setting off a premature depolarization of the adjacent tissue that may precipitate ventricular fibrillation. The rate of local repolarization and readiness to initiate the next cardiac cycle is modulated by local innervation of the heart by branches of both the sympathetic and parasympathetic nervous system. In general, sympathetic fibers predominate in the left ventricular myocardium and have the effect of increasing irritability and stimulating depolarizations. Parasympathetic fibers predominate in the innervation of the specialized cardiac conduction system and have the effect of slowing heart rate and reducing automaticity.

Because autonomic cardiac modulation is profoundly sensitive to acute emotional stress such as intense anger, fear, or sadness, it is not surprising that acute emotions can stimulate arrhythmias. Indeed, instances of sudden cardiac death related to sudden emotional distress have been noted throughout history in all cultures. Two studies have demonstrated that in addition to depression, a high level of anxiety symptoms raises the risk of further coronary events in patients following myocardial infarction by two to five times that for nonanxious comparison patients. This effect is independent of the effect of depression. Risk is increased in both the immediate postinfarct period and over 18-month follow-up. Recently completed analyses of prospectively recorded epidemiological data in community samples demonstrate that phobic anxiety and mixed anxiety symptoms pose an increased risk of sudden cardiac death but not of nonfatal myocardial infarction, even after adjusting for other cardiovascular risk factors. High levels of anxiety symptoms are associated with a tripling of risk of sudden cardiac death.

Hostility and Type A Behavior Pattern The relation between a behavior pattern characterized by easily aroused anger, impatience, aggression, competitive striving, and time urgency (Type A) and coronary heart disease dominated studies in psychosomatic cardiology in the 1970s and 1980s. Several large prospective epidemiological studies found the Type A pattern to be associated with a nearly twofold increased risk of incident myocardial infarction and coronary disease–related mortality. In the 1980s, however, studies using a variety of measures of the Type A pattern and a variety of clinical endpoints, in a variety of patient populations, failed to lend convergent validity to the Type A construct as a risk factor for adverse cardiovascular outcomes across a range of clinical populations. For example, Type A pattern is associated with reduced (not increased) mortality in myocardial infarction patients with frequent premature ventricular contractions. Nevertheless, the observation of increased risk of coronary disease incidence and mortality associated with Type A pattern in nonclinical populations still appears valid. Moreover, group therapy to modify Type A behavior pattern was associated with reduced reinfarction and mortality in a 4.5-year study of patients with prior myocardial infarction. Type A behavior modification therapy has also been demonstrated to reduce episodes of silent ischemia on ambulatory electrocardiographic monitoring. A recent meta-analysis of 23 randomized controlled trials evaluated the additional impact of psychosocial treatment on rehabilitation from documented coronary artery disease. Relaxation training, stress management, and group social support were the predominant modalities of psychosocial intervention. Anxiety, depression, biological risk factors, mortality, and recurrent cardiac events were the clinical endpoints studied. These studies included a total of 2024 patients in intervention groups and 1156 control subjects. Psychosocial treatment patients had greater reductions in emotional distress, systolic blood pressure, heart rate, and blood cholesterol level than

comparison subjects. Patients who did not receive psychosocial intervention had 70 percent greater mortality and 84 percent higher cardiac recurrent event rates during the first 2 years of follow-up.

Hostility as a core component of the original Type A concept has received considerable empirical support as a predictor of coronary heart disease outcomes. Low hostility is associated with low coronary disease risk in studies of workplace populations. In addition, hostility is associated with several physiological processes that in turn are associated with coronary disease, such as reduced parasympathetic modulation of heart rate, increased levels of circulating catecholamines, and increased lipid concentrations during interpersonal conflict. Conversely, submissiveness has been found to be protective against coronary disease risk in women. Adrenergic receptor function is downregulated in hostile men, presumably an adaptive response to heightened sympathetic-adrenergic drive and chronic overproduction of catecholamines resulting from chronic and frequent anger. Because anger and hostility frequently coexist with depression, anxiety, and low social support, recent investigations of psychosocial factors associated with coronary heart disease have increasingly invoked the more global descriptors of low social support and poverty.

Vital Exhaustion Vital exhaustion, a state of fatigue associated with decreased interest in work, pessimism, and burnout, has been identified as a risk factor for incident myocardial infarction in European (predominantly Dutch) studies. Because the vital exhaustion concept overlaps with depression, its independent contribution remains uncertain.

Acute Mental Stress Acute mental stress has a significant effect on coronary artery blood flow, which may be of significance in patients with preexisting coronary disease. States of fear, excitement, and especially acute anger reduce blood flow through atherosclerotic coronary segments, provoke coronary spasm, and are associated with abnormal left ventricular wall motion and electrocardiographic evidence of myocardial ischemia. Mental stress–induced ischemia is associated with increased risk of subsequent cardiac events in patients with known coronary disease and may occur even in patients who do not demonstrate evidence of ischemia during exercise stress testing. Recent studies, however, indicate that relaxation training can alter autonomic activation during mental stress, implying a potential therapeutic role for such training in stress-induced ischemia.

Sudden cardiac death triggered by mental stress was demonstrated in a study of deaths in the aftermath of a major California earthquake. Following a surge of sudden deaths on the day of the earthquake, there was a several-day period of reduced incidence of sudden cardiac death, suggesting that only those predisposed to sudden cardiac death by underlying disease were affected by the monumental, acute stressor. Deaths were primarily associated with emotional stress rather than physical exertion. Sudden death without antecedent angina, suggesting cardiac arrhythmia, as well as deaths preceded by chest pain, suggesting acute coronary occlusions, were observed. Other studies have led to estimates that between 20 and 40 percent of sudden cardiac deaths are precipitated by acute emotional stressors.

Valvular Heart Disease and Anxiety Disorders The relationships between valvular heart disease and psychiatric disorder have been a matter of considerable interest over the past several decades. In panic disorder, mitral valve prolapse is detected in 10 to 25 percent of patients studied with echocardiography. However, prolapse also occurs in a substantial portion of the population without panic disorder, and the nature of the relationship remains uncertain. The subjective experience of valve prolapse (fluttering, chest pressure, etc.) may trigger panic sensations; alternatively, the association may be purely coincidental. Obsessive-compulsive disorders, tic disorders, and Tourette's disorder are associated with poststreptococcal immune system–mediated inflammatory responses similar to those leading to glomerulonephritis and rheumatic heart disease, a finding stimulated by consideration of the ticlike quality of movement disorders occurring in rheumatic fever. This association would lead to the expectation of an excess of rheumatic valvular heart disease in patients with disorders in the obsessive-compulsive spectrum.

Smoking The relationship between cigarette smoking and mental illness, particularly depression, has been well documented. Individuals with a lifetime history of depression are far more likely to have smoked than those without a depression history. Moreover, individuals with a history of depression, who have smoked, are far less likely to quit smoking successfully. As the prevalence of smoking trends downward in the United States, this association is strengthened. Inasmuch as smoking is such a powerful risk factor for ischemic heart disease, smoking cessation intervention is a matter of considerable interest for the psychiatrist, cardiologist, and primary physician. Buproprion (Wellbutrin) has been demonstrated to improve “quit rate” in smokers as a supplement to nicotine replacement and behavior therapy. The duration of pharmacotherapy is typically 2 to 3 months. Nortriptyline has also been shown to improve smoking cessation rates. Success in smoking cessation appears to be augmented by longer-term behavioral treatment.

PSYCHIATRIC PROBLEMS IN PATIENTS WITH CARDIAC DISEASE

Arrhythmias Ventricular arrhythmias may be asymptomatic or may cause palpitations, lightheadedness, dizziness, syncope, or sudden cardiac death. Patients who experience life-threatening rhythm disturbances are prone to secondary adjustment, mood, and anxiety disorders. The cardiovascular symptoms may lead to profound disruption of social roles and capacity for autonomous functioning. Even patients without symptoms may be counseled to avoid activities such as driving, which may be hazardous in the event of an arrhythmic event. Psychodynamically, because of the recurring, unpredictable, and sudden quality of the course of illness, issues of dependence on others and loss of control are especially prominent, as well as anxiety about death itself.

Treatment of cardiac rhythm disorders can engender psychiatric complications as well. Many antiarrhythmic agents have psychiatric side effects, including delirium, hallucinations, paranoid ideation, and mood disturbance. Lidocaine (Xylocaine) and procainamide (Pronestyl) are especially likely to have these effects. Implanted automatic pacemaker-defibrillators have supplanted chronic antiarrhythmic medical therapy in a substantial portion of patients who have experienced ventricular tachycardia–ventricular fibrillation. Regrettably, cardioversion by one of these devices may occur in a conscious patient, who experiences the sensation of one or more powerful shocks or blows to the chest. Although recent surveys have shown that most patients with automatic pacemaker-defibrilators seem satisfied with their devices, approximately 10 percent develop clinically significant anxious or depressed mood symptoms, including symptoms of posttraumatic stress, associated with defibillator discharges. Avoidance behaviors and anxiety in the setting of discharge-associated stimuli reduce quality of life for patients who have experienced shocks during such ordinary activities as sexual relations, showering, and low-intensity exercise. Risk factors for psychiatric complications in patients with automatic defibrillator-pacemakers include discharges early after implantation, repetitive discharges, and a high cumulative number of discharges.

Valve Replacement Valve replacement was among the first of the open heart surgeries to be developed, and pioneering work in psychiatric aspects of cardiovascular surgery demonstrated a high prevalence of delirium in early postcardiotomy patients. This delirium can be attributed to toxic or metabolic processes in many cases. Prolonged exposure to the intensive care unit (ICU) environment with sleep deprivation, sensory stimulation, and simultaneous monotony led to the phenomenon of delirium following a lucid interval (so-called ICU psychosis), but shortened ICU stays and better attention to maintenance of day-night cycles, noise reduction, and the provision of privacy have greatly reduced the extent of this phenomenon.

Delirium Delirium is a common problem in severely ill cardiac patients. Three main categories of patients are at risk: patients with severe congestive heart failure, patients receiving antiarrhythmic agents for tachyarrhythmias early after myocardial infarction or cardiac surgery, and patients following cardiac surgery. In congestive heart failure patients, delirium commonly results from hypoxia, hyponatremia, hyperammonemia, or azotemia, as pulmonary congestion and poor end-organ perfusion progress. Patients receiving lidocaine and procainamide may appear psychotic or delirious, even at nominally therapeutic blood levels. The clinical picture in postoperative patients may include all of these elements; in addition, cerebrovascular incidents during surgery, infection, sedatives, and narcotics may contribute to delirium. Management relies on correcting the underlying abnormality while treating psychosis or agitation with antipsychotic agents. Other sedatives should generally be avoided, although the agitated patient may benefit from concurrent administration of lorazepam (Ativan) with haloperidol (Haldol). Intravenous haloperidol can be administered frequently, especially if hemodynamic monitoring is in place. Very high dosages, however, may be associated with arrhythmias, including torsade de pointes. Prolonged cardiac conduction can occur with thioridazine (Mellaril) and chlorpromazine (Thorazine), especially in patients taking type 1A antiarrhythmic agents. b-Adrenergic receptor antagonists (beta-blockers) may cause elevated concentrations of antipsychotic drugs.

Coronary Artery Bypass Graft Surgery Coronary artery bypass graft surgery does not have an advantage over medical management of coronary artery disease with respect to survival, except in cases of left main coronary artery or left anterior descending artery obstruction, but surgery may be more effective than medication in ameliorating angina symptoms and improving exercise tolerance, functional capacity, and overall quality of life. Coronary artery bypass graft surgery is one of the most frequently performed surgeries in the United States. Psychiatric complications after this surgery have been noted since its inception and persist despite improvements in cardiopulmonary bypass and anesthetic and surgical technique. Persistent, subtle, memory and cognitive impairment may occur after this surgery. In a recent study of over 2100 elective coronary artery bypass graft surgical patients at 24 centers, clinical observation yielded an adverse neurological event rate of 6.1 percent. Death, focal neurological impairment (stroke), or stupor occurred in 3.1 percent; these events were predicted by older age, proximal aortic atherosclerosis, and prior history of neurological disease. Nonspecific impairment in intellectual function occurred in 2.6 percent, and seizures in 0.4 percent. Risk factors for these events were older age, systolic hypertension on admission, pulmonary disease, and excessive alcohol use. Identified cases were limited to those whose clinical record recorded the neurological impairment; it is possible that unrecorded impairment occurred with a substantially higher incidence. Adverse cerebral outcomes

substantially increase hospitalization duration, in-hospital mortality, and the need for discharge to institutional supportive care.

Mild-to-moderate depression occurs in approximately one-third of patients following coronary bypass surgery but may remit within weeks to months. Depressive symptoms are present in almost 40 percent of coronary artery bypass graft patients 6 months after surgery, but the presence of depression in the early postoperative period is not correlated with depression at 6-month follow-up. Depression at this later point is associated with increased mortality at 3-year follow-up. Subtle changes in cognition are frequently associated with depression after coronary bypass surgery. The linkage of cognitive and affective disturbances after this surgery may be attributable to small vessel cerebrovascular changes seen in many elderly persons with depression. Such cerebrovascular pathology may be exacerbated by cardiopulmonary bypass. Trials randomizing patients to coronary artery bypass graft surgery or angioplasty have shown near equivalence in quality-of-life measures over the first 3 years after treatment but greater improvement in daily role function after the former.

Congestive Heart Failure The syndrome of congestive heart failure results from numerous causes of heart disease but represents the most common final common pathway toward disability and mortality. Treatment of heart failure patients usually includes digoxin (Lanoxin), diuretics, and angiotensin-converting enzyme inhibitors or angiotensin antagonists. Heart transplantation and left ventricular assist devices are options in refractory cases. Apart from their evaluation as heart transplant candidates, there has been relatively little study of the psychiatric problems of heart failure patients. Clinically, it appears that adjustment disorders, depression, and anxiety are relatively common problems in this population. Treatment of depression in heart failure patients is discussed below. Disorders of alertness and cognition occur in patients with hypotension, hepatic failure, or renal failure secondary to heart failure. Diagnosis of psychiatric disorders in patients with congestive heart failure requires clinical judgment, as symptoms of heart failure may confound the psychiatric presentation. Dyspnea and orthopnea, for example, may resemble panic, and orthopnea in particular may interfere with sleep. Hopelessness, decreased self-esteem, suicidal ideation, and other cognitive aspects of affective illness are not normally present in heart failure patients and may help to make the distinction.

Heart Transplantation and Left Ventricular Assist Devices Heart transplantation is available for about 2500 patients annually in the United States. It provides approximately 75 percent 5-year survival for patients with severe heart failure, who would otherwise have less than 50 percent 2-year survival. Candidates for heart transplantation typically experience a series of adaptive challenges as they proceed through evaluation, waiting, perioperative management, postoperative recuperation, and long-term adaptation to life with a transplant. These stages of adaptation typically elicit anxiety, depression, elation, and working through of grief. Although quality of life improves in most respects for most patients who undergo heart transplantation, myriad difficulties can occur. Common medical problems of transplant survivors include infections, graft rejection, graft coronary artery disease, lymphoproliferative disorders and other malignancies, cerebrovascular accidents, renal insufficiency, hypertension, and adverse effects of immunosuppressive drugs. Return to work is problematic, and other social role functioning may remain limited even after physical recovery from heart transplant surgery. Family adjustments to shifting patterns of chronic illness and recovery may be chaotic. Sexual dysfunction affects a third or more of male heart transplant recipients. Psychiatric difficulties in heart transplant patients include primary and secondary mood disorders, delirium, addiction to analgesic and anxiolytic agents, and anxiety. Serotonergic antidepressants and nortriptyline (Aventyl) are well tolerated in heart transplant recipients with depression.

LEFT VENTRICULAR ASSIST DEVICES Left ventricular assist devices have been approved as a bridge to heart transplantation and are undergoing clinical trials for long-term treatment of congestive heart failure. These devices consist of a conduit that drains the left ventricle of the heart, connected to a mechanical pump implanted in the abdomen, which in turn drains into a conduit connected to the ascending aorta. The pump is powered by an external power source, such as a battery that can be worn on a vest, permitting the patient to ambulate freely. Patients with left ventricular assist devices may recover from the clinical complications of left ventricular functional impairment, with improved renal, hepatic, cerebral, and peripheral circulation leading to improved exercise tolerance, functional capacity, and general well-being. They are subject, however, to complications such as bleeding, infection, anorexia (presumably related to gastroparesis or reduced gastric filling capacity), and stroke. Depression and organic mental syndromes occur frequently. Prior cerebrovascular disease appears to be a risk factor for psychiatric and neuro-psychiatric complications in patients with left ventricular assist devices. Caregiver burden is substantial for family members of assist device patients when they are discharged from the hospital.

PSYCHOSOCIAL EVALUATION IN TRANSPLANTATION An emerging body of evidence has demonstrated that preoperatively assessed psychosocial variables predict not only psychiatric but also medical outcomes after heart transplantation. Personality disorders, substance abuse disorders, dimensional measures of coping skills and social support, and clinically assessed compliance history have been linked to increased risk of poor postoperative compliance, rejection episodes, and increased mortality. Psychiatric assessment of transplant candidates may identify opportunities for intervention prior to transplantation, with subsequent improvement in outcome. Ethical quandaries are inherent in the role of transplant service psychiatrist, as conflicting ethical agendas present themselves in the course of work with potential transplant patients. Only by systematically explicating the issues can the psychiatrist protect the dialogue with the patient that is the basis of further therapeutics.

CARDIOVASCULAR FACTORS IN PSYCHIATRIC TREATMENTS

Tricyclic agents cause orthostatic hypotension and cardiac conduction disturbances. In combination with diuretics, vasodilators, or benzodiazepines, their effect on blood pressure is exaggerated. In toxic levels they may precipitate ventricular arrhythmias, but at therapeutic doses they exhibit type 1A antiarrhythmic properties, similar to those of quinidine (Duraquin). Studies of type 1 antiarrhythmic therapy for patients with myocardial infarction and ventricular ectopy demonstrated that antiarrhythmic therapy was associated with increased mortality. Consequently, tricyclic agents are no longer recommended as first-line drugs in treatment of depression in patients with ischemic heart disease. Cardiovascular effects of serotonergic antidepressants in patients with impaired left ventricular function, including patients with coronary artery disease and prior myocardial infarction, are lowering of heart rate by two to four beats per minute and increased left ventricular ejection fraction. They have no effect on cardiac conduction, blood pressure, or arrhythmias. Compared with nortriptyline treatment, side effects occur less frequently and result in lower rates of treatment discontinuation in depressed heart disease patients treated with selective serotonin reuptake inhibitors. Buproprion in high doses may be associated with increased blood pressure and ventricular ectopic activity. Trazodone (Desyrel) and nefazodone (Serzone) may be associated with ventricular ectopy and orthostatic hypotension. Venlafaxine (Effexor) therapy in higher dosages is associated with sustained elevations of blood pressure (Table 25.4-1).

Agent	Effects
Tricyclic antidepressants	Orthostatic hypotension Delayed cardiac conduction, heart block Type 1A antiarrhythmic effect Ventricular arrhythmias in overdose Tachycardia
Selective serotonin reuptake inhibitors	Bradycardia (rare) Increased ejection fraction
Monoamine oxidase inhibitors	Hypotension Peripheral edema
Bupropion	Hypertension
Nefazodone, trazodone	Hypotension Premature ventricular contractions
Venlafaxine	Hypertension, especially at high dosage

Table 25.4-1 Cardiovascular Effects of Antidepressants in Patients With Heart Disease

In an open-label study, patients treated with sertraline (Zoloft) for depression following myocardial infarction demonstrated improved mood ratings, a low rate of cardiovascular side effects, and a low rate of withdrawal from treatment because of adverse events. There were no significant hemodynamic effects or effects on cardiac conduction or arrhythmias. A small study of interpersonal psychotherapy for depressed patients after myocardial infarction also demonstrated improvement in mood.

Drug Interactions and the Cytochrome System Drug-drug interactions mediated by the hepatic cytochrome P450 system are of theoretical importance, although few of these interactions have been proven to be clinically significant. Some potential interactions are listed on Table 25.4-2. Of clinical note, serotonergic antidepressants may prolong bleeding in occasional patients via an effect on platelets; they do not have a systematic effect on coagulation as measured by the Protime test even in patients treated with warfarin (Coumadin). Although fluoxetine (Prozac) inhibits the cytochrome P450 (CYP) isoenzyme CYP 3A4, which metabolizes cyclosporine, studies have indicated no significant effect on cyclosporine concentrations in heart and renal transplant patients. One study suggests that cyclosporine concentrations may increase during nortriptyline treatment, although nortriptyline is not regarded as an inhibitor of this enzyme system. Clinically significant bradycardia has been reported very rarely in patients treated with serotonergic agents along with b-adrenergic receptor antagonism. Lithium levels may be

raised by the use of diuretics affecting the proximal renal tubule (thiazides) and by angiotensin-converting enzyme inhibitors.

P450 Isoenzyme	Metabolizes	Inhibited by
CYP 2D6	Propranolol Timolol Metoprolol Encainide Mexiletine Flecainide Fluoxetine Paroxetine Tricyclic antidepressants Venlafaxine	Fluoxetine Paroxetine Sertraline (weak)
CYP 1A2	Amitriptyline Imipramine Propranolol	Fluvoxamine
CYP 3A4	Lidocaine Quinidine Nefazodone Sertraline Venlafaxine Alprazolam Diltiazem Nifedipine Verapamil Cyclosporine	Fluoxetine Fluvoxamine Nefazodone Sertraline
CYP 2C19	Citalopram Clomipramine Diazepam Imipramine Propranolol	Fluoxetine Sertraline

Table 25.4-2 Selected P450 System-Related Potential Psychiatric and Cardiovascular Drug Interactions

Electroconvulsive Therapy in Patients With Cardiovascular Disease Electroconvulsive therapy (ECT) is a highly effective treatment for severe depressive and manic episodes. During ECT, heart rate and blood pressure increase substantially, followed by a vagally mediated bradycardia. Patients with ischemic heart disease or ventricular arrhythmias are at increased risk of myocardial infarction or ventricular tachyarrhythmias. Atropine is commonly used to reduce airway secretions during ECT and may reduce the extent of bradycardia, but it may exacerbate the tachyarrhythmia associated with the ECT stimulus. b-Adrenergic receptor antagonists, conversely, may precipitate heart block during ECT. Few studies have systematically controlled concurrent treatment and cardiac diagnoses in assessing effects of ECT in cardiac patients, but available information suggests that patients with cardiac disease are more likely to experience cardiovascular complications during ECT than comparison patients without heart disease. Most complications are transient, however, and do not necessarily preclude use of this modality. In patients with preexisting heart disease ECT-related arrhythmias can be reduced and almost eliminated by pretreatment with b-adrenergic receptor antagonists such as labetalol (Normadyne).

CARDIOVASCULAR PRESENTATIONS OF PSYCHIATRIC DISORDERS: CHEST PAIN, ARRHYTHMIA, PALPITATIONS

Somatization disorder, panic disorder, anxiety, and depression can all present with somatic complaints and represent a substantial issue in ambulatory and emergency cardiology practice. In studies of patients presenting with the chief complaint of palpitations, these diagnoses account for about 30 percent of cases. In this population, psychiatric disorder is associated with more frequent recurrent symptoms, emergency room visits, hypochondriacal concerns, and impairment in activities of daily living.

SUGGESTED CROSS-REFERENCES

Section 14.6, Section 14.7, and Section 14.9 contain further information on depression and its treatment, and Chapter 15 and Chapter 16 provide reviews of panic disorder and somatoform disorders. Chapter 10 provides useful information on neurophysiology, diagnosis, and management of delirium and cognitive disorders. Section 25.3 on obesity and Section 25.9 on stress provide information related to primary and secondary prevention efforts in cardiac disease. The clinical approach to the patient and the general hospital setting in which many of these contacts occur is discussed in Section 25.12. General issues pertaining to the experience of surgery and of serious general medical illness are discussed in Sections 28.1 on surgery and Section 28.5 on death, dying, and bereavement.

25.5 RESPIRATORY DISORDERS

MICHAEL G. MORAN, M.D.

Although usually unconscious and autonomous, breathing is intimately embedded in the psychic experience of human beings. Psychological distress commonly expresses itself in alterations of breathing, such as tachypnea during anxiety or panic. Conversely, disordered or impaired breathing quickly disrupts a person's sense of calm and even survival (e.g., the distress of any pulmonary patient who is acutely hypoxemic). Respiratory disease is likely to become a more prevalent problem for physicians caring for any patient population as the smoking habits of an older population begin to take their toll in the form of chronic obstructive pulmonary disease. In addition, the prevalence of marijuana smoking among younger persons may adversely interact with other pulmonary conditions, such as asthma.

The interaction of psychic and somatic influences becomes more complex when the etiology and maintenance of symptoms of pulmonary disorders is taken into consideration. For example, self-destructive or depressive feelings may generate or give momentum to a smoking habit, which could eventually result in chronic obstructive pulmonary disease.

The psychiatrist may be asked to evaluate pulmonary patients as to (1) the possible psychiatric origins of pulmonary symptoms, (2) the issues impeding compliance with a medical regimen, (3) the emotional distress arising from loss of function due to the pulmonary illness, and (4) psychiatric issues, such as delirium, caused by the treatment of the pulmonary condition.

ASTHMA

Diagnosis and Pathophysiology Asthma is a chronic and episodic illness, characterized by widespread narrowing of the tracheobronchial tree. Symptoms include coughing, wheezing, chest tightness, and dyspnea. Nocturnal symptoms and exacerbations are common. During an episode, nonspecific irritants such as perfume and smoke may trigger a worsening of the symptoms. Some patients may also have sinusitis and aspirin sensitivity. Diagnosis requires confirmation of reversible airway obstruction, usually established by spirometry. Pulmonary function tests demonstrate reduced maximal forced expiratory flows, with elevated residual volumes or functional residual capacity, or both. Irreversible changes in the lung are unlikely to occur.

The pathophysiology of airway inflammation in asthma has not been fully specified. Cells that may participate in the process include mast cells, macrophages, eosinophils, and activated T helper cells. These and other cells interact in a complex manner that results in the production of numerous chemical mediators. Neural influences may amplify the resulting intense local inflammatory process. Vascular permeability, smooth muscle contraction, mucosal edema, and mucus production result.

Prevalence, Morbidity, and Mortality Asthma is a common illness, affecting up to 5 percent of Americans. Onset may occur in infancy or early childhood and remissions during the teenage years are common. The mortality rate from asthma is reported to have increased, but at least one carefully constructed study suggests that morbidity, not mortality, is on the rise. Coexisting chronic obstructive pulmonary disease, usually caused by smoking, significantly reduces survival among patients with asthma. Factors contributing to the increase in morbidity include inappropriate use of b_2 adrenergic receptor agonists, underestimation of illness severity by the patient or physician, socioeconomic impediments to medical care access, and psychiatric factors.

Asthma as a Psychosomatic Illness The definition of *psychosomatic illness* has evolved considerably over the past 50 years. In the 1940s, Franz Alexander and others worked with patients who had medical illnesses they considered psychic in origin. Asthma was one of a group of the “Holy Seven” illnesses (i.e., peptic ulcer, asthma, ulcerative colitis, rheumatoid arthritis, hypertension, neurodermatitis, and hyperthyroidism) thought to be psychosomatic. The wheezing and bronchial secretions of the asthma patient were interpreted as a suppressed cry for the mother. Although Alexander took a predominantly psychoanalytic approach, he understood the intricacies of what is now called a biopsychosocial matrix. His long-term research projects on asthma and six other illnesses opened the door to the study of psychosomatic disorders and helped to solidify the significance of psychiatry's relationship to the rest of medicine. Alexander's work led to certain developments by some of his followers, and to what may now be considered a radicalization of treatment for these conditions, sometimes involving only psychotherapy or psychoanalysis. Poor outcomes and an expanded understanding of the physiology of asthma and the other six illnesses subsequently produced a backlash: a radical dismissal and underestimation of psychiatric contributions to symptoms and morbidity. Current formulations of the pathogenesis and maintenance of asthma embrace subtle interactions between organic and psychiatric elements.

Psychiatric Aspects of Asthma Research suggests that psychiatric forces may affect the clinical expression of asthma in several ways: altered awareness of airway resistance, suggestibility to airway constriction, and comorbidity with panic disorder and depression.

Suggestibility and Airway Awareness The assumption that suggestibility to airway constriction confirms the presence of psychopathology or psychosomatic vulnerability is weak but pervasive. Suggestible patients are more likely to be anxious and to feel physically vulnerable than nonsuggestible patients, but their actual comparative risk for more asthma episodes or symptoms as a result of stressful life events is unknown.

Perception of changes in airway resistance appears to be an important event in asthma self-care. The patient's timely reports of dyspnea can also help to initiate an appropriate medical response. From patient to patient there is considerable variability in reported breathlessness for a given degree of experimentally induced airway obstruction. Up to 15 percent are unable to detect even marked changes in airway resistance. However, in an individual patient, increasing breathlessness usually correlates closely with decreased forced expiratory volume (FEV) in 1 second (FEV_1). Patients with labile airways (over 50 percent variability in FEV_1 in a day) have an especially limited perception of increases in airway resistance, as do the elderly. Some research suggests that poor ability to perceive airway changes predicts a worse course for the illness; other reports show no difference in this ability between severely ill and less ill patients.

The respiratory response to hypoxemia is mediated by the carotid body. Some asthma patients have an impaired response that is probably an inherited defect of that structure; these individuals perceive dyspnea poorly and are at increased risk for fatal asthma.

Anxiety and Panic Disorder Coexisting anxiety or panic disorder probably worsens the course of asthma, and the prevalence of panic disorder and agoraphobia among asthma patients is higher than in the general population. Up to 30 percent of persons with asthma meet the criteria for panic disorder or agoraphobia. Panic disorder appears to be underrecognized in asthma patients, and its symptoms may be misunderstood by both the patient and physician as arising from an exacerbation of asthma. Hyperventilation, a common symptom of both anxiety and panic disorder, may trigger an exacerbation of a pulmonary illness. The mechanism may be via brainstem overreactivity to low arterial carbon dioxide (CO_2) levels. Lactate infusion tests, breathing elevated levels of carbon dioxide, and voluntary hyperventilation have been shown experimentally to induce panic attacks in individuals with panic disorder. Voluntary hyperventilation may be the most specific test and lactate infusion the most sensitive.

Medullary brainstem centers are connected to the hippocampus, which receives data from a number of sensory modes, and the parahippocampus, which may be abnormal in panic disorder patients. Incoming body sensory data, including chest wall and intratracheal air movement, together with abnormal brainstem sensitivity to elevated partial pressure of carbon dioxide (Pco_2) or elevated serum lactate, may provoke the panic response and hyperventilation. The final pathway appears to be through the locus coeruleus, which fires in response to hypercapnia, and may be a controlling site for the intense autonomic outflow of panic attacks.

Repeated experience with severe dyspnea or near-suffocation provides little in the way of cognitive or emotional protection for future episodes. Such events often seem only to traumatize patients, and may lead to the development of anxiety disorders or panic disorders. Cohorts of panic disorder patients are more likely than

patients with other anxiety disorders to have an antecedent history of lung disease.

Patients with both asthma and panic disorder seem to have greater anticipatory anxiety about both dyspnea and anxiety itself than patients who are not comorbid. The fear of dyspnea may directly trigger asthma attacks. An extremely high level of anxiety predicts increased rates of hospitalization and asthma-associated mortality. Certain personality traits in asthma patients appear to be associated with greater use of corticosteroids and bronchodilators, as well as longer hospitalizations than would be predicted from pulmonary function alone. Such traits include intense fear, emotional lability, sensitivity to rejection, and lack of persistence in difficult situations.

If a patient attributes symptoms of panic to asthma, the use of antianxiety medications such as corticosteroids, b_2 adrenergic receptor agonists, and theophylline (Theo-Dur) may worsen the panic disorder. Careful use of peak flow meters during periods of dyspnea and a diary correlating peak flow rates with experiences of breathlessness can help patients to determine the origin of their symptoms.

Depression and the High-Risk Asthma Patient Many researchers suggest that depression has a meaningful and negative effect on the course of asthma. Shame and low self-esteem, common symptoms of depression, are seen in many chronically ill patients and are risk factors for a severe course. Patients who feel they are worth little tend to manage their asthma poorly, and compliance with a medication regimen may suffer. The sleep disturbances of depression could adversely affect self-care, as could the concentration and attention deficits of the mood disorder. Sleep deprivation may reduce a patient's proprioceptive capacity to detect changes in airway resistance and can erode daytime cognitive performance. In a severely depressed patient unconscious suicidal wishes may find expression in self-neglect. In addition to these behavioral manifestations, the hypothetical parasympathetic dominance of depression could contribute to airway reactivity and constriction.

Although there is no asthma-prone personality, psychopathology of the level of personality disorders raises the risk for near-fatal episodes. High levels of aggression, denial of or disregard for asthma symptoms, and psychotic signs are associated with poor outcome or fatal episodes.

Asthma deaths occur by one of two courses: gradual deterioration and abrupt onset, with the gradual course being more common. Typically, the patient and the physician underestimate the severity of the episode and are not aggressive enough in their approach. b_2 adrenergic receptor agonist inhalants may actually provide an illusion of reduced bronchoconstriction, which gives the patient false assurance; progressive airflow obstruction in these instances is detectable only by peak flow measurements. The abrupt decline is less common and the mechanism less understood. The immunohistology differs from that in patients with a gradual course, and eosinophils are less plentiful in the airways.

Certain demographic characteristics have a clear association with greater risk for death from asthma. Minority group status, once thought to be a risk factor, is now believed to be a surrogate marker for poverty. With low socioeconomic position comes poor access to high-quality health care, indigent housing with high levels of dust-mite and cockroach antigens, low levels of social support, and low educational status.

Family members of patients with severe asthma tend to have higher than predicted prevalence rates of mood disorders, posttraumatic stress disorder, substance use, and antisocial personality disorder. How these conditions contribute to the genesis or maintenance of asthma in an individual patient is unknown. The familial and current social environment may interact with a genetic predisposition for asthma to influence the timing and severity of the clinical picture. The interaction between family psychopathology and the clinical course of asthma may be especially insidious in adolescents. In turn, the adolescent's developmental need for and fear of emotional separation from the family often becomes entangled in battles over medication adherence as well as other modes of diligent self-care.

Vocal Cord Dysfunction This syndrome of abnormal vocal cord movement may imitate asthma and lead to misdiagnosis. Patients may present a history of years of refractory asthma with intubations, corticosteroid treatment, even immunomodulator use or tracheostomy. Diagnosis is very difficult on physical examination because the abnormal vocal cord movement can produces laryngeal sounds that resemble wheezing (over the chest) or stridor (over the larynx). Laryngoscopy is usually necessary to make the diagnosis. Adduction of the anterior two-thirds of the cords is the classic finding.

The psychiatrist may be asked to see the patient with vocal cord dysfunction for several reasons. The change in diagnosis to vocal cord dysfunction from asthma may be disorienting, and regret and anger about past unnecessary treatment can ensue. Some patients with vocal cord dysfunction may have a comorbid psychiatric diagnosis and traumatic childhood history that contributes to the appearance or maintenance of the symptoms, and interferes with their care.

Adverse Effects of Drugs Many of the oral and inhaled medications for treating asthma produce varying degrees of alertness, stimulation, tremor of the extremities, agitation, and sleep disruption. Both physician and patient may misinterpret these symptoms and signs as an anxiety disorder that requires separate treatment, often with a benzodiazepine. The physician must try to separate drug effects from the signs and symptoms of a new anxiety disorder. Adjustment of the dose and timing of administration of the offending pulmonary medication can often address the patient's complaints adequately.

Oral corticosteroids produce varying degrees of memory disturbance, sleep disturbance, emotional lability, depression, and hypomania or mania. Most patients experience some kind of dysphoria, a few feel energized. These effects tend to be dose-dependent, and usually present few problems at doses lower than the equivalent of 30 mg of prednisone (Deltasone) per day; however, even at these dosages, patients report problems with sleep continuity and irritability.

Treatment The psychiatrist should address (1) psychiatric factors contributing to the severity of asthma, (2) family system problems, and (3) drug adverse effects and interactions. There are other important considerations, such as countertransference problems among staff and physicians treating chronically ill patients.

If an accurate diagnosis of panic disorder, other anxiety disorder, or depressive disorder is made, medication may be indicated. Benzodiazepines are usually not needed for anxiety disorder or panic disorder but may be indicated for short-term use while beginning an antidepressant agent. These medications are generally acceptable for most asthma patients, as Pco_2 levels tend to be normal unless the patient is in overt respiratory failure. Despite mild stimulating effects, many patients tolerate conventional doses of selective serotonin reuptake inhibitors. Nortriptyline (Pamelor) is a good alternative drug. Monoamine oxidase inhibitors should be avoided because of potentially catastrophic interactions with other asthma drugs that have direct and indirect sympathomimetic activity. Cognitive-behavioral psychotherapy or stress reduction practices such as meditation and yoga are useful for many patients. Psychodynamic psychotherapy is recommended as a component for complete therapy of depression. Family system interventions, such as education and multifamily groups, can help to identify members who need special support and treatment.

Although offending medications such as corticosteroids can sometimes be stopped or reduced, the psychiatrist may need to plan the treatment of any syndrome resulting from the adverse effects of medication without making such adjustments. Mood disorders should be treated as in other situations. The chief difference in treating such syndromes in the medically ill patient resides in the need for vigilance for delirium or other cognitive disorders, and for drug-drug interactions. Patients with asthma and other medical illnesses have an increased vulnerability to infection and metabolic disturbances and are usually on several other medications. As a result, there may be a lowered threshold for adverse events, such as delirium from anticholinergic effects from an added tricyclic antidepressant medication. The psychiatrist should start at lower doses and proceed with close follow-up for dosage adjustment.

A 32-year-old respiratory therapist with a history of asthma presented to the emergency room with severe dyspnea of several hours' duration. She had been working “doubles” in her hospital for the preceding 3 weeks and was fatigued and sleep deprived. She noticed a sudden increase in her wheezing earlier in the day, and had been unable to control symptoms with her usual regimen of inhaled bronchodilators. On examination, she was found to be anxious and depressed: she had recently broken up with a boyfriend. After the patient achieved stabilization with nebulized bronchodilators, a psychiatrist was asked to see her before she left the emergency room. During that interview conscious feelings of rage and sadness were noted and interpreted in connection with the breakup. The psychiatrist also noted upper airway stridor when the patient cried, and recommended that she have a laryngoscopic examination. This was accomplished, and a coincident diagnosis of vocal cord dysfunction was made. For her asthma the patient was placed on a regimen of inhaled steroids, and was asked to keep careful daily records of peak expiratory flows. She was referred to a speech therapist for the vocal cord dysfunction. The psychiatrist recommended outpatient psychotherapy and nortriptyline for her mood symptoms.

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Diagnosis and Pathophysiology Chronic obstructive pulmonary disease refers to a spectrum of disorders that are characterized by three pathophysiological aspects. The bronchial component is manifested as chronic bronchitis with chronic cough and sputum production. The second component is the acinar enlargement of emphysema, and is associated with smoking or $alpha_1$-antitrypsin deficiency. The third component is inflammation, which produces fibrosis and narrowing of the

airways, thought to be important in the production of airway resistance and airflow obstruction.

Clinicians usually recognize two forms of the disease: chronic bronchitis and emphysema. The former classically presents with CO_2 retention, hypoxemia, bronchial symptoms, dyspnea on exertion, and a history of recurrent bouts of acute bronchitis (“the blue bloater”). The latter form typically manifests severe hypoxemia, very little CO_2 retention, dyspnea on exertion, asthenic habitus, and severe air trapping with large residual volumes (“the pink puffer”).

Smoking is recognized as the single greatest risk factor and most important cause of chronic obstructive pulmonary disease. Other environmental elements may serve a modifying role, including air pollutants, childhood respiratory infections, the level of bronchial hyperresponsiveness, and constitutional and genetic factors other than $alpha_1$-antitrypsin deficiency.

Prevalence, Morbidity, and Mortality Chronic obstructive pulmonary disease affects more than 16 million Americans. The rate of cigarette use is in the decline among the population at large, but is rising among teenagers and predicts a large cohort of future patients with chronic obstructive pulmonary disease. Morbidity of the disease appears in the forms of lost time at work, decreased capacity for joyful exercise and exertion, early medical retirement, and recurrent episodes of respiratory deterioration leading to hospitalization. Mortality rates are increasing, especially among women. Chronic obstructive pulmonary disease is now the fifth leading cause of death in this country.

Measurement of FEV_1 is the standard for assessment of clinical course and response to therapeutic interventions, and provides data for predicting prognosis and mortality.

Psychiatric Aspects Psychiatric issues affect many facets of the course of chronic obstructive pulmonary disease from etiology to ongoing symptoms and the appearance of related respiratory syndromes, as well as psychiatric comorbidity and its effects on rehabilitation.

Smoking Emotional and social factors probably influence many persons to begin or continue cigarette smoking, which is a major element in the etiology of the disease. Education is notoriously weak as an isolated antismoking intervention, but probably serves as a positive influence on vacillating ambivalent smokers. Several researchers have shown that depression among smokers is associated with low rates of successful cessation, suggesting the possible utility of a concerted effort to diagnose and treat depression in this group of patients.

The older patient with chronic obstructive pulmonary disease commonly resists counseling to stop smoking by countering that there will be no benefit: “It doesn't matter now.” Some of these patients will respond to education about the significance of ongoing irritant effects of smoke and the effects of carbon monoxide on oxygen-carrying capacity and thus on exercise tolerance. In making the case for cessation, attempts should be made to appeal to aspects of the self or health that are important to that individual: personal attractiveness smoking increases facial wrinkling, affects the smell of the breath and clothes); exercise capacity (smoking reduces endurance by several mechanisms); independence (continued disease progress will erode autonomy through loss of function); longevity and ability to enjoy children and grandchildren (increased morbidity and mortality).

Panic Disorder, Anxiety Disorders, and Drug Effects As for asthma, prevalence rates for both panic disorder and anxiety disorders are increased among patients with chronic obstructive pulmonary disease. Anxiety disorders occur at rates of 16 to 34 percent, above the rate for the general population of 15 percent. Panic disorder prevalence rates among chronic pulmonary obstructive disease patients range from 8 to 24 percent, higher than the general prevalence of 1.5 percent.

Patients with chronic obstructive pulmonary disease can benefit from the use of inhaled sympathomimetic agents, but two points deserve emphasis. First, use of high doses can produce hypokalemia. Second, inadequate bronchodilatation with inhaled agents may lead to the use of oral b_2 adrenergic receptor agonists, which have a high incidence of adverse effects, including tremor, anxiety, and interference with sleep.

Anticholinergic drugs such as atropine and ipratropium (Atrovent) reduce the volume of sputum without changing viscosity, and induce beneficial bronchodilatation. There is limited absorption of these inhaled drugs, thus there is little concern for central nervous system effects.

The role of theophylline and related medications in chronic obstructive pulmonary disease is controversial. Since its use continues, psychiatrists must be aware of the stimulating adverse effects and the resulting tremor, nervousness, and sleep disruptions. Long-acting preparations and careful timing of the dose can help reduce effects on sleep. Any of the oral bronchodilators can cause psychiatric symptoms, but extended-release albuterol (Ventolin) is probably the biggest offender in terms of sleep disruption, agitation, and anxiety. Avoidance of this medication may be particularly important among elderly patients who are prone to delirium.

Corticosteroid use is also controversial in patients who have chronic obstructive pulmonary disease. Some small fraction of patients who have coincident asthma or a significant bronchospastic component to their disease exacerbations may benefit from either short-term or long-term courses of corticosteroid treatment. For some of these patients, alternate-day oral administration and inhaled steroid use may be useful. Both these measures reduce blood and brain concentrations of the steroid, and thus the likelihood of psychiatric adverse effects, including mood alteration, cognitive disturbances, delirium, and sleep disorders.

Nighttime symptoms in the patient with chronic obstructive pulmonary disease deserve special attention. Reports of choking or erratic breathing, heavy snoring, or abrupt awakenings due to dyspnea should suggest the diagnosis of obstructive sleep apnea. The patient may report none of these symptoms, as the awakenings that occur are usually not enough to register in memory. Daytime somnolence, depressed mood, and cognitive disturbances are the more likely complaints, but the patient may not mention these and the psychiatrist must solicit them. Nocturnal polysomnography is usually necessary to make the diagnosis because it permits adequate documentation of the number and severity of apneic episodes.

Rehabilitation The care of many patients with chronic obstructive pulmonary disease remains suboptimal, largely because of reversible factors. Many physicians do not intervene early enough in the disease, consider it only irreversible, avoid attending to comorbid depression and anxiety, and believe that rehabilitation is only an in-hospital treatment that most patients do not need.

Exercise conditioning is an essential aspect of rehabilitation, and should include upper-extremity and respiratory muscle training. Malnutrition may affect between 25 and 50 percent of patients with chronic obstructive pulmonary disease. These and other measures improve mood and sense of well-being even among patients whose objective measures of pulmonary function do not change in an extended rehabilitation program.

Mood appears to influence exercise tolerance and activity level. Patients with depressed mood or poor self-esteem have less exercise tolerance for a given level of pulmonary function. The effect of pulmonary function on mood is less clear. For one group of patients not yet on supplemental oxygen, level of pulmonary symptoms directly influenced mood and level of function. In another study of a group with severe airflow impairment, functions such as self-care, eating, and ambulating were affected but mood was not. These data suggest a resilience of mood over time to the effects of functional loss.

Treatment The psychiatrist should (1) diagnose and treat comorbid psychiatric disorders, (2) be alert to drug adverse effects and give advice regarding their dosing and timing, and (3) maintain a high index of suspicion for treatable coexisting sleep disorders.

Treatment of comorbid psychiatric disorders can help with day-to-day functioning as well as promote the best results from rehabilitation programs and ongoing rehabilitation efforts. Antidepressant medications are the best choice for anxiety and panic. Benzodiazepines are problematic, chiefly for chronic bronchitic retainers of CO_2. Levels of CO_2 as low as 44 mg Hg have been associated with ventilatory suppression by these medications. Amelioration of depression with psychotherapy and an antidepressant agent can improve quality of life, interpersonal relationships (and thus family support), and overall physical comfort.

In a patient who is chronically ill with chronic obstructive pulmonary disease daytime symptoms of fatigue, depression, and even somnolence will sometimes be dismissed as to be expected and result in no further investigation. Patients will usually not present symptoms of sleep disturbances as such in obstructive sleep apnea, so the psychiatrist must be vigilant about these symptoms in this context and must help make appropriate referrals to a sleep laboratory.

A 61-year-old man, a former cigarette smoker with chronic obstructive pulmonary disease with chronic elevation of Pco_2 presented to the pulmonary clinic with chronic fatigue and an acute exacerbation of his dyspnea. He was on 24-hour oxygen supplementation by nasal cannula. Evaluation revealed an overweight man with normal vital signs, no change in his FEV_1, and a chest X-ray that was unchanged from previous studies. His pulmonologist referred him for psychiatric evaluation because no organic cause could be found for the dyspnea. The psychiatrist found the man to be slightly confused, with some mild changes in short-term memory; the patient had a history of occasional use of alprazolam (Xanax) for anxiety. The patient said that when anxious, he would also sometimes increase his oxygen flow rate above what was recommended by his pulmonologist. Arterial blood gases evaluations were ordered. The psychiatrist obtained a history of severe snoring, occasional awakenings with panic, and chronic daytime somnolence. To rule out obstructive sleep apnea, the psychiatrist recommended a sleep study and recommended cessation of the benzodiazepine, to which the patient may have been very sensitive because of his chronic Pco_2 elevation. The benzodiazepine may also have worsened the sleep apnea and contributed to a mild daytime delirium. The blood gases obtained at that visit revealed an acute deterioration with greater than usual elevations of Pco_2 and slightly worse hypoxemia. The psychiatrist recommended careful adherence to prescribed flow rates of oxygen to avoid “oxygen toxicity” and suppression of hypercapneic ventilatory drive, another possible source of the delirium. For the panic and anxiety the psychiatrist prescribed paroxetine (Paxil).

SUGGESTED CROSS-REFERENCES

Many psychiatric diagnoses have a respiratory component. Section 11.4 discusses caffeine-related disorders, Section 11.9 nicotine-related disorders, and Section 11.5 cannabis-related disorders. Chapter 15 discusses anxiety disorders, and Chapter 21 discusses sleep disorders (including sleep apnea). Somatoform disorders are discussed in Chapter 16, and stress and psychiatry is covered in Section 25.9.

25.6 ENDOCRINE AND METABOLIC DISORDERS

VICTORIA C. HENDRICK, M.D., AND THOMAS R. GARRICK, M.D.

Endocrine disorders may produce symptoms that are indistinguishable from psychiatric illnesses. While physical manifestations of endocrine disease provide clues to the diagnosis, they are not always present. The effect of endocrinopathies on psychiatric symptomatology has been studied particularly for disorders of the thyroid and adrenal glands. Less is known about psychiatric sequelae of other endocrine disorders such as acromegaly, diabetes mellitus, prolactin-secreting tumors, and hyperparathyroidism. While several hormones directly influence neurotransmitter function (e.g., thyroid hormones and corticosteroids affect b-adrenergic receptor binding and density), biogenic amines have a reciprocal role, influencing hormone synthesis and release. However, little research has been done on the effect of psychiatric or psychological factors on endocrine disease. Stressful life events have been postulated to play a role in the onset of Graves' and Cushing's diseases, but studies have been limited by methodological deficiencies, including retrospective designs and absence of control groups.

GENERAL PRINCIPLES

Endocrinology is the study of hormones, or chemical mediators, that travel from their site of production to influence the function of other tissues. They exist as peptides, steroids, or amines. Endocrinopathies result from excessive or deficient amounts of a hormone or from resistance to a hormone's action (e.g., when target tissues do not respond to normal levels of the hormone. These latter cases are primarily hereditary and are characterized by normal or elevated concentrations of a hormone despite an absence or deficiency of the hormone's action. Increased concentrations result from the lack of normal negative feedback on the hormone's production, a consequence of the failure or deficiency of the hormone's action.

Hormone production is regulated largely by the concentrations and activity of the hormones themselves and additionally by hormones from other sites. For example, hypothalamic releasing factors regulate the production of pituitary hormones. The pituitary gland, situated in the sella turcica at the base of the skull, is divided into the anterior and posterior lobes. The anterior pituitary produces six hormones: thyroid-stimulating hormone (TSH), which regulates the production of thyroid hormones; growth hormone (GH), which promotes growth and development; prolactin, which stimulates lactation; luteinizing hormone (LH) and follicle-stimulating hormone (FSH), which are necessary for gonadal function in men and women; and adrenocorticotropic hormone (ACTH), which controls adrenal cortex production of glucocorticoids. The posterior pituitary stores two hormones: antidiuretic hormone (arginine vasopressin [AVP]), which regulates fluid balance, and oxytocin, which is necessary for milk letdown during breast feeding. Both are produced by the hypothalamus. The hypothalamus additionally produces releasing factors that influence pituitary hormone production: growth hormone–releasing hormone (GHRH) and growth hormone–release-inhibiting factor (i.e., somatostatin), which influence production of GH; gonadotropin-releasing hormone (GnRH), which influences production of LH and FSH; prolactin-release-inhibiting factor (i.e., dopamine), and prolactin-releasing factor (PRF), influencing prolactin production; and thyrotropin-releasing hormone (TRH) and corticotropin-releasing hormone (CRH), which influence TSH and ACTH release, respectively.

In addition to the hypothalamus and the pituitary, the major endocrine organs include the adrenal, thyroid, and parathyroid glands and the ovaries and testes. Endocrinopathies may produce a variety of psychiatric symptoms, as hormones affect a variety of organ systems. Patients are more likely to present primarily with psychiatric symptoms early in the course of endocrine disease and to experience a worsening of the psychiatric condition and emergence of physical symptoms with the progression of the disorder.

Endocrine disorders are common medical conditions, particularly in elderly adults. Thus, especially in this population, an evaluation for endocrine function is an essential part of the initial diagnostic workup. To identify potential endocrine etiologies, a laboratory evaluation should include serum electrolytes, fasting blood sugar, TSH, and calcium determinations. Psychiatric symptoms will not resolve until the underlying endocrine disturbance is corrected and may worsen with psychotropic agents. Psychiatric disorders that appear to result from an endocrine condition are categorized in the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) under mental disorders due to a general medical condition, with the medical condition stated on Axis III.

THYROID DISORDERS

The thyroid hormones, triiodothyronine (T_3) and thyroxine (T_4), are produced from the thyroid gland and are necessary for regulation of metabolic activity and protein synthesis. They are formed from a common precursor, thyroglobulin, stored in the thyroid follicles. In extrathyroidal tissues, T_4 is converted to T_3, the metabolically active hormone. TSH produced by the anterior pituitary, promotes the synthesis and release of these hormones and is in turn regulated by TRH, produced in the hypothalamus. Low serum concentrations of thyroid hormones stimulate release of TRH and TSH. The central nervous systems (CNS) neurotransmitter dopamine decreases TSH secretion, as do glucocorticoids.

T_3 and T_4 are tightly protein bound to thyroxine-binding globulin (TBG), so that only 0.3 percent of T_3 and 0.02 percent of T_4 are free. Total serum T_4 concentrations vary with TBG concentrations; for example, exposure to estrogens (pregnancy and oral contraceptives) raises TBG and therefore serum T_4 concentration, while androgens have the opposite effect. Free thyroxine concentration (FT_4I), which measures the percentage of free T_4, produces a more accurate determination of thyroid function. FT_4I is elevated in hyperthyroid patients and low in hypothyroid patients and is thus an essential test in the assessment of thyroid status. Measures of TSH concentrations are also necessary in the workup of thyroid disorders. Concentrations are elevated in thyroidal hypothyroidism and usually low in pituitary-hypothalamic hypothyroidism. The normal concentration range of TSH is 0.3 to 4.7 mIU/L. FT_4I and free T_3 index (FT_3I) range from 5 to 11 and 75 to 175, respectively.

The TRH stimulation test (TRH infusion test) is sometimes used in the workup of thyroid function. After the patient's baseline TSH concentration is obtained, TRH is administered intravenously and TSH concentrations are then measured at regular intervals. A normal response is a rise in TSH of 5 µU/mL or more above baseline. In hypothyroid patients the response is exaggerated; in hyperthyroid patients it is blunted. With the development in the past decade of highly sensitive TSH testing, the TRH stimulation test is seldom used clinically. Its use as a diagnostic tool in the psychiatric assessment of depression has similarly waned, as its specificity and sensitivity are poor. For example, while some patients with depression display an increased TSH concentration following TRH infusion, others have a blunted response. Tests of radioactive iodine uptake are used to determine the activity of the thyroid gland. A patient receives a small amount of oral radioactive iodine and a scan then determines the amount taken up by the thyroid gland.

Disorders of the thyroid gland fall into two general categories: hyperthyroidism and hypothyroidism. Of all the endocrine disorders, disorders of the thyroid are the most common.

Hyperthyroidism

Definition and Comparative Nosology Hyperthyroidism, or thyrotoxicosis, results from overproduction of thyroid hormone by the thyroid gland. The most common cause is Graves' disease. Toxic nodular goiter causes another 10 percent of cases among middle-aged and elderly patients. Other causes include hyperfunctioning solitary thyroid adenomas, thyroiditis, use of exogenous thyroid hormone, TSH-producing pituitary adenoma, pituitary resistance of suppression of TSH secretion by thyroid hormone, thyroid carcinoma, choriocarcinoma, hydatiform moles, and struma ovarii.

Subclinical hyperthyroidism describes a condition in which circulating thyroid hormone concentrations are normal but the TSH response to TRH is blunted or absent. Patients may experience symptoms of hyperthyroidism such as nervousness, irritability, fatigue, and tachycardia. Subclinical hyperthyroidism may progress to overt hyperthyroidism.

Thyroid storm (thyrotoxic crisis), a life-threatening syndrome, is usually precipitated by illness or injury but may also develop following withdrawal of antithyroid drugs or following therapy with radioactive iodine. Symptoms include marked tachycardia, weakness, fever, and altered mental status.

Epidemiology In the general population, the prevalence of hyperthyroidism is about 0.5 percent. Graves' disease is the most common cause, accounting for 80 percent of cases. Graves' disease occurs four times more frequently in women than men and occurs primarily in the third and fourth decades. The prevalence of thyroiditis is estimated to be 5 to 9 percent in women in the postpartum period, usually resolving spontaneously by 1 year following delivery.

Etiology Patients with Graves' disease produce thyroid-stimulating antibodies and frequently have a family history of other autoimmune disorders such as systemic lupus erythematosus and myasthenia gravis. Hyperthyroidism from toxic nodular goiter results from the lack of response of thyroid nodules to normal feedback regulation. In the case of thyroiditis, hyperthyroidism results from inflammation-induced damage to the thyroid gland, which then spills the stored colloidal thyroid hormones.

Diagnosis and Clinical Features Signs and symptoms of hyperthyroidism include increased pulse, arrhythmias, elevated blood pressure, fine tremor, heat intolerance, excessive sweating, increased appetite, weight loss, palpitations, tachycardia, frequent bowel movements, menstrual irregularities, muscle weakness from catabolism of muscle protein, exophthalmos, lid lag, infrequent blinking, and hyperactive deep tendon reflexes. The patient with thyroiditis may experience pain and tenderness in the thyroid region.

Psychiatric features include nervousness, fatigue, insomnia, mood lability, and dysphoria. Speech may be pressured, and patients may demonstrate a heightened activity level. Cognitive symptoms include a short attention span, impaired recent memory, and an exaggerated startle response. Patients with severe cases may exhibit visual hallucinations, paranoid ideation, and delirium. While some symptoms of hyperthyroidism resemble those of a manic episode, an association between hyperthyroidism and mania has rarely been observed. A patient with Grave's disease (also called exophthalmic goiter) is illustrated in Figure 25.6-1.

FIGURE 25.6-1 Exophthalmic goiter. Note lid retraction and enlarged thyroid. (Reprinted with permission from Douthwaite AH, editor: *French's Index of Differential Diagnosis*, ed 7. Williams & Wilkins, Baltimore, 1954.)

Pathology and Laboratory Examination Laboratory examination will reveal increased concentrations of total and free T_4 (FT4). Concentrations of total and free T_3 are usually elevated, but this is not necessary to make the diagnosis of hyperthyroidism. The TSH concentration is abnormally low, as its production is suppressed by the elevated thyroid hormone concentrations, and the TSH response to TRH is blunted. Uptake of radioactive iodine by thyroid hormone is increased, except in cases of hyperthyroidism due to thyroiditis or ingestion of thyroid hormone.

Differential Diagnosis Panic disorder, generalized anxiety disorder, and social and specific phobias present with symptoms that resemble hyperthyroidism, including tachycardia, diaphoresis, and tremulousness. Other conditions that produce symptoms of autonomic hyperarousal include hypoglycemia, diabetes, dehydration, and pheochromocytoma. Chronic obstructive pulmonary disease may produce anxiety, diaphoresis, dyspnea, and tachycardia. In some cases, hyperthyroidism may produce severe agitation resembling a manic state. Certain medications (e.g., appetite suppressants, stimulants, and street drugs such as cocaine and amphetamines) may also produce these symptoms. Laboratory testing will distinguish between hyperthyroidism and other medical conditions.

Course and Prognosis Rates of remission of Graves' disease depend on the type and length of treatment: patients treated with antithyroid drugs for 6 months have a rate of remission of approximately 30 percent, compared with 80 percent in patients treated for 2 years. Patients treated with radioiodine rarely experience a recurrence of hyperthyroidism. However, permanent hypothyroidism is a common complication of radioactive iodine treatment. Patients who undergo surgical ablation have a relapse rate of approximately 10 percent and are also at risk for permanent hypothyroidism. Hyperthyroidism due to thyroid nodular disease is permanent but remits with radioactive iodine therapy; in contrast, thyroiditis is a short-lived condition, lasting only a few weeks and resolving spontaneously.

Treatment Treatments for Graves' disease are (1) antithyroid drugs, (2) radioactive iodine (RAI), and (3) surgical thyroidectomy. The antithyroid drugs, propylthiouracil (PTU) and methimazole (Tapazole), inhibit synthesis of thyroid hormone. Propylthiouracil additionally inhibits the monodeiodination of T_4 to T_3. Methimazole has the advantage of single-day dosing. Initial doses of methimazole range from 10 to 40 mg, and of propylthioruracil from 75 to 100 mg, three times a day. The doses should be adjusted as the patient returns to a euthyroid state. Usual maintenance doses of methimazole are 5 to 10 mg a day and of propylthiouracil, 50 to 100 mg a day. A rare and serious adverse effect of these medications is agranulocytosis. Other adverse effects include pruritus, rash, and fever. Length of treatment varies from 6 months to 2 years. These medications may not produce a therapeutic effect for several weeks, because of the long half-life of T_4. Some clinicians combine the antithyroid drugs with thyroxine replacement to prevent iatrogenic hypothyroidism.

While some patients with Graves' disease respond to antithyroid drugs, most require RAI. An RAI uptake test done prior to administration of ^{131}I allows determination of the appropriate dose. Hypothyroidism may complicate RAI therapy, and patients may subsequently require thyroid hormone replacement.

Subtotal thyroidectomy is an option for patients who have an allergy to antithyroid drugs or are unwilling to undergo RAI therapy. Patients should receive antithyroid drugs, potassium iodide, or b-adrenergic receptor antagonists so that they are euthyroid prior to surgery, to reduce the risk of postoperative thyrotoxic crisis. Subtotal thyroidectomy has several potential complications, such as hypoparathyroidism and injury to the recurrent laryngeal nerve. Patients may have recurrent hyperthyroidism after surgery if insufficient thyroid tissue is removed.

b-Adrenergic receptor antagonists such as propanolol (Inderal), metoprolol (Lopressor), atenolol (Tenormin), or nadolol (Congard) can provide symptomatic relief while treatment is in progress. Atenolol (50 to 100 mg a day) and nadolol (80 mg a day) have the advantage of once-daily dosing. These medications should be used cautiously in patients with asthma or heart failure.

Iodine (given as a solution of potassium iodide or as Lugol's solution) inhibits thyroid hormone. The brief duration of its antithyroid action (a few weeks) limits its use to pretreatment prior to surgery, management of thyroid storm, and speeding the reduction in thyroid hormone concentration following RAI therapy.

Treatment of thyroid nodular goiter consists of b-adrenergic antagonists and RAI. Treatment of thyroiditis consists of a brief course (a few weeks) of b-adrenergic antagonists, as this condition is short-lived.

For patients with psychotic symptoms, medium-potency antipsychotics are preferable to low-potency drugs, as the latter can worsen tachycardia. Similarly, tricyclic

drugs should be used with caution, if at all, in these patients. In general, the psychiatric symptoms resolve with successful treatment of the hyperthyroidism.

Hypothyroidism

Definition and Comparative Nosology Hypothyroidism results from inadequate synthesis of thyroid hormone and is categorized as either overt or subclinical. In overt hypothyroidism, thyroid hormone concentrations are abnormally low, TSH is elevated, and patients are symptomatic; in subclinical hypothyroidism, patients are by definition asymptomatic, with normal thyroid hormone concentrations but elevated TSH. Patients with normal levels of circulating T_3 and T_4 but an elevated TSH or exaggerated TSH response to TRH infusion are described as having subclinical hypothyroidism.

Hashimoto's thyroiditis (chronic lymphocytic thyroiditis) is the most common cause of hypothyroidism in adults. Most patients have a mild-to-moderate goiter but are asymptomatic and euthyroid; approximately 20 percent are hypothyroid. Occasionally, especially as the illness first develops, patients may be hyperthyroid.

Other causes of hypothyroidism include idiopathic atrophy, endemic hypothyroidism from a deficiency of dietary iodine, hypopituitarism (e.g., from postpartum pituitary necrosis), hypothalamic disease resulting in deficient production of TRH, and iatrogenic hypothyroidism (e.g., caused by drugs such as lithium [Eskalith] or antithyroid drugs or from surgical or chemical thyroidectomy). The risk of developing overt (grade I) hypothyroidism following long-term lithium use is estimated at 20 percent. The risk of developing subclinical hypothyroidism is another 20 percent and is higher in women and in patients with thyroid autoantibodies. Lithium's antithyroid effects are related to the length of treatment and appear to be more persistent in the presence of antithyroid antibodies. Patients with rapid-cycling bipolar disorder are especially vulnerable to lithium's antithyroid effects.

Hypothyroidism must be distinguished from euthyroid sick syndrome, in which any severe nonthyroidal illness may decrease conversion of T_4 to T_3, resulting in abnormally low T_3 concentrations.

Myxedema is a syndrome in which patients with hypothyroidism have infiltration of the skin by a mucopolysaccharide that produces puffy subcutaneous swelling, especially in the eyes, face, and extremities.

Epidemiology The prevalence of overt, or clinical, hypothyroidism is approximately 2 percent in women and less than 0.1 percent in men. Subclinical hypothyroidism also predominates in women, occuring in approximately 7.5 percent of women and 3 percent in men. Women appear to have a higher rate of hypothyroidism because of their greater rates of autoimmune disease. As the prevalence of autoimmune disease rises with age, the prevalence of both overt and subclinical hypothyroidism also rises, particularly in women.

Etiology Antibodies against the thyroid are the most prevalent cause of hypothyroidism. Because autoimmune disease occurs more often in women—the result of female reproductive hormones on immunological response—hypothyroidism predominates in women. The symptoms of hypothyroidism may result from decreased postsynaptic b-receptor number and function associated with low concentrations of thyroid hormones. Hypothyroidism additionally is associated with reduced central serotonin activity. Brain synthesis of serotonin is reduced in hypothyroidism, and the prolactin and cortisol responses to the serotonin agonist fenfluramine are blunted in hypothyroid patients (compared with euthyroid controls), suggesting reduced central serotonin activity. Also, serum serotonin concentrations correlate positively with serum T_3 concentrations.

The increased T_4 activity observed in psychiatric patients may reflect a compensatory mechanism to maintain normal levels of thyroid function in the brain. The increase in T_4, the prohormone, rather than T_3, the active hormone, makes more T_4 available for uptake into the brain without increasing peripheral thyroid activity, which would place a metabolic strain on the body. Alternatively, the increased T_4 concentrations may reflect a lower rate of peripheral conversion of T_4 to T_3.

Diagnosis and Clinical Features Symptoms of hypothyroidism tend to develop with TSH concentrations of 8 to 12 mEg/L or above and correspond to the degree of hormone deficiency. Signs and symptoms are varied and include cold intolerance, constipation, muscle cramps, paresthesias, menstrual disturbances (amenorrhea or menorrhagia), dyspnea, dizziness, syncope, reduced hearing, poor appetite, weight gain, brittle and thinning hair, husky voice, deep tendon reflexes, bradycardia, cardiomegaly, low-voltage complexes on electrocardiography (ECG), increased cholesterol and triglyceride concentrations, and normochromic, normocytic anemia from a reduced rate of red blood cell production.

Psychiatric symptoms include depressed mood, apathy, impaired memory and concentration, and a long response latency. Also, hypothyroidism may contribute to treatment-refractory depression. A psychotic syndrome of auditory hallucinations and paranoia, named “myxedema madness,” has been described in some patients. Patients with severe cases may exhibit diminished cerebral blood flow, with subsequent coma or death.

Subclinical hypothyroidism may produce depressive symptoms and cognitive deficits, although these tend to be less severe than those produced by overt hypothyroidism. Further, subclinical hypothyroidism more than doubles the lifetime risk of developing major depressive disorder. Subclinical hypothyroidism has been reported to reduce the efficacy of antidepressant treatment. The lifetime prevalence of depression in patients with subclinical hypothyroidism is approximately double that of the general population. These patients display a lower response rate to antidepressants and a greater likelihood of responding to T_3 augmentation than euthyroid patients with depression. After controlling for age and gender, the presence of antithyroid antibodies appears to be weakly associated with episodes of bipolar disorder but not with depressive (unipolar) disorders.

> A 45-year-old male with bipolar I disorder had been well on lithium monotherapy for 5 years, but over the course of several months he became increasingly withdrawn and reported fatigue and poor concentration. The patient's family noted he was forgetful and uncharacteristically listless and apathetic. No stressors were identified, and the patient's lithium concentration was therapeutic. His TSH µg concentration was elevated at 14 mEq/L. The patient was treated with levothyroxine 0.05 µg and within 6 weeks experienced an improvement in energy and a subjective return to baseline cognitive functioning. His TSH determined 8 weeks following initiation of thyroid replacement therapy was normal at 3.3 mEq/L.

Pathology and Laboratory Examination Of the thyroid function assays, TSH testing is the most sensitive assay for hypothyroidism. TSH levels are low in those with hypothyroidism produced by hypothalamic or pituitary disease and high if caused by thyroid gland dysfunction. Patients with thyroid autoimmune disease exhibit antithyroid antibody titers (of antimicrosomal or antithyroglobulin antibodies). T_4 concentrations are low, and T_3 concentrations may be either low or normal. Among patients with depression, a relative increase of total or free T_4 or both and a relative decrease in T_3 concentration is common. This condition, termed “euthyroid hyperthyroxinemia,” has also been observed among acutely admitted psychiatric and medical patients and thus is not specific to depression.

Both blunted and exaggerated TSH responses to TRH have been found in patients with refractory depression to TRH; the exaggerated TSH response (indicating subclinical hypothyroidism) is more consistently associated with treatment refractoriness. Although data are inconclusive, some studies have reported a greater prevalence of antithyroid antibody titers in patients with bipolar disorder and depression (estimated at 9 to 25 percent) than the general population rate of approximately 5 percent.

Differential Diagnosis Depression may present with symptoms similar to hypothyroidism, including lethargy, poor concentration, impaired memory, and apathy. Bipolar patients with depression may have lithium-induced hypothyroidism and thus thyroid testing is essential for diagnostics. Certain medications, including barbiturates, carbamazepine (Tegretol), and phenytoin (Dilantin), may lower total and free thyroid hormone concentrations by increasing their hepatic metabolism. Pernicious anemia presents with macrocytic anemia, lethargy, and decreased appetite. The incidence of pernicious anemia is increased in patients with autoimmune illnesses such as thyroiditis. The changes accompanying normal aging, like hypothyroidism, are associated with slight weight gain, thinning hair, dry skin, and slowed response latency.

Course and Prognosis The onset of hypothyroidism is usually gradual, except in cases of surgical or chemical thyroid ablation. Hypothyroidism in children (cretinism) may produce permanent physical and mental retardation. The physical and mental symptoms in adults are usually reversed by thyroid replacement. However, long-standing hypothyroidism may produce permanent cognitive deficits, possibly from neuronal death resulting from thyroid deficiency in the brain.

Depression in hypothyroid patients is unlikely to resolve until thyroid levels return to normal. Thyroid hormone alone may suffice to induce remission of the depressive changes, although standard antidepressant treatment may also be necessary for those with more severe cases.

Subclinical hypothyroidism has been associated with rapid-cycling bipolar disorders and with refractoriness to antidepressant treatment. Additionally, subclinical hypothyroidism has a high likelihood of progressing to overt hypothyroidism, particularly in women.

Treatment Current preparations of exogenous thyroid hormone include levothyroxine (Levothroid, Lexoxyl), synthetic T_4, liothyronine (Cytomel), synthetic T_3; liotrix (Thyrolar), mixed synthetic T_4 and T_3, and desiccated thyroid (Armour). Levothyroxine is preferred as it provides the most uniform thyroid replacement. Doses are typically between 50 and 200 mg a day. Replacement of thyroid hormone should be gradual, especially in patients over age 50 and those with a history of cardiac disease, to avoid precipitating angina or cardiac arrhythmias. The starting dose of levothyroxine for these patients should not exceed 0.05 mg daily. TSH concentrations should be measured 6 weeks after initiation of thyroid hormone treatment. Clinical improvement may not occur for several weeks.

For patients presenting with severe psychiatric symptoms (e.g., psychosis or suicidal depression), urgent psychiatric treatment is necessary. Psychotropic agents should be given at low doses initially, as the reduced metabolic rate in hypothyroid patients may produce reduced breakdown and therefore higher blood concentrations of medications.

The treatment of subclinical hypothyroidism is controversial. Since patients are by definition asymptomatic, there is no clear medical reason to treat. On the other hand, some patients experience increased energy and decreased constipation and skin dryness following treatment with thyroid supplementation. Thyroid testing should be followed at least yearly. Thyroid supplementation, however, should be considered for the following patients with subclinical hypothyroidism: (1) patients who exhibit thyroid antibodies, as they are at high risk of progression to overt hypothyroidism; (2) patients who are depressed, as subclinical hypothyroidism may produce treatment refractoriness (these patients should receive a 6-week trial of thyroid replacement before receiving antidepressant medications); (3) those who have a goiter; (4) those who have hypercholesterolemia (as subclinical and overt hypothyroidism increase serum lipid concentrations and hence the risk of coronary heart disease); and (5) patients taking lithium. Further, a trial of thyroid augmentation should be initiated for patients who (1) have a serum TSH concentration above 10 mU/L, (2) exhibit deficits in memory or cognitive functioning, or (3) have a rapid-cycling bipolar disorder, as some (but not all) studies have found subclinical hypothyroidism to be a risk factor in rapid cycling.

Thyroid supplementation can be administered in the form of levothyroxine 0.05 to 0.2 mg a day or liothyronine 0.025 to 0.1 mg a day. Thyroid supplementation can similarly be used for patients who become hypothyroid while taking lithium. Valproate (Depakene) and carbamazepine are reasonable alternatives to lithium for patients with a history of thyroid dysfunction or with lithium-induced hypothyroidism, as it has no effects on thyroid functioning.

The response to treatment should be assessed by frequent clinical and laboratory evaluations for thyroid hormone and TSH concentrations. TSH will diminish as T_3 and T_4 return to normal ranges. Care should be taken to not overtreat and place patients in a state of hyperthyroidism. A patient showing improvement after treatment for myxedema is illustrated in Figure 25.6-2 and Figure 25.6-3.

FIGURE 25.6-2 Patient with myxedema on admission from hospital. (Reprinted with permission from Haughton CS: Psychosis with myxoedema. Med J Aust *2:*766, 1959.)

ADRENAL DISORDERS

The adrenal gland produces three major steroid hormones, glucocorticoids, mineralocorticoids, and sex steroids. Of these, the main steroids produced by the adrenal gland are cortisol, aldosterone, testosterone, and estrone/estradiol. Glucocorticoids promote gluconeogenesis, lipolysis, and glycogenesis, increase catecholamine activity during stress, and inhibit inflammatory reactions. Aldosterone's effect is primarily to increase renal sodium reabsorption and potassium excretion. Only a small proportion of circulating sex steroids are produced by the adrenal glands; their major site of production is the gonads.

Cortisol production is under the control of ACTH from the anterior pituitary, which in turn is regulated by CRH from the hypothalamus. Negative cortisol feedback occurs at pituitary, hypothalamic, and suprahypothalamic levels. CRH secretion follows a circadian pattern, subsequently producing circadian patterns of ACTH and cortisol concentrations, with their concentrations peaking in early morning and reaching a nadir in the evening. CRH release is also influenced by emotional and physical stress.

Hypercortisolism

Definition and Comparative Nosology Spontaneous Cushing's syndrome results from adrenocortical hyperfunction and can develop from either excessive secretion of ACTH (which stimulates the adrenal gland to produce cortisol) or from adrenal pathology (e.g., a cortisol-producing adrenal tumor). Cushing's disease, the most common form of spontaneous Cushing's syndrome, results from excessive pituitary secretion of ACTH, usually from a pituitary adenoma. Cushing's syndrome is ACTH dependent if the syndrome results from the effect of ACTH on the adrenal gland, and non-ACTH-dependent, in cases of excessive cortisol regardless of ACTH levels (e.g., as a result of an adrenal adenoma).

The hypothalamic-pituitary-adrenal axis responsivity to stressors may be influenced by stress in infancy and even during in utero development. Studies in primates and rodents show that prenatal stress may induce long-lasting effects on hypothalamic-pituitary-adrenal axis regulation; offspring whose mothers were stressed during

pregnancy show greater hypothalamic-pituitary-adrenal axis response to stressors than control offspring.

Epidemiology and Etiology The prevalence of Cushing's disease is approximately 40 per million, and it occurs far more frequently in women, particularly in the third and fourth decades of life. The most common cause of spontaneous Cushing's syndrome is an ACTH-producing pituitary adenoma. Other causes are autonomous ACTH-producing tumors such as oat cell carcinoma of the lung, islet cell pancreatic tumors, or thymomas. An adrenal adenoma or adrenocortical carcinoma and nodular adrenal hyperplasia are ACTH-independent causes of increased cortisol concentrations.

The relation of stressful life events to the onset of Cushing's syndrome is controversial; some studies find a greater frequency of adverse life events prior to the development of the disorder, while others find no such association. Similarly, the relation between depressive symptoms and the onset of Cushing's syndrome remains inconclusive; some studies report a high frequency of depression preceding the physical manifestations of the illness, while others find no greater rate of depressive symptoms than noted in control groups.

Cognitive impairment in hypercortisolemic patients is believed to result from the effect of corticosteroids on hippocampal formation. Among other tasks, the hippocampus is involved in selective attention, learning, and memory. Hippocampal damage can result from prolonged exposure to high corticosteroid concentrations, and higher plasma cortisol concentrations are associated with smaller hippocampal volume. Reduced hippocampal volume is in turn associated with lower scores on memory tests. In electrophysiological studies, the response to relevant (but not to irrelevant) stimuli is reduced following short-term cortisol administration, which suggests that cortisol impairs selective attention and discrimination of important information. Several researchers have suggested that the cognitive impairments in patients with clinical depression (many of whom have hypothalamic-pituitary-adrenal axis dysregulation) may result in part from cortisol effects on the hippocampus.

The exogenous use of steroids may also produce psychiatric sequelae. The likelihood of psychiatric adverse effects increases in direct proportion to prednisone dosage. Dosages under 40 mg a day are associated with an incidence of psychiatric symptoms below 2 percent, but this rate rises to almost 20 percent when the dosage exceeds 80 mg a day.

Diagnosis and Clinical Features The clinical features of Cushing's disease include a characteristic “moonfacies” or rounded face from accumulation of adipose tissue around the zygomatic arch (Fig. 25.6-4). Truncal obesity, a “buffalo hump” appearance, results from cervicodorsal adipose tissue deposition. The catabolic effects of cortisol on protein produce muscle wasting, slow wound healing, easy bruising, and thinning of the skin leading to abdominal striae. Bones become osteoporotic, sometimes resulting in pathological fractures and loss of height (Fig. 25.6-5). Diabetes may occur in some patients as a result of the gluconeogenesis stimulated by the high glucocorticoids concentrations. Chronic ACTH stimulation of the adrenal glands may lead to excess androgen production, with secondary hirsutism, acne, and amenorrhea. Hyperpigmentation may also occur, as ACTH is a precursor of a-melanocyte-stimulating hormone, which produces a skin-darkening effect. Although cortisol's mineralocorticoid effects are mild, at high concentrations it produces sodium retention, potassium loss, metabolic alkalosis, and edema. Hypertension occurs in most patients.

FIGURE 25.6-4 Cushing's syndrome. Plethoric “moonface.” (Reprinted with permission from Douthwaite AH, editor: *French's Index of Differential Diagnosis*, ed 7. Williams & Wilkins, Baltimore, 1954.)

FIGURE 25.6-5 Cushing's syndrome. Legs thin owing to atrophy of thigh muscles. Some abdominal obesity with marked striae. (Reprinted with permission from Douthwaite AH, editor: *French's Index of Differential Diagnosis*, ed 7. Williams & Wilkins, Baltimore, 1954.)

Psychiatric symptoms are myriad. Most patients experience fatigue, and approximately 75 percent report depressed mood. Of these, approximately 60 percent experience moderate or severe depression. The severity of depression does not appear to be influenced by the underlying cause of the Cushing's syndrome. Depressive symptoms occur more commonly in female patients than in male patients with Cushing's syndrome.

Emotional lability, irritability, decreased libido, anxiety, and hypersensitivity to stimuli are common. Somatic symptoms and elevated euroticism scores on the Eysenck Personality Inventory have also been reported, with significant improvement following normalization of cortisol concentrations. Patients may develop social withdrawal as a result of shame regarding their physical appearance. Paranoia, hallucinations, and depersonalization are estimated to occur in 5 to 15 percent of cases. Cognitive changes are common, and approximately 83 percent of patients experience deficits in concentration and memory. The severity of these deficits correlates with plasma cortisol and ACTH concentrations.

Manic and psychotic symptoms occur much less frequently than depression, in approximately 3 to 8 percent of patients, but reach 40 percent in patients with adrenal carcinomas. In iatrogenic hypercortisolism and adrenal carcinomas, however, mania and psychosis may predominate. The psychiatric disturbances in prednisone-treated patients tend to appear within the first 2 weeks of treatment and occur more commonly in women than men.

> T. S. was a 40-year-old white woman who was diagnosed with membranoproliferative glomerulonephritis and began being treated with prednisone 20 mg a day. Within 10 days of beginning the steroid treatment, her mood became elevated, her speech was pressured, her sleep diminished from 8 to 6 hours a night, and her activity level was heightened. She reported that her house “has never been so clean!” Within 2 weeks of discontinuing the prednisone, her mental state returned to baseline.

Steroids withdrawal can also produce psychiatric disturbances, particularly depression, weakness, anorexia, and arthralgia. Other steroid-induced withdrawal symptoms include emotional lability, memory impairment, and delirium. Withdrawal symptoms can persist for up to 8 weeks following corticosteroid withdrawal.

Patients presenting with mood lability or depression in association with muscle weakness, obesity, diabetes, easy bruising, cutaneous striae, acne, hypertension, and

(in women) hirsutism and oligomenorrhea or amenorrhea benefit from an endocrinological evaluation.

Pathology and Laboratory Examination In Cushing's syndrome, plasma and urine concentration of cortisol increase, and normal circadian rhythms of cortisol secretion are blunted or absent. Administration of metyrapone, which blocks cortisol synthesis, is normally followed by increased cortisol production. No such increase occurs in cases of adrenal or ectopic origin; in cases of pituitary origin, postmetyrapone response is augmented. Another test that distinguishes pituitary from adrenal cause of Cushing's syndrome is the dexamethasone (Decadron) suppression test (DST). Administration of 1 mg of the synthetic steroid dexamethasone does not suppress cortisol in patients with Cushing's syndrome of adrenal origin or other nonpituitary origin but does suppress cortisol in pituitary Cushing's syndrome.

The overnight DST is considered the procedure of choice for screening for Cushing's syndrome. It involves administering 1 mg dexamethasone at midnight and determining the plasma cortisol concentration the following morning. Plasma cortisol concentrations above 200 nmol/L indicate a high likelihood of Cushing's syndrome. The overnight 1-mg DST is simple to administer and has greater specificity and sensitivity than other screening procedures such as measurements of urinary free cortisol. Because plasma cortisol concentrations vary considerably during the day, an isolated measurement of plasma cortisol is not adequate to screen for Cushing's syndrome.

In the early 1980s the DST was a popular neuroendocrine challenge test in psychiatry, because a positive result (i.e., nonsuppression of cortisol following dexamethasone administration) was believed to be a useful marker for melancholic depression. However, the DST is now used infrequently because its clinical use is limited by low specificity and sensitivity. Additionally, medical illnesses, weight loss, stress, and concomitant medications confound the DST results.

Differential Diagnosis Patients with Cushing's syndrome commonly have mood changes very similar to those of patients with a major depressive episode. Both groups of patients have a shortened rapid eye movement (REM) latency, increased cortisol concentration, and abnormal findings on DSTs. The physical manifestations of Cushing's syndrome help distinguish between the two diagnoses, but they may be absent early in the course of the illness. Other distinguishing symptoms of Cushing's syndrome are greater irritability and mood lability; greater tendency to feel best in the morning (in contrast to patients with major depression, who tend to feel worse then); and less guilt and hopelessness than patients with major depression.

Treatment and Course The treatment of pituitary ACTH-producing tumors involves surgical resection or pituitary irradiation. Adrenal adenomas and carcinomas are removed surgically, and in the case of carcinomas, chemotherapy is instituted subsequently. Medications that antagonize cortisol production (e.g., metyrapone or mitotane [tysobren]) or suppress ACTH (e.g., serotonin antagonists such as cyproheptadine [Periactin]) are sometimes used but have met with limited success.

Following treatment, hypertension and electrolyte imbalances correct quickly. The physical stigmata and subtle cognitive deficits may take months or years to resolve. Following successful treatment of Cushing's syndrome, most patients experience significant improvement in depressive and anxiety symptoms.

For patients undergoing prednisone treatment, lithium and neuroleptic medications during the course of treatment help prevent the development of manic or psychotic symptoms. Steroid psychosis resolves following discontinuation of the medication. Prednisone should be tapered rather than discontinued abruptly, to allow the pituitary gland, which has been suppressed, to resume its production of ACTH.

Adrenocortical Insufficiency

Definition and Comparative Nosology Adrenocortical insufficiency results from inadequate production of three major steroid hormones, glucocorticoids, mineralocorticoids, and sex steroids, by the adrenal gland. In *primary adrenal insufficiency,* adrenal hypofunction results from adrenal gland disease (e.g., autoimmune disease, infection, idiopathic atrophy, metastatic tumor). ACTH and CRH concentrations increase in response to low concentrations of adrenal steroids. Because ACTH is metabolized to a-melanocyte-stimulating hormone, which promotes melanocyte activity, the skin may become hyperpigmented as ACTH concentrations increase.

Secondary adrenal insufficiency results from deficient ACTH secretion caused by pituitary disease, and *tertiary adrenal insufficiency* refers to deficient hypothalamic secretion of CRH. Adrenal aldosterone production tends to be less affected by secondary or tertiary forms of adrenal insufficiency.

Epidemiology The prevalence of Addison's disease is estimated at 110 per million population, with an incidence of 5.6 per million per year.

Etiology Autoimmune destruction of the adrenal cortex produces over 90 percent of cases of Addison's disease. Secondary and tertiary adrenal insufficiency result primarily from withdrawal of exogenous corticosteroids or ACTH, as their administration suppresses the hypothalamic-pituitary-adrenal axis. Less common causes include pituitary tumors, trauma, infectious disease (e.g., human immunodeficiency virus [HIV]), infarction, and surgical ablation.

Diagnosis and Clinical Features Clinical symptoms usually do not become apparent until more than 90 percent of the adrenal cortex is damaged. Adrenal insufficiency can be life threatening, particularly in cases of acute adrenal insufficiency (e.g., following adrenal hemorrhage from infectious processes or use of anticoagulants). Symptoms include weakness, hypoglycemia, hyponatremia, hyperkalemia, nausea, diarrhea, fever, psychotic symptoms, and shock.

Chronic adrenal insufficiency produces more-subtle symptoms, including fatigability, salt craving, weight loss, vitiligo, nausea, hyperpigmentation, loss of body hair, muscle cramps, apathy, irritability, and mild-to-severe depression. Symptoms develop insidiously over months or years. A diagnosis of adrenocortical insufficiency is made primarily on the basis of plasma cortisol concentrations during the ACTH stimulation test. Following intravenous administration of 250 µg of cosyntropin (Cortrosyn), cortisol concentrations normally peak in 30 to 90 minutes. A normal test result is defined as a baseline cortisol concentration of at least 5 µg per 100 mL, a rise between baseline and stimulated cortisol concentrations of more than 7 µg per 100 mL, and a stimulated cortisol concentration above 18 µg per 100 mL. Low cortisol responses to this test indicate adrenal insufficiency.

Pathology and Laboratory Examination Common laboratory findings include low serum concentrations of sodium, high concentrations of potassium, and low or normal plasma cortisol concentrations. The diagnosis of adrenal insufficiency is particularly likely if plasma cortisol concentrations in the early morning (when they should be peaking) are low.

In cases of primary adrenal insufficiency, ACTH concentration rises and cortisol concentration does not rise following ACTH stimulation. In cases of adrenal insufficiency resulting from pituitary disease, ACTH concentrations are low or normal, and the response to CRH is blunted. If the adrenal insufficiency results from hypothalamic disease, the ACTH response to CRH administration is adequate but cortisol concentrations may fail to rise because of adrenal atrophy following prolonged ACTH deficiency.

Differential Diagnosis The symptoms of chronic adrenal insufficiency overlap those of depression. Easy fatigability, muscle cramps, anorexia, and lethargy may also lead to a diagnosis of chronic fatigue syndrome. In cases of acute adrenal insufficiency (e.g., following abrupt discontinuation of steroid administration), patients may develop a psychotic or delirious syndrome.

Course and Prognosis Physical and mental symptoms respond quickly to steroid replacement. A patient's prognosis depends largely on the underlying cause of the adrenal dysfunction. In cases of chronic adrenal insufficiency, patients have an unremitting illness requiring lifelong steroid treatment.

Treatment Acute adrenal insufficiency requires immediate treatment with intravenous hydrocortisone in addition to fluid replacement with saline solution and potassium supplementation. In cases of primary adrenal insufficiency, a mineralocorticoid (e.g., fludrocortisone [Florinef]) is also required. In cases of chronic adrenal insufficiency, prednisone or hydrocortisone is administered orally as maintenance treatment. Patients should be encouraged to carry a card or bracelet listing their diagnosis, medications, dosages, and physician.

HYPERPROLACTINEMIA

Definition and Comparative Nosology Prolactin, produced by the anterior pituitary, stimulates milk production from the breast and modulates maternal behavior. Its production is inhibited by dopamine (also known as prolactin-inhibiting factor) produced by the tuberoinfundibular neurons of the arcuate nucleus of the hypothalamus. Normal concentrations (5 to 25 ng/mL in women and 5 to 15 ng/mL in men) fluctuate during the day, peaking during sleep. Exercise and emotional

stress can increase prolactin concentration.

Epidemiology and Etiology Hyperprolactinemia most frequently results from prolactin-secreting pituitary adenomas (prolactinomas) and idiopathic hyperprolactinemia, two conditions that occur more commonly in women. Medications that block dopamine action (e.g., antipsychotics, methyldopa [Aldomet], reserpine [Diupres]) raise prolactin concentrations up to 20 times. Neuroleptic medications raise prolactin concentrations up to 20-fold in a dose-dependent fashion, with prolactin concentrations reaching plateau. All antipsychotics appear equally likely to raise prolactin concentrations, with the exception of clozapine (Clozaril) and olanzapine (Zyprexa). Other medications that may increase prolactin concentrations include oral contraceptives, estrogens, tricyclic drugs, serotonergic antidepressants, and propranolol. Hypothyroidism raises prolactin concentration because TRH stimulates prolactin release. Acromegaly is also associated with hyperprolactinemia, as a result of the lactogenic properties of GH. Hypothalamic disease (e.g., craniopharyngiomas), may also result in an elevation of prolactin levels, as the hypothalamus exerts an inhibitory influence on prolactin secretion. Physiological hyperprolactinemia occurs in pregnant and breast-feeding women; nipple stimulation also increases prolactin concentrations.

Traumatic childhood experiences such as separation from parents or living with an alcoholic father have been reported to produce predisposition to hyperprolactinemia. Stressful life events are also associated with galactorrhea, even in the absence of increased prolactin concentrations.

Diagnosis, Clinical Features, and Laboratory Examination Patients with high prolactin concentrations may be asymptomatic, although symptoms usually develop when prolactin concentrations reach 60 to 100 ng/mL. Women may experience amenorrhea because prolactin suppresses normal menstrual cycling, and men may develop gynecomastia. Both women and men may experience low libido, decreased fertility, and galactorrhea (inappropriate lactation), although the latter occurs primarily in women. Headache and visual impairment may result in cases of pituitary adenomas.

Women with pathological hyperprolactinemia have been reported to experience higher levels of depression, anxiety, and hostility than controls, which lessen with normalization of prolactin concentration.

Treatment A laboratory workup, the initial step in treatment, should include thyroid function tests, a pregnancy test, and a chemistry panel. A brain imaging study, either magnetic resonance imaging (MRI) with gadolinium or computed tomography (CT) with contrast, should be done.

Bromocriptine (Parlodel), a dopamine agonist, reduces the synthesis and secretion of prolactin. In approximately 80 percent of cases, bromocriptine at doses of 2.5 to 5 mg twice or thrice daily is effective treatment. However, many patients cannot tolerate the adverse effects of bromocriptine, which can include severe nausea and dizziness. Alternative medications include quinagolide, pergolide (Permax), and cabergoline (Dostinex). Medication use must continue indefinitely, as medication discontinuation usually leads to a relapse of hyperprolactinemia.

Radiotherapy is another treatment strategy for patients who are refractory to medication treatment. Surgical removal through transphenoidal surgery is used far less often now than 10 years ago, because of the high rate of recurrence of prolactinomas.

ACROMEGALY AND GIGANTISM

GH, produced by the anterior pituitary, stimulates protein synthesis, lypolysis, and growth of skeletal cartilage. Its production is stimulated by GH-releasing factor and inhibited by somatostatin, both of hypothalamic origin. If GH concentrations are excessively high in childhood, gigantism may develop. Acromegaly results from an excess of GH in adulthood, after fusion of the epiphyses of the long bones, so that height is not affected. The prevalence of acromegaly is approximately 4 in 100,000. Acromegaly most frequently results from a pituitary tumor (Fig. 25.6-6). Other causes include ectopic production or excessive hypothalamic production of growth hormone releasing factor. The longer the illness, the more extreme the symptoms. The nose, jaw, tongue, and soft tissues of the hands and feet become enlarged, as do the heart, liver, and kidneys. Organ enlargement can lead to congestive heart failure. No specific psychiatric symptoms have been consistently associated with acromegaly or gigantism, or with elevated GH levels. Adjustment disorder may occur from changes in physical appearance and from living with a chronic illness. Laboratory studies show high GH concentrations. The most reliable test for acromegaly is measurement of GH following an oral glucose tolerance test. In acromegalic patients, GH secretion does not show the normal suppression by glucose. Brain imaging studies may show a pituitary tumor. Treatment involves pituitary ablation through surgery or radiation. Dopamine agonists such as bromocriptine and apomorphine, which normally increase GH levels, have the opposite effect in patients with acromegaly. The serotonin antagonist cyproheptadine may also reduce GH levels. A historical case of gigantism is illustrated in Figure 25.6-7.

POLYCYSTIC OVARY SYNDROME

Polycystic ovary syndrome is one of the most widespread endocrine disorders in women. Clinical features include hirsutism, obesity, male-pattern alopecia, acne, and irregular menstrual cycles. Ultrasonography shows enlarged ovaries with multiple cystic follicles. Normal-appearing ovaries, however, do not rule out the condition. LH concentrations are usually high while FSH concentrations are low or normal. Other laboratory findings include elevated concentrations of androstenedione, testosterone, estrone, and prolactin. Because of the absence of ovulation, estrogen is unopposed by progesterone, placing patients at risk for endometrial hyperplasia and carcinoma. Another long-term risk is type II diabetes, which occurs seven times as frequently as in the reference population, secondary to insulin resistance associated with hyperandrogenism. An association between depression and hyperandrogenism in women has been noted in several reports. Initiation of oral

contraceptive treatment has been reported to improve mood, possibly by the reduction in androgen concentration that results from suppression of ovarian activity.

Prevalence rates vary depending on the criteria used to make the diagnosis but are estimated to be approximately 8 percent of women of reproductive age. Rates reach 30 to 75 percent when they are based on women presenting for treatment of menstrual irregularities or hirsutism.

The pathogenesis of polycystic ovary syndrome is not clear. Dysregulation of the rate-limiting enzyme involved in androgen biosynthesis in the ovaries has been implicated. Polycystic ovary syndrome appears to follow an autosomal dominant mode of inheritance. Emotional stress in puberty has been reported as a risk factor for the development of polycystic ovary syndrome.

The differential diagnosis includes pituitary and adrenal disorders such as hyperprolactinemia, acromegaly, and congenital adrenal hyperplasia, which can produce menstrual irregularities and hirsutism. These can be distinguished from polycystic ovary syndrome by laboratory and clinical assessments.

Treatments include antiestrogens such as clomiphene (Clomid), gonadotropins, laparoscopic surgery, and low-dose oral contraceptives. Weight reduction is also recommended. Hirsutism may respond to spironolactone, an androgen receptor antagonist, but it may be difficult to tolerate as it commonly produces mood changes, decreased libido, and fatigue.

ANDROGEN INSENSITIVITY SYNDROME

Androgen insensitivity syndrome, or testicular feminization, is a rare X-linked recessive disorder that produces a variable appearance of external genitalia depending on the degree of androgen receptor defectiveness. In cases of complete androgen insensitivity, patients with a 46 XY karyotype are phenotypically female. Body fat and hair distribution are typically female, and breasts develop after puberty. The vagina, however, is short and blind or may be absent altogether (Fig. 25.6-8). An inguinal hernia is a common clinical presentation in prepubertal children, and the diagnosis may not be made until surgical repair of the hernia reveals a testis. Postpubertally, primary amenorrhea is a common presentation. With the exception of the undescended testes, internal genitalia are absent. Surgical removal of the testes is recommended, as the development of gonadal tumors is a concern. The psychosexual development is feminine, and it is therefore recommended that these individuals be raised as females. In patients with incomplete testicular feminization, the appearance of external genitalia is more virilized and ambiguous. The degree of virilization varies, depending on the extent of androgen insensitivity. Patients who have been raised as males and who have undergone genital reconstructive surgery have generally experienced poor anatomical and functional results. In most cases, it is recommended that patients be raised as females, and that gonadectomy be performed before puberty to avert further virilization. Careful evaluation of infants and children with ambiguous genitalia is important for early diagnosis and gonadectomy.

25.7 PSYCHOCUTANEOUS DISORDERS

LESLEY M. ARNOLD, M.D.

Psychocutaneous disorders include dermatological diseases affected by the presence of psychiatric symptoms or stress and psychiatric illnesses in which the skin is the target of disordered thinking, behavior, or perception. Evidence of the nervous system's involvement in skin pathophysiology provides possible links between stress or psychiatric disturbances and many dermatological diseases.

CLASSIFICATION

The psychocutaneous disorders discussed in this section are classified in the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) (Table 25.7-1). Psychological factors affecting medical condition include dermatological diseases in which comorbid psychiatric disorders or symptoms or stress affect their course. The dermatological disorders listed are most commonly affected by psychiatric factors, but many other dermatological diseases (e.g., genital herpes) may also be influenced by these factors. Somatoform disorders contain dermatological problems that are not fully explained by a known dermatological disease. Delusional disorder, somatic type, is the most likely diagnosis for dermatological patients with delusions of parasitosis. The differential diagnosis of delusions of parasitosis includes major depressive disorder, bipolar I disorder, schizophrenia, psychotic disorder due to a general medical condition, and substance-induced psychotic disorder. Delusional patients must also be differentiated from patients with nondelusional obsessive concerns about infestation (obsessive-compulsive disorder). A preoccupation with a defect in appearance (body dysmorphic disorder) has a delusional variant, classified as a delusional disorder, somatic type. Trichotillomania is classified under the impulse-control disorders. Psychogenic excoriations and onychophagia would probably be included under the category of impulse control disorder not otherwise specified, but like trichotillomania, these disorders frequently have symptoms that overlap with obsessive-compulsive disorder. Many propose to include all of the impulse-control disorders under the broad category of obsessive-compulsive spectrum disorders, although this is not part of the DSM-IV classification. Finally, factitious disorders include factitious dermatitis (dermatitis artefacta) and psychogenic purpura. Some cases of psychogenic purpura are thought to result from a conversion disorder but further confirmation is needed.

I. Psychological factors affecting medical condition
Atopic dermatitis
Psoriasis
Alopecia areata
Urticaria and angioedema
Acne vulgaris
Rosacea
Telogen defluvium
Primary hyperhidrosis
Seborrheic dermatitis
Prurigo nodularis
II. Undifferentiated somatoform disorder
Chronic idiopathic pruritis
Idiopathic pruritis ani, vulvae, and scroti
III. Pain disorder
Idiopathic glossodynia
Dysesthetic (essential) vulvodynia
IV. Other somatoform disorder
Body dysmorphic disorder
V. Delusional disorder, somatic type
Delusions of parasitosis
Delusions of a defect in appearance
Delusions of a foul body odor
VI. Impulse-control disorder (obsessive-compulsive spectrum disorders)
Trichotillomania
Psychogenic excoriation
Onychophagia
VII. Factitious disorder
Factitious dermatitis
Psychogenic purpura

Table 25.7-1 DSM-IV Classification of Psychocutaneous Disorders

PSYCHOLOGICAL FACTORS AFFECTING MEDICAL CONDITION

Atopic Dermatitis Atopic dermatitis (also called atopic eczema or neurodermatitis) is a chronic skin disorder characterized by pruritus and inflammation (eczema), which often begins as an erythematous, pruritic, maculopapular eruption (Fig. 25.7-1). Scratching in response to the pruritus can lead to lichenification, excoriations, and infections. Atopic dermatitis arises most commonly during early infancy, childhood, or adolescence and is frequently associated with a personal or family history of atopic dermatitis, allergic rhinitis, or asthma. A national census of dermatological disease in the United States in 1977 found atopic dermatitis to be a common disorder, affecting 7 per 1000 individuals and 24 per 1000 children, with a female to male ratio of 1.2 to 1.0. The prevalence of atopic dermatitis has increased to more than 10 percent in the past decade, possibly because of greater exposure to provocative factors such as outdoor pollution, reagents in highly insulated buildings, house mites, food additives, and increased parental and physician awareness of the disorder. Atopic dermatitis can resolve spontaneously, especially in mild cases, but most patients experience persistent or relapsing symptoms. A 20-year follow-up study of 47 patients with a diagnosis of atopic dermatitis by the age of 2 found that 72 percent continued to have signs of the disorder. In another study, symptoms persisted or recurred in 77 to 91 percent of adult patients who had moderate or severe symptoms as teens. In general, comorbid asthma or hayfever, late onset, severe dermatitis and a family history of atopic dermatitis correlate positively with disease chronicity.

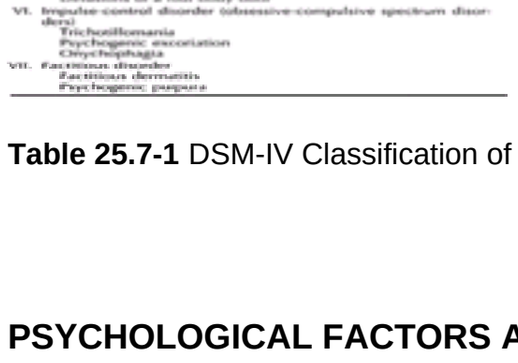

FIGURE 25.7-1 Atopic dermatitis. Note the maculopapular eruption behind the knees. (Courtesy of D.F. Mutasim.)

The cause of atopic dermatitis is unknown, although recent studies suggest a genetic influence. Concordance rates were higher in monozygotic (0.75) than dizygotic (0.25) twins, and the prevalence of atopic dermatitis in children with two affected parents was 81 percent versus 56 percent for those with a single affected parent. Heritable traits identified so far appear to affect the immune system, which exhibits an imbalance of immunoregulatory T cells that may explain the defective cell-mediated immunity and increased immunoglobulin E (IgE) production seen in atopic dermatitis. Another important feature of atopic dermatitis is the abnormal mediator release by mast cells and basophils. Increased release of histamine contributes to the characteristically severe pruritis. Growing evidence for the role of neuropeptides such as substance P, a neuropeptide released by cutaneous nerves that can cause histamine secretion from mast cells, provides a possible link

between the central nervous system (CNS) and atopic dermatitis.

Although genetic factors probably underlie the development of atopic dermatitis, environmental factors frequently trigger or exacerbate the disease. Affected patients seem to have a lower response threshold and more prolonged reaction to pruritic stimuli than controls. Environmental triggers include food allergy or intolerance, contact irritants and allergens, aeroallergens (house dust mites, pollen, molds, human and animal dander), microbes, hormones, climate, sweating, and stress. A vicious circle of itching, scratching, and lesion aggravation frequently develops and contributes to symptom chronicity. Stressful life events often precede the onset and exacerbation of atopic dermatitis. How stress affects this disorder is unclear, but it may involve the relationship between stress, neuropeptides, and immune function.

Methodological problems have limited many studies examining the role of psychiatric factors in atopic dermatitis that infer causal relationships when only an association or correlation was found in cross-section. However, well-controlled studies have found adult atopic dermatitis patients to be more anxious and depressed than clinical and disease-free control groups. Anxiety or depression exacerbates atopic dermatitis by eliciting scratching behavior. In another study of pruritus associated with atopic dermatitis and other dermatological conditions, depressive symptoms appeared to amplify the itch perception. Recent studies of children with atopic dermatitis found most to be well adjusted psychiatrically with secure maternal attachments, compared with normal controls. About a third of the children with severe atopic dermatitis symptoms had significantly higher morbidity levels on behavioral screening questionnaires. The emotional state in children with atopic dermatitis was closely related to the severity of the illness. Certain dimensions of family environment such as independence and organization correlated with less severe symptoms of atopic dermatitis, while parental responses of attention or physical contact reinforced scratching.

Different modalities of psychiatric treatment for atopic dermatitis exist. Some strive to reduce stress and interrupt the vicious circle of itching and scratching. Controlled studies have established that relaxation training, habit reversal training, cognitive-behavioral techniques, and stress management training led to significant and stable adjunctive treatment responses beyond those of standard medical care as well as reducing anxiety and depression. Controlled trials of psychotropic drug treatment found that topical doxepin (Sinequan) cream was effective in reducing pruritus in atopic dermatitis patients, probably related to doxepin's potent histamine antagonism. Trimipramine (Surmontil), another antidepressant with histamine receptor antagonism, decreased the fragmentation of sleep and reduced the time spent in stage 1 sleep, which secondarily reduced the amount of scratching during the night in atopic dermatitis patients.

Psoriasis Psoriasis is a chronic, relapsing disease of the skin with variable clinical features. Characteristic lesions involve both the vasculature and the epidermis and have clear-cut borders and noncoherent silvery scales with a glossy, homogeneous erythema under the scales (Fig. 25.7-2). Some patients also develop nail dystrophy and arthritis. It affects 1 to 2 percent of the United States general population and is equally common in women and men, with most developing initial lesions in the third decade of life. Early onset (before age 15) predicts greater disease severity with a higher percentage of body surface involvement and a worse treatment response. A family history of psoriasis is more common in early-onset patients. For most patients psoriasis persists throughout life, with unpredictable exacerbations. Spontaneous remissions have been reported and have lasted between 1 and 54 years.

FIGURE 25.7-2 Psoriasis. The characteristic lesions have clear-cut borders and silvery scales. (Courtesy of D.F. Mutasim.)

The pathogenesis of psoriasis is not completely understood, but it appears that several systems involved in skin repair, inflammatory defense mechanisms, and immunity may contribute to its development. A genetic predisposition to the disease is indicated by a higher incidence of psoriasis in relatives of patients and higher rates of monozygotic (0.65) than dizygotic (0.30) concordance as well as correlations with the human major histocompatibility gene complex (HLA) and non-HLA loci. However, external factors frequently affect the course of psoriasis. Common triggers of psoriasis include cold weather, physical trauma, acute bacterial and viral infections, and drug-related effects associated with corticosteroid withdrawal and with the use of b-adrenergic receptor antagonists and lithium. Lithium-induced psoriasis typically occurs within the first few years of treatment, is resistant to treatment, and resolves after discontinuation of lithium treatment.

The adverse effect of psoriasis on the quality of life can lead to stress that can in turn trigger more psoriasis. In a recent survey of psoriatic patients, 46 percent reported daily problems secondary to psoriasis. The 40 to 80 percent of patients who reported that stress triggered psoriasis often described disease-related stress, resulting mainly from the cosmetic disfigurement and social stigma of psoriasis, rather than stressful major life events. Psoriasis-related stress may have more to do with psychosocial difficulties inherent in the interpersonal relationships of patients with psoriasis than with the severity or chronicity of psoriasis activity. The mechanism of stress-induced exacerbations is unknown but may involve the nervous, endocrine, and immune systems in such a way that descending autonomic information from the CNS is transmitted to sensory nerves in the skin, resulting in release of neuropeptides such as substance P into the skin. These neuropeptides help initiate and maintain the inflammatory response in psoriatic lesions.

Controlled studies have found psoriatic patients to have high levels of anxiety and depression and significant comorbidity with a wide array of personality disorders from the revised third edition of DSM (DSM-III-R), including schizoid, avoidant, passive-aggressive, and obsessive-compulsive personality disorders. Patients' self-report of psoriasis severity correlated directly with depression and suicidal ideation, and comorbid depression reduced the threshold for pruritus in psoriatic patients. Heavy alcohol drinking (>80 grams of ethanol daily) by male psoriatic patients may predict a poor treatment outcome.

These possible links between the CNS and psoriasis have led to the development of psychosocial interventions in its treatment. Controlled studies have shown meditation, hypnosis, relaxation training, cognitive-behavioral stress management, and symptom control imagery training to be effective in reducing psoriasis activity.

Alopecia Areata Alopecia areata is a nonscarring hair loss in patches of typically well-demarcated smooth skin with breakage of the hair shaft resulting in characteristic “exclamation-mark hairs.” Hair loss often involves the scalp but can also affect the brows, lashes, beard, and body hair and varies from a single patch to multiple patches or total hair loss (Fig. 25.7-3). Alopecia areata accounts for about 2 percent of new dermatologic outpatient visits in the United States, with an estimated 1 percent of the U.S. population having at least one episode by the age of 50. The incidence is equal in men and women and peaks during the third to fifth decade. The prognosis is variable; 20 to 30 percent never recover from the first episode, and another 30 percent recover completely. Factors associated with poor prognosis include rapid evolution, prepubertal onset, ophiasis (loss of hair along the scalp margins), multiple episodes, associated atopy, severe nail changes, and loss of eyebrows and eyelashes.

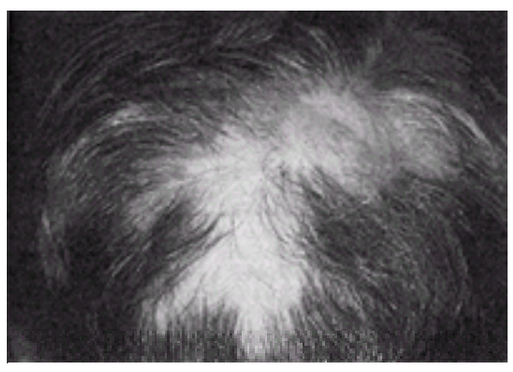

FIGURE 25.7-3 Alopecia areata. Note the typical patch of hair loss on the scalp. (Courtesy of D.F. Mutasim.)

The pathogenesis of alopecia areata is not completely understood but probably involves immunological and genetic factors. About 30 percent of patients report a positive family history. Some preliminary evidence implies that alopecia areata is an autoimmune disorder with T suppressor cell dysfunction, association with other autoimmune conditions, and frequently positive responses to immunosuppressive treatment such as corticosteroids or to induced, delayed-hypersensitivity reactions to a variety of sensitizers.

The role of psychiatric factors in the development of alopecia areata has been debated. The few controlled studies have yielded contradictory findings regarding the rates of psychopathology and the role of psychosocial events or stress in the onset of alopecia areata. In the 6 months preceding the onset of symptoms, events with a negative impact, exits from social fields (e.g., death, divorce), uncontrolled events, and socially desirable and undesirable events were significantly more frequent in alopecia areata patients than in controls. However the actual impact of these events on the development of alopecia areata is unclear. Recent, uncontrolled studies of lifetime comorbid psychiatric disorders in adults with alopecia areata found that many had lifetime psychiatric diagnoses, particularly major depression, generalized anxiety disorder, and paranoid disorder, suggesting that adult patients with alopecia areata may be at risk for comorbid psychiatric disorders. In another study, symptoms of depression and anxiety were more common in children with alopecia areata than in controls. Patients with highly stress reactive alopecia areata report more depressive symptoms than patients who do not note a relationship between stress and alopecia areata. A double-blind, placebo-controlled trial of imipramine (Tofranil) 75 mg daily found that the patients on imipramine had significantly more hair regrowth than controls, and this effect was independent of a reduction in anxiety or depression.

Urticaria and Angioedema Urticaria (also known as hives) is characterized by circumscribed, raised, erythematous, usually pruritic areas of edema that involve the superficial dermis (Fig. 25.7-4). When the edema extends into the deep dermis, subcutaneous or submucosal layers, it is called angioedema. About 15 to 20 percent of the general population develop urticaria at some point in their lives, with a peak incidence between ages 20 and 40. The male to female ratio is equal in children, but more women than men develop urticaria in adulthood. Most patients with acute urticaria (duration less than 6 weeks) readily respond to treatment of the underlying cause, usually infection or intolerance to specific drugs or food. However, in about 70 percent of patients with chronic urticaria or angioedema (duration greater than 6 weeks), the cause is unknown. Chronic idiopathic urticaria often responds poorly to usual dermatological treatment, although the prognosis improves with mild severity, short duration of the episode, and positive response to antihistamines. About 20 percent of patients with chronic idiopathic urticaria still have symptoms after 10 years. The manifestations of urticaria result from the release of vasoactive mediators in the skin, primarily histamine from mast cells or basophils. The release of these mediators can result from either immunological (IgE dependent or complement mediated) or nonimmunological mechanisms (agents that directly release mediators from mast cells and basophils).

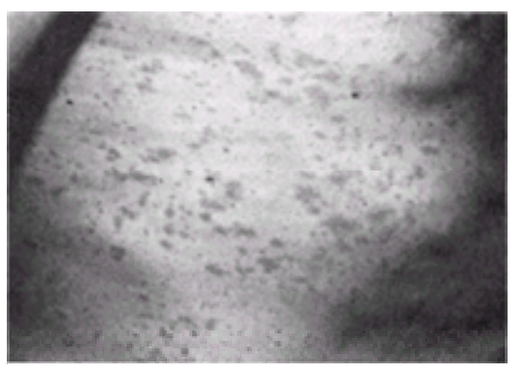

FIGURE 25.7-4 Urticaria. Note the circumscribed, raised areas of edema on the chest and abdomen. (Courtesy of D.F. Mutasim.)

Psychiatric factors have been implicated in the development of some types of urticaria. The typical “halo-hives” (papules surrounded by a white halo) of adrenergic urticaria that develops after acute emotional stress are associated with increased plasma noradrenaline and adrenaline concentrations, are reproduced with intradermal injection of noradrenaline, and resolve after treatment with the b-adrenergic receptor antagonist propranolol (Inderal). Most psychiatric studies, however, have focused on chronic idiopathic urticaria. Early psychodynamic theories about urticaria have been abandoned because no association between a specific personality conflict and urticaria could be proved, but recent controlled studies using well-documented psychometric instruments have found that patients with chronic idiopathic urticaria were frequently depressed and anxious and that women were more likely to experience significant psychiatric symptoms. However, whether the psychiatric symptoms resulted from urticaria or were a contributing causal factor in its development or exacerbation is unclear. Stress may also lead to the secretion of such neuropeptides as vasoactive intestinal peptide and substance P, which can cause vasodilation and contribute to the development of urticarial wheals.

While only one well-controlled study found that psychological treatment (hypnosis with relaxation) reduced pruritus (but not number of hives), controlled studies of psychotropic drugs demonstrated that antidepressant medications are effective in the management of chronic idiopathic urticaria. Doxepin at low dosages (10 mg three times a day) was more effective than diphenhydramine (Benadryl) (25 mg three times a day) for the control of chronic idiopathic urticaria, and 25 mg of nortriptyline (Pamelor) three times a day was significantly better than placebo in the treatment of pruritus and wheals. Whether the efficacy of antidepressants was solely a product of antihistaminic activity or involved a central effect as well is not known. An open trial found that both comorbid panic disorder and urticaria responded to treatment with selective serotonin reuptake inhibitors (SSRIs), suggesting a possible role for serotonergic mechanisms as well.

Acne Vulgaris Acne vulgaris is a common sebaceous gland disease typified by a variety of lesions including comedones, papules, pustules, or nodules and possible development of pitted or hypertrophic scars as a result. Occasionally present at birth, most cases develop in patients between the middle to late teens. The course is usually self-limited with spontaneous remission after several years, although acne may persist through the third decade and later, particularly in women. Acne is more common and tends to be more severe in men.

The etiology of acne is multifactorial. Patients frequently report stress-induced aggravation of acne, although the mechanism is unknown. One theory is that via the hypothalamic-pituitary-adrenal axis, stress leads to higher glucocorticoid and androgen concentrations, which can both exacerbate acne. Acne interferes significantly with social and occupational functioning, with a positive association between the severity of the acne, anxiety, and poor self-image. Patients with even mild-to-moderate acne experience significant psychological distress and body image concerns. Interestingly, successful treatment of acne with isotretinoin (Accutane) reduced both anxiety and depressive symptoms. A controlled study of adjunctive psychological treatment of acne patients receiving medical dermatological treatment demonstrated that biofeedback-assisted relaxation and cognitive imagery treatment significantly reduced acne severity compared with that in medical control groups.

Other Dermatologic Conditions

Rosacea Rosacea, a disorder of the cutaneous vasculature that occurs in adults between the ages of 30 and 60, is characterized by facial flushing, erythema, inflammatory lesions, lymphedema, and rhinophyma (hypertrophy of vascular and connective tissue of the nose). Rosacea is more likely to present on the cheeks and chin of women, while men tend to get rosacea on the nose. Development is probably multifactorial, with genetically susceptible individuals experiencing recurrent facial flushing (an important first stage in the pathogenesis of rosacea) when exposed to a variety of provocative environmental factors including emotional stimuli such as anxiety, excitement, or embarrassment. In past studies, patients frequently reported a connection between stress and the development of rosacea and were inclined to be more anxious than patients with alopecia areata or lichen planus.

Telogen Defluvium Telogen defluvium (also called telogen effluvium) is the increased loss of normal club hairs because of a perturbation of the hair cycle by drugs, high fever, childbirth, and crash dieting. More women than men seek clinical attention for telogen defluvium. Reports suggest that emotional stress can induce telogen defluvium, but the limited documentation in these older reports makes it difficult to conclude firmly that the patients had telogen defluvium and not other diagnoses

such as alopecia areata.

Primary Hyperhidrosis Primary hyperhidrosis is excessive sweating in response to mental stimuli and typically affects the palms, soles, and axillae. Patients usually present before the age of 20 and often have a positive family history. Although the pathophysiology is not completely understood, it involves the sympathetic nervous system and integration at the level of the hypothalamus. The disorder can cause considerable embarrassment and avoidance, but open studies have successfully used hypnosis, assertiveness training, systematic desensitization, and instrumental conditioning in the treatment of hyperhidrosis.

Seborrheic Dermatitis Seborrheic dermatitis, a common disorder affecting about 2 to 5 percent of the population, occurs slightly more often in male patients and at two age peaks: within the first 3 months and in the fourth to seventh decade of life. The cause of the increased sebum production (seborrhea) of the scalp and sebaceous follicle-rich areas of the face and trunk is unknown, but reports suggest that emotional stress may aggravate the symptoms.

Prurigo Nodularis Prurigo nodularis, a chronic disorder distinguished by intense localized pruritus and discrete hard nodules, occurs mainly in middle-aged women. The cause is unknown, but stress-induced exacerbations have been reported.

UNDIFFERENTIATED SOMATOFORM DISORDER

Chronic Idiopathic Pruritus Pruritus, or itching, is the most common symptom of dermatological disorders and of several systemic diseases including chronic renal disease, hepatic disease, hematopoietic disorders, endocrine disorders, malignant neoplasms, drug toxicity, and neurological syndromes (e.g., multiple sclerosis). Other problems such as advanced age, infections with internal parasites, and viremia can also be associated with pruritus.

Although pruritus is a common and distressing symptom, its pathophysiology is not completely understood. In histamine-induced pruritus, psychic trauma lowers itch threshold, aggravates itch intensity and prolongs itch duration, and its duration was more pronounced in subjects reporting “moodiness” during stressor exposure. Recent stressful life events have also been correlated with an increased ability to detect itch, and a study of pruritus in psoriasis, atopic dermatitis, and chronic idiopathic urticaria drew a direct correlation between pruritus severity and the degree of depressive symptoms, possibly due to a reduced itch threshold. Psychiatric factors may influence the perception of itch by several mechanisms. The hypothalamus and other components of the limbic system may modulate sensory perception through the sensory cortex, and elevation of corticotropin-releasing factor in some depressed patients may increase CNS opiate concentrations, enhancing the perception of pruritus. Neuropeptides such as substance P may also be released in response to stress and produce itching. Chronic idiopathic pruritus and idiopathic pruritus ani (itching in the anal area), vulvae (itching in the vaginal area), and scroti (itching in the scrotum) frequently have been called psychogenic, but more study is needed to determine how psychiatric and other CNS disorders contribute to the development of pruritus. Antidepressant medications, particularly the tricyclic drugs, can relieve pruritus of many origins. Behavioral treatment aimed at interrupting the itch-scratch cycle may be important in the management of pruritus and the prevention of complications such as *lichen simplex chronicus*, a condition of prominent skin markings and thickening of the tissue that develops secondary to long-term scratching. Techniques include habit reversal training and cognitive-behavioral therapy.

PAIN DISORDER

Glossodynia Glossodynia (also called burning mouth syndrome) is an unexplained, prolonged sensation of pain, burning, or both inside the oral cavity, most frequently at the tip and lateral borders of the tongue and often accompanied by other symptoms such as dryness, paresthesia, and changes in taste and smell. It affects up to 5 percent of the general dental population and occurs mostly in women with a mean age of 55 to 60. Symptoms are long-lived, lasting from months to up to 18 years. Several possible causes for glossodynia have been proposed including candida glossitis, vitamin B deficiencies, diabetes mellitus, estrogen deficiency at menopause, inadequate dental fillings, denture wear, parafunctional oral habits, salivary disturbances, and galvanism. The condition is often considered idiopathic.

Psychiatric factors are thought to play an important role in many patients with glossodynia. Controlled studies found higher rates of depression and anxiety in glossodynia patients, but causal relationships are uncertain. Currently no evidence supports a correlation between stressful life events and glossodynia. In open trials antidepressants (monoamine oxidase inhibitors, tricyclic drugs, and SSRIs) and benzodiazepines have shown beneficial effects in patients with glossodynia.

Vulvodynia Vulvodynia is chronic vulvar and perineal discomfort of variable severity with burning, stinging, irritation, or rawness. It is a clinical problem of importance to dermatologists, gynecologists, and primary care physicians. In general gynecological outpatient practices, the prevalence can be as high as 15 percent. The age distribution is variable, ranging from the mid-20s to the late 60s and older. Vulvar pain frequently has an acute onset but can become chronic, lasting for several months or years. Many patients seek help from several physicians and try multiple therapies, frequently with unsatisfactory results.

Vulvodynia without an identifiable medical cause was once thought to be psychological, but more-recent diagnostic techniques and discoveries have permitted identification of the medical cause of many cases, including vulvar dermatoses, cyclic candidal vulvitis, vulvar papillomatosis, and vulvar vestibulitis. However, many cases of “essential” or dysesthetic vulvodynia remain, in which the cause is unknown. Dysesthetic vulvodynia is postulated to result from a problem with cutaneous perception, either centrally or at the nerve root. It occurs more frequently in perimenopausal or postmenopausal women and is characterized by constant vulvar or perineal discomfort with frequent urethral and rectal discomfort as well. These patients have less dyspareunia and less point tenderness on examination than patients with vulvar vestibulitis.

In a controlled study, patients with vulvodynia of any cause were significantly more likely than patients with other vulvar pathology to somatize and to be anxious, were more bodily aware, and were more bothered by many different symptoms in addition to vulvar complaints. Vulvodynia patients also consulted more doctors and experienced more sexual dysfunction related to their symptoms. Patients with dysesthetic vulvodynia were even more distressed than other vulvodynia patients with more anxiety and suggestibility. The role of comorbid psychiatric symptoms needs further study, but they may influence the perception of pain through central mechanisms. In a retrospective study of psychotropic treatment of vulvodynia, the patients with dysesthetic vulvodynia responded to the tricyclic drug amitriptyline (Elavil). Other types of vulvodynia were less responsive to antidepressant treatment. The amitriptyline dosage ranged from 10 mg to 100 mg per day, with an average daily dosage of 60 mg and an average treatment duration of 7 months. Other tricyclic drugs such as nortriptyline and desipramine (Norpramine) may also be effective and possibly better tolerated than amitriptyline, but more study is needed.

Body Dysmorphic Disorder Body dysmorphic disorder is a preoccupation with an imagined defect in appearance, and patients with this disorder who are concerned about the appearance of their skin or hair frequently consult dermatologists. Some patients with body dysmorphic disorder pick the skin in an attempt to improve their appearance, as discussed below. Although body dysmorphic disorder is classified as a somatoform disorder, it has phenomenological similarities to obsessive-compulsive disorder.

DELUSIONAL DISORDER, SOMATIC TYPE

Delusions of Parasitosis Delusions of parasitosis is the fixed belief that one is infested with living organisms despite a lack of medical evidence of such infestation. Patients also frequently experience tactile hallucinations described in many cases as crawling, biting, or stinging or other perceptual abnormalities such as auditory hallucinations of buzzing or other sounds. Delusions are often of a cutaneous invasion, so patients frequently present to dermatologists. Delusions of parasitosis appears to be uncommon, with an equal sex distribution in patients under the age of 50 and a female to male ratio of 3 to 1 in patients 50 and older.

Delusions of parasitosis has been associated with many medical disorders including tuberculosis, syphilis, chronic lymphocytic leukemia, polycythemia vera, malignant lymphoma, congestive heart failure, arteriosclerosis, diabetes mellitus, vitamin B_{12} deficiency, pellagra, renal failure, hypothyroidism, and hepatic disease and the dermatological disorders stasis dermatitis and vitiligo. Neurological conditions associated with delusions of parasitosis include dementia, Parkinson's disease, Huntington's disease, cerebral infarction, and CNS tumors. Some of the disorders appear to cause delusions of parasitosis, while others seem to at least contribute to its development. Delusions of parasitosis can also occur after long-term use of amphetamines, methylphenidate (Ritalin), cocaine, or alcohol or use of phenelzine (Nardil), pargyline, and corticosteroids. The disorder usually remits with discontinuation of the drug.

Several psychiatric disorders may also exhibit delusions of parasitosis as part of their clinical presentation, including major depressive disorder, bipolar I disorder, and schizophrenia. Delusions of parasitosis also occurs as a single somatic delusion with no other impairment of thought or thought process, called monosymptomatic hypochondriacal psychosis and classified under delusional disorder, somatic type, in DSM-IV. Because their mental status is otherwise intact, these patients may be more likely than those with other psychiatric disorders to seek care from a dermatologist. Other patients develop tactile hallucinations (formication) but do not have

delusions about the cause of the symptoms and are less likely to have a history of psychiatric disorders than those with delusions of parasitosis.

Characteristic features of delusions of parasitosis include a specific precipitant, a history of potential or actual exposure to contagious organisms or actual infestation, and a history of multiple consultations with physicians and other professionals such as entomologists and exterminators. However, many patients, particularly those with an isolated delusion of infestation, are reluctant to accept psychiatric evaluation because of the implication that the infestation is not real. Patients make multiple attempts at treatment and often use nontraditional therapies to eradicate the "bugs," such as repetitive washing, checking, and cleaning; excoriation of the skin with needles, knives, or fingernails; and discarding or destroying possessions, including the family pet. The delusion may be shared by others *(folie à deux)*, and the fear of contaminating others is often present. The patients usually bring in specimens for examination by the physician but all that is found is inanimate material, nonharmful insects, or bits of hair and skin. Descriptions of the offending parasite vary from the imprecise "things" or "bugs" to detailed explanations of the organism's (usually insects, spiders, or worms) appearance, behavior, and life cycle. Patients frequently report social isolation and loss of employment as a result of the delusions, and patients have rarely been reported to commit suicide. Dermatologists have noted that the mistaken worries about infestation span a spectrum from nondelusional to delusional thinking. Sometimes the preoccupation with infestation resembles obsessions in that it is distressing, anxiety provoking, persistent, recurrent, and difficult to resist or control. Furthermore the repetitive behaviors that often accompany the preoccupation are compulsive. Many patients have both obsessional and delusional thinking, which may have important treatment implications.

One must seek underlying medical and psychiatric conditions that may be contributing to the delusions of parasitosis. Patients with delusions of parasitosis as an isolated delusion (delusional disorder, somatic type) respond to treatment with the potent neuroleptic pimozide (Orap). Only one controlled study of the treatment of delusions of parasitosis with pimozide exists, and 10 of 11 patients improved after 6 weeks of 1 to 5 mg per day. A follow-up study indicated that many patients treated with pimozide could discontinue the medication after a mean treatment duration of 5 months without recurrence of the delusions. In other anecdotal reports pimozide doses up to 12 mg per day have been used. There are uncontrolled reports of efficacy with other antipsychotic medications including chlorpromazine (Thorazine), trifluoperazine (Stelazine), haloperidol (Haldol), risperidone (Risperdal), and fluphenazine (Prolixin). Although pimozide is most commonly advocated for the treatment of delusions of parasitosis (particularly delusional disorder, somatic type), there is no conclusive evidence that pimozide is superior to other antipsychotics. A case report of successful treatment with naloxone (Narcan) and naltrexone (ReVia) suggests a disorder in the endogenous opiate system, and interestingly, pimozide is the only neuroleptic used in delusions of parasitosis that is a potent opiate antagonist. Pimozide may be antipruritic as a result of its opiate antagonism, and the relief of pruritus or paresthesias could contribute to improvement in delusions of parasitosis. There are also case reports of successful treatment of delusions of parasitosis with tricyclic drugs and electroconvulsive therapy. Because of the obsessive characteristics of many patients with delusions of parasitosis, the symptoms may possibly respond to the SSRIs, but more study is needed. Psychotherapy has minimal efficacy in the treatment of this disorder. However, behavior therapy may have a role in treatment, especially for the obsessive-compulsive characteristics of many patients with delusions of parasitosis, but more study is needed. Dermatologists have advocated an approach to patients with delusions of parasitosis that allows development of a therapeutic relationship with them. This is accomplished by listening to patients' stories, asking how the condition affects their lives, being alert to any area in which they will accept help, and trying to reduce their sense of isolation.

Other Delusions In the delusional variant of body dysmorphic disorder, the preoccupations with a defect in appearance are of delusional intensity, although the distinction between an obsessive concern and delusions is not always clear. Delusional body dysmorphic disorder may respond preferentially to SSRIs, and if a patient does not completely respond to an SSRI, the addition of an antipsychotic such as pimozide may help.

The delusion of a foul body odor is another encapsulated somatic delusion that a dermatologist may encounter. Treatment data are limited, but pimozide and other antipsychotic medications may be effective.

OBSESSIVE-COMPULSIVE SPECTRUM DISORDERS

Psychogenic Excoriation Psychogenic excoriations (also called *neurotic excoriations*) are lesions caused by scratching or picking in response to an itch or other skin sensation or because of an urge to remove an irregularity on the skin from preexisting dermatoses such as acne *(acné excoriée)*. Lesions are typically found in areas that the patient can easily reach (e.g., the face, upper back, and the upper and lower extremities) and are a few millimeters in diameter and weeping, crusted, or scarred, with occasional postinflammatory hypopigmentation or hyperpigmentation (Fig. 25.7-5). The patients usually acknowledge the self-inflicted nature of the lesions. There is an incidence of 2 percent among dermatology clinic patients and a predominance of women. Most studies report a mean age of onset between 30 and 45 years of age, although *acné excoriée* can begin in adolescence and persist into adulthood. The mean duration of symptoms is 5 years, with a better prognosis for patients who have had the symptoms for less than 1 year.

FIGURE 25.7-5 Psychogenic excoriation. The self-induced nature of the condition is suggested by the relative sparing of the lateral upper back, where the patient cannot easily reach.

The behavior in psychogenic excoriation sometimes resembles obsessive-compulsive disorder in that it is repetitive, ritualistic, and tension reducing, and patients attempt (often unsuccessfully) to resist excoriating, a behavior they find ego-dystonic. Patients also sometimes describe obsessions about an irregularity on the skin or preoccupations with having smooth skin and may excoriate in response to the thoughts. The preoccupation with appearance can be severe enough to meet criteria for body dysmorphic disorder, a disorder also thought to be related to obsessive-compulsive disorder. The excoriative behavior can also have features characteristic of impulse-control disorders in that the patients often act automatically and sometimes experience increased tension before the behavior, with transient pleasure or relief immediately afterward. Thus, behaviors can span a compulsivity-impulsivity continuum from purely obsessive-compulsive to purely impulsive with mixed symptoms in between. The case below illustrates the mixed compulsivity-impulsivity of psychogenic excoriation.

> A 22-year-old woman with no past medical history presented with a 3-year history of excoriation of acne lesions. She described herself as "obsessed" with having a "flawless" complexion. When blemish eruptions occurred, she became depressed and worried constantly that people would look at her skin and think she was unclean. She became reluctant to leave her home and repeatedly examined and washed her face. She picked facial lesions until "something came out" and could "work at" her face for 30 minutes at a time, becoming completely focused on the behavior. At other times, she found herself picking her face automatically, while doing homework or watching television. She tried to resist the urge to excoriate the lesions but felt she had little control over the behavior. She reported feeling tension build with the urge to pick her face and some relief of tension and anxiety and frequently pleasure upon acting. However, the behavior was often followed by self-reproach, as she was aware that she was making her skin worse.

The repetitive and tension-reducing nature of the behavior and the resistance to performing the behavior are consistent with compulsions. Obsessive features include the preoccupation with a flawless complexion and cleanliness. The automatic enactment of the excoriation and the sense of tension before the behavior and pleasure upon acting are characteristic of impulsivity.

Studies examining the psychiatric comorbidity of patients with psychogenic excoriation found depressive and anxiety disorders to be common. A recent report noted that patients with impulsive excoriative behavior had a high rate of comorbid bipolar disorders, consistent with studies of other impulse-control disorders in which bipolar disorders are frequently comorbid.

Case reports and open trials demonstrate the responsiveness of compulsive skin picking or scratching to treatment with the serotonin reuptake inhibitors fluoxetine

(Prozac), sertraline (Zoloft), clomipramine (Anafranil), and fluvoxamine (Luvox). One controlled trial of the treatment of psychogenic excoriation found that fluoxetine may be beneficial. There are also case reports of successful treatment of psychogenic excoriation and acné excoriée with behavioral therapy.

Trichotillomania Trichotillomania is a disorder of chronic hair pulling currently classified as an impulse-control disorder in DSM-IV, but like psychogenic excoriations, the hair pulling has characteristics of both impulsivity and compulsivity. It causes significant distress or impairment in functioning and leads to notable alopecia, most commonly of the scalp hair, but lashes, brows, pubic hair, and other body hair may be involved (Fig. 25.7-6). The extracted hair may also be chewed or swallowed, leading to trichobezoars. Patients may also develop infections at the site of hair pulling, a change in texture or color of the hair or carpal tunnel syndrome from pulling. In a survey of college freshmen, the lifetime prevalence of trichotillomania (by strict criteria) was 0.6 percent for both men and women but rose to 3.4 percent for women and 1.5 percent for men if all hair pulling with noticeable hair loss was included. The condition typically persists for years, with a mean age of onset of 13 years. The prognosis appears to be better with hair pulling of 6 months' duration or less, but most do not seek treatment.

FIGURE 25.7-6 Trichotillomania. Note the typical findings of an area of incomplete alopecia involving the frontal and vertex scalp.

Researchers have identified two types of hair pulling. In the focused style, patients focus solely on the pulling without attention to other thoughts and activities. Symptoms resemble obsessive-compulsive disorder in that there is resistance to the pulling and relief with pulling. However, most patients engage in an automatic style of pulling that occurs during situations described as “sedentary or contemplative” such as reading or watching TV. Many patients have a combination of these two styles.

In clinical samples of trichotillomania, Axis I comorbidity included anxiety, mood, obsessive-compulsive, substance use, and eating disorders. The most frequent comorbid Axis II disorders included Cluster B (histrionic, borderline) personality disorders and Cluster C (obsessive-compulsive, passive-aggressive) personality disorders. However, whether one particular personality disorder is characteristic of patients with trichotillomania is unclear. Patients with trichotillomania frequently have first-degree relatives with obsessive-compulsive disorder and trichotillomania, and family histories of mood disorders, substance use disorders, anxiety disorders, and schizophrenia.

In a double-blind crossover study, trichotillomania responded preferentially to the antiobsessional agent clomipramine over desipramine, and in another report, response to clomipramine negatively correlated with anterior cingulate and orbital frontal metabolism on position emission tomography (PET) examination, a finding also characteristic of obsessive-compulsive disorder. Open studies of the antiobsessional SSRI fluoxetine reported positive short- and long-term results, but controlled studies have yielded mixed results. Two placebo-controlled studies found that fluoxetine was not superior to placebo in the treatment of trichotillomania, but in a double-blind crossover study of clomipramine and fluoxetine, both medications had positive treatment effects on trichotillomania. Case reports and open trials also relate successful treatment with other SSRIs including fluvoxamine, paroxetine (Paxil), and sertraline, and other antidepressants, lithium, and buspirone (Buspar). Pimozide augmentation of clomipramine or fluoxetine and olanzapine augmentation of fluoxetine have also proved useful in case studies. The behavioral treatment of habit reversal was reported effective in trichotillomania and involves increasing awareness of situations or stressors associated with hair pulling, relaxation training, and competing response training. Hypnosis and other behavioral treatments have also been useful in case reports.

Onychophagia Onychophagia (repetitive nail biting) is a common behavior that can begin as early as age 4, with a peak between the ages of 10 and 18 years of age and appears to be familial. Severe onychophagia can lead to significant medical and dental problems such as hand infection and craniomandibular disorders. Onychotillomania, the picking or tearing of the nail, may be a variant of the behavior. Like trichotillomania and psychogenic excoriation, onychophagia possesses the phenomenological features of repetition, resistance, and relief and may therefore be one of the obsessive-compulsive spectrum disorders. Like trichotillomania, a double-blind crossover study demonstrated that onychophagia responded preferentially to clomipramine over desipramine. Many forms of behavioral therapy, including habit reversal, have been efficacious.

FACTITIOUS DISORDERS

Factitious Dermatitis Factitious dermatitis (also called dermatitis artefacta) is a disorder in which the skin is the target of self-inflicted injury. As in other factitious disorders, patients intentionally produce lesions to assume the sick role and typically deny the self-inflicted nature of the disorder. Factitious dermatitis can present with a wide variety of lesions depending on the methods used by the patient. Sometimes patients simulate actual medical dermatoses or aggravate a preexisting dermatological condition. Lesions consist of excoriations, blisters, purpura, ulcers, erythema, edema, sinuses, and nodules. Methods used by patients include rubbing, scratching, picking, cutting, puncturing, sucking, biting, application of suction cups, occlusion, applications of dye or heat or caustic substances onto the skin, or the injection of caustics, infected material, blood, feces, or other substances into the skin. Skin damage can be extensive with full-thickness skin loss and severe scarring requiring plastic surgery or even amputation. Despite the variety of factitious lesions, they have some common features. Affected sites tend to be easily accessible to the patient and are more prominent on one side of the body, depending on the handedness of the patient. Excoriated lesions frequently have sharp geometric borders with normal surrounding skin or lines at the margin if a caustic is used and some liquid dripped out of the site. There is no evidence of the natural progression of the lesions through the different stages of development. The history is often vague and hollow, and patients are often very suggestible as to the site of the next lesion. The use of an occlusive dressing such as an Unna Boot (a dressing that hardens to form a protective covering) can help make the diagnosis because the lesions heal when the patients are unable to reach them.

Factitious dermatitis occurs in about 0.3 percent of dermatology patients, with a reported female to male ratio between 3 to 1 and 8 to 1 and greatest frequency in adolescents and young adults. It reportedly begins after severe psychosocial stress, usually involving loss, threatened loss, or isolation. As in other factitious disorders, the patient often has experience in medicine either from prior exposure to illness or employment in a health care field. The prognosis varies; some cases resolve after a brief episode while others become lifelong problems. In a classic long-term study, 30 percent of patients continued to produce lesions more than 12 years after the onset of their symptoms.

Physicians must distinguish factitious dermatitis from other forms of self-inflicted dermatoses described in the sections above. Although borderline personality disorder is commonly comorbid with factitious dermatitis, some patients with borderline personality disorder readily acknowledge that they damage their skin in an impulsive act that resembles obsessive-compulsive spectrum disorders. Self-mutilation by impulsive patients may result from low serotonergic function and may respond to the SSRI fluoxetine. Other self-mutilating patients with psychosis or mental retardation do not have the other characteristics of a factitious disorder. Physicians must also eliminate the possibility of malingering.

The management of factitious dermatitis involves developing an empathic, therapeutic relationship between the dermatologist and the patient. Since the patients deny the self-inflicted nature of the lesions, they usually do not immediately accept a referral to a psychiatrist, and direct confrontation may disrupt the doctor-patient relationship. However, once a therapeutic relationship has been established, some patients will accept a psychotherapeutic approach.

Psychogenic Purpura The spontaneous appearance of recurrent bruising (purpura) is a rare dermatological disorder often following an injury or surgical procedure and typically initiated by pain, burning, or stinging succeeded by warmth, erythema, swelling, sometimes pruritus, and, after hours or days, ecchymosis. Blood coagulation and hemostatic test results, however, remain normal. The incidence is unknown, but women are affected more frequently than men, with a female to male ratio of 20 to 1. The age of onset varies from 9 to 53 years, with most between the ages of 14 and 40. Three different proposed mechanisms currently exist:

autoerythrocyte sensitization, conversion reaction, and factitious disorder.

Autoerythrocyte sensitization (Gardner-Diamond syndrome) attempts to explain the appearance of lesions after trauma and postulates that during the injury patients became sensitized to the stroma of extravasated erythrocytes. Many patients' bruises are reproduced by intracutaneous injection of washed red blood cells or erythrocyte stroma, but some patients do not have a positive response to the injections. Furthermore, tests for circulating antibodies to red blood cell components have been negative, no abnormalities in immunological function have been evident, and immunosuppressive treatment and desensitization with autologous blood products have been unsuccessful.

The limited evidence for autoerythrocyte sensitization has led some authors to advocate a psychogenic cause for the purpura. Purpura often begins after a significant psychosocial stressor, and most patients present with several other unexplained somatic symptoms and conversion symptoms and have significant comorbid psychiatric symptoms, including depression, anxiety, and personality disorders, particularly borderline and histrionic personality disorders. However, the differentiation between conversion and factitious purpura has been less clear because patients thought to have conversion symptoms and those found to have factitious disorder share many common features. In addition, physicians can identify no mechanism for a conversion reaction or convincingly disprove factitious causation in many cases. The underlying psychiatric cause is therefore unresolved and awaits further information about possible psychophysiological mechanisms.

PSYCHIATRIC CONSULTATION-LIAISON WITH DERMATOLOGISTS

Disorders at the interface of psychiatry and dermatology are varied. Developments in both fields have improved understanding of psychocutaneous disorders. Continued collaboration between dermatologists and psychiatrists is needed to further the understanding of these disorders.

Psychocutaneous disorders are best managed when the psychiatrist and dermatologist have a close working relationship. Because many patients with psychocutaneous disorders are initially reluctant to accept a psychiatric referral, dermatologists must educate the patients about the role of stress and psychiatric problems in their skin disorder and sometimes initiate treatment with psychotropic medications. In some medical centers, psychodermatology clinics in which a psychiatrist is present in the dermatology setting have been established to improve the management of psychocutaneous disorders. Because the psychiatrist is readily available at these clinics and part of the medical team, patients may be more willing to accept psychiatric evaluation and treatment.

SUGGESTED CROSS-REFERENCES

Somatoform disorders are discussed in Chapter 16, delusional disorders in Section 13.2, impulse-control disorders in Chapter 22, obsessive-compulsive disorders in Chapter 15, and factitious disorders in Chapter 17.

25.8 MUSCULOSKELETAL DISORDERS

TERESA A. RUMMANS, M.D., KEMUEL L. PHILBRICK, M.D., AND M. KEVIN O'CONNOR, M.D.

Numerous diseases come under the umbrella of musculoskeletal disorders. The three most common musculoskeletal disorders encountered by psychiatrists are rheumatoid arthritis, systemic lupus erythematosus, and fibromyalgia. Although there is no single unifying theory for the development and pathogenesis of these conditions, multidimensional explanations currently aid in integrating them into one category. They involve primarily biological but also psychological and social components. This section focuses on the etiology, presentation, diagnosis, and treatment of these diverse but similar musculoskeletal disorders.

RHEUMATOID ARTHRITIS

The name rheumatoid arthritis was coined in 1859, only a generation after the first distinct clinical description in 1800 by Augustin Landre-Beauvais. However, ample evidence indicates that rheumatoid arthritis afflicted diverse individuals prior to surfacing in the medical literature. Thomas Sydenham offered a detailed description of a chronic joint disease with distinguishing features suggesting rheumatoid arthritis in 1676. Disiderius Erasmus, who died in 1536, was portrayed by the Flemish painter Quinten Metsys with swelling of three metacarpophalangeal joints clearly visible on his right hand. Constantine IX, the Byzantine emperor who ruled a half-millenium earlier, was afflicted with a chronic, polyarticular, deforming joint disorder; the description offered by a courtier inclines historians to suspect it was rheumatoid arthritis. Reaching even further back in time, 13 of 213 well-preserved skeletons of Native Americans dating back at least 3000 years were subjected to both gross and radiological examination that revealed extensive joint erosions consistent with rheumatoid arthritis.

The specific nosology of rheumatic diseases continues to pitch and roll with continental preferences and episodic surging advances in the understanding of pathophysiology, but rheumatoid arthritis remains under the rubric of disorders involving the immune system, connective tissue, and joints. The first two editions of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-I, DSM-II) regarded rheumatoid arthritis as psychosomatic. By contrast, the disease is not directly mentioned in the fourth edition of DSM (DSM-IV), although rheumatological disorders are cited as one example of illness in which psychological factors may affect a medical condition.

Epidemiology Rheumatoid arthritis does not respect geography or race; it has been identified in all areas of the world and every ethnic group that has been studied. Prevalence rates, however, do show ethnic and geographic partiality. Asian populations enjoy a lower prevalence rate, while North American and many European populations have a lifetime prevalence of definite rheumatoid arthritis among white adults that hovers around 1 percent. Peak prevalence rates of 5.3 percent were discovered in select Native American populations. Rates in African populations vary; African-Americans have a rate roughly parallel to that of white Americans, whereas in Africa, this prevalence holds for urban populations but is significantly lower in many rural populations. Some attribute this disparity to excess mortality from infections associated with rheumatoid arthritis among rural Africans with limited access to medical care. Other epidemiological studies have concluded that this disparity in disease incidence despite similar genetic background reflects the supplemental role of environmental factors in the genesis of rheumatoid arthritis.

The disease afflicts women two to three times more often than men, regardless of age. The peak age of onset (usually placed in the early to mid-40s) is difficult to determine, owing to the varied diagnostic criteria used, but men are more commonly affected several years later than women. Studies on both sides of the Atlantic have demonstrated a decrease in age-adjusted annual incidence rates in women but not men; this has prompted the suggestion that oral contraceptives may influence the onset of rheumatoid arthritis.

Family and twin studies support a definite genetic predisposition. An association between rheumatoid arthritis and various genes and genomic subtypes in the human lymphocyte antigen (HLA)-D complex is established. Different ethnic groups demonstrate selective associations (e.g., North American whites possess an association with HLA-DR4, Israeli Jews with HLA-DR1, and Yakima Indians with HLA-Dw16). These associations do not offer complete accountability for the susceptibility to rheumatoid arthritis, however, suggesting that as yet unidentified genes outside the HLA complex also participate. These genetic factors appear to extend to the propensity for particular toxic reactions to medications encountered by patients with rheumatoid arthritis. For example, adverse effects of gold therapy such as proteinuria and thrombocytopenia appear genetically linked to the presence of the HLA-DR3 allele. Thus far, however, HLA typing has not been able to predict response to a particular treatment regimen.

Etiology Despite impressive advances in knowledge regarding the genetic and immunological contributions to rheumatoid arthritis, it remains a condition of unknown cause whose progression is well described but without identification of the specific factors that fuel disease maintenance and progression. Considerable current research attention is focused on the possibility that it may result from infection by an unknown but ubiquitous organism occurring in a genetically susceptible host.

Clinical tradition, buttressed by anecdotal lore and flawed research, long attributed causal strength to a psychological style characterized by restricted emotional expression (with particular emphasis upon the inability to express anger), obsessionality, dependency, and depression. However, appreciation grew for the weaknesses inherent in retrospective research (conducted without appropriate control groups and with inadequate attention to the concurrent medical status of participants) and the breadth of clinical severity of rheumatoid arthritis and subsequent studies have not validated any etiological contribution of the “arthritic personality.”

Studies attempting to clarify whether acute stress might play a precipitant role in the onset of rheumatoid arthritis have come to varying conclusions, leading some to suggest that subtypes of patients may exhibit differential sensitivity to the potential triggering effects of stress. Other reviewers attribute the diversity of results to the equal diversity of methodological inadequacies of these studies. Distressed interpersonal relationships are especially prominent in the literature of stressors experienced by patients with rheumatoid arthritis, despite the lack of evidence for etiological significance.

The capacity to measure suppression of cellular and humoral immune responsiveness following stress has appropriately fueled speculation that there may be a psychoneuroimmunologic circuit whereby psychological issues wield biochemical central nervous system effects that trigger immunological responses, forming the foundation for rheumatoid arthritis. Much of this research remains limited to animal models, with no significant contribution as yet to the understanding of a potential role of psychological stress in rheumatoid arthritis. Nonetheless, suggestive results in animal studies continues to invite translation research involving rheumatoid arthritis patients.

Diagnosis and Clinical Features Rheumatoid arthritis is a systemic, chronic, inflammatory, and progressive disease. Patients usually experience a prodromal syndrome that may include vague constitutional symptoms, fleeting musculoskeletal pain, and variable morning stiffness that may last for weeks or months without yielding to diagnosis. Although a few patients experience abrupt onset, most note an insidious beginning followed by gradual involvement of multiple joints in a symmetrical pattern. A few patients have an asymmetrical pattern.

Although no joint is necessarily spared, symmetrical polyarthritis of the peripheral joints is most common. Morning stiffness is almost pathognomonic and can serve as a rough gauge of disease activity. Constitutional symptoms as well as local inflammation in affected joints continue. Over years, these joints suffer articular destruction, consequent instability, and subsequent deformity with collateral pain and functional impairment (Fig. 25.8-1). Neurological, ocular, pulmonary, cardiac, vascular, hematopoietic, gastrointestinal, hepatic, renal, muscular, and dermatological sequelae are well described with persistent active rheumatoid arthritis. Neurological corollaries of the disease are generally limited to the peripheral nervous system, relieving the central nervous system of primary consequences, although rare instances of delirium have occurred, perhaps related to central rheumatoid vasculitis.

FIGURE 25.8-1 Acute rheumatoid arthritis: showing the spindle-shaped swelling of the joints between the first and second phalanges, and the swelling in connection with the wrist and metacarpophalangeal joints. (Reprinted with permission from Douthwaite AH, editor: *French's Index of Differential Diagnosis*, ed 7. Williams & Wilkins, Baltimore, 1954.)

The American College of Rheumatology has simplified diagnostic criteria for rheumatoid arthritis, presently requiring four of the following seven clinical features: morning stiffness, arthritis of three or more joint areas, arthritis of the hand joints, symmetrical arthritis, rheumatoid nodules, serum rheumatoid factor, and typical radiographic changes. The first four of these must be present for at least 6 weeks. These criteria provide a sensitivity in excess of 90 percent and a specificity of 89 percent when used with control patients who have rheumatic diseases other than rheumatoid arthritis.

Pathology and Laboratory Examination Synovial hyperplasia and hypertrophy associated with vascular changes, inflammatory edema, and mononuclear cellular infiltration form the pathological hallmarks of early rheumatoid activation. Continuing immunological activation, including T and B lymphocyte infiltration with subsequent B cell transformation to antibody-producing plasma cells, marks the ongoing inflammation of the rheumatoid synovium. Cartilagenous and bony destruction is attributed to the production of various degradative and proteolytic enzymes as well as cytokinetic activation of demineralizing osteoclasts. The systemic sequelae of rheumatoid arthritis, including constitutional symptoms, are ascribed to inflammatory effector molecules produced by the synovium.

No single test offers explicit confirmation of rheumatoid arthritis. However, rheumatoid factors (largely immunoglobulin-M [IgM] autoantibodies) are found in nearly 70 percent of afflicted adults and only 5 percent of healthy adults. With advancing age, the latter percentage increases, and up to 20 percent of adults over 65 may test positive for a rheumatoid factor without clinical evidence of disease. Adding to the potential for misapprehensions, numerous other rheumatic and infectious diseases are associated with the presence of rheumatoid factor. Other laboratory findings that commonly accompany active RA include rheumatoid arthritis elevated acute phase reactants such as C-reactive protein and the erythrocyte sedimentation rate; normochromic, normocytic anemia; thrombocytosis; and turbid synovial fluid with increased protein content and white cell count.

Course and Prognosis Although the course of rheumatoid arthritis is variable, defying prediction for any given patient, more than 80 percent of patients experience persistent disease activity with some joint deformity 10 years after diagnosis. Radiographic evidence of joint damage can precede overt evidence by 6 to 7 years. Although remissions are most apt to occur in the first year, the rate of progression of joint destruction is greatest during the first 6 years, slowing considerably thereafter. Infection, drug therapy, and secondary gastrointestinal bleeding contribute to increased mortality, particularly in patients with especially severe articular disease. Overall, the median life expectancy of individuals with rheumatoid arthritis is estimated to be reduced by 3 to 7 years. Prognosis is somewhat better for patients who experience a more abrupt onset of illness, respond to first-line therapies, and have neither rheumatoid factor nor rheumatoid nodules.

Hormonal influences appear important in women with rheumatoid arthritis. Most women experience amelioration of symptoms during pregnancy, with early recurrence after parturition. Women with prior pregnancies and women taking oral contraceptives share a reduced incidence of the disease. Oddly, although women are clearly more prone to rheumatoid arthritis, female hormones may attenuate disease activity.

Most of the attention given to ascertaining the comorbidity of psychiatric disorders and rheumatoid arthritis has focused upon depression. There are suggestions in the literature that the incidence of anxiety spectrum disorders is mildly increased in patients with rheumatoid arthritis and that the incidence of psychotic disorders is decreased; however, both of these observations are controversial, and study results vary.

A recurring challenge in the determination of the comorbidity of depression with rheumatoid arthritis is the considerable overlap between somatic neurovegetative signs and symptoms suggesting depression and the physical manifestations of rheumatoid arthritis itself. Attempts to excise the diagnostic influence of such symptoms have supported the view that depression is comorbid with rheumatoid arthritis in about 20 percent of individuals, a rate approximating that in other chronic illness populations but about three times the general community rate. Studies attempting to delineate concomitant factors serve to expose associations but do not reliably imply causality, as these efforts have largely been cross-sectional rather than prospective. One possible exception is the relationship between pain and depression; increasingly, it appears that when pain and depression surface in concert, pain antedates development of mood disruption.

A linear relation between raw measures of disease activity and depression does not exist. Collateral factors that do influence the experience of depression include pain (both as reflected in self-report instruments and as documented with observed pain behaviors), perception of unpredictability regarding the clinical course of rheumatoid arthritis, degree of functional impairment (with particular emphasis on the loss of valued activities rather than sterile measures of strength or mobility), individual coping style, and the quality of environmental support, especially from significant relationships. Among individuals with rheumatoid arthritis, depression is more frequent in those who are not married, whose duration of disease is greater, and who have a higher occurrence of medical comorbidities.

Patients' preconceptions and expectations regarding their likely clinical course, their perception of the extent to which they can exercise some control over this course, and their personal cognitive style are important modifiers of their experience of the illness and their potential for depressive complications. Patients who tend to be passive, avoidant, and inordinately prone to fantasy, emotional expressivity, and catastrophization regarding their illness fare less well (with regard to experience of depression) than those who demonstrate active involvement and a problem-solving focus toward their disease.

The presence of depression in patients with rheumatoid arthritis deserves vigorous clinical attention as it may significantly affect clinical course. Individuals with rheumatoid arthritis and depression (compared with patients with similar objective measures of arthritic activity without depression) commonly demonstrate poorer functional status, an increased number of reported painful joints, more pronounced experience of pain, increased health use, increased bed days, and increased inability to work.

Treatment Pharmacotherapy for rheumatoid arthritis is stratified in four broad camps: anti-inflammatory agents, disease-modifying drugs, immunosuppressive agents, and experimental therapies. Aspirin, nonsteroidal anti-inflammatory drugs (NSAIDs), and glucocorticoids effectively decrease acute signs and symptoms but they offer little benefit in retarding disease progression. In contrast, although they offer little anti-inflammatory or analgesic benefit, disease modifiers such as gold compounds, antimalarial agents, penicillamine (Cuprimine), and sulfasalazine (Azulfidine) offer both clinical and serological evidence of benefit. In patients who cannot tolerate these agents or whose disease has progressed despite these medications, a third strategy uses immunosuppressive agents such as azathioprine (Imuran), cyclophosphamide (Cytoxan), methotrexate (Folex), or even cyclosporine (Sandimmune). Experimental approaches include total lymphoid irradiation, lymphoplasmapheresis, or administration of monoclonal antibodies to T cells. The conventional approaches are all associated with potential toxicity and they cannot ensure sufficient disease amelioration or arrest to satisfy each individual with rheumatoid arthritis. This has prompted diverse suggestions, many of which are expensive and avidly promoted, from the alternative medicine community, but none of these have weathered close scrutiny.

Potential psychiatric side effects of commonly used medications for rheumatoid arthritis are numerous. Cognitive dysfunction and delirium may accompany toxic levels of salicylates. The NSAIDs cross the blood-brain barrier and contribute to blockade of prostaglandin production, which in turn affects the function of various neurotransmitters. NSAIDs have been associated with cognitive impairment, frank delirium, depression, mania, and psychotic symptoms. Geriatric patients are especially susceptible to these adverse effects. Mood lability, sleep disruption, delirium, and psychosis are well-recognized potential effects of the glucocorticoids and are often dose sensitive. Patients who require corticosteroids for effective management but tolerate them poorly may benefit from concomitant prophylaxis with lithium (Eskalith, Lithobid). A variety of NSAIDs increase serum lithium concentrations and require cautious monitoring to avoid lithium intoxication. Antimalaria agents are associated with delirium, depression, depersonalization, and psychotic symptoms, but the gold compounds enjoy a benign history with respect to psychiatric adverse

effects. Immunosuppressive agents are typically used in low doses for patients with rheumatoid arthritis, enabling most patients to tolerate them without significant psychiatric sequelae.

In addition to pharmacotherapy, these patients commonly benefit from physical therapy guidance to balance appropriate elements of rest and exercise, as well as possible use of occasional splinting or reliance upon orthotic devices. With more advanced disease, surgery can offer significant relief of pain, correction of deformity, and consequent improvement in functional capacity.

The psychiatrist caring for patients with rheumatoid arthritis will do well to ascertain the patient's opportunities for education about the disease. Maximizing a patient's understanding of rheumatoid arthritis addresses the potent desire for control and thereby alleviates some measure of the vulnerability these patients often experience because of the unpredictable course of the disease. Frank discussion of compliance with medical pharmacotherapy is indicated, as multiple studies have shown wide variations in adherence to medical recommendations, particularly among patients with disease of longer duration and greater severity. Generally, NSAIDs are those most frequently ignored. Cognitive-behavioral therapy has consistently demonstrated effectiveness in reducing both pain behaviors and patients' self-report of pain. Studies also underscore the value of social support in ameliorating the experience of pain and functional impairment.

Psychotropic agents selected for use in patients with rheumatoid arthritis should minimize the side effects that prove especially problematic for individuals contending with this disease. Sleep, which is often disrupted by pain, can be assisted by the combination of an NSAID and trazodone (Desyrel), with appropriate cautionary advice regarding orthostasis to patients who face decreased mobility. There are no studies demonstrating differential efficacy of one antidepressant agent versus another. However, the tricyclic drugs exert mild anti-inflammatory effects independent of their mood-altering benefit. Unfortunately, anticholinergic effects (prominent among the tricyclic drugs and also present with the serotonergic agent paroxetine [Paxil]) can aggravate the significant difficulties with dry oral and ocular membrances in patients whose rheumatoid arthritis is associated with Sjögren's syndrome. Patients with rheumatoid arthritis who also require mood stabilization may experience fewer fluctuations in serum concentrations with use of carbamazepine (Tegretol) or valproic acid (Depakote), as the NSAIDs can effectively increase lithium levels and toxicity by increasing renal tubular reabsorption of the lithium ion. Gold compounds, as well as amyloid or vasculitic involvement of the kidneys, can impair renal function and alter serum lithium concentrations. On the other hand, carbamazepine can induce hepatic metabolism of cyclosporine and is therefore not ideal in that combination. The choice of a lopamine receptor antagonist for a patient with rheumatoid arthritis who develops delirum can be challenging; the lower-potency agents present heightened anticholinergic toxicities, whereas the high-potency agents may provoke extrapyramidal effects that can be both difficult to recognize in a relatively immobile rheumatoid patient and especially threatening for a patient who can ill-afford further compromise of flexibility and mobility. The serotonin-dopamine antagonists, such as risperidone (Risperdal) or olanzapine (Zyprexa), may offer appropriate efficacy with less risk to such patients.

SYSTEMIC LUPUS ERYTHEMATOSUS

Systemic lupus erythematosus is a connective tissue disease of unclear etiology, characterized by recurrent episodes of destructive inflammation of several organs including the skin, joints, kidneys, blood vessels, and central nervous system (CNS). *Lupus* is the Latin word for wolf, and the choice of this term to designate the group of patients suffering from combination of skin, joint, nervous system, and vascular manifestations of this disease seems unfortunate in retrospect, for only rarely today do the facial edema and skin changes that occur in this disease cause its victims to take on a lupine visage. They are more likely to take on the appearance of Cushing's disease because of the high-dose corticosteroids used in treatment.

Epidemiology In the United States, systemic lupus erythematosus is estimated to appear in between 1.8 and 4.6 persons per 100,000 population per year and to be present in 0.1 percent of women at any one time. Its peak incidence occurs in women between the ages of 15 and 25 years.

Etiology Systemic lupus erythematosus is thought to result from dysregulation of the immune system, which results in production of antibodies against the self. The deposition of immune complexes along with complement leads to inflammation. Why this occurs is likely to become apparent only as more is learned about the cellular biology of the immune system.

Diagnosis and Clinical Features The diagnosis of systemic lupus erythematosus is not a simple matter, particularly early in the course of the disease before the characteristic immunological markers become clearly abnormal. In a manner similar to what is contained in the American Psychiatric Association's DSM, the American Rheumatism Association formulated and in 1982 revised criteria for the diagnosis of systemic lupus. A person is said to have the disease if any four of the following are or have been present: malar rash (Fig. 25.8-2), discoid rash, photosensitivity, oral ulcers, arthritis, serositis (pleuritis or pericarditis), renal disorder (proteinuria or cellular casts), neurological disorder (seizures or psychosis), hematological disorder (anemia, leukopenia, thrombocytopenia), immunological disorder, abnormal titer of antinuclear antibody. Fatigue commonly associated with active systemic lupus erythematosus has been found to correlate with other conditions found occasionally without systemic lupus erythematosus such as fibromyalgia.

FIGURE 25.8-2 Woman with lupus erythematosus malar rash. (Courtesy of M. Kevin O'Connor, M.D.) (See Color Plate 8.)

Course and Prognosis The course is highly variable, and prognosis for the most part rests on whether there is involvement of the kidney or other vital organs as well as responsivity to immunosuppressant treatments.

Treatment Biological treatment of systemic lupus erythematosus is determined by the severity of the disease and whether or not there is involvement of a vital organ such as the kidney. NSAIDs, salicylates (particularly nonacetylated salicylates), and antimalarial agents are used in the management of the arthritis and dermatitis seen in lupus. Glucocorticoids and the immunosuppressant agents cyclophosphamide (Cytoxan) and azothioprine are reserved for the more severe life-threatening forms of the disease.

This disease is highly unpredictable, often incapacitating, potentially disfiguring, and not infrequently death dealing, and its treatment requires administration of potentially toxic drugs. It is difficult to conjure up a more demanding challenge to the adaptational capacities of systemic lupus erythematosus patients, many of whom are adolescents or young adults. Appropriate application of the biopsychosocial model that emphasizes attending to the interplay between the biological and psychosocial elements of a disease such as lupus seems to hold out the greatest opportunity for positive therapeutic intervention.

The psychiatrist involved in a systemic lupus erythematosus or rheumatological treatment program would be interested in promoting positive interactions between patients and the program staff and ensuring a tolerant attitude on the part of these staff members. A high-quality psychoeducational program to help patients acquire the knowledge and maturity necessary to deal as effectively as possible with their disease is essential. Installation of hope, avoidance of demoralization, and finding of meaning in the experience of such an illness all seem necessary to having the patients live as well as possible with this often chronic and disabling illness. No controlled studies exist indicating the best programmatic approaches for this patient population. The needs of lupus patients are highly individualized, and it is difficult to imagine that one monolithic approach would answer all of the difficulties encountered by them. Working through the affects associated with incapacity and loss is important. How one goes about this involves considerable skill in brief psychotherapy.

The consulting psychiatrist is asked to see such patients for three broad reasons. One is an adverse psychological response to the disease, characterized by poor compliance with medical regimens and other self-defeating behaviors. Adjustment level symptoms of anxiety and minor depression are commonly encountered. The

need for close medical scrutiny, limitations on personal freedom, mandated avoidance of exposure to the sun, and daily use of sometimes toxic medications all require a level of personal maturity and acceptance that is difficult to achieve under the best of circumstances, particularly by individuals struggling with other major developmental issues and concerns in their lives. Treatment consists of the known effective interventions for adjustment disorders, primarily education, support, and processing emotional responses associated with loss, as well as facilitating a degree of mastery and deriving meaning in the midst of difficult life circumstances. The judicious use of psychoactive medications for symptomatic relief has a place here as well.

The psychiatrist may also be consulted because of the neuropsychiatric complications of direct involvement of the CNS. Lupus causes small vessel vasculitis in the brain. Microhemorrhages and microinfarcts are common pathological findings at autopsy. Cognitive impairment, psychotic symptoms, and florid delirium with marked behavioral abnormalities are all encountered in lupus cerebritis patients. No reliable or sufficiently sensitive test exists to confirm or exclude CNS involvement. The diagnosis is often made by history. The appearance of new symptoms or intensification of preexisting symptoms in sites outside the CNS that coincides with a major behavioral change is one of the more reliable signs suggesting CNS disease. Following the exclusion of CNS infections or other acute processes that could conceivably explain the behavioral and neurological alterations seen in lupus cerebritis, a trial of high-dosage immunosuppressant drug therapy is often administered to determine whether a therapeutic response can be achieved.

Psychiatric treatment is dictated by the predominant clinical picture as it relates to similar primary conditions known to respond to such treatments. No well-designed control trials exist indicating superiority of one treatment over another. Judicious use of antipsychotic agents, mood-stabilizing agents, or both in patients with hallucinations and delusions is reasonable and reportedly effective. However, like most psychiatric disorders thought to be due to general medical conditions, the response of these syndromes to treatment and comparison with similar or primary psychiatric illness has not been determined in longitudinal comparison trials.

The third reason for a psychiatric consultation is psychiatric complications of the treatment of lupus. The immunosuppressant agents used to modify autoantibody production that seems integral to lupus disease activity can in and of themselves cause psychiatric illness including depression, hypomania, delirium, and various psychotic states. NSAID have been reported to cause delirium as well as mild forms of cognitive dysfunction. Adrenal corticosteroid hormones are notorious for causing psychopathology.

OTHER CONNECTIVE TISSUE DISEASES

A number of connective tissue disorders (including Sjögren's syndrome, periarteritis nodosa, and rheumatoid arthritis) can be complicated by inflammation of the blood vessels supplying the brain. These are associated with a variety of neuropsychiatric syndromes, particularly in patients with the more severe form of vasculitis. When the CNS is involved, a number of psychiatric symptoms can appear. Treatment is directed as for a primary psychiatric illness. Symptomatic treatment with known psychoactive drugs, protection from harm and injury, and support in either the hospital or the outpatient setting are the most useful interventions. However, virtually all of the connective tissue diseases create limitation, uncertainty, and occasional psychological dysfunction. Close and careful medical assessment and follow-up is needed. These diseases can create considerable turmoil in the lives of their victims.

FIBROMYALGIA

Fibromyalgia is a nonspecific disorder characterized by many diffuse complaints including pain, stiffness, tender muscles and joints, overwhelming fatigue, distress, and sleep disturbances. Diffuse musculoskeletal pain has been described throughout the history of mankind, but the symptoms were clustered into a named syndrome within the past 100 years or so. In 1904, William Gowers hypothesized that the chronic back pain resulted from an inflammatory change in the fibrous tissue of the muscles and the back producing “muscular rheumatism.” In 1976, the term “fibromyalgia” was introduced by P. Kahler Hench.

The syndrome of fibromyalgia has been called many names over the years, including fibrositis, fibromyositis, myofibrositis, and myofascial pain syndrome. As a result, in 1990 the American College of Rheumatology (ACR) established criteria defining fibromyalgia (Table 25.8-1), standardization that allows the syndrome to be classified and studied.

I. Widespread Pain
Pain must be present for 3 months, widespread and not localized to one area. Involvement includes left and right side of the body, above and below the waist, and axial-skeletal pain.

II. Presence of 11 of 18 tender-point sites
Digital palpation must elicit pain in at least 11 of possible 18 tender point sites. These bilateral sites include occiput, lower cervical, trapezius, supraspinatus, second rib, lateral epicondyle, gluteal, greater trochanter, and knees.

Table 25.8-1 The 1990 American College of Rheumatology Criteria for the Classification of Fibromyalgia

Epidemiology The consensus document on fibromyalgia from the second world conference on myofascial pain and fibromyalgia, Copenhagen, 1992, found fibromyalgia to be the most common cause of widespread musculoskeletal pain, with prevalence rates varying between 0.7 and 3.2 percent. Using the ACR criteria for fibromyalgia, Frederick Wolfe and coworkers estimated the point prevalence of fibromyalgia in a randomized, population-based sample of individuals living in Wichita, Kansas, to be 2 percent overall (3.4 percent for women and 0.5 percent for men). Progressively higher rates have generally been noted in medical clinics and rheumatology clinics. The prevalence of fibromyalgia increases with age up to age 80 in both sexes.

Additional findings from this study included a stronger than expected association with failure to complete high school, reduced household income, divorced status, and increased visits to physicians. Psychological associations were found with elevated T scores on somatization, depression, and anxiety subscales of Derogates' Symptom Checklist-90-Revised (SCL-90-R). Depression and anxiety subscales on the Arthritis Impact Measurement Scales (AIMS) were also elevated.

Etiology The etiology and pathogenesis of fibromyalgia are unknown. Extensive histochemical and biochemical evaluations of musculoskeletal and neurological systems in patients with fibromyalgia have demonstrated only findings consistent with inactivity and disuse. However, these findings may only represent the final outcome of a more complicated neuropsychiatric process.

Possible clues pointing to a more complex etiological picture are found by exploring the associated symptoms of fibromyalgia, especially sleep disturbances, fatigue, and pain. Sleep deprivation can produce transient symptoms of fibromyalgia such as fatigue. Inactivity and deconditioning may render the patient more susceptible to muscle pain. This creates a vicious cycle and a downward spiral producing significant disability.

Indeed, sleep studies reveal that patients with fibromyalgia syndromes have alpha rhythm electroencephalogram (EEG) abnormalities during non–rapid eye movement sleep, increase in stage 1, a reduction in delta sleep, and an increased number of arousal. Other conditions such as periodic limb movement, obstructive sleep apnea, inflammatory joint diseases, some psychiatric illnesses, and noxious environmental stimuli can produce similar sleep abnormalities that are associated with fatigue, pain, and emotional distress. Harvey Moldofsky has postulated that serotonin metabolism, which is associated with sleep and wake cycle and pain, may be connected to sleep disturbances and affective disturbances found in patients with fibromyalgia.

Given the numerous psychological and psychiatric features that have been associated with fibromyalgia, many psychosomatic etiologies have been investigated. Don Goldenberg reviewed the literature on the relationship between fibromyalgia to psychiatric disorders. He found that studies using the Minnesota Multiphase Personality Inventory-2 (MMPI-2) demonstrated elevations in hypochondriacal and hysteria (less so depression) subscales similar to those of other chronic pain patients. Additional evaluation using a number of psychological instruments including the SCL-90-R, the Spielberger State Trait Anxiety Inventory, and the Beck Depression Inventory have found that fibromyalgia patients do not differ significantly from medically ill patients, especially those with pain. However, patients with fibromyalgia have a higher lifetime prevalence of major depression, panic disorder, obsessive-compulsive disorder, and somatization disorder than the general

population.

Diagnosis and Clinical Features Diagnosis of fibromyalgia can be difficult. Fibromyalgia is really a syndrome rather than an entity with clear signs and symptoms, laboratory findings, and specific treatments. The signs and symptoms include widespread pain with tenderness at multiple specified anatomical sites. Additional features may include sleep disturbance, fatigue, complaints of weakness, headaches, cold sensitivity, paresthesia or dysesthesia, swelling, Raynaud's phenomena, restless legs, exercise intolerance, and irritable bowel and bladder. Psychological abnormalities, especially depression, anxiety, and chronic pain with functional disability, often develop and aggravate the condition. No one sign or symptom is diagnostic, and no laboratory data including serological studies, electromyography (EMG), or muscle or nerve biopsies exist to confirm the diagnosis of fibromyalgia.

Because of the diagnostic difficulties, fibromyalgia is often confused with a number of other conditions (Table 25.8-2). The evaluation should focus on ruling out disorders with similar features. Evaluations should include a complete history and examination; laboratory assessment including electrolytes, calcium and magnesium concentrations, serum creatinine, liver function tests, complete blood count, sedimentation rate, antinuclear antibody, thyroid-stimulating hormone test and (when appropriate) MMPI-2 or a similar psychological screening test. Additionally, more extensive but specific serological markers for specific diseases such as cortisol concentrations or viral titers, X-rays, EMG, and even muscle or nerve biopsies should be considered when the signs or symptoms point in a specific direction.

Musculoskeletal disorders
Rheumatoid arthritis
Osteoarthritis
Polymyalgia rheumatica
Giant cell arteritis
Polymyositis/dermatomyositis
Systemic lupus erythematosis
Metabolic-endocrine myopathies
Hypothyroidism, hyperthyroidism
Hypoparathyroidism, hyperparathyroidism
Hypocorticalism, hypercorticalism
Drug induced (alcohol, steroids)
Paraneoplastic syndrome associated with cancer
Infections especially viral infections
Psychiatric disturbances
Dysthymic disorder
Generalized anxiety disorder
Somatization
Chronic pain syndrome

Table 25.8-2 Differential Diagnosis of the Fibromyalgia Patient

Course and Prognosis The natural history of the syndrome is not well delineated. Therefore, the course and prognosis are quite variable. Reports range from complete remission to total disability, with no identifiable factors differentiating those who will improve from those who will have a chronic disabling condition.

Treatment No single medical or psychiatric intervention has been shown to be uniformly effective for fibromyalgia. The current approach to the patient with fibromyalgia combines supportive counseling, behavioral modification, education, physical conditioning, and limited pharmacological interventions. Regular evaluations to identify and address any concomitant aggravating conditions such as sleep disturbance and depression should be performed routinely.

Control trials of current pharmacological and nonpharmacological interventions have provided hope for alleviating some of the suffering associated with this condition. Trials have shown beneficial effects with amitriptyline (Elavil), clomipramine (Anafranil), dothiepin, alprazolam (Xanax), and cyclobenzaprine (Flexeril). Optimal dosages and duration of treatment have not been fully established. Nonpharmacological interventions have been studied in controlled trials. Those noted to improve overall status include cardiovascular fitness, education and physical training, EMG biofeedback, and hypnotherapy.

OTHER ISSUES

Bone Mineral Density and Depression Major depressive disorder has been associated with neuroendocrine abnormalities, especially hypothalamic dysfunction. The changes include hypercortisolism, diminished secretion of growth hormone, hypothalamic hypogonadism, and anorexia. These changes have also been associated with changes in the bone mineral density in women.

David Michelson and colleagues studied the relationship between past or current history of major depression and bone mineral density in 48 women (24 with history of depression and 24 without). They found that the women with history of depression had lower bone mineral density. Additionally, these women had higher urinary cortisol excretion, lower serum osteocalcin concentration, and lower urinary excretion of dexoypyridinoline. This study highlights the musculoskeletal problems—specifically lower bone mineral density—that people with psychiatric problems can develop. Along with depression, lower bone mineral density has been reported for schizophrenia, anorexia nervosa, and other psychiatric conditions. The underlying pathophysiology is not clear, but the implications may be quite significant. Many with psychiatric conditions are young. Studies such as this one suggest a higher lifetime risk of complications such as bone fractures from the decreased in bone mineral density associated with depression.

Steroid-Induced Psychiatric Problems In addition to the problems of adaptation and the neuropsychiatric comorbidity encountered in patients with musculoskeletal diseases that involve the CNS, considerable psychiatric morbidity is associated with the treatment of these illnesses, particularly by administration of corticosteroid hormones. The adrenal corticosteroids are used widely in the treatment of most connective tissue diseases to modulate the production of autoantibodies. Corticosteroids have been known to cause significant psychopathology for nearly 50 years. Given the profound effect of corticosteroids on cellular metabolism including that of the neuron, it is perhaps surprising that their rate of psychiatric complication is not higher than the reported 17 percent.

Clinically, the observed psychopathology tends to defy precise criteria-based classification such as that in DSM-IV. A mixture of affective, psychotic, and neurocognitive deficit symptoms are often encountered. More rarely, pure forms of major depressive disorder or bipolar disorder can be seen. One of the more interesting paradoxes noted in the literature is that excessive endogenous production of corticosteroids seen in such disorders as Cushing's syndrome is more likely to cause depression, whereas exogenous administration of pharmacological doses of corticosteroids often produces euphoria resembling that in manic depressive illness. The risk of inducing severe psychopathology associated with the administration of corticosteroids is dose related but is highly variable and unpredictable. Patients known to have had serious psychiatric complications from the use of corticosteroids in the past may not be at increased risk when retreated with the same agent. A past history of psychiatric disorders does not seem to increase the risk of an adverse reaction.

SUGGESTED CROSS-REFERENCES

Some aspects related to musculoskeletal disorders and rheumatoid arthritis are discussed in different contexts in Section 1.11 on psychoneuroendocrinology, Section 1.12 on the immune system and central nervous system interactions, Chapter 16 on somatoform disorders, Section 25.1 on the history, classification, and current trends in psychosomatic medicine, Section 25.9 on stress and psychiatry, and Section 25.10 on behavior and immunity.

25.9 STRESS AND PSYCHIATRY

JOEL E. DIMSDALE, M.D., FRANCIS J. KEEFE, ĦH.D., AND MURRAY B. STEIN, M.D.

Stress is one of the old war-horses of psychiatry. It has been invoked as a cause of major psychopathology, a precipitator or trigger of psychiatric illness, and a contributor to considerable mental anguish. Similar roles have been cast for stress vis-a-vis illness throughout medicine. Many of the suggested links are intuitively appealing because somatic distress is commonly experienced in the face of unpleasant events and thoughts. However, the removal of stress is frequently associated with the cessation of diverse physical symptoms. At Appomatox, Ulysses S. Grant had an incapacitating migraine that disappeared instantaneously on the morning when General Lee announced his intention to surrender. Such instantaneous associations between stress and various symptoms are obvious, but whether stress causes an illness is much more difficult to demonstrate.

The slipperiness of the term “stress” is both an advantage and a disadvantage. It is an advantageous term because it is all-embracing and allows a synthesis of many aspects of life's experience; it is disadvantageous because its referents are diverse. *Stress* refers both to a subject and a predicate, an event and the consequences of that event. For clarity, it is probably wise to eschew use of the word “stress” altogether and to use different terms for its various meanings. Thus, it is much clearer to refer to stressful events or stressors and the resulting strain or stress responses incurred.

HISTORY

Stress was coined by Hans Selye (1907–1982) who observed that many highly diverse ways of perturbing the organism resulted in common physiological responses. The concept was unusual at the time because medical research focused on specificity—that specific pathogens elicited unique pathological responses. Selye found that highly diverse stimuli seemed to result in similar changes. From animal studies he reported that there is a general adaptation system to perturbation. He called it general because the response was similar across diverse stimuli; “adaptation” because he believed that the physiological changes represented the organism's efforts to respond to the stressor; a “system” because these responses were well orchestrated, involved diverse organ systems, and followed certain phases. Selye invoked the adrenocortical system as the crucial responder to stressful stimulation. He observed that any novelty or perturbation of the system was associated with an elevation of adrenocortical activity, at least transiently, and that if stressors were unremitting, diverse pathological changes would be evident. Like all groundbreakers, Selye was guilty of oversimplification, a weakness that has become abundantly clear with the accumulation of additional empirical data. Not all organisms respond to all perturbations with the general adaptation system. However, his insights were crucial in shaping the field. As a result of his prolific scholarship, the term “stress,” has become so popular that it is used constantly, even when the researchers would prefer more precision.

The other groundbreaker in the field of stress research was Walter Cannon (1871–1945). Although he made major contributions in gastroenterology and roentgenology, his long-abiding interest was in the physiology of emotion and the autonomic nervous system. Cannon methodically investigated the other great pathway of stressful responses, the sympathetic nervous system. Cannon is noted for his studies of gastric erosion and of cardiovascular response; he also focused on more immediate or short-term responses to stressors.

There are earlier antecedents to the concept of stress. For centuries physicians and patients have made the association between adverse life events and illness. In law, for instance, there is a long history of tort cases alleging that emotional arousal secondary to a stressful event causes miscarriage. The links between emotion and sudden cardiac death have been repeatedly noted in sources as diverse as the Bible, anthropological texts, and clinical experience. Such links were repeatedly observed by crucial figures in the history of medicine. William Harvey in the seventeenth century and William Osler in the nineteenth century frequently allude to the relationship between adverse life events and illness onset. Many contemporary cultures regard illness as the outcome of being out of balance with the environment and its demands, a manifestation of inadequate coping with diverse stressors.

The evidence for this relation is hardly unanimous. Physicians who see their patients briefly and from a highly specialized perspective are rarely familiar with the nuances of their patient's lives, and thus it is not surprising that many specialists deny the existence of such connections. On the other hand, researchers criticize the oversimplification of most studies that examine stress and illness.

A major conceptual problem that has hindered progress in this field is the confusion of *cause* and *trigger* of illness. The allegation that a stressor “caused” an illness is difficult to demonstrate in most human studies, which impose a short-term stressor and examine the resultant physiological changes. Illnesses such as myocardial infarction usually become evident only after a long accumulation of coronary artery disease. As a result, how can one say that “stress caused a myocardial infarction”? There is, however, an alternative hypothesis that provides very strong evidence for a link between stressors and illness. This argument emphasizes that stressors trigger illness in individuals whose underlying illness is latent or subclinical. Such a case is demonstrated routinely in psychophysiology and in psychosomatic medicine studies. For instance, studies of the physiological response to stressors in normal individuals demonstrate large-amplitude changes in physiological levels of blood pressure, gastric motility, and hormonal levels. When such psychophysiological studies are extended to patient groups, incontrovertible evidence is seen for the role of stressors as trigger events in eliciting pathophysiological phenomena. For instance, even discussing emotional conflicts can elicit life-threatening arrhythmias in vulnerable individuals (Fig. 25.9-1).

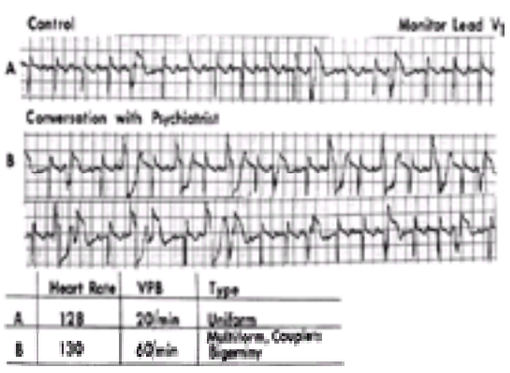

FIGURE 25.9-1 Impact of stress on electrocardiogram. (Reprinted with permission from Lown B: Sudden cardiac death: Biobehavioral perspective. Circulation *76* [Suppl]:I186, 1987.)

Another key conceptual problem centers on the issue of vulnerability versus resilience or stress versus coping. Following a long medical tradition, researchers initially focused on the virulent stressor, treating it like a virulent pathogen that would infect all individuals despite their varied life experiences. Thus, the initial stress research examined the physiological consequences of stressor imposition. The variability in the data motivated investigators to study the subtleties of how people interpreted the stressful challenges. Initially these interpretations were framed in terms of defensive styles, that is, how individuals guard themselves against painful emotional stressors. Subsequently, the inquiry broadened and investigators examined individuals' defensive behaviors, information-seeking behaviors, affiliative behaviors, and overall problem-solving behaviors. This heterogeneous combination is referred to as coping behavior. One of the clearest explications of this complex

process of stressor stimulation and coping mediation was suggested by Richard Rahe in 1974 (Fig. 25.9-2).

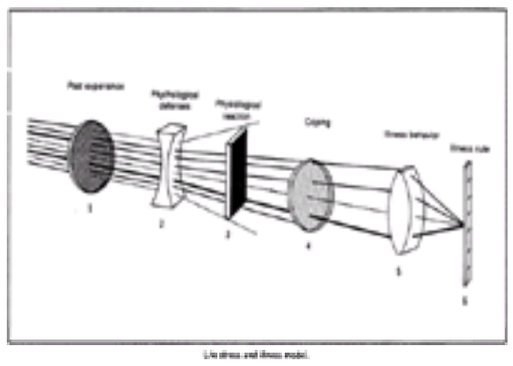

FIGURE 25.9-2 Step 1 in the stress and coping model represents a person's perception of his or her recent life events, which are indicated by light rays of differing intensities. (Thicknesses of the lines indicate the intensities of life-change magnitudes assigned to those events.) Much like a polarizing filter that can reduce or augment selected light rays, a person's perception of the events can alter their magnitudes. Such alterations depend, in part, on a person's prior experience with an event, on current social supports, and on biographical assets, such as income and education. Steps 2 and 3 in the stress and coping model indicate the effects of psychological defenses that can diffract away signals resulting from perceived recent life events that typically stimulate a variety of psychophysiological responses. A negative lens is used in step 2 to represent the potential function of psychological defenses. A box drawn for step 3 indicates the arena of psychophysiological responsivity. Once perceived recent life events can stimulate a number of psychophysiological responses (step 3). If those responses are interpreted by the person and are potentially dangerous to the person's health, they are called symptoms. Step 4 in the model is indicated by a color filter that absorbs light rays of certain frequencies. In much the same way, certain response-reduction (coping) techniques can absorb selected symptoms. The coping activities listed successfully absorbed two of the four symptoms. Two persisting symptoms not absorbed by the coping activities outlined may lead a person to adopt various illness behaviors. Those behaviors entail symptom recognition and concern, beliefs that the medical profession can help, and a willingness to conform to various sick-role expectations. A positive lens in step 5 indicates a patient's focusing attention on persistent symptoms in the presence of a physician, who then arrives at a diagnosis. The data are then entered into a medical record, step 6. (Reprinted with permission from Rahe RH, Floistad I, Bergan T, Ringal R, Gerhardt R, Gunderson E, Arthur R: A model for life changes and illness research: Cross-cultural data from Norwegian Navy. Arch Gen Psychiatry *31:*172, 1974.)

MEASURING STRESS PSYCHOLOGICALLY

Doctors have always asked about the stressors in their patients' lives because obtaining such information is at the core of history taking. “What sorts of things aggravate your symptoms? Are you facing any unusual burdens or challenges?” With certain symptoms such as angina, the link between stressor and illness is immediately obvious. However, it appears that many illnesses not traditionally thought of as stress-sensitive are aggravated by stressful conditions and the mechanisms for this link are complex.

Approximately 70 years ago Adolf Meyer suggested that psychiatrists employ a “life chart” in evaluating their patients. The idea is elegant in its simplicity. A patient's life is plotted on a line, beginning with birth and ending in the present. Various important life events are penciled in, as are the onset or worsening of health problems. The life chart is a very effective way of eliciting a clinical history. Sometimes, recurrent patterns of association between life events and illness episodes are suggested (Fig. 25.9-3).

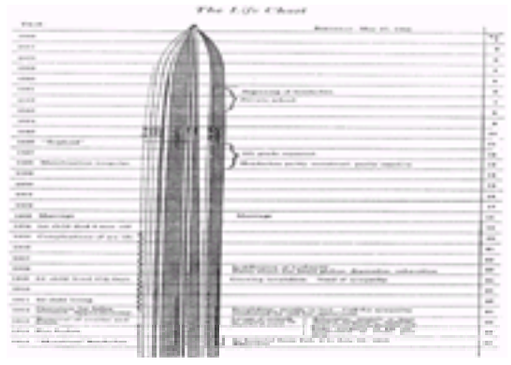

FIGURE 25.9-3 Meyerian life chart. (Reprinted with permission from *The Collected Papers of Adolf Meyer,* vol 3. The John Hopkins Press, Baltimore, 1951.)

The next step in the evolving field of life events was developed by the fruitful collaboration of Thomas Holmes and Richard Rahe who believed that some kind of list of commonly encountered stressors would be more useful than the relatively free-form process of taking an unstructured history. After considerable research they developed a list of 43 life events ranging in severity from death of a spouse to receipt of a traffic ticket (see Table 25.9-1). The checklist or Schedule of Recent Events can be self-administered and requires very little time to complete. It is noteworthy that both positive and negative life events are tallied by the form. The underlying assumption is that all life events, be they positive or negative, impose a demand for adaptation and that such demands are stressful. While at first blush this may seem counterintuitive, it is indubitably true that positive life events like getting married bring with them a host of stressors. Another characteristic of the Holmes-Rahe approach is that the items are weighted; they are not treated as equivalent in adaptational demand. After considerable research, the investigators observed that most people rank stressors similarly and thus it is possible to assign a specific “number” of life change units to the occurrence of each specific stressor. This technique has been used in hundreds of studies and has demonstrated that numerous illnesses follow on the heels of increases in life stress. It is not that the high-scoring individual is at risk, but rather that the individual with an increase in life stress units is at risk for any number of health consequences.

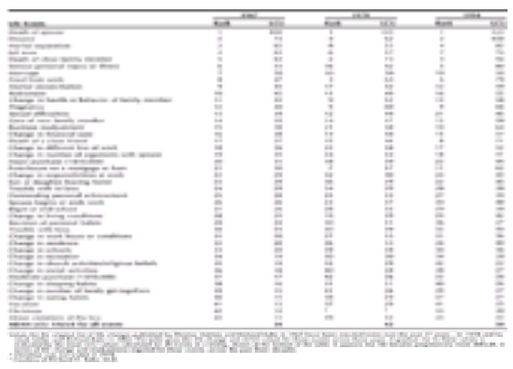

Table 25.9-1 Life-Change Scaling Results Across Time†

There are many criticisms of this approach, and alternative ways of measuring stressful life events have been proposed. The criticisms take one of six forms.

1. Some investigators feel that negative life events carry with them far greater anguish and adaptational pressure, and that the positive life events may be ignored.
2. Some investigators question the utility of adding all the life change units together and coming up with one number to represent the total stressful exposure of the individual. Whereas the Holmes-Rahe approach may be extremely useful for epidemiological research, for clinical use it may be more helpful to have subscales that list the stressors associated with job pressure, home pressure, and others, in separate categories.
3. Some theorists believe that inventories of relatively rarely occurring stressful events are of limited utility, and that more is to be gained by measuring the accumulation of the more common microstressors that individuals encounter frequently.
4. Some investigators doubt the validity of a universal weighting to stressful events and favor allowing individuals to apply their own idiosyncratic assessment of the stressfulness or emotional travail elicited by events.
5. Some investigators believe that the nuances of stressful life events are so complex that they can be identified only by skilled interviewers and that self-administered scales are of questionable validity.
6. Finally, common to all scales that measure stressful events is the problem of retrospective distortion. Patients forget, disavow, deny, and repress. As a result, when patients are asked to retrospectively report life events, they tend to forget events that are shrouded in the past. On the other hand, patients' beliefs sometimes cause them to ‘look for' events harder if they have sustained an illness that they feel is elicited by stress.

SELECTED PHYSIOLOGICAL RESPONSES TO STRESSORS

The body's reaction to stress—in this sense defined as anything (real, symbolic, or imagined) that threatens an individual's survival—is to put into motion a set of responses that seeks to diminish the impact of the stressor. Another way of viewing this is that a stressor disrupts an organism's equilibrium, and the stress response consists of the initiation of physiological systems that seek to react to the stressor, bring about an adaptive response, and restore homeostasis. Much is known about the physiological response to acute stress, but considerably less is known about the response to chronic stress. This represents a major gap in the ability to relate the effects of stress to the occurrence of psychiatric illness in humans. Many stressors occur over a prolonged period of time or have long-lasting repercussions (e.g., loss of a spouse is followed by months or years of loneliness; a violent sexual assault is followed by years of apprehension and worry about walking outside at night or about being alone at home). Animal models that can capture this reverberation or echo of stress are lacking and, as a result, what is known about the effects of real-life stressors on humans is limited. However, what is known about the neuroendocrine and immune response to laboratory stressors is growing apace and will ultimately inform the understanding of why and how stress has a deleterious effect on humans.

Neurotransmitter Responses to Stress Stressors of many kinds activate noradrenergic systems in the brain (most notably in the locus coeruleus) and cause the release of catecholamines from the autonomic nervous system. Prior exposure to chronic stress results in enhanced synthesis of brain norepinephrine, apparently through the induction of tyrosine hydroxylase, the rate-limiting step in catecholamine synthesis. Although an animal exposed chronically to a given stressor may develop tolerance (both behaviorally and in terms of noradrenergic activation) to it over time, this same animal may exhibit an enhanced response to a novel stressor. In other words, chronic stress may dampen the autonomic nervous system response to that particular stress but leave the animal more sensitive to the effects of ensuing stressors. Stressors also activate serotonergic systems in the brain as evidenced by increased serotonin turnover. Recent evidence suggests that although glucocorticoids tend to enhance overall 5HT functioning, there may be differences in glucocorticoid regulation of serotonin-receptor subtypes that may have implications for serotonergic functioning in depression and related illnesses. For example, glucocorticoids may increase serotonin (5-hydroxytryptamine [5-HT] type 2 (5-HT_2)-mediated actions of 5-HT, possibly contributing to the intensification of actions of the central nervous system of these receptor types that have been implicated in the pathophysiology of major depressive disorder. Stress also has the effect of increasing dopaminergic neurotransmission in mesoprefrontal pathway.

Since the late 1980s it has become clear that amino acid and peptidergic neurotransmitters are also intricately involved in the stress response. Studies have shown that corticotropin-releasing factor (CRF) (as a neurotransmitter, not just as hormonal regulator of hypothalamic-pituitary-adrenal axis functioning), glutamate—through *N*-methyl-D-aspartate (NMDA) receptors—and g-aminobutyric acid (GABA)—all play important roles in the generation of the stress response or in modulation of other stress-responsive systems such as dopaminergic and noradrenergic brain circuitry. As these interactions come to be better understood, it is likely that they will enhance the knowledge base of how stress responses are coordinated and individualized for specific stressors.

Endocrine Responses to Stress In response to stress, CRF is secreted from the hypothalamus into the hypophysial-pituitary-portal system. CRF acts at the anterior pituitary to trigger release of adrenocorticotrophic hormone (ACTH). Once ACTH is released, it acts at the adrenal cortex to stimulate the synthesis and release of glucocorticoids. Glucocorticoids themselves have myriad effects within the body, but their actions can be summarized in the very short term as promoting energy utilization, increasing cardiovascular activity (in the service of the “flight-or-fight” response), and inhibiting functions such as growth, reproduction, and immunity.

This hypothalamo-pituitary-adrenal axis is subject to tight negative feedback control by its own endproducts (i.e., ACTH and cortisol) at multiple levels including the anterior pituitary, the hypothalamus, and suprahypothalamic brain regions such as the hippocampus. It is now known that the hypothalamo-pituitary-adrenal axis is also influenced by multiple extrinsic systems, which should not be surprising given the coordinated nature of the stress response. For example, in addition to CRF, numerous secretagogues (i.e., substances that elicit ACTH release) exist that can bypass CRF release and act directly to initiate the glucocorticoid cascade. Examples of such secretagogues include catecholamines, vasopressin, and oxytocin. Interestingly, different stressors (e.g., cold stress versus hypotension) trigger different patterns of secretagogue release, again demonstrating that the notion of a uniform stress response to a generic stressor is an oversimplification.

A relevant feature of the hypothalamo-pituitary-adrenal axis response to stress is that it varies depending on whether the organism (most of these data come from rats) is exposed to the stressor on a single occasion, more than once, or over a prolonged period of time. Interestingly, it has not been possible yet to rely on a model that can predict whether sensitization (an enhanced response to the same stress over time) or *desensitization* (a reduced response to the same stress over time) will occur for a given stressor. Nonetheless, the fact that the stress response can change dramatically depending on the frequency and duration of exposure highlights the necessity of specifying these elements when trying to understand the role of stress in clinical psychiatric illness.

Immune Response to Stress Part of the stress response consists of the inhibition of immune functioning by glucocorticoids. However, this inhibition may reflect a compensatory action of the hypothalamo-pituitary-adrenal axis to mitigate other physiological effects of stress. Stress can cause immune activation through a variety of pathways. CRF itself can stimulate norepinephrine release via CRF receptors located on the locus coeruleus, which activates the sympathetic nervous system, both centrally and peripherally and increases epinephrine release from the adrenal medulla. In addition, there are direct links of norepinephrine neurons that synapse upon immune target cells. Thus, in the face of stressors there is also a profound immune activation, including the release of humoral immune factors (*cytokines*) such as interleukin-1 (IL-1) and IL-6. These cytokines can themselves cause further release of CRF, which in theory serves to increase glucocorticoid effects and thereby self-limit the immune activation.

Life stresses such as divorce, school examinations, and caring for a sick relative have been shown in numerous studies to have a deleterious effect on antiviral immunity (e.g., as manifest in increased herpes simplex virus recurrence rates or as reduced cellular immunity) in humans. In one well-controlled study volunteer subjects who had been exposed to high levels of stress in the preceding year were at greater risk than low-stressed subjects for developing clinical colds following the intranasal administration of respiratory viruses by droplet. Acute stress has been shown in most studies to increase the activity of natural killer cells, which are involved in the early, nonspecific cellularly mediated response to infection. In contrast, the effects of chronic stress on natural killer cell activity are less clearly defined. The tentative consensus about the effects of stress on immune function is that whereas small amounts of stress may enhance immune function, excessive stress seems to impair it. The functional health significance of these stress-related alterations in immunity remains to be determined.

STRESS AND PSYCHIATRIC ILLNESS

Historical Conceptualization Mental disorders have been ascribed to an imbalance in bodily humors, to the influence of external spiritual or other supernatural forces, and to moral or somatic deficiency. In the early to mid-1800s a school of thought emerged, led by Philippe Pinel (1745–1826) of the Salpetriere in Paris and Amariah Brigham (1798–1849) in America, that the expression of mental illness was affected by life circumstances and, more broadly, by societal factors. These various influences converge in the biopsychosocial model proposed by Meyer. This orientation held that an individual's response to stress is modified by a number of intrinsic factors (e.g., genetic vulnerability, premorbid personality) and extrinsic factors (e.g., social support). The model incorporated individual temperamental and experiential characteristics such as potential vulnerability (or resiliency) factors, stressful life events as initiating or exacerbating factors, and a variety of support networks as potentially modifying factors for the occurrence of mental illness. For the most part, this multideterminate model of mental illness dominates modern psychiatric thinking.

The current diagnostic nomenclature of the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) does not emphasize this biopsychosocial model of the nature and genesis of psychiatric disorders because of the decision to have the DSM expound a descriptive, phenomenological typology, one that would

be least governed by theoretical or other subjective interpretations. Thus, in DSM-IV, major depressive disorder is major depressive disorder whether it appears in the context of job loss, divorce, or for no apparent reason. There are interesting inconsistencies in this approach. For example, major depressive disorder may not be termed major depressive disorder in DSM-IV when it appears in the context of bereavement. There is, in this instance, an acquiescence to the fact that bereavement so frequently results in a depressive syndrome (albeit temporary and perhaps slightly different in character than non–bereavement-related depression), that it should be differentiated from major depressive disorder.

What if individuals develop major depressive disorder following the loss of their home in an earthquake? According to DSM-IV, if such a person develops a depressive syndrome, it might be considered an adjustment disorder (if short-lived) but, if it is persistent, then a diagnosis of major depressive disorder applies. Why, one might ask, is this scenario treated differently from a depressive syndrome following bereavement? Following a traumatic stressor (e.g., earthquake), one might better diagnose posttraumatic stress disorder. Not necessarily, because although posttraumatic stress disorder is another exception to the DSM-IV rule that the nomenclature should be atheoretical (it is one of several disorders for which the occurrence of a stressful life event is pivotal for diagnosis) it has its own characteristic symptoms that are not equivalent to the depressive syndrome. Thus, like many psychiatrists who struggle to understand the influence of life events on the emotional functioning of patients, DSM-IV continues to struggle with the best way to classify and incorporate stressful life events into diagnosis. In the face of this ongoing debate, however, much research has been conducted that serves to enhance the knowledge base of the relationship between stress and psychiatric illness.

Stress and Psychotic Disorders There is little reason to suspect that stress plays a role in the pathogenesis of schizophrenia. Most current etiological theories of schizophrenia focus on genetic and prenatal environmental factors or a combination thereof. There is, however, ample evidence that adverse life events and a stressful social or familial milieu play an important role in determining the course of illness in general and episodes of relapse in particular.

Chronic interpersonal stress, usually studied in the context of the family, has been shown to be an important risk factor for relapse in schizophrenia. Studies of *expressed* emotion, a proxy for familial tumult, have demonstrated that persons with schizophrenia residing in homes with high expressed emotion tend to relapse at twice the rate of those who live in families with low expressed emotion. Other stressors that plague the lives of many patients with schizophrenia—poverty, homelessness, and criminal victimization—also powerfully affect the clinical course of such patients. Combined with evidence that schizophrenia renders the individual more susceptible and sensitive to the negative effects of even minor stressors, it is obvious that stress plays a major role in the course of schizophrenia. Considerable research has been conducted examining the effects on relapse rates of psychosocial interventions that seek to enhance the ability of schizophrenia patients to cope with stressful events.

Researchers have been interested in determining the neurobiological mechanisms through which stress exacerbates schizophrenia. Schizophrenia has been hypothesized to involve dysfunction within brain neuronal circuits involving dopamine and other excitatory neurotransmitters such as glutamate. Deficits in the cognitive functions of a patient with schizophrenia mediated by the dorsolateral prefrontal cortex have strongly implicated this region of the brain in the pathophysiology of schizophrenia. Abnormal dopaminergic functioning within the mesocortical system (which provides innervation to the prefrontal cortex and cingulate cortex) might underlie some of these deficits in cognitive functioning. Some animal studies suggest that the mesocortical projections to the prefrontal cortex are particularly sensitive to stress-induced activation.

Alan Breier et al. used 2-deoxyglucose (2DG) infusions to induce glucose deprivation and monitored the ensuing physiological stress responses in patients with schizophrenia and healthy control subjects. They found that intravenous 2DG injection resulted in significantly larger increases in plasma levels of the dopamine metabolite homovanillic acid in patients with schizophrenia than in controls. Moreover, these investigators found that patients with the smallest prefrontal cortices were the most susceptible to the 2DG-induced stress, at least in terms of their plasma homovanillic acid response. These data lend support to the hypothesis that dysfunction within prefrontal-subcortical connections in schizophrenia may mediate the susceptibility to stress-induced exacerbation of symptoms seen in this disorder. The extent to which this metabolic stressor represents a suitable analog for psychosocial stressors remains to be determined.

Mood Disorders Recent advances in psychiatric epidemiology suggest that a simple relationship may not exist between stressful life events and mood disorders. Most studies of stress and depression suffer from a number of methodological shortcomings. There is a tendency for depressed patients to selectively recall negative life events and to associate these events with their current difficulties. Although these effects can be minimized by ascertaining life events when patients are not in episodes of depression, there is additional evidence that depressed patients really do experience more negative life events than nondepressed patients. This difference may be accounted for predominantly by an excess of *dependent events*—that is, events that may conceivably have been caused by the individual's actions while depressed (e.g., losing a job due to poor performance, failure in school) as opposed to being independent of the depression (e.g., property loss, family illness). This confound complicates the interpretation of most early studies of life events and depression.

Another way of thinking about the relationship between stress and depression is to focus not on specific life events but rather on the effects of chronic stress. Studies in this genre are few (e.g., examining rates of depression in mothers of chronically ill children compared to mothers of healthy children), but those that do exist tend to support a relationship between chronic stress and the propensity for major depressive disorder. To the extent that most animal models of depression (e.g., chronic restraint, forced swim) are subchronic or chronic stress paradigms, the study of the effects of chronic stress on depression in humans offers the possibility for convergence and cross-fertilization between the preclinical and epidemiological knowledge bases.

There is a fundamental similarity between the neuroendocrine effects of stress on humans and the neuroendocrine abnormalities in major depressive disorder. For over twenty years major depressive disorder has been recognized as associated with overactivity of the hypothalamo-pituitary-adrenal axis, as inferred by increased plasma cortisol and ACTH concentrations, increased urinary free cortisol, increased cerebrospinal fluid cortisol, and cortisol resistance to dexamethasone suppression. A critical question is where in the hypothalamo-pituitary-adrenal axis the physiological abnormality in depression might lie. Challenge studies with corticotropin-releasing hormone (CRH), which have demonstrated reduced ACTH responses to CRH in depressed patients compared to control subjects, suggest that chronic CRH secretion (with compensatory downregulation of CRF receptors at the pituitary level) may be an important feature of major depressive disorder. Current thinking tends to position hypothalamic CRH hypersecretion as the driving force behind the hypothalamo-pituitary-adrenal abnormalities found in major depressive disorder but the neurochemical basis for CRH hypersecretion remains a topic of ongoing research.

Might persons with a genetic diathesis for depression be more susceptible to the depression-inducing effects of stressful life events? Information has been collected about stressful life events and the onset of major depressive episodes in a population-based sample of female-female twins in Virginia. Several life events (e.g., assault, serious marital problems, divorce or breakup) were found to powerfully predict onset of major depressive disorder in the month of occurrence. However, genetic liability was also found to have a significant impact on risk of major depressive disorder. The researchers concluded that the onset of major depressive disorder was best explained by a model that posited genetic vulnerability to the depressogenic effects of stressful life events. Thus, this study provides rare empirical evidence of what has been viewed as a truism in contemporary psychiatric teachings: genes and stressful life events operate in concert to elicit depressive episodes.

Anxiety Disorders In comparison to the voluminous literature on stress and depression, there is less empirical research on the relationship between stress and anxiety disorders. These studies are marred by similar methodological shortcomings found in the literature on depression. Despite these limitations it seems reasonable to conclude that panic disorder frequently has its onset or recrudescence in the context of stressful life events. In particular, there is some evidence to suggest that either interpersonal conflict or serious illness (in a significant other) may trigger the onset of panic disorder in susceptible individuals. Given the fact that patients with panic disorder are often somatically preoccupied and likely to interpret physical sensations as life-threatening, it is not too surprising that the occurrence of illness in someone close to the patient might precipitate the onset or an exacerbation of panic in the patient.

The effects of chronic stress on the course of anxiety disorders has not been empirically studied, although it seems intuitive to expect that a relationship should exist. In terms of the effects of early life stressors, there is growing evidence that certain adverse early life events such as sexual or physical abuse may be risk factors for the later development of panic disorder, particularly in women.

In light of the known effects of stress on hypothalamic-pituitary-adrenal axis functioning, an association between panic attacks—themselves a stressful experience—and hypothalamic-pituitary-adrenal axis activation would be expected. Surprisingly, no significant increase in plasma cortisol levels has been found in association with spontaneous panic attacks or with lactate-induced panic attacks. Moreover, 24-hour blood sampling in patients with panic disorder reveals considerable heterogeneity in plasma cortisol across patients. Taken together, these observations underscore the notion that a typical stress response, from a neuroendocrine perspective, is not seen consistently across psychiatric disorders. This conclusion is strengthened by the findings with regard to hypothalamic-pituitary adrenal axis functioning in another anxiety disorder, posttraumatic stress disorder.

Posttraumatic Stress Disorder DSM-IV recognizes the existence of a group of disorders that are, by definition, stress-related. Included here are posttraumatic stress disorder and, new to DSM-IV, acute stress disorder. The latter has its onset following particularly traumatic (often life-threatening) events such as violent assault or serious accidents, and is denoted by the presence of prominent dissociative symptoms (e.g., derealization, numbing). At present, it is not known whether acute stress

disorder is of prognostic significance in terms of heralding the onset of more chronic psychiatric symptoms, nor is it known what risk factors exist for the development of acute stress disorder itself. In contrast, much is known about the prevalence of posttraumatic stress disorder and risk factors for its development.

Whereas posttraumatic stress disorder was not long ago considered to be a disorder only of war veterans (15 percent of Vietnam veterans may suffer from this disorder), it is now recognized as a highly prevalent disorder affecting a much larger segment of the population. Among the traumatic stressors that can elicit this disorder are relatively rare events such as natural disasters and frighteningly common events such as criminal victimization. In prior editions of the DSM, it was noted that in order to qualify for this diagnosis, the traumatic event needed to be “beyond the range of normal human experience.” Epidemiological research has shown that horrible things happen to many people and must be considered part of the human experience. Consequently, although debate continues, it is now generally accepted that any life-threatening or perhaps, life-altering event can be considered sufficiently traumatic that it is capable of eliciting posttraumatic stress disorder. With this definition in place, recent surveys place the lifetime rate of the disorder in the community at around 10 percent.

The occurrence of posttraumatic stress disorder following severe psychological trauma provides the most persuasive evidence in favor of certain kinds of stress causing psychiatric illness. It is important to note, however, that the neuroendocrine profile of patients with posttraumatic stress disorder is not what one might expect to see following chronic stress, nor is it akin to what is observed in major depressive disorder. Whereas the latter two conditions would be expected to be associated with hypercortisolism, most recent studies of patients with posttraumatic stress disorder have demonstrated rather subtle hypocortisolism. Although the neurobiological implications of this finding remain to be elucidated, the message for stress researchers is clear: there is no longer any hope that a uniform neuroendocrine stress response explains the heterogeneity of psychiatric disorders encountered in the wake of psychological stress.

Most severe psychological stressors do not result in the development of posttraumatic stress disorder or other forms of psychiatric illness. Certain characteristics of the stressor seem to increase the propensity to develop posttraumatic stress disorder following exposure; these include the magnitude of the stressor, the occurrence of physical injury, and the occurrence of peritraumatic dissociation. However, individual differences also contribute to the variance in posttraumatic stress disorder expression following trauma exposure; these include female gender, genetic vulnerability, and a history of exposure to early childhood trauma.

The latter finding has been both particularly intriguing and exceptionally controversial. The controversy has been spurred in part by the methodological difficulties inherent in assessing the nature and severity of childhood trauma. Concerns range from the possibility that some individuals might recall being sexually victimized in childhood when this has not actually occurred (i.e., the so-called false memory syndrome) to the possibility that some traumatized individuals might have suppressed the memories of childhood victimization and therefore may be unable to report that they were indeed traumatized. With all these potential sources of “noise” coming into play, it is all the more impressive that a consistent “signal” emerges from a variety of studies, all suggesting that early experiences of victimization predispose an individual to developing posttraumatic stress disorder when later exposed to psychologic trauma.

Much more speculative but on the cutting edge of traumatic stress research are recent studies that suggest that psychological trauma may result in quantifiable abnormalities in neurocognition (e.g., attention) and even in neuroanatomy (e.g., hippocampal volume). If replicated, these studies promise to dramatically alter the understanding of the effects of stress on psychiatric disorders and ultimately on normal and pathological brain development.

STRESS AND NONPSYCHIATRIC ILLNESS

Stressors are relevant to all illnesses, not just primary psychiatric conditions. There is an enormous literature linking stressors to the entire panoply of illness, a literature generally referred to as psychosomatic medicine. The term “psychosomatic” has been dropped from current nomenclature because of a misperception that it refers primarily to psychoanalytic theories of behavior and illness or to a simplistic assumption that all illness has its origin in struggles with adversity and with emotional conflict. Stress and the psychosomatic link pertain to some of the most prevalent and deadly diseases. The links are multiple—ranging from physiological perturbations elicited by stressors to various illness-promoting behaviors that are resorted to under conditions of emotional travail.

TREATMENT

Pharmacotherapy Many different psychiatric conditions are worsened by stressors. When major psychiatric conditions like depression or psychosis are present, the most appropriate medications are those for the Axis I diagnosis. However, more typically the picture is primarily one of anxiety or insomnia, perhaps not of as great a magnitude as that found typically in anxiety disorder, but still very distressing to the patient. In such settings pharmacological therapy with anxiolytics or short-term hypnotic agents can be extremely helpful. The field has lurched from one extreme to another in terms of prescription of such medication. Clearly, the unsupervised long-term prescription of this type of medication brings with it risks for drug dependence. On the other hand, depriving patients of such medication when they are in crisis is unconscionable. Short-term use of low-dose benzodiazepines is of considerable utility in helping patients struggle with unusual stressors. This intervention in association with supportive psychotherapy is extremely effective in crisis intervention.

Cognitive-Behavioral Therapy Cognitive-behavioral therapy methods are increasingly used to help individuals better manage their responses to stressful life events. These treatment methods are based on the notion that cognitive appraisals of stressful events and the coping efforts related to these appraisals play a major role in determining the response to stress.

A model of stress and coping has been developed that serves as the conceptual foundation for most cognitive-behavioral stress-management protocols. This model maintains that there are two types of cognitive appraisal that are especially important in mediating reactions to stress. The first, *primary appraisal,* refers to the way in which an individual evaluates the significance or meaning of a given event. When events (e.g., being diagnosed with a chronic illness such as rheumatoid arthritis) are appraised as harmful and threatening (e.g., “Because of my rheumatoid arthritis, I will never be able to do anything I really care about”), the individual is more likely to become anxious, depressed, and withdrawn. However, if the same event is viewed as challenging (e.g., “Although my arthritis prevents me from doing some physically demanding activities, there are many other important and meaningful activities that I can do and enjoy”), then more positive outcomes are more likely to occur. *Secondary appraisal* refers to the process of evaluating what can be done about the stressful event. Several factors can influence such secondary appraisals including the breadth of individuals' repertoire of coping skills, their mastery of specific coping skills, and their expectation that their skills will be effective.

Cognitive-behavior therapy approaches to stress management have three major aims. The first aim is to help individuals become more aware of their own cognitive appraisals of stressful events. The second aim is to educate individuals about how their appraisals of stressful events can influence negative emotional and behavioral responses and to help them reconceptualize their abilities to alter these appraisals. The third aim is to teach individuals how to develop and maintain the use of a variety of effective cognitive and behavioral stress management skills.

Efficacy Stress Management A number of controlled studies have documented the efficacy of cognitive-behavioral therapy stress management protocols. Two recent controlled studies examining this therapy in the treatment of individuals suffering chronic diseases are good examples of such research.

Individuals with rheumatoid arthritis not only must cope with frequent pain episodes, but also with major disruptions in their work and family life. One hundred and forty-one rheumatoid arthritis patients were randomly assigned to one of three groups: (1) a comprehensive cognitive-behavioral therapy stress management program, (2) an attention control group, or (3) a standard care control condition. Patients in the stress management and attention control conditions met weekly for 10 weeks and then monthly for an additional 15-month maintenance phase. At the end of the 10-week treatment phase of the study, patients in the cognitive-behavioral therapy group had significant improvements in pain, helplessness, self-efficacy, coping, and health status. When the outcomes for the three treatment conditions were compared at 15-month follow-up it was found that subjects in the cognitive-behavioral therapy group were much more likely to report maintenance of their treatment gains. These results suggest that cognitive-behavioral therapy may provide an effective means of reducing pain and psychological distress in patients with rheumatoid arthritis.

The efficacy of stress management has also been demonstrated in individuals suffering from inflammatory bowel disease. Eighty such subjects were randomly assigned to either a stress management intervention or a control group. Subjects in the stress management condition had six group sessions focusing on training with relaxation techniques, time management skills, and communication skills. There were significant improvements in measures of physical and psychological functioning in patients undergoing stress management whereas there were no changes in these measures in patients in the control condition. These benefits were not due to changes in subjects' medication status since no changes in medications were noted over the course of the study.

Stress-Management Training When cognitive-behavioral therapy is used for stress management, training is provided in a wide range of stress management skills. Although space limitations preclude a discussion of all these skills, it is important to highlight five skills that form the core of almost all such stress management

programs: self-observation, cognitive restructuring, relaxation training, time management, and problem solving.

Self-Observation One of the most effective ways of helping individuals become more aware of how they respond to problem situations is to have them keep a daily record of their behavior. A daily diary format (Table 25.9-2) is often used with patients being asked to keep a record of how they responded to challenging or stressful events that occurred each day. Entries are made in three columns: antecedents, behaviors, and consequences. In the "antecedents" column, patients record a specific environmental event that they perceived as stressful. The event might be an interpersonal stressor such as having an argument with a spouse or a confrontation with a coworker, or an intrapersonal stressor such as a flare in pain symptoms, or a major natural disaster. To assess appraisals of the stressor, patients are asked to rate how stressful they found this event on a 0 to 100 scale (e.g., 0 = not at all stressful; 100 = the most stressful event I have ever experienced). In the column marked behavior, patients are instructed to record their cognitive and behavioral reactions to the stressful event. The term "behavior" is broadly defined so that it not only encompasses overt behavioral responses, but also more covert cognitive, affective, and physiological responses. Thus, in the behavioral response column individuals might indicate specific coping behaviors they engaged in (e.g., avoidance), cognitive responses to the stressor (e.g., "I am overwhelmed and can't deal with this right now"), negative emotions (e.g., anxiety, depression), and physiological responses (e.g., increased sweating, heart rate, or nausea). In the column marked "consequences," patients record the outcomes resulting from their behavior in this situation.

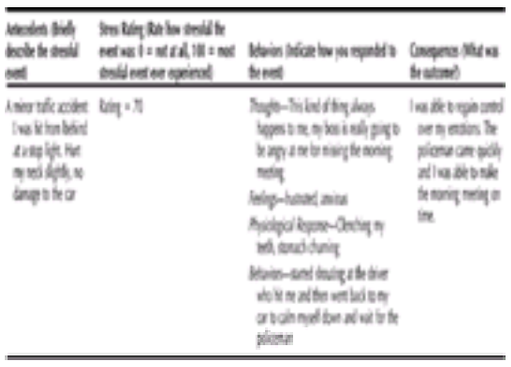

Table 25.9-2 Daily Diary Format for Recording Stress-Related Behaviors

Self-observation is effective for several reasons. First, it makes individuals aware of behaviors that they usually fail to notice. An individual whose style of dealing with social anxiety is to use avoidance, for example, may avoid potentially stressful situations in a more or less automatic fashion (e.g., routinely refuse invitations), use very subtle forms of avoidance (e.g., arriving late or leaving a party early), or arrange their lifestyle (e.g., work alone) so that they have very few chances to confront their fears. By keeping a record of their own behavior, individuals begin to recognize these behavioral patterns. A second important feature of self-observation is that it helps individuals to see how their cognitive-behavioral responses are linked to situational antecedents and consequences. Participants who keep daily diaries are often struck by the variations in their own reactions across different events. For example, while they may cope effectively with one stressful event (e.g., meeting an important work deadline), they find themselves unable to deal with another stressful event (e.g., an argument with their teenage son or daughter). Self-observation highlights the role that coping efforts, cognitive appraisals, and physiological responses play in explaining these very different responses to stressful situations. A third reason that self-observation is effective is that it makes individuals aware of how they might change their behavior to more effectively manage stress. Interestingly, individuals who keep daily diary records of stress-related behaviors often make changes in their own behavior, even before other stress management methods are introduced.

Cognitive Restructuring A hallmark of cognitive-behavioral therapy is its insistence that cognition plays a central role in the stress and coping process. In cognitive-behavioral therapy cognitive appraisals about stressful events are considered to be the key factor in determining stress-related responding. Given this emphasis on cognition, it is not surprising that a major thrust of cognitive-behavioral therapy approaches to stress management is on helping participants to become aware of and to change their maladaptive thoughts, beliefs, and expectations.

Cognitive therapists have developed protocols for helping distressed individuals restructure dysfunctional or maladaptive thinking patterns. Such cognitive restructuring begins by educating patients about the cognitive model and that the underlying cognition is a major determinant of emotional responding. According to the cognitive model, emotional reactions that are excessive or prolonged are often the result of cognitions that are distorted or dysfunctional.

The second step in cognitive restructuring is monitoring and analyzing dysfunctional thoughts. Table 25.9-3 lists a number of stress-related thoughts that might be identified through daily diary records. As can be seen, each of these thoughts can be linked to a negative emotion. A careful analysis of each thought also reveals an inherent error in logic. Certain types of errors or cognitive distortions occur quite frequently and individuals can thus be taught to recognize them.

Stressor	Cognition	Emotion
Painful medical procedure	I know I won't be able to tolerate the pain	Fear
Argument with a friend	She will never speak to me again	Discouragement
Co-worker injured on the job	It is my fault. I should have warned him about the danger	Guilt
Late for a deadline	It's hopeless, I'm always messing things up	Depression
Spouse criticizes you	He just doesn't get it. He will never understand what I am trying to do.	Anger

Table 25.9-3 Stress-Related Negative Thoughts

The third step in cognitive restructuring is to challenge and change cognitive distortions. Participants are often provided with a list of key questions (Table 25.9-4) that can be applied to their own negative thoughts. They are asked to select one or two questions that are useful in identifying the underlying logical problems in their thinking. Finally, participants develop a rational response that represents a more accurate and helpful cognitive response to the situation.

Is there an alternative explanation?
What is the evidence that this thought is true?
What will be the effect of continuing to think this way?
What is the best outcome, worst outcome, and most realistic outcome?
What is the likelihood that this will happen?

Adapted from Beck JS: *Cognitive Therapy: Basics and Beyond*. Guilford Press, New York, 1995.

Table 25.9-4 Key Questions for Challenging Negative Automatic Thoughts

Table 25.9-5 illustrates how one might change various overly negative stress-related thoughts to more adaptive rational responses. If the rational response is to be effective, it must be used frequently, ideally each time the negative thought occurs. To ensure that this occurs, patients are given home practice assignments in which they are asked to expose themselves to stressful events, monitor their negative thoughts, and respond with a more rational thought pattern. They are also asked to keep records of the resulting consequences, both in terms of changes in emotions and behaviors.

Negative Thought	Rational Response
I have no control over this situation.	It's true that I can't change what happened, but I can control how I respond.
I can't return to my old job, I am worthless.	Even though I may not be able to do the same kind of work, there a number of other jobs that I may be able to do.
It's not fair that I am being treated this way.	Life is not always fair, sometimes things go my way, other times they don't.
I am a burden on my family.	My family has had to give me more support lately, but I do a lot of things for them as well.
No one really cares about me.	There are people in my life (e.g., spouse or child) that I can turn to for support and love.

Table 25.9-5 Negative Thoughts and Rational Responses

Relaxation Training Relaxation skills can be very helpful in managing stress. When individuals learn to relax, their overall muscle tension is reduced, as is their overall level of autonomic arousal. Individuals who are able to relax are also more likely to be able to think more rationally and to be able to restructure negative cognitions when faced with stressful events. Finally, relaxation skills may be helpful in reducing maladpative behavior patterns.

In the 1920s Edmund Jacobson developed progressive relaxation training as a way to help individuals to control excessive muscle tension. Jacobson approached relaxation as a motor skill and emphasized that, like any skill, repeated practice was necessary for skill mastery. In traditional Jacobsonian relaxation training the goal is to heighten an individual's awareness of very low levels of muscular tension. The patient is instructed to focus on sensations that occur when tensing a single large muscle group (e.g., the forearm flexors—tensed by bending the left hand back at the wrist). The individual is then instructed to release the tension in that muscle group and study the resulting physical sensations. With repeated practice, trainees often become quite adept at recognizing “control signals” indicative of tension and letting the tension go. Traditional Jacobson relaxation training is effective; however, it does require a substantial time commitment on the part of the participant.

In the 1950s Jacobsonian relaxation training was modified by behavior therapists so that it could be more easily incorporated into treatment programs. The modified training program was similar to Jacobson's in emphasizing that relaxation could be achieved by using a series of exercises involving tensing and relaxing muscle groups, but differed in that it was much briefer. Numerous modified versions of Jacobson's original method have been developed and refined over the years.

One of the most important tasks in relaxation training is helping patients learn how to generalize their skills in relaxation from home practice sessions to stressful and demanding daily life events. Several techniques are used to enhance generalization. The first is a method developed by Jacobson called differential relaxation. In differential relaxation, the trainee is instructed to engage in a daily task and only use the muscles that are necessary for carrying out the task. For example, while writing one's name there needs to be activity in muscles of the hands and arms, but the muscles in the face, lower trunk, legs, and feet can be deeply relaxed. Differential relaxation is initially practiced in relatively easy situations (e.g., sitting or standing) where the demands are minimal. Over time, however, patients learn how to use differential relaxation in situations that are challenging and stressful. A second generalization method is termed the mini-practice. This consists of a brief relaxation procedure in which the trainee takes a deep breath, and then while slowly exhaling focuses on sensations of relaxation flowing downward from the muscles of the face to those of the neck, shoulders, trunk, and legs. The mini-practice takes approximately 30 seconds and thus can be done repeatedly over the course of a day. Individuals are encouraged to develop innovative reminders to cue themselves to perform frequent mini-practices every day. As individuals increase this frequency, they often report that relaxation becomes more or less an automatic and habitual response.

Time Management A stressful event, (e.g., caring for a sick child), can place inordinate demands on time. When exposure to such an event is prolonged or is combined with exposure to other stressors, the demands on time and energy are multiplied. In such circumstances individuals often report feeling that they have lost control of their daily schedule and, that as a result, they have little or no time in which to attend to their own needs.

Time management methods are designed to help individuals restore a sense of balance to their lives. The first step in training in time management skills is designed to enhance awareness of current patterns of time use. To accomplish this goal, individuals might be asked to keep a record of how they spend their time each day, noting the amount of time spent in important categories such as work, family, exercise, or leisure activities. Alternatively, they may be asked to list the important areas in their lives and then asked to provide two time estimates: (1) the amount of time they currently spend engaging in these activities, and (2) the amount of time they would like to spend engaging in these activities. Frequently, there is a substantial difference in the time individuals would like to spend on important activities and the amount of time they actually spend on them. With awareness of this difference comes increased motivation to make changes.

The second step in time management is designed to help individuals set their priorities. In setting priorities an important distinction can be drawn between urgency and importance. To explore this distinction it is helpful to envision a table that has the dimension of importance along one axis and the dimension of urgency along the other axis. Patients are then encouraged to enter into each quadrant of the table examples of activities from their own lives and to reflect on the patterns they observe. Individuals may note that much of their time is spent doing activities that are in the Urgent-Not Important quadrant or the Not Urgent-Not Important quadrant. Alternatively, they may report that they spend little or no time engaging in activities in the Not Urgent-But Important quadrant. Patients are encouraged to discuss the benefits that can come from increasing the priority they give to such important but less urgent activities as exercising, resting, relaxing, or doing volunteer work. They are also encouraged to try to match the time spent engaging in such meaningful activities with the priority they place on the activity.

Once participants have developed a better sense of their priorities, they are ready to move on to the third step in time management: goal setting. Goal setting focuses on specific behavior change targets that fit with an individual's long-term priorities. First, the individual is asked to identify a goal to be accomplished in the next week. The goal, for example, might be to lose 2 pounds or to sign up for an exercise program. Second, patients are asked to critically analyze the goal to ensure that it is reasonable, specific, and personally meaningful. Many of us set unrealistic goals (e.g., losing 10 pounds in a week) when trying to change our own behavior and as a result fail, feel frustrated, and give up. By helping a participant to set goals that are more reasonable, one can enhance the likelihood of success and increase compliance with stress management efforts. In the third step of goal setting, individuals are asked to reconfirm a time frame (e.g., a week) in which they will meet the goal. This step is important in reducing procrastination, a common obstacle to effective time management. Finally, the individual's efforts in reaching the goal are reviewed. Successful completion of a goal that has been long neglected can be very rewarding. Even if the goal was not achieved, important information about goal setting can be gleaned by reviewing performance. Perhaps the goal was set too high or the individual lacks the skills necessary to achieve the goal.

Problem Solving Problem solving is a skill that is introduced in the later stages of stress management training. As trainees attempt to apply what they have learned about stress management, they may find that some problem situations are particularly challenging and difficult to manage using only one or two stress management techniques.

Problem solving involves several basic steps. The first is problem identification during which the key problematic aspects of a stressful event such as problematic behaviors, thoughts, feelings, and physiological responses are identified. For example, dealing with the aftermath of a hurricane may be perceived as stressful because it is associated with particular (1) behavioral problems—having to clean up while simultaneously caring for one's children, (2) overly negative thoughts—“We will never recover from this event,” (3) negative feelings—fear, anger, depression, and (4) physiological responses—muscle tension, fatigue, and sleep problems. Helping an individual understand the various facets of their problematic responses is often helpful because it suggests what skills might be particularly useful. For example, if the problem is mainly a somatic one (increased tension), then relaxation-based strategies may be the most effective.

The second step in problem solving is generating alternatives. Brainstorming is used to generate a wide range of alternative problem solutions. The rules of brainstorming include: (1) the individual should offer as many solutions as they can, even if the solutions do not immediately seem reasonable; (2) no criticism is allowed; and (3) there should be an attempt to mix and match solutions in creative ways. One reason that brainstorming is effective in problem solving is that because of its rules it reduces the tendency to prematurely judge and reject possible coping options. Using this approach a participant can often generate a list of 5 to 10 potential solutions.

The third step in problem solving involves evaluating the alternatives and selecting the best solution. To begin this process a participant can be asked to rate the likelihood that each solution will have a positive outcome. It is often helpful to discuss some of the factors that influence how the participant makes these ratings (e.g., cost, availability of resources, effect of the solution on others). The result is a full review of the pros and cons of each solution. Typically, one solution stands out as the best and most practical.

The final step of problem solving involves implementing the solution. Participants basically try to apply the best solution in the problem situation and then review their progress with the therapist.

There is growing recognition that developing problem-solving skills is crucial to the maintenance of the effects of cognitive-behavioral therapy. Participants who learn how to approach a problem situation and formulate and implement effective coping options benefit in several important ways. First, they are often able to anticipate problems and make plans to avoid them. Second, they cope with setbacks more effectively and are able to get their coping efforts back on track after a setback so as to prevent a major relapse. Finally, they are better prepared for termination because they have learned to engage in a form of self therapy in which they can pinpoint and solve their own problems.

A 55-year-old married man was seen in psychiatric consultation because of symptoms of profound anxiety and depression following the destruction of his home in an earthquake. While he and his family survived intact, his home was a total loss. He developed chest pains and a myocardial infarction while trying to argue with insurance adjusters regarding the loss. In the coronary care unit he was apprehensive, tremulous, and tearful.

In the coronary care unit he was treated with low dose benzodiazepines to alleviate some of his anxiety symptoms. He made an uneventful recovery. During the next 6 months there were frequent aftershocks, and he became fearful, complained of difficulty sleeping, and felt guilty for not having taken better earthquake precautions to preserve his former house. Symptoms progressed to frank depression, and his chest pain symptoms worsened. The depression responded to treatment with a selective serotonin reuptake inhibitor; however, he continued to be preoccupied about his losses and the unpredictability of the future.

In cognitive behavioral therapy he began to chart the occurrence of his worries about future earthquakes and noted that the worries were more evident when he was paying bills for house renovation. He began to attend to some of the negative thoughts associated with the bills (“I'll never receive enough insurance reimbursement; my credit rating will be destroyed unless I pay the bill immediately”). In addition, he began a program of cardiac rehabilitation with exercise training that reassured him that he was recovering well. He also began regular meditation twice daily which he found helpful for his anxiety symptoms. After 10 weeks of treatment, he reported considerable improvement in his symptoms.

This case history demonstrates the confluence of adverse life events, physical illness, and emotional distress and the pharmacologic and psychotherapeutic treatment of stress-related psychopathology.

25.10 BEHAVIOR AND IMMUNITY

JOHN M. PETITTO, M.D., AND DWIGHT L. EVANS, M.D.

Researchers in psychiatry were instrumental in founding the discipline of psychoneuroimmunology, research that is attempting to dissect the complex interactions between the brain and immune systems as well as identify common signaling pathways shared by these systems. In the 1960s two psychiatrists performed landmark studies demonstrating that the brain could modulate parameters of the immune response. George Solomon and his colleagues demonstrated that early experience could produce long-term changes in immune function in animals. In a series of studies, Marvin Stein and coworkers showed that hypothalamic lesions could modify immune processes and anaphylactic responses across species of laboratory animals. They speculated that the hypothalamus transmits signals to the immune system via its control of neuroendocrine and autonomic activity that could modulate immune physiology. Subsequent research, in particular the pioneering collaborative studies of psychologist Robert Ader and immunologist Nicholas Cohen, provided the most compelling and powerful illustrations of the interrelationships between the central nervous system (CNS) and the immune system and heightened interest in psychoneuroimmunological research. Ader and Cohen behaviorally conditioned mice by pairing saccharin (a conditioned stimulus that has no intrinsic immunomodulatory actions) with an immunosuppressant, cyclophosphamide (an unconditioned stimulus). They showed that when behaviorally conditioned mice were exposed to saccharin alone at a later time, saccharin itself resulted in inhibition of antibody production following immunization with sheep red blood cells. Because immunologists had long held that the immune system was a self-regulated autonomous system, Ader and Cohen initially faced considerable skepticism. To demonstrate further that the physiological changes in immune activity elicited by behavioral conditioning were clinically meaningful and could alter the health status of the organism, Ader and Cohen subsequently showed that exposure to saccharin alone could modify the course of murine systemic lupus erythematosus.

This area of inquiry has considerable potential to provide new insights into understanding processes that may affect the development and pathogenesis of neuropsychiatric disorders and could lead to novel strategies to treat and prevent some forms of mental illness.

NEUROBIOLOGY OF BRAIN-IMMUNE INTERACTIONS

Regulation of systemic homeostatic processes such as modulation of blood pressure and gastrointestinal physiology by the CNS has been recognized for a number of years. Thus, it is not surprising that the brain might also play a role in immunoregulation as well as receive sensory input from the immune system, which in turn can help inform the brain to engage in adaptive behaviors that can affect the well-being of the organism. As the field has progressed, the need for multidisciplinary research strategies to disentangle the complex interactive mechanisms between systems (e.g., CNS, endocrine system, and immune system) and within systems has become increasingly apparent. Figure 25.10-1 is a schematic summarizing the various levels of neuroimmune interactions identified by basic research studies to date.

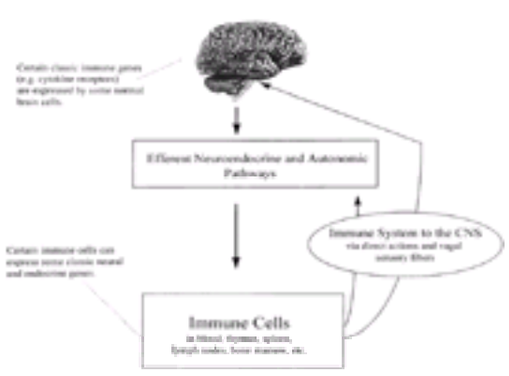

FIGURE 25.10-1 Schematic diagram of central nervous and immune system interactions. Neural and endocrine pathways can modulate parameters of immune system physiology, and the peripheral immune system can transmit signals to the brain. The central nervous and immune systems are now known to share particular endogenous signaling molecules previously thought to be unique to either the CNS or peripheral immune cells.

More than three decades ago psychiatric researchers began to explore the hypothesis that stressful emotional states and their accompanying changes in the brain (e.g., hypothalamus) could modify immune homeostasis by neuroendocrine and sympathetic outflow pathways from the CNS. It is now known that various hypothalamic-pituitary signals possess modulatory properties on some immune cell subsets. Much attention has been given to the actions of the hypothalamic-pituitary-adrenal axis on components of immune system functioning, in part because alterations in hypothalamic-pituitary-adrenal axis physiology have been well documented in the field of biological psychiatry (e.g., major depressive disorder). Although preclinical studies have documented varied immunomodulatory effects of different neuropeptides (e.g., adrenocorticotropic hormone [ACTH], corticotropin-releasing factor [CRF], endorphins, thyrotropin-releasing hormone [TSH]), most emphasis has been given to the role of adrenal steroids. The known immunosuppressive effects of high doses of synthetic steroids led to the commonly held view that behavioral state–induced (e.g., stress, bereavement, depression) elevations in adrenal corticosteroids would suppress immune activity. It is now appreciated, however, that under physiological conditions, endogenous adrenal steroids have bidirectional and complex immunomodulatory actions on immune cell circulation patterns between blood and immune organs (e.g., spleen) and on immune cell function. Attesting to the complexity of brain-immune interactions in vivo, it is apparent that even the neuroimmunomodulatory actions of adrenal cortisol in association with stressful events and psychiatric disorders such as major depressive disorder are not yet clear. Immune organs such as the thymus and spleen are innervated by sympathetic efferent fibers. David Felten and colleagues and others have found that noradrenergic nerve terminals are in close proximity to lymphocytes forming functional neuroeffector contacts.

A working hypothesis of research in the field has been that neurobiological changes in the brain associated with stress and mental illness may result in alterations in the activity of the hypothalamic-pituitary-adrenal axis, and descending sympathetic autonomic pathways that innervate immune organs, or both, which in turn can modify immune status and susceptibility to disease in vulnerable individuals. Preclinical research indicates that the neural modulation of immune activity involves limbic forebrain and cortical regions, brain areas involved in the expression of emotional, cognitive, and thought processes. Relevant to understanding how stress and depression might alter immune physiology in humans, Michael Irwin and colleagues, for example, have shown that intracerebroventricular CRF administration produces increased emotional reactivity and central activation of descending sympathetic pathways, which leads to reductions in the function of natural killer cells residing in the spleen.

To begin to understand how complex phenomena such as behavioral conditioning can affect immunity, several research laboratories have used multidisciplinary approaches to begin to dissect the neural, endocrine, and immune mechanisms involved. Donald Lysle and colleagues, for example, have extended the work of Ader and Cohen by examining how behavioral conditioning effects are translated to changes in immunity. They have shown that conditioned environmental stimuli (inherently nonaversive stimuli) previously paired with an aversive event (footshock stress) can themselves induce pronounced changes in immune status and modify disease course in animals. In this model, they found that opioid systems are involved centrally, that sympathetic pathways transduce the effects to cells of the immune system peripherally (e.g., subsets of splenic lymphocytes), and that release of nitric oxide by macrophages is a key immunoregulatory step in modulating other components of the immune response (e.g., T cell responsiveness).

Analogous to the discovery years ago that digestive system peptides such as cholecystokinin (CCK) and vasoactive intestinal polypeptide (VIP) were present in the CNS, cytokines and their receptors (e.g., interleukin-1 [IL-1] receptors) are now being identified in brain, and their role as neuromodulators, growth factors, and

mediators of immunelike responses in the CNS is being explored. Immune cell–derived signals such as cytokines communicate with endocrine and brain cells, and it is now known that cells of the immune, endocrine and central nervous systems share common signals and receptors. The function of immunomodulators (e.g., IL-1) on brain cells and neuromodulators such as norepinepherine on immune cells is the focus of ongoing research.

Recently, several areas of inquiry have begun to shed light on the potential clinical significance of immune cell–derived signals on the brain and behavior. Cytokines derived by immune cells, in particular proinflammatory cytokines (e.g., IL-1, IL-6, tumor necrosis factor-alpha), can cross the blood-brain barrier. Because cytokines are large molecules, however, most do not readily cross the blood-brain barrier. New evidence from the laboratories of Steve Maier, and colleagues shows that the afferent sensory fibers of the vagus nerve (once viewed as an exclusively efferent cranial nerve) can carry signals initiated by peripheral cytokines to brainstem areas including the nucleus tractus solitarii. Increased concentrations of certain peripheral cytokines can elicit a sickness syndrome in animals that includes mild leukocytosis, fever, increased levels of slow-wave sleep, increased production of acute phase proteins by the liver, decreased activity and exploration, reduced social interaction, increased sensitivity to pain and depressive-like symptoms. It has been theorized that this signal by the immune system provides a message to the brain to aid in initiation of an adaptive, recuperative process by modifying the organism's physiology (e.g., fever can act to reduce severity of infection by a subset of microorganisms) and behavior (e.g., decreased exploration of the environment to preserve energy). Maier and Linda Watkins have also posed the hypothesis that both psychological and physical stressors activate much of the same neurobiological circuitry that is activated by infectious agents or immune cell–derived products that elicit the sickness syndrome. This intriguing avenue of investigation may provide new insights into understanding some of the enigmatic immune and acute phase–like changes described in some individuals experiencing major depressive disorder or other psychiatric syndromes.

PSYCHOSOCIAL FACTORS, DEPRESSION, AND IMMUNE STATUS

The effects of various forms of stress on measures of immune status in humans are well documented. Several notable studies relating psychosocial and emotional factors to immune-based diseases are discussed in this section. Although the role of emotional factors in the onset and course of immune-based diseases has not been firmly established, considerable evidence indicates that psychosocial factors can influence the course of general medical illnesses. Depression has been associated, for example, with increased mortality in elderly patients in nursing homes and with lower 6- and 18-month survival rates following myocardial infarction. Amanda Ramirez and colleagues showed that severe life stress increased the likelihood of relapse in women with breast cancer by nearly sixfold, and research studies by our group on the effects of life stress and depression in men infected with the human immunodeficiency virus (HIV) indicate that high levels of severe life stresses (but not stresses common to daily living) were associated with greater risk of early HIV disease progression and reductions in natural killer (NK) cells and $CD8^+$ T cells over time. Although the studies cited support the hypothesis that stressful life events may affect immune status and disease course, generally research studies in the field from different groups have yielded mixed results. Also, in the particular studies cited above, stress and depression were found to influence individuals who were vulnerable; individuals with existing impairments or reduced immunological plasticity, rendering them more susceptible to the influence of adverse events on health outcome.

In one of the most promising studies to date David Spiegel and coworkers found that a psychosocial group intervention was associated with improved survival in women with breast cancer. They examined the effects of weekly supportive group therapy on survival time in a randomized, long-term follow-up study of patients with metastatic breast cancer. They predicted that the psychotherapeutic intervention would improve quality of life; however, it also influenced the course of the disease. Breast cancer patients who took part in weekly supportive group therapy lived twice as long as matched breast cancer patients who received the same cancer treatment interventions but did not participate in group therapy. Fawzy and colleagues also found that a group intervention increased NK cell function and survival in men with malignant melanoma. Studies are currently under way to replicate and extend these findings.

Perhaps the strongest evidence relating psychosocial events to susceptibility to clinically meaningful endpoints comes from experimental laboratory studies in humans. Sheldon Cohen and colleagues inoculated subject volunteers with cold virus (e.g., rhinovirus) and found that psychosocial stress preceding inoculation was associated with an increased rate of acute respiratory infection. A. A. Stone and coworkers showed that psychosocial factors were correlated with increased cold symptoms in subjects with confirmed rhinovirus infection following experimental inoculation. Moreover, because as many as one-third of subjects with known rhinovirus infection do not exhibit cold symptoms, they also determined whether recent life events, mood, and perceived stress were related to development of cold symptoms following confirmed infection with rhinovirus virus. They found that significantly more major life events occurred during the year preceding rhinovirus infection in the subjects who developed cold symptoms. Current mood and perceived stress were not associated with an increased likelihood of developing cold symptoms.

After many years of research in the field, Stein and his colleagues concluded that the available literature on immune correlates of depression were “findings in search of meaning.” Although studies spanning more than 20 years have examined the relation between clinical depression and immunity, results are inconclusive and data conflicting. The same immune parameters have been reported as increased, decreased, or unchanged by different clinical studies. These discrepancies in the literature may stem in part from differences across studies, including duration and severity of symptoms, temporal parameters (e.g., when samples are drawn for assays), and subject variables such as sex, age, and trait variable (e.g., heritable personality characteristics) among others. Understanding how these variables may interact to produce changes in immune responsiveness may be particularly important for designing clinical psychiatric investigations. In a meta-analytic assessment of this literature several years ago Tracy Hebert and Shelda Cohen found that the most consistent immune changes associated with major depression were reductions in NK activity, mitogen-induced T cell activity, and numbers of certain lymphocyte subsets. Reductions in these in vitro laboratory immune measures should be viewed cautiously. Substantive data indicating that alterations in these in vitro laboratory immune measures correlate with reduced immunocompetence in vivo are lacking. More-recent data may provide another viable interpretation. The work of Michael Maes and colleagues and others now suggests that at least in subgroups of depressed patients, reduced NK activity and altered T cell proliferative responses may present together with estimates of immune activation and inflammatory-like responses (and possibly autoimmune-like laboratory correlates). Many of these findings, such as elevations in acute phase reactants (e.g., haptoglobin concentrations) and increased concentrations of inflammatory cytokines, together with some of the behavioral characteristics (e.g., reduced activity, reduced interest in typically pleasurable activities, reduced social interaction) seem to fit within the theoretical framework of the sickness syndrome described above. Reductions in select cellular immune parameters such as NK activity with concomitant measures of immune activation (e.g., nonspecific antinuclear and antiphospholipid antibodies, acute phase reactants, and increased production of certain proinflammatory cytokines) are often exhibited by individuals diagnosed with certain systemic autoimmune diseases.

NEUROIMMUNE INTERACTIONS ASSOCIATED WITH MAJOR NEUROPSYCHIATRIC DISORDERS

Recent advances have led to new insights into potentially effective treatments that could slow the course of neurodegeneration in patients with Alzheimer's disease. Knowledge of basic processes in the CNS such as the fundamental neuroimmunology of microglial cells, astrocytes, and their secretory products is a vital area of research that has recently led to discovery of immune-based drug therapies (e.g., new cyclooxygenase inhibitors) with the potential to treat Alzheimer's disease and other neurodegenerative diseases. This sets an important precedent for future research seeking to determine the clinical potential for understanding the role of neuroimmune interactions in mental illness.

The field is advancing to the stage at which testable hypotheses examining the role of neuroimmune processes in the pathogenesis of these major neuropsychiatric disorders can be examined. As noted above, certain cytokines and their receptors are now known to be constituents of the normal brain. Understanding their neurobiological function could provide important new clues for unraveling the etiology and pathogenesis of major neuropsychiatric disorders such as schizophrenia and dementia of the Alzheimer's type. For example, Petitto and colleagues and others are determining the molecular neurobiology of the prototypical cytokine, IL-2. Clinical investigations have detected increased levels of IL-2 in the concentrations cerebrospinal fluid (CSF) of schizophrenic patients manifesting symptoms of psychosis, and increased concentrations of IL-2 have been measured in the hippocampi of Alzheimer's disease patients postmortem. The authors have cloned and sequenced the subunits of the IL-2 receptor from the normal brain and have found that IL-2 can modulate the release of endogenous dopamine from striatal slices in vitro and modify behaviors in animals in vivo that are known to be mediated by forebrain dopamine pathways. This prototypical cytokine has also been shown to have trophic effects on both fetal glial cells and neurons and to possess a variety of other actions involved in brain development (e.g., effects on myelin basic protein expression).

Epidemiological findings prompted reconsideration of whether prenatal viral infection or the maternal immune response to such a putative agent may serve as an environmental trigger for the expression of schizophrenia in individuals with genetic loading for the disorder. The hypothesis that early neurodevelopmental alterations may account for key pathophysiological abnormalities seen in the mature brain of individuals with schizophrenia is being examined extensively by neuroscientists. For example, during early development an event such as viral infection or birth trauma in a genetically susceptible individual could possibly disrupt the normal timing for IL-2 and other neurotrophic cytokine stimulation of neuronal growth and migration. If this occurred in a region such as the hippocampus in which IL-2 receptors are enriched, it could contribute to the alterations in this region (e.g., abnormal orientation of subsets of hippocampal neurons) that are seen in postmortem brains of individuals with schizophrenia.

Although there has been ongoing interest in whether autoimmune-like processes may be operative in neuropsychiatric disorders such as schizophrenia, clinical research support for this theory comes largely from nonspecific, correlative data. Often the group mean values for various laboratory measures of immune status (e.g., cytokines, elevated $CD5^+$ lymphocytes) differ significantly from those of normal controls; however, for the most part the actual values themselves fall within the range of normal limits. Some of the issues that researchers are struggling with in this field are similar to those being dealt with by researchers studying systemic autoimmune disorders. People with a chronic schizophrenia (including never-medicated subjects) have a significantly higher frequency of certain autoantibodies than control subjects. This also occurs in people with certain systemic autoimmune disorders; like in groups of individuals with schizophrenia, it is often unclear what role they play in the pathogenesis of autoimmunity against the tissue targeted in the disease (e.g., inflammation and destruction of the pancreas in autoimmune diabetes). Many such autoantibodies are frequently found to be nonspecific. Therefore the various autoimmune-like or proinflammatory-like findings suggesting autoimmune involvement in many neuropsychiatric disorders may be equally likely to reflect epiphenomena. Since the brain is a more immune-privileged organ than others, classic end-organ autoimmune signs (e.g., infiltration of inflammatory cells) are not common to the brain unless the integrity of the blood-brain barrier is compromised. The brain's internal immune cells such as microglia could play a significant role, and microglial responses are an important focus of current research in Alzheimer's disease, for example.

FUTURE DIRECTIONS

Research on brain-immune interactions could provide vital new clues to advance our understanding of psychiatric disorders of the brain such as schizophrenia, depressive disorders, and dementia of the Alzheimer's type. Fundamental understanding of the molecular basis of neuroimmune interactions operative in the pathogenesis of these psychiatric disorders could lead to development of novel therapeutic agents and intervention strategies. Learning more about how behavioral conditioning may exert potent effects on immune physiology, and identifying the combination of psychosocial factors that may affect the course of immune-based diseases such as HIV disease, cancer, and lupus could also lead to useful behavioral therapies to complement conventional medical treatment approaches. These are a few of the many promising directions that research into neuroimmune interactions may go.

25.11 PSYCHO-ONCOLOGY

MARGUERITE S. LEDERBERG, M.D., AND JIMMIE C. HOLLAND, M.D.

Psycho-oncology, or the study of the psychological aspects of cancer, continues its exponential growth, enriched by the new perspective of Eastern European researchers and other international contributions. After describing the phenomenology, prevalence, and treatment of psychiatric syndromes in cancer patients, another generation of researchers focused on subsyndromal stress responses through quality-of-life research. The needs of a large and growing population of long-term survivors continue to be elucidated. The third generation is studying the families of cancer patients, with results that are already of practical importance. The ethical issues of the postmodern era are sharper than ever, as exemplified by the physician-assisted suicide debate, which reached the United States Supreme Court. Deoxyribonucleic acid (DNA) technology continues to spawn ever larger populations of healthy individuals made aware of their genetic risk for cancer, creating psychological and ethical problems we must yet learn to manage. Finally, the role of psychological factors in cancer risk and survival continues to evoke a mix of provocative scientific findings and public overinterpretations.

ADAPTIVE RESPONSE

The diagnosis of cancer creates a crisis that requires patients to adapt quickly to catastrophic news. They must try to control the level of emotional distress while making crucial treatment decisions. Major concerns are fear of death, dependency, disfigurement, disability, and abandonment as well as disruptions in relationships, role functioning, and financial status. Patient responses are modulated by medical, psychological, and interpersonal factors. Medical factors include site of disease, symptoms, and predicted course; psychological factors include preexisting character style, coping ability, ego strength, developmental stage of life, and the impact and meaning of the cancer at that stage. Interpersonal factors refer to family and social support and include the input of the health care team. Affectively, patients may experience reactions ranging from extreme anxiety, sadness, fear, and anger to numbness and lack of reactivity. Guilt and attribution mechanisms play a major role. Cognitively, patients may become highly focused and seek information aggressively or become confused, paralyzed, and unable to concentrate. Somatic complaints may increase, and daily activity, appetite, and sleep are often disrupted. This acute stress response may be severe, but it is usually variable and transient, as patients respond to their rapidly changing reality. Generally, the stress is not so long-lasting as to interfere with the significant areas of functioning outlined in Table 25.11-1. When impairment lasts more than 2 weeks or symptoms are incapacitating, the patient should be evaluated for a psychiatric disorder.

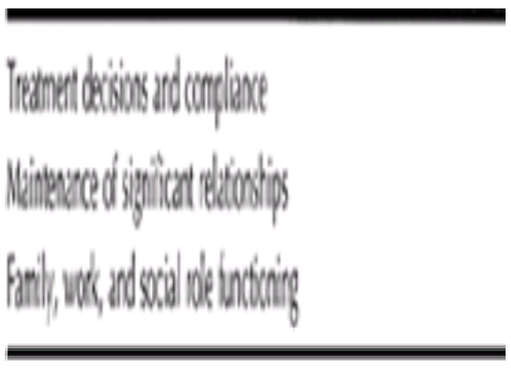

Table 25.11-1 Significant Areas of Functioning for the Cancer Patient

SUBSYNDROMAL STRESS RESPONSES AND QUALITY OF LIFE

In absolute terms, subsyndromal responses to chronic stress account for much human suffering that is amenable to treatment, particularly in cancer patients, whose significant psychological problems are primarily reactive. Two categories in the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) recognize the importance of stress in medical conditions: (1) psychological factors affecting medical condition and (2) acute stress disorder.

Well-validated measures can assess quality-of-life at any point in the illness. They help predict response to future treatment and are factored into the outcome measures of therapeutic trials for noncurative treatments, addressing the crucial question: is the toxicity worth the gain?

PSYCHIATRIC SYNDROMES IN CANCER PATIENTS

Epidemiology

Symptoms Table 25.11-2 lists the most common symptoms found in a group of cancer patients with advanced disease. Five of the top seven are in the psychological realm and are present in more than 50 percent of patients. Three of the next ten are present in 12 to 45 percent of patients.

Symptom	% Positive
Fatigue	74
Worry	71
Sadness	66
Pain	63
Drowsiness	61
Dry mouth	56
Insomnia	54
Poor appetite	45
Nausea	44
Bloating	39
Difficulty in concentration	38
Constipation	33
Change in taste	36
Cough	30
Sexual dysfunction	24
Incontinence	12
Nightmares	11

Table 25.11-2 Symptoms in Patients With Cancer

Syndromes The incidence of psychiatric disorders in mixed inpatient and outpatient populations is about 50 percent, two-thirds of which represent adjustment disorders and psychological problems directly related to the cancer. Thus most of the observed pathology can be assumed to reflect the burden of the illness. Later studies have shown higher incidence of these disorders in inpatients, between 20 and 45 percent depression, depending upon the diagnostic criteria, and an incidence of delirium rising 15 percent to 75 percent with worsening disease. These figures are similar to those found in other comparably ill patients, contrary to persistent myths about how much worse cancer patients must feel. This distortion still affects members of the medical profession, leading to therapeutic nihilism, with negative consequences for patients. It raises the threshold of psychological distress that doctors consider “abnormal” enough to require treatment. Studies of psychiatric consultation data reveal that treatable syndromes such as major depression and delirium continue to be underdiagnosed and undertreated, even in hospice populations, despite known effectiveness in cancer patients.

Treatment

General Principles The hallmark of psycho-oncological treatment is therapeutic activism, with simultaneous use of several modalities in an aggressive attempt at rapid relief of symptoms. Our growing understanding of cancer and cancer treatments as traumatic events makes this not only humane, but also essential to improving subsequent adjustment. The physician must also address the family and the family-staff interface and must remain active throughout the terminal stages of the illness. Psychiatrists must be prepared for the existential plight of the cancer patient, which intensifies the expectable countertransference reactions. They must resist the urge to distance themselves from a painful situation, while guarding against overinvolvement. They must be aware of the patient's physical condition, yet not allow acute physical or emotional distress, legitimate despair, and bars to communication such as tracheostomies, to prevent a thorough evaluation. This requires overcoming fear and guilt and engaging the patient as deeply as one's interviewing skills allow.

Areas of Assessment Assessment of cancer patients is outlined in Table 25.11-3. It begins with the standard psychiatric history, which should also include an exploration of the patient's understanding of the illness and its meaning. Of particular importance is the prognosis: What is it? What are the patient and family being told? What are they absorbing? Major discrepancies in this area can exist among patients, family members, and staff, which lead to unnecessary stress and disruption. The next area is the impact of medical factors on mental state, and the last is the role of the environment, especially the patient's family, and their interface with the health care system. The recurrent demands of cancer treatments promote intense relationships between the patient or family and their medical caregivers, which, if dysfunctional, can lead to psychiatric symptoms and impair care.

Table 25.11-3 Areas of Assessment of Cancer Patients

Treatment Modalities

MEDICAL TREATMENT The psycho-oncologist must recommend medical treatments such as correcting metabolic imbalances and removing offending drugs. Optimum symptom relief must be sought, especially for pain and insomnia. Insomnia is readily acknowledged but is often mistreated with hypnotics or antihistamines that cause habituation or daytime sedation and may worsen symptoms of depression and delirium. Depressed patients benefit from a sedating antidepressant, such as amitriptyline (Elavil) or trazodone (Desyrel): mildly confused or anxious ones benefit from a low dose of a neuroleptic at bedtime. Short- to medium-acting benzodiazepines or zolpidem (Ambien) are the best hypnotics in uncomplicated situations. The psychiatrist should also work with the attending oncologist on such symptoms as nausea, vomiting, diarrhea, and dry mouth, following classically described principles of liaison psychiatry.

PSYCHOTHERAPEUTIC INTERVENTIONS A review of more than 40 psychotherapeutic interventions, which include crisis intervention, cognitive problem solving, supportive therapy with both an educational and a psychodynamic focus, showed that all had a beneficial effect. Working with individual patients or groups, the psychotherapies lowered distress, increased self-esteem and self-image, decreased anxiety, and gave patients a better sense of control. Current innovations focus on populations with special needs. Telephone counseling is an effective form of intervention in rural areas. Videophones have an added advantage for isolated homebound patients, patients in isolation, or children who need to maintain a sense of connection to a hospitalized parent. Patient reports indicate that instructional videotapes are well received.

The usual case begins in a crisis intervention mode, but if the patient remains physically well, may shift into formal therapy. Many cancer patients are happy to leave psychotherapy when they feel better, and return only episodically, when in relapse or crisis. This is not treatment resistance, it is inherent in the original treatment contract. Two major issues for patients are the reality of a shortened life span and the coming death. Despite their close connection, these are often dealt with separately, the first as a negotiable issue on a continuum with other life problems, the second as the mysterious and frightening absolute that it is. Psychiatrists must overcome their own reflexes to stay with the first and avoid the second issue. Later in their course, many patients come to an ambivalent acceptance of, even a yearning for, death. It is important to recognize both sides of the ambivalence and help families and staff tolerate and accept it as well. Families may be feeling ambivalent at this time also and need support. If the patient dies, previously known caregivers are in a unique position to offer bereavement counseling.

Groups are helpful to cancer patients because of mutual support, validation, ventilation, and learning. Formats include education groups, often led by oncology staff with minimal emphasis on expression of feelings; support groups, often led by a mental health professional with emphasis on affective expression; hybrid groups, which include both structured and unstructured portions; and self-help groups, which increase patients' sense of empowerment. Patients who received time-limited adjunct psychological therapies have shown persistence of the positive effects on coping, self-esteem, and quality of life measures, long after the intervention is terminated.

Given psychological prescreening and support, veteran patient volunteers can be invaluable to new patients for orientation, counseling, and rehabilitation. Educational and support programs can be built into the medical routine, as in presurgery education groups, postsurgery rehabilitation groups, and waiting room groups. The growing number of survivors has prompted development of innovative posttreatment programs that include educational and psychotherapeutic modalities, self-help groups, and social activism networks.

BEHAVIORAL TECHNIQUES Behavioral techniques such as hypnosis, self-hypnosis, active and passive relaxation, desensitization, and distraction are useful in a growing range of situations in oncology, including relief of acute and chronic anxiety related to surgery and painful procedures; relief or prevention of conditioned symptoms, such as anticipatory nausea and vomiting associated with chemotherapy; and improved management of almost all pediatric problems.

SOCIAL SERVICES Social workers who are available in large centers or community institutions are a first line of psychological support. They perform a triage function, alerting staff to patients with serious psychopathology. Their classic role is to help patients and families find their way to the large array of community resources. If social workers are not available, psychiatrists and other psychotherapists must fulfill this function.

PSYCHOPHARMACOLOGY Medications play an important role which is discussed below under each psychiatric syndrome. There is an important general caveat: given that cancer patients are usually on many drugs, it is imperative to know of any possible psychotropic drug interactions, especially with respect to the cytochrome P450 system.

Specific Syndromes: Diagnosis and Treatment

Psychological Factors Affecting Medical Conditions The category psychological factors affecting medical conditions should be reserved for conditions and behaviors that affect the course of the existing illness, such as nicotine addiction causing continued smoking in lung cancer patients or compulsive high-risk behaviors in immunosuppressed patients.

Adjustment Disorders Adjustment disorders with depressed mood, anxious mood, and mixed emotional features represent the largest group of Axis I diagnoses found in cancer patients. They are on a continuum, with acute stress responses at one end and mood and anxiety disorders at the other. Commonly used interventions include (1) brief individual psychotherapy focused on helping patients clarify and normalize their intense conflicted feelings and on setting and achieving short-term goals, especially those related to the illness; (2) couple or family interventions to shore up coping and reinforce communication and bonding; (3) educational and referral interventions to maximize the patient's and family's mobilization and integration into a network of support; (4) behavioral techniques to dampen physiological arousal and increase the patient's sense of control; and (5) pharmacological interventions, usually benzodiazepines, (using lower doses in very ill or older patients).

Anxiety Disorders Anxiety in response to a major illness is universal, and until recent changes in DSM classifications, it was difficult to describe the full range of patient reactions. Anxiety may be part of a normal stress response, or an acute stress disorder, or an anxiety disorder due to a general medical condition. The latter two are comparatively new diagnoses whose presentation and course in a cancer population have not been authoritatively described in a research context, but they are a welcome addition to the diagnostic lexicon. The importance of dissociative phenomena for the former must be emphasized, while the latter requires the symptoms to be a direct physiological consequence of the illness and not a subsyndromal adjustment reaction. Anxiety may be a component of delirium and major depression. It is rarely a full-blown anxiety disorder, in which it usually represents an exacerbation or a recurrence of preexisting disorder.

ETIOLOGY Drugs commonly found to cause anxiety in cancer patients include bronchodilators, frequently used in lung cancer patients; steroids, the mainstay of many protocols; interferon; and antipsychotics (including metoclopramide [Reglan] commonly used as an antiemetic) that cause akathisia, which is often mistaken for anxiety by both patient and staff. All the drugs that can cause encephalopathy and delirium can also give a picture of anxiety.

DIAGNOSIS Anxiety may be a panic disorder, with or without agoraphobia, which responds to the usual treatments plus supportive psychotherapy in relation to the cancer illness. Posttraumatic stress disorder has aroused much recent interest, and several studies have shown a high incidence of posttraumatic symptoms in patients and their parents. The full syndrome is rare, and the diagnosis may be overused, but it is useful to conceptualize many of the reactions seen in cancer patients as a reactivation of earlier traumatic responses by the cancer experience, and to see cancer recurrences as reactivations of the earlier trauma. When a diagnosis of cancer precipitates the emergence, or relapse, of delayed posttraumatic stress disorder due to previous stressors (e.g., the Vietnam war or the Holocaust), supportive psychotherapy must attempt to defuse the unconscious resonance between the cancer and the original trauma. In patients with generalized anxiety disorder and anxiety disorders not otherwise specified, one must be careful to rule out other causes of anxiety. Common ones include agitated depression, delirium (especially in a patient taking several anticholinergic drugs), and other drug adverse effects.

TREATMENT Treatment of anxiety disorders includes removal of the cause when possible, behavioral techniques, environmental interventions, and supportive psychotherapy. Pharmacological interventions follow the usual lines, but antipsychotics are often used empirically to good effect, especially when early delirium is a possibility. In more-chronic conditions, the lack of psychomotor, respiratory, and cognitive adverse effects make the buspirone (Buspar) a useful alternative. Pharmacological intervention in posttraumatic stress disorder is under intense investigation; clonidine (Catapres) and several types of antidepressants have been found useful in selected cases.

Major Depression Depressive symptoms in cancer patients may be coincidental, a symptom of a medical disorder, or a functional reaction. Several authors have attempted to discriminate the core symptoms of major depression in medically ill patients, since vegetative signs are often due to the illness. The *inclusive* approach counts all symptoms regardless of etiology. The *etiological* one counts them only if they are not related to physical illness. The *substitutive* one replaces somatic criteria with cognitive ones. The *exclusive* one uses the strictest nonsomatic research criteria. This explains the 4 to 10-fold differences in reported incidence. Self-report symptoms inventories such as the Hamilton Rating Scale for Depression (HAM-D) or the Beck Depression Inventory (BDI) are useful for screening purposes but are not very discriminating. Replacing the somatic criteria with other psychological ones improves the results, but there is no substitute for a clinical interview.

CLINICAL FEATURES Feelings of worthlessness and excessive guilt are powerful discriminants between normal sadness and major depression. Although common in cancer patients, they are mild and transient, and patients usually maintain intact self-esteem. Depressed patients, in contrast, experience intense self-loathing. Similarly, recurrent thoughts of death are common in cancer patients, but they do not have the morbid intensity and desire characteristic of depressed patients. Cognitive impairment is also a useful discriminant, although one must consider anxiety states and delirium when it is prominent. Other criteria—appetite changes, sleep changes, and loss of energy—can still be used to diagnose the cancer patient who is physically well.

DIFFERENTIAL DIAGNOSIS The differential diagnosis includes adjustment reactions with depressive mood and with mixed emotional features, dysthymia, mood disorder due to a general medical condition, and substance-induced mood disorder. A large number of medical disorders and drugs may cause an organic mood syndrome (Table 25.11-4).

Drugs
Chemotherapeutic agents: prednisone, dexamethasone, procarbazine, vincristine, vinblastine, L-asparaginase, tamoxifen, interferon
Addictive effect of narcotics and many other drugs known to cause depression, such as antihypertensives, benzodiazepines, antiparkinson agents, and β-adrenergic receptor antagonists
Tumor effects
Hormone-secreting tumors
Central nervous system tumors
Associated medical conditions
Uremia
Viral encephalopathies
Electrolyte imbalances

Table 25.11-4 Causes of Mood Disorders in Cancer Patients

TREATMENT Depressed cancer patients respond well to pharmacological treatment. Selective serotonin reuptake inhibitors have become first-line drugs, especially sertraline (Zoloft) and paroxetine (Paxil). Fluoxetine (Prozac) requires a long washout period, especially before using procarbazine (Matulane), a drug with incidental monoamine oxidase inhibitor (MAOI) features. It in turn requires a washout period before antidepressants can be used. Antidepressant selection is guided by the adverse-effect profile, gearing the choice to the patient's medical condition. Maprotiline (Ludiomil) has dopamine-blocking activity and hence may cause an increased incidence of dyskinesias in conjunction with commonly used antiemetics such as metoclopramide. Cardiac adverse effects are not usually a problem in patients with a normal electrocardiogram (ECG). Postural hypotension usually does not disturb bedridden patients. Anticholinergic adverse effects should be avoided in elderly patients at risk for anticholinergic delirium or patients at risk for gastrointestinal obstruction. Sedation is frequently a desired effect, and the use of sedating antidepressants such as nefazodone (Serzone) or trazodone obviates the need for hypnotics. Several tricyclic drugs improve the effectiveness of opiates. An average starting dose of amitriptyline is 10 to 25 mg orally at bedtime raised in 10- to 25-mg increments up to 100 mg or more. If needed, routes of administration may be varied: the oral and intramuscular routes are well known: the per rectum route has been described for amitriptyline but its pharmacokinetics are not known. Intravenous antidepressants have been rarely used outside the research setting.

MAOIs are seldom used in cancer patients because of the complex dietary restrictions and the numerous drug interactions involved with their administration. Low-dose lithium combined with an antidepressant may be useful for treatment-resistant medically ill patients. It can usually be continued uneventfully, although attention must be paid to hydration and sodium balance. Acute lithium toxicity has been reported with combined fluoxetine and lithium use. Renal insufficiency is a

contraindication, but end-stage renal disease can be managed with a 300-mg dose after each dialysis. Medically ill patients must be monitored for lithium toxicity in the presence of vomiting and dehydration (e.g., during acute cytotoxic therapy), hypercalcemia, renal impairment (e.g., with cisplatin [Platinol] treatment), possible hypothyroidism (e.g., radiation to the neck or treatment with lymphokines), or when there is an increased cardiac arrhythmia (e.g., preexisting heart disease, or use of digoxin [Lanoxin], bronchodilators, or cardiotoxic chemotherapy agents such as doxorubicin [Adriamycin]). Radiation therapy is not a contraindication, except possibly for cranial irradiation whose adverse effects mimic lithium toxicity, making monitoring difficult. Lithium's modest ability to stimulate the bone marrow is an asset during the recovery phase of chemotherapy, although colony-stimulating factor (G-CSF) has made that obsolete. It is also used to prevent and treat steroid-induced psychotic disorders, although haloperidol (Haldol), and other antipsychotic agents as well as valproate (Depakote), and clonazepam (Klonopin) are more frequent alternatives.

Psychostimulants have been used in patients with advanced cancer. Dextroamphetamine (Dexedrine) and methylphenidate (Ritalin) are given in dosages from 2.5 to 10 or 15 mg per day in divided doses, as early in the day as needed to prevent insomnia. Pemoline (Cylert) has caused rare but serious liver impairment. Increased appetite, energy, and well-being are seen within 24 hours; hence these drugs are used in terminal patients or as diagnostic probes before a course of antidepressant treatment. The dosage may be increased if tolerance develops. The main adverse effects are cardiac but are very rare, even in patients with predisposing factors.

SUICIDE Suicidal thoughts and wishes are common in cancer patients, but studies show that the incidence of actual suicide is no more than approximately twice that of the general population. The true incidence may be higher due to underreporting. Table 25.11-5 outlines suicide vulnerability factors in cancer patients. In responding to suicide threats, remember that many patients harbor suicidal feelings sometimes but learn to hold them back because of family and staff disapproval. Patients feel guilty, burdened, and angry. It is therapeutic to acknowledge the validity of their suicidal feelings and encourage ventilation without encouraging action. Treatment must be instituted for the first eight factors listed in Table 25.11-5. Inadequate symptom control is a frequent cause, and good symptom relief often stops the suicidal threats. Rarely, a competent patient presents a difficult problem by continuing to threaten or ask for help in dying. The hospitalized patient must be given intense ongoing support including open discussions about treatment options. Ambulatory patients are free to exercise all their options, although they rarely do so. Medical staff and family may need to be reminded of the competent patient's right to refuse all treatments, even lifesaving ones. This also extends to the right to stop treatment.

Depression and hopelessness
Poorly controlled pain
Mild delirium (disinhibition)
Feeling of loss of control
Exhaustion
Anxiety
Preexisting psychopathology (substance abuse, character pathology, major psychiatric disorder)
Acute family problems
Threats and history of prior attempts of suicide
Family history of suicide
Other usually described risk factors in psychiatric patients

Adapted from Breitbart W: Suicide in cancer patients. Oncology 1:49, 1987.

Table 25.11-5 Suicide Vulnerability Factors in Cancer Patients

Delirium, Dementia, and Other Cognitive Disorders

ETIOLOGY Delirium can be caused by the primary disease, by associated medical diseases, and by treatment (Table 25.11-6). Drug toxicity is probably the most common cause, most often (1) narcotic analgesics, especially drugs with a long plasma half-life, such as methadone (Dolophine) or morphine; (2) anticholinergic drugs, which are often multiple and cumulative in effect and include antiemetics (the centrally active drugs most commonly prescribed in cancer patients), antidepressants, antipsychotics, antiparkinsonian drugs, and anesthesia preparations; (3) sedatives and hypnotics, especially long-acting ones that are cumulative or those taken after ketamine (Ketalar) and halothane (Fluothane) anesthesia; and (4) drugs known to have psychoactive adverse effects, such as digitalis glycosides, b-adrenergic receptor antagonists, (beta-blockers), bronchodilators, antihypertensives, and antibiotics, such as amphotericin (Fungizone). In addition, drug withdrawal may be a common cause of delirium, especially in postoperative patients whose drug treatment was interrupted for surgery and not promptly restarted.

Medications (worsened by polypharmacy and by hypoalbuminemia, which increases the amount of circulating unbound drug)
Opioids
Benzodiazepines
Anticholinergic drugs
Sedative-hypnotics
Steroids
Cardiac glycosides, β-adrenergic receptor antagonists, antihypertensives
Anticonvulsants
Antihistamines
Bronchodilators
Antibiotics
Drug withdrawal
Metabolic and nutritional causes
Oxygen deprivation
Fluid, electrolyte, and osmolarity imbalance (sodium, calcium, phosphorus, magnesium; hyperglycemia and hypoglycemia, hypercarbia)
Vitamin deficiencies (thiamine, niacin, B_{12}, folate)
Infections, especially in immunosuppressed hosts
Vital organ failure (liver, kidney)
Vascular disorders
Endocrine and hormonal disorders
Tumors of the pituitary, thyroid, parathyroid, adrenal, and pancreas
Multiple endocrine neoplasia syndromes
Carcinoid tumors (mainly ovary, lung, stomach, and intestinal tract

Table 25.11-6 Medical Causes of Delirium in Cancer Patients

Other risk factors include increased age, preexisting central nervous system (CNS) problems, low serum albumin which raises the serum concentration of unbound drugs, other metabolic abnormalities, a history of alcohol or substance abuse, and temperature dysregulation. With an increase from 0 to 3 risk factors, the incidence rises from 2 to 50 percent, bringing longer hospital stays and poorer outcomes. Elderly persons whose delirium may unmask an underlying dementia may never return to premorbid levels of function.

DIAGNOSIS Psychiatric consultation is frequently requested by the time a patient manifests the blatant clouding of consciousness and the cognitive, perceptual, and behavioral abnormalities of delirium. In the earlier stages, however, the symptoms of delirium are subtle and routinely missed. Even as the patient becomes overtly withdrawn, suspicious, and erratic in mood and behavior, family and staff may interpret this as stress, anxiety, poor coping, or anger. They may collude in finding excuses for the patient's behavior, deny the impairment, and make inappropriate demands or scapegoat patients and blame them for their bad behavior. Benzodiazepines are often given to treat anxiety, but they worsen the symptoms of delirium because of disinhibition; more rarely, antidepressants are prescribed. Diagnosis requires a high index of suspicion. Delirium may be a hyperactive syndrome with hallucinations, delusions, and hyperarousal, or it may be hypoactive with partial obtundation. Its cause is often multifactorial, and treatment must be instituted even while the causes are being investigated.

TREATMENT Management includes the usual environmental measures to decrease confusion and guarantee patient safety (e.g., use of bed rails, night lights, repeated orientation) and an antipsychotic such as haloperidol, chosen because of its lack of sedation and overall safety. The beginning dose ranges from 0.5 mg in a cachectic patient to 2 mg or even 5 to 10 mg in a stronger one, using the intramuscular or intravenous route in agitated or disruptive patients. The dose is halved for intravenous administration; it takes effect within 15 minutes and may be repeated hourly two or three times, after which it is preferable to supplement any further use with intravenous lorazepam (Ativan) in doses of 0.5 to 2 mg every 6 hours as needed, to achieve adequate sedation. Raising the dose of haloperidol much higher increases the incidence of seizures and other adverse effects without adding much therapeutic effectiveness. However, there are reports of treating resistant delirium with doses of haloperidol up to 1 to 1.5 grams in a 24-hour period without ill effect. Thioridazine (Mellaril) or chlorpromazine (Thorazine) may be used when sedation is desired and hypotension is not an acute problem. Molindone (Moban) carries the lowest risk of seizures. Risperidine (Risperdal) and olanzepine (Zyprexa) are being increasingly used, but their use is limited in the very ill by the lack of parenteral forms. These new preparations are under development and will soon be

available.

The main adverse effects of antipsychotics relevant to cancer patients are the dystonias, including rare ones that involve muscles of respiration and deglutition, which can be mistaken for underlying disease and go untreated; akathisia, which is mistaken for agitation, delirium, anxiety, and agitated depression; and neuroleptic malignant syndrome.

Follow-up evaluations are more reliable with the sequential use of a standardized instrument, such as the Delirium Rating Scale (DRS) and the Memorial Delirium Assessment Scale (MDAS). The well-known Mini-Mental State Examination is focused on cognition alone, hence is more useful for dementia. The discussion of delirium can also be applied to other mental syndromes—namely amnestic disorder; psychotic disorder due to an organic delusional syndrome, general medical condition, with delusions or with hallucinations, and mood disorder due to a general medical condition. They are rare in pure form, and their cause should be established by the appropriate workup.

Personality Disorders Personality disorders are an infrequent cause of psychiatric consultation. Since the patients' symptoms are chronic and egosyntonic, it is often the family and staff who feel stressed by a worsening of the patient's usual dysfunctional modes of adaptation and who ask for help because of increased conflict and disrupted treatment. Nevertheless, personality-disordered patients do have acute stress syndromes, which may be overlooked because of the chronic issues. Evaluation should search for both Axis I and Axis II disorders, and any disorders should be actively treated. Environmental measures should be implemented to decrease conflict and improve patient care, including both family and staff in the intervention.

The dynamics of difficult patients and ways of dealing with them have been well described in the psychiatric literature. The feelings of anger and guilt that patients with personality disorders routinely induce in mental health staff also occur in oncology staff. The latter may find them harder to deal with because they are not trained to recognize these feelings as part of the patient's pathology and are disarmed by the genuine pathos of the patient's condition. Explanations, support, and guidance are helpful.

Schizophrenia and Other Psychotic Disorders Contrary to earlier beliefs, cancer is no rarer in patients with schizophrenia than in the general population. Schizophrenia patients may appear less often in doctors' offices because their disease interferes with early and consistent seeking of care. They give idiosyncratic meanings to their symptoms and may tolerate them without complaint, often because of a high pain threshold. The patients' unreliability continues throughout the treatment course and may complicate postoperative and long-term medical management. When treating hospitalized schizophrenia patients it is important to ensure continuity of care. Ongoing medications can usually be continued, except for a brief operative period. The medical staff needs help in handling bizarre behaviors and reassurance about intimidating mannerisms. They need a precise protocol and written orders for the management of aggressive or disruptive episodes, as well as clear understanding of the legal and ethical considerations governing the patient's right to refuse medical treatment and leave the hospital.

Bipolar Disorders Patients with bipolar disorders in remission can be maintained on lithium with few problems. Acutely manic patients must be brought under control as rapidly as possible, using intravenous haloperidol if necessary. Otherwise, they may be treated as usual.

Substance Use Disorders Alcohol withdrawal on the second or third day in the hospital may elicit a psychiatric consultation for anxiety, poor coping, or postoperative delirium. Thoracic, head, and neck cancer patients are at high risk for this, as well as for nicotine withdrawal since they stop smoking upon diagnosis or admission. The symptoms are those of anxiety and can be severe enough to include depersonalization and marked cognitive distortions. Fear is eased by giving explanations and symptoms are relieved by benzodiazepines. Transdermal nicotine patches (Nicotrol, Habitrol, Nicoderm CQ), are increasingly used to ease the distress of patients forced to stop smoking suddenly because of a diagnosis of cancer. Other substance withdrawal syndromes rarely occur. Surreptitious drug use is more likely, manifesting itself as a fluctuating organic mental state with erratic difficulties in the delivery of care.

Somatoform Disorders The development of cancer in patients with a somatoform disorder can create difficult diagnostic problems because patients incorporate the cancer into their psychiatric disorder and elaborate on physical symptoms in their usual manner. That is, the somatization disorder patients continue to plead for surgery for a multiplicity of symptoms; the conversion reaction patients become paralyzed at the first hint of real leg weakness; and the psychogenic pain patients maintain the same abnormal relationship to pain they have always had. The resultant syndromes are complex, involving both organic and psychogenic components. Physicians often feel manipulated and frustrated by these compulsive behaviors and in trying to correct them either underestimate them and delay treatment or give up and overtreat psychosomatic symptoms. A psychiatric evaluation and ongoing psychotherapeutic relationship will let the psychiatrist work with the oncologist and staff to set limits and treat the patient appropriately.

Factitious Disorders Patients may enter a hospital claiming to have cancer and turn out to have a chronic factitious disorder with physical symptoms. Their presentation and course fit the usual description, and on being confronted, they often leave angrily to seek other care.

Cancerophobia The negative reaction to cancer in our society often makes it the object of excessive fear, comparable to syphilis or germs in the past and acquired immune deficiency syndrome (AIDS) today. Transient cancerophobia may be a response to a specific event (e.g., a cancer death in the family) and often occurs when new personnel start work on a cancer ward. Fixed cancerophobia ranges from a neurotic symptom to a hypochondriacal fixation, an obsession, or a somatic delusion. It is associated with a broad spectrum of diagnoses, and management depends on making the appropriate diagnosis. The symptoms are often quite resistant.

Psychiatric Syndromes and Tumor Site

Primary Nervous System Cancers Tumors that arise in the CNS (brain or spinal cord) account for 3 percent of deaths in all cancer patients. They account for 20 percent of all childhood tumors and are the second most common tumor in children under age 15. Psychiatric symptoms are present in almost all patients with supratentorial tumors and are the presenting symptom in 25 percent of these patients. In one series, they represented the presenting complaint in 12 percent of patients with subtentorial tumors. There are also reported cases of spinal cord tumors initially diagnosed as conversion reactions. Presenting symptoms vary enormously depending on the location of the tumor and whether it is invasive or encapsulated. They commonly include personality change, anxiety disorders, and mood disorders.

Metastatic Neoplasms Brain metastases are the most common complication of systemic cancer, occurring in 25 to 30 percent of patients. Their frequency is increasing as cancer treatment improves survival, and the central nervous system provides a sanctuary for malignant cells hiding behind the blood-brain barrier. Lung tumors account for 35 to 40 percent of CNS metastases; breast, kidney, and colon tumors account for approximately 15 percent each; and other tumors, malignant melanoma, carcinomas of the bladder, liver, thyroid, testicle, uterus, and ovary account for the rest. Leukemia spread to the brain was more common before CNS prophylaxis by radiation and intrathecal therapy. In a series of 199 patients, headache (49 percent) and mental disturbances (32 percent) were the most common presenting symptoms, and cognitive impairment (58 percent) the most common presenting sign. It was far more frequent than papilledema.

SPINAL METASTASES Spinal metastases occur in 5 to 10 percent of patients with cancer, usually in late stages of the disease, but they may be the presenting sign in as many as 8 percent of patients. The diagnosis is often delayed, even in advanced disease, if patients' pain complaints are not taken seriously. In one series, epidural spinal cord compression was the presenting symptom for 47 percent of primary care patients.

LEPTOMENINGEAL METASTASES Also known as carcinomatous meningitis, leptomeningeal metastases are the diffuse, multifocal seeding of the leptomeninges by cancer. They are found in 5 to 8 percent of patients with solid tumors, 5 to 29 percent of patients with non-Hodgkin's lymphoma, and 11 to 70 percent of patients with leukemia. Psychiatric symptoms are often present (e.g., anxiety, mood instability, personality change), sometimes without focal signs. When neurological symptoms are present, they relate to widely separated parts of the neuraxis and may lead to diagnostic skepticism and an early psychiatric diagnosis.

Nonmetastatic Neurological Complications of Cancer Many local and systemic factors contribute to neurological complications in cancer patients. These are particularly relevant to psychiatry because a mild or subacute encephalopathic presentation is common in debilitated cancer patients and can be initially attributed to psychological factors.

CENTRAL NERVOUS SYSTEM INFECTIONS Because of severe immunosuppression caused by chemotherapy, cancer patients are susceptible to a wide range of infectious agents. Mild headache and low-grade fever may be the only systemic factors accompanying mental state changes. Fungal agents have become as common as bacterial ones, also accounting for the less acute presentation. Opportunistic viral infections can cause leukoencephalopathy.

CEREBROVASCULAR DISEASE Cerebrovascular diseases cause symptoms in only 7 percent of cancer patients, but they present as encephalopathy more

commonly than with acute or localizing signs. They are associated with the bleeding tendencies secondary to bone marrow depression, with the coagulopathies commonly found in cancer patients, and with locally induced tissue damage and treatment toxicity.

PARANEOPLASTIC SYNDROMES The *paraneoplastic* refers to an uncommon group of disorders, defined as remote, nonmetastatic effects of cancer on the nervous system. In 50 percent of cases, the symptoms precede the discovery of the cancer and run an independent course. They can affect all parts of the nervous system. Dementia, particularly with loss of memory, is a common feature in several variants, which are grouped under the name “carcinomatous encephalomyelitis,” of which several cases have turned out to be leukoencephalopathies. Mild-to-severe cerebellar dysfunction and abnormalities of peripheral nerve muscle function are commonly found as well. Small cell lung cancer, Hodgkin's lymphoma and ovarian cancer are the most frequent associated tumor types. Suggested causes include toxins secreted by the tumor, competition for essential substrates, opportunistic infections, and most likely autoimmune reactions mounted against the underlying tumor.

Endocrine and Hormonal Effects of Tumors Tumors of endocrine glands may be physiologically active and produce anxiety and mood disorders, confusional states, and occasionally psychosis. Carcinoid tumors can cause anxiety syndrome. Carcinoma of the pancreas reportedly has been associated with an increased incidence of depression, sometimes as the presenting symptom.

General Clinical Considerations No specific picture is associated with this wide range of CNS disorders, which require a high index of suspicion for accurate diagnosis. Signs of cognitive impairment in older patients are too easily dismissed without a full medical workup. Signs of affective ability are labeled mood disorder. Symptoms of pain are too easily thought to be functional if the first workup does not yield an organic cause. Symptoms of a chronic nature may be too readily labeled character pathology, and associated physical complaints dismissed as conversion reactions. This is complicated by the fact that true conversion reactions in cancer patients frequently present as an elaboration of an organic symptom. Suspicion should be aroused by an abrupt change from the premorbid personality, an unusual age of onset for symptoms, a lack of family history, associated physical symptoms, and a poor response to treatment.

Psychiatric Problems Due to Cancer Treatment Radiation and most of the drugs used in cancer treatment have significant adverse effects, and are even carcinogenic in tumoricidal doses. Patients may become transiently more ill from the treatment than from the disease, developing adverse effects such as hair loss that have great emotional impact. Steady compliance requires more courage and endurance than medical staff realizes. Patients may become upset about the adverse effects, convinced they represent disease progression, depressed about the paradoxical nature of treatment, and generally so exhausted they develop clinical depression and anxiety. If untreated, they delay or stop treatment, moving to alternative treatments and jeopardizing their survival. Later adaptation is also impaired. Many patients, however, come to feel dependent on continued treatment as a means of holding the cancer at bay. Anxiety levels rise at the end of treatment, associated with this fear and with the difficulty of making a transition to the survivor status. This can be assuaged by acknowledging it, exploring its cause, and making concrete plans for continued medical supervision and psychological support.

Radiation Therapy Radiation-induced encephalopathy is the most common neuropsychiatric complication of radiation treatment. It takes several forms. The first is an uncommon, immediate (minutes to hours) syndrome with symptoms of increased intracranial pressure. The second is an early-delayed (6 to 16 weeks) syndrome with headaches, somnolence, and sometimes no focal signs. Both respond to steroids and are usually self-limited. The third is an irreversible late-delayed (months to years) form associated with atrophy or necrosis. It presents with headaches and personality changes and only later progresses to focal signs and seizures. Irreversible focal radiation necrosis has also been described.

Other forms of radiation-induced cognitive dysfunctions have come to the fore in a growing population of long-term survivors (mainly from Hodgkin's disease and childhood leukemia) who have undergone whole brain radiation. A short-term memory deficit has been observed, as well as a long-term decrease in intelligence quotient (I.Q.) of as much as 10 to 25 points. Even in the presence of a normal I.Q., neuropsychological problems and learning disorders have been documented. Although the studies in this area have many shortcomings, it is generally believed that the threshold of the brain's tolerance to radiation must be revised downward. Elderly and very young persons are the most affected. A recent controlled study in postradiation brain tumor patients showed that methylphenidate (Ritalin) improved cognition, mood, and functioning.

Radiation therapy can be associated with a high level of psychological distress. Nausea, vomiting, and mild-to-moderate fatigue can lead to fear, anxiety, depression, and occasionally major depressive episodes. Sexual impairment is common following radiation to the pelvic area—impotence in men and dyspareunia in women. The latter, related to vaginal fibrosis, is improved by dilatation. Acute transient gastrointestinal problems (e.g., diarrhea and food intolerance) are common; severe irreversible ones are rare.

Chemotherapy The immediate effects of chemotherapy include nausea and vomiting, which occur within 2 to 6 hours and last up to 24 hours. Table 25.11-7 lists the drugs most likely to cause these symptoms. The most emetogenic drugs cause symptoms in virtually all patients; the less emetogenic ones are variable. The reasons for the marked interpatient variability are not understood. Both chemotherapeutic drugs and radiation cause vomiting by central mechanisms.

Severe and moderate emesis (requires prophylactic combination antiemetics)	Mild emesis (requires occasional antiemetics)
Cisplatin	Etoposide
Dacarbazine (DTIC)	Mitomycin
Dactinomycin	Plicamycin
Mechlorethamine (nitrogen mustard)	Ifosfamide
Carboplatin*	Methotrexate
Cyclophosphamide*	5-Fluorouracil
Doxorubicin	Hydroxyurea
Daunorubicin	Bleomycin
Idarubicin	Vinblastine
Cytarabine	Vincristine
Procarbazine	Chlorambucil
Carmustine (BCNU)	
Lomustine (CCNU)	

* Peak emesis: 8 to 12 hours after administration.

Table 25.11-7 Emetogenic Potential of Commonly Used Anticancer

Classical conditioning is an important mechanism in the causation of several reactions to chemotherapy: anticipatory nausea and vomiting, which occurred in 25 to 75 percent of patients before the use of better antiemetics; anticipatory immune suppression, whose clinical significance has not been established; and learned food aversion, which can be minimized by avoidance of staples and favorites. Patients develop a conditioned response to sights and smells reminiscent of the chemotherapy experience. After termination of treatment, these symptoms lessen, but one study found that 6 to 140 months after treatment, 63 percent of patients still reported nausea, 5 percent reported vomiting, and 80 percent still reported anxiety with specific stimuli.

All these reactions are presumed to represent conditioned responses, and treatment approaches have been formulated accordingly. Prophylactic antiemetic and antianxiety treatments are used to prevent or decrease the initial episode or conditioned response (Table 25.11-8). With the advent of highly specific, centrally acting antiemetic agents such as the serotonin (5-hydroxytryptamine [5-HT]) type 3 (5-HT_3) blockers ondansetron (Zofran) and granisetron (Kytril), the success of antiemetic regimens has greatly increased. Other cheaper agents such as metoclopromide, lorazepam, and dexamethasone (Decadron) continue to be commonly used as well. The usual regimens still include lorazepam, steroids, metoclopramide, or prochlorperazine (Compazine). The latter two are neuroleptics with the usual side effects, but the briefness of administration makes tardive dyskinesia rare. Akathisia occurs in 10 to 20 percent of patients on metoclopramide, but coincident use of lorazepam lowers the incidence to below 3 percent. Mild sedation is acceptable or even welcome. Hypotension may limit the use of prochloperazine and chlorpromazine. Dronabinol (Marinol) a tetrahydrocannabinol, is no more effective than other drugs and has a similar adverse effect profile plus a significant incidence of dysphoric reactions in older patients. However, the inhalation route is effective in experienced users. Its legalization is a controversial issue in several states, where its use may constitute a felony. Dexamethasone (Decadron) in one intravenous bolus is generally well tolerated.

Neurotransmitter blocking agent	Metoclopramide* 3 mg/kg IV, 30 min before therapy and 1 1/2 hours after therapy or Ondansetron 0.15 mg/kg, IV, 30 min before therapy and 1 1/2 and 3 hours after therapy
plus	
Steroid	Dexamethasone* 20 mg IV, 20 min before therapy
plus	
Benzodiazepine	Lorazepam 1.5 mg/m² (max, 3 mg) IVPB before thetapy
or	or
Antihistamine	Diphenhydramine* 50 mg—oral, IV, or IM—every 4 hours as needed for restlessness or acute dystonic reaction

* Should also be used in oral form for delayed nausea and vomiting, starting 24 hours after cisplatin therapy.

Table 25.11-8 Current Chemotherapy Antiemetic Regimens

Behavioral methods are important, effective ways to lessen the reactions to chemotherapy, and are most effective when instituted before the conditioned response is established. They include hypnosis and progressive muscular relaxation with guided imagery or relaxation with cognitive distraction, to block both the conditioned stimulus and the conditioned response; systemic desensitization, which extinguishes the conditioned response; and cognitive distraction, which blocks perception of the conditioned stimulus. Patients are also helped by reassurance about the frequency and normalcy of their responses.

CNS Toxicity Chemotherapeutic agents may cause neuropsychiatric problems indirectly by causing metabolic abnormalities or other organ failure, or by direct CNS toxicity. Although all chemotherapeutic agents are selected because they interfere with basic cell processes, they are remarkably well tolerated and have surprisingly little CNS toxicity. However, few problems are found because few are looked for, and mild impairment may be the rule rather than the exception. This view is of pragmatic importance because underdiagnosed organic mental disorders lead to further disqualification of patient complaints and predispose to further psychological decompensation and management problems. Table 25.11-9 lists the agents most likely to be associated with neuropsychiatric complications. Some drugs, such as vincristine (Oncovin, Vincasar), cause neurotoxicity in all dosage schedules; others, such as cisplatin cause neurotoxicity only at higher doses. Carmustine (BiCNU) is neurotoxic mainly when given by the intracarotid route or in conjunction with radiation therapy. Some drugs have mild, transient toxicity; others have delayed or irreversible toxicity, or both. It is usually (but not always) dose related and cumulative. Some drugs, like methotrexate (Folex, Mexate), when given intrathecally, may cause several syndromes: a reversible encephalopathy, a delayed irreversible one, and a variable dementia or developmental delay when coadministered with radiation therapy. Initially, mood changes, personality changes, and subtle cognitive changes may predominate, leading to psychiatric consultation. Only later does the encephalopathic nature of the condition become manifest.

Table 25.11-9 Neurological Complications of Chemotherapeutic Drugs

Combination of radiation with chemotherapy and the use of the intrathecal route or of very high doses leads to a higher incidence of problems. Recognition may be complicated because the changes may occur months to years after treatment.

Table 25.11-10 lists agents for which mood or psychotic symptoms have figured prominently. All of these also cause cognitive disorders. (Anxiety has not been included because it is ubiquitous.) These syndromes are often reversible and remit spontaneously if drug administration is stopped. This may take only a few days or up to several weeks. If the offending drug cannot be discontinued, symptomatic treatment should be instituted.

Dacarbazine: depression and suicide reported, especially when used with hexamethylmelamine
Vinblastine: frequent reversible depression
Vincristine: 5 percent incidence of hallucinations: depression noted
L-Asparaginase: reversible depression noted
Procarbazine: MAOIs, concurrent tricyclic drugs, and selective serotonin reuptake inhibitors are contraindicated: associated with mania and depression: potentiates alcohol, barbiturates, phenothiazines
Hydroxyurea: hallucinations reported
Interferon: anxiety, depression with suicidal ideation common at high doses
Steroids: frequent alterations of mental state, ranging from emotional lability through mania or severe, suicidal depression to frank psychosis
Tamoxifen: depression: rare delusional syndrome

Table 25.11-10 Chemotherapy Agents Associated With Mood and Psychotic Symptoms

Disorders of special senses include ototoxicity, associated with cisplatin and several commonly used antibiotics; visual disturbances, associated with mitotane (Lysodren) and tamoxifen (Nolvodex); and gustatory and olfactory hallucinations described with vinblastine (Velban). These disorders may occur slowly or suddenly, reversibly or permanently, and often result in acute psychological distress requiring psychiatric consultation. Long-term effects of ototoxicity in children add considerably to the educational and neuropsychiatric impairment of these patients. The diagnosis is often missed in younger children, the very ones in whom early intervention is essential to minimize later developmental impairment.

Antineoplastic Hormones and Biological Modifiers The hormonal agents listed in Table 25.11-11 are used mainly in prostate and breast cancer. They are associated with depressive symptoms and many adjustment disorders related to their sexual adverse effects such as feminization, masculinization, and disorders of sexual functioning. Of the biological modifiers listed in Table 25.11-11, the cytokines cause the widest range of confusional and affective states. The interferons, interleukin-2, tumor necrosis factor, and colony stimulating factors are naturally present in the body in low concentrations. Their normal elevation during naturally occurring infections is responsible for what patients describe as “flu” symptoms. Recombinant DNA technology has made them available for use against cancer. Interferon causes an acute reversible encephalopathy with confusion, lethargy, and hallucinations. One case of delayed progressive encephalopathy was reported. A reversible depression is common, with severe fatigue and loss of concentration. Aldesleukin (Proleukin), a human interleukin-2 derivative, causes headache, agitation, disorientation, and confusion, which are dose-related and reversible. A rare, severe encephalopathy was also reported. These drugs have become frightening to patients who hear of the multiple adverse effects. The severe depression may respond to antidepressant medication.

Types of antineoplastic hormones
Androgens (danazol)
Antiandrogens (flutamide for prostate cancer)
Estrogens (diethylstilbestrol [DES])
Antiestrogen (tamoxifen for breast and ovarian cancer)
Progestins (megestrol for anorexia)
Adrenocorticoids (dexamethasone)
Antiadrenals (aminogluthamide)
Antiprogestins (mifepristone)
Aromatase inhibitors (aminoglutethimide)
Types of antineoplastic biological
Antibodies (epidermal growth factor receptor)
Immune cells (lymphokine-activated killer cells, tumor-infiltrating lymphocytes)
Vaccines (melanoma cells)
Immune enhancers (levamisole)
Differentiation agents (retinoic acid)
Cytokines (interleukin-2, interferon)
Immunosuppressants (immunoglobulins)

Table 25.11-11 Antineoplastic Hormones and Biological Modifiers

Tailor-made vaccines against various parts of the malignant cell are being developed in increasingly sophisticated ways. They remain difficult to make, the results are partial, they are limited to research-based programs, but they are of great scientific interest and have much unexplored potential. They also give rise to near magical hopes in many sophisticated patients who must deal with the currently inevitable disappointments.

Surgery Many studies on the psychological effects of mastectomy, hysterectomy, colostomy, and prostatectomy report the high cost paid in quality of life and recommend that more emphasis be placed on this dimension. Laryngectomy patients and those who undergo extensive head and neck procedures suffer considerable psychiatric morbidity; the loss of voice is catastrophic for many, and the blow to self-image severe. Patients who have had curative limb amputations can have a good psychological outcome. There is little systematic information about patients who undergo unusual and extreme procedures, such as pelvic exenteration, hemipelvectomies, and forequarter amputations.

Bone Marrow Transplantation Bone marrow transplantation is being used for an increasing number of childhood and adult cancers. It is no longer an innovative treatment, but is expensive enough that insurance companies sometimes still call it “experimental” in some cancer patients, to avoid paying for it. It is commonly recommended for leukemias and lymphomas whose prognosis is poor with other treatments, and it is increasingly used to treat advanced solid tumors such as breast cancer. It is a potentially curative treatment for otherwise lethal disorders. It succeeds best when given to patients in remission, with as little previous treatment as possible. Yet it has a baseline mortality of 5 to 15 percent, an uncomfortable course, and a significant incidence of graft-versus-host disease. Undertaking such a course of action, especially when the patient is doing relatively well, can be very stressful for patients, families, and caregivers.

New Supportive Technologies The use of life supports and nutritional supports in the critically ill patient has created a spate of psychological, legal, and ethical issues that are widely discussed in the lay press. Less well known are developments in the nutritional support of cancer patients who can no longer ingest food because of physical obstruction (e.g., in head and neck cancers) or because of physiological failure (e.g., radiation enteritis). In the former, a percutaneous endoscopic gastrostomy or jejunostomy, and in the latter, home parenteral nutrition allow a significant improvement in quality of life. It also relieves the family from the anguish of watching the patient “starve to death,” which engenders feelings of guilt, which may turn to anger toward the medical staff. Of these home-based technologies, home parenteral nutrition creates the most major changes in family structuring routines such as the preparing and sharing of meals and are time and labor intensive, causing adaptational strains that may bring them to psychiatric attention.

Cancer Pain Management

Incidence Cancer pain is prevalent and varies with stage and site of disease. An overall incidence of 51 percent rises to 74 percent in advanced disease, of which 40 to 50 percent is said to be moderate to severe and 20 to 30 percent excruciating. Treatment failures range from 10 to 30 percent, depending on the skill of the treating physician. The psychiatrist has a special role to play, especially as pain specialists are rare.

Pain and Psychiatric Symptoms Patients with pain have a significantly higher incidence of depression and anxiety. It has been suggested that chronic pain may be a depressive equivalent, that pain may cause psychiatric syndromes, and that pain may coexist with psychopathology in vulnerable subjects. In cancer patients, the evidence suggests that these emotional reactions both result from, and contribute to, the experience of pain and that treatment of one improves the other. A review of the impact of biobehavioral factors on adult cancer pain concluded that the role of personality factors was inconsistent, the relationship to affective states minimal, the environmental influences weak, and the role of cognitive factors unexplored. Hence, the psychiatric consultant is wise to avoid diagnostic inferences that minimize the patient's complaints. Patients with significant psychopathology are indeed more difficult to evaluate, hence the consultant must help the staff make the same aggressive efforts at symptom relief for these patients as for other patients. The incidence of psychiatric complications is particularly high when pain is underestimated and undermedicated by caretakers, an event that recurs with a regularity that cries out for explanations.

Undertreatment The undertreatment of pain in cancer patients is a resistant problem that has frustrated specialists in the field for many years. The most concrete causes are lack of available resources and knowledge gaps. However, even knowledgeable, compassionate staff are afraid of “addicting” patients with metastatic cancer. And if not that, they may continue to minimize patient complaints and measure them against some unspoken internal standard of how much pain is expectable in a given situation. Their need to underestimate pain is intimately related to their deepest motivations and defenses in doing this difficult work. They must protect themselves against too much empathic identification as well as sadistic arousal and guilt. An occasional lapse into blaming the victim is an all-but-irresistible human response to such a difficult situation. Practitioners become less attuned to their patients' pain as the pain becomes more severe. They also often do not differentiate between depression, anxiety, pain, or other inadequate symptom control.

Psychiatric Interventions Psychiatrists and other outside consultants, such as pain specialists, can reorient staff responses in a supportive, nonjudgmental way. They can emphasize the need to respect the patient's statements and model the use of a concrete instrument such as the Memorial Pain Assessment Scale. Daily charting makes it harder for staff to ignore persistent patient complaints. Psychiatrists can also give staff a sympathetic and respectful insight into the patient's psychological state and undermine the staff's covert pain standard by emphasizing the extent of the patient's illness and the progressiveness of the disease; they can sympathize with the staff's own difficulties and uncertainties, ensure adequate pain management along the principles outlined below, and educate (and reeducate) about the low addiction risk. Psychiatrists' role in bringing about optimal pain relief is a powerful intervention in itself, but it is most complete when integrated into supportive psychotherapy oriented to helping the patient to differentiate between pain and suffering and develop appropriate responses to both (Table 25.11-12).

Behavioral approaches have been effectively used by patients who claim an increased sense of control, decreased anxiety, and decreased pain. In one study, doctors appeared to underestimate the value of these methods, compared with the patient's own estimate of them. Hence, it is useful for psychiatrists to make a point of recommending and administering them. They include relaxation techniques, guided imagery, distraction techniques, and biofeedback (Table 25.11-13).

Table 25.11-13 Cognitive-Behavior Therapy Techniques for Cancer Patients

Types of Patients For treatment purposes, cancer patients with pain fall into 5 categories.

1. *Acute pain cancer patients* respond well to treatment but develop tolerance to all known strong analgesics and require more medication if the pain lasts beyond a few days or weeks. This is often inappropriately viewed as “addiction” or drug-seeking behavior by staff. Studies show that these patients wean themselves easily and voluntarily when their pain eases.
2. *Chronic pain cancer patients;* the treating physician must not lose sight of the progression of disease in these patients, even if it is very slow. Unlike nonmalignant chronic pain patients, whose symptoms may not change over many years, cancer patients generally do have worsening pain and the doctor must respond.
3. *Chronic pain patients who develop cancer* may have addictive problems and are at high risk for escalating psychological problems. Nevertheless, their cancer pain creates an additive requirement for medication.
4. *Cancer patients with a drug abuse problem*. If actively abusing or taking methadone, these patients are already tolerant and must be given a correspondingly larger amount of medication to achieve adequate pain control. This must not be viewed as abusing behavior. If not currently abusing, these patients are at risk for relapse, but they need sympathy and support, not a suspicious, withholding approach.
5. *Dying patients* may be adequately medicated, but one needs to address all physical symptoms, emotional suffering, and existential issues as well. A poignant dilemma is that of pain relief versus alertness. If the need for opioids is so great, moments of wakefulness can be increased by using psychostimulants.

Types of Pain Cancer patients are subject to several different kinds of pain, summarized in Table 25.11-14. The distinctions are important because they call for different treatment strategies; somatic and visceral pain is more responsive to opiates, while neuropathic and sympathetically maintained pain responds better to adjuvant medications. Most advanced cancer patients have more than one kind of pain and require complex treatment regimens. Table 25.11-15 and Table 25.11-16 outline the neurophysiology of pain. Table 25.11-17 shows pain syndromes in cancer patients.

Nociceptive pain	
Somatic pain	Usually but not always constant, aching, gnawing, and well localized; e.g., bone metastases
Visceral pain	Usually but not always constant, deep, squeezing, poorly localized, with possible cutaneous referral; e.g., pleural effusion leading to (1) deep chest pain, (2) diaphragmatic irritation referred to shoulder
Neuropathic pain	Burning dysesthetic pain with shocklike paroxysms associated with direct damage to peripheral receptors, afferent fibers, or CNS, leading to loss of central inhibitory modulation and spontaneous firing; e.g., phantom limb pain; can involve sympathetic somatic afferents
Psychogenic pain	Variable characteristics, secondary to psychological factors in the absence of medical factors; vanishingly rare as a pure phenomenon in cancer patients but often an additional factor in the presence of organic pain

Table 25.11-14 Types of Pain

Table 25.11-15 Neurophysiology of Nociceptive Pain

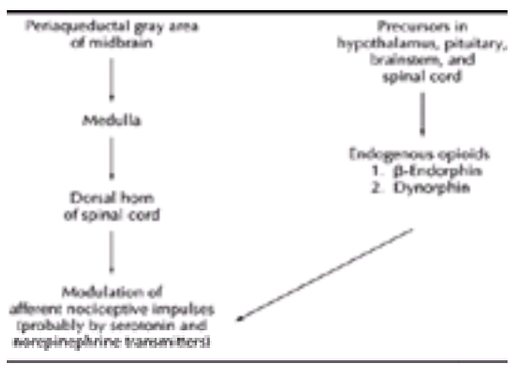

Table 25.11-16 Endogenous Pain Suppression Pathways

Table 25.11-17 Pain Syndromes in Cancer Patients

Diagnosis A careful evaluation may require an etiologic workup, even in a patient receiving only supportive care, because certain pains can be eradicated even in very ill patients. One should weigh the benefits of better pain relief against the intrusion of diagnostic and therapeutic procedures in each individual case.

Treatment Aggressive multimodal treatment should be the norm. Drugs are the mainstay but should always be part of a broader approach. Other modalities include palliative radiation and anesthetic and neurosurgical techniques (Table 25.11-18), behavioral interventions, and psychological support.

Anesthetic approaches
Myofascial trigger-point injections
Peripheral, autonomic, and intrathecal nerve blocks
Nitrous oxide
Surgical approaches
Tumor resection and debulking
Shunting and decompression
Neurosurgical anesthetic approaches
Neuroablative procedures; e.g., neurectomy, tractectomy, cordotomy
Neurostimulatory procedures; e.g., transcutaneous electrical nerve stimulation (TENS)
Neuropharmacological procedures; e.g., epidural and intrathecal opioids and local anesthetics

Table 25.11-18 Anesthetic and Surgical Approaches to Cancer Pain Management

The World Health Organization (WHO) three-step ladder for cancer pain control (Fig. 25.11-1) is a drug-treatment method with documented effectiveness in many settings. The use of drugs begins with nonnarcotic analgesics, moves to moderately strong opiates, then to strong opiates, culminating in a continuous morphine drip if necessary. Nonnarcotic analgesics may be used throughout because they potentiate stronger ones: aspirin and indomethacin (Indocin) inhibit prostaglandin E_2, which is known to be active in the development of bone metastases. Along with biphosphanates, they play a special role in treating bone pain. Adjuvant drugs should be used simultaneously throughout. Table 25.11-19 and Table 25.11-20 give the drug characteristics and Table 25.11-21 gives the treatment guidelines.

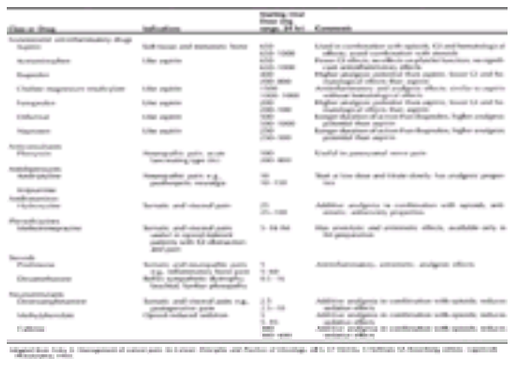

Table 25.11-19 Nonopioid and Adjuvant Analgesic Drugs in the Management of Cancer Pain

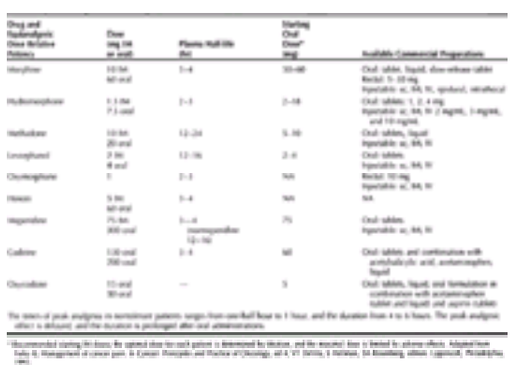

Table 25.11-20 Opioid Analgesics for Management of Cancer Pain

Table 25.11-21 Guidelines for the Rational Use of Analgesics in the Management of Cancer Pain

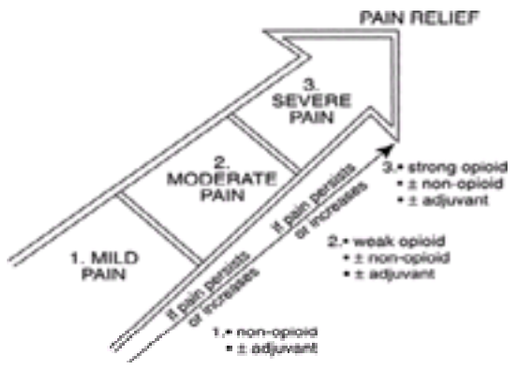

FIGURE 25.11-1 A simple paradigm for the appropriate drug treatment of increasing levels of pain. The World Health Organization's three-step ladder for pain control was developed to rationalize the pharmacological treatment of differential levels of pain. The combinations of drugs that are most appropriated for mild, moderate, and severe pain are indicated. The drugs recommended for a higher level should not be used until the drugs for lower levels of pain have exhausted their effectiveness. However, drugs of increasing strength should be readily used as needed to keep pain under control. (Adapted from Foley KM, Inturrisi EC: Analgesic drug therapy in cancer pain: Principles and practice. In *Medical Clinics of North America: Cancer Pain*, R Payne, KM Foley, editors. Raven, New York, 1987.)

A good pain regimen may require several drugs or the same drug used in different ways and administered via different routes. For example, intravenous morphine may be supplemented by self-administered oral rescue doses, or a continuous epidural drip may be supplemented by bolus intravenous doses. Transdermal patches may provide baseline concentrations in patients for whom intravenous or oral intake may be difficult. Patient-controlled analgesia systems for intravenous opiate administration result in better pain relief with lower total dose and patient self-tapering if pain improves.

Opioids are a common cause of delirium and hallucinosis. A frequent mechanism of psychotoxicity is the accumulation of drug or metabolites whose duration of analgesia is shorter than their plasma half-life (morphine, levorphanol [Levo-Dromoran] and methadone). Using drugs such as hydromorphone (Dilaudid) with half-lives closer to their analgesic duration can relieve the problem without loss of pain control. Cross tolerance is incomplete between opiates, hence several should be tried in any patient, with the dosage lowered when switching drugs.

The importance of maintenance as opposed to as-needed administration cannot be overemphasized. It improves pain control, increases drug efficiency, and relieves patient anxiety; as-needed orders do not provide the immediate response of patient-controlled analgesia and allow pain to increase while waiting for the rug to be given. It perversely sets up the patient for staff complaints about drug-seeking behavior. Even on maintenance treatment, extra doses should be available for breakthrough pain, and their repeated use should signal the need for raising the maintenance dose.

Knowing equianalgesic doses of different drugs and different routes of administration is important to avoid accidental undermedication. For example, when changing a patient from intramuscular to oral morphine, one should multiply the intramuscular dose by 6 to avoid causing the patient pain and provoking drug-seeking behavior.

Many adjuvant drugs are psychotropics with which the psychiatrist is very familiar, but in some cases, their analgesic effect is separate from their primary psychotropic effect. Commonly used adjuvants include antidepressants, phenothiazines, butyrophenones, antihistamines, amphetamines, and steroids (Table 25.11-19). They are particularly important in neuropathic and sympathetically maintained pain, in which they can be the mainstay of treatment.

Other developments in pain control include more-intrusive procedures such as nerve blocks or the use of continuous epidural infusions starting before surgery to prevent phantom pain and other chronic postoperative pain syndromes.

Palliative Care Despite increasingly visible efforts by dedicated specialists, palliative care is still not the rule. If it were, the right-to-die movement would arouse far less public support. Lack of training is a major cause, but the transition from active treatment to palliative care can also be emotionally difficult for physicians, patients, and families. It is sometimes avoided altogether, and active or experimental treatment is continued to the end; this may be satisfactory if it truly meets the patient's and family's emotional needs. Sometimes, a pretense of active treatment is continued. This may work but is likely to cause psychological problems if it is being done because of medical avoidance in the face of patient and family ambivalence. A well-negotiated transition to palliative care often decreases anxiety after the patient and family go through an appropriate grief reaction. A positive outcome is much more likely if the physician and staff project a conviction that palliative care will be an active, involved process, with no hint of withdrawal or abandonment. When this fails or when the family cannot tolerate the transition, the ensuing stress frequently results in psychiatric consultation.

The psychiatrist must correct any therapeutic defeatism present, especially in the areas of relief of psychiatric symptoms, pain, insomnia, and vomiting, and support the oncologist if disengagement is an issue. This is best done by role-modeling careful attention to all aspects of patient care. Strengthening caregivers' intellectual defenses and providing concrete opportunities for intervention diminishes withdrawal behaviors and benefits patients directly. Other symptoms that benefit from psychopharmacological interventions include fatigue, cachexia, anorexia, dyspnea, and sedation as well as opioid and steroid adverse effects.

Another major transition involves deciding whether to have the patient die at home or in a hospice—a sensitive question with many implications for survivors. Hospices often have built-in psychological supports that are not available for home care patients and must be provided as needed on an individual basis.

One should engage terminally ill patients in dynamic issues to the extent that they are physically able to participate. Often, the most precious gift one can give them is to reawaken their interest in the richness of their own experiences. This may be their one remaining possession, as the others slip away. Existential despair and spiritual distress often evoke feelings of helplessness and ignorance in the therapist, leading to their being ignored or shunted to a religious advisor. Indeed, religious and spiritual beliefs are an important, but not exclusive, vehicle for these experiences, which are intimately embedded in the patient's psychological coping style. All of them should be sympathetically and respectfully included in therapy as they are often the key to a sense of emotional healing. Table 25.11-22 suggests ways of helping patients recast their experiences.

Futility → discover a sense of meaning/purpose
Disappointment → find sources of satisfaction in past and current events
Remorse → carry out remediation, taking care of unfinished business

Adapted from N. Cherny.

Table 25.11-22 Common Dimensions of Spiritual Suffering

Ethical Issues

Psychiatry-Ethics Interface In today's contentious social climate, ethical and legal dilemmas multiply with increasing stress, often resulting in psychiatric consultation. Often, reactive psychopathology has developed and must be assessed and treated. If inappropriate psychiatric labeling has occurred, the psychiatrist must remove the label, redefine the situation, bring out the underlying ethical issues, and set a decision-making process in motion. To be effective in these situations, psychiatrists must be clear about the difference between psychiatric issues on the one hand and ethical and legal ones on the other. They must diagnose and act decisively in the former, be restrained and humble in the latter, and educate others about the distinction. If they understand the ethical issues, have a precise knowledge of the legal constraints operating in the case, and call for appropriate consultation, their interviewing skills and experience in conflict reduction can make them valuable participants. A few major ethical issues in the care of cancer patients are discussed below, with emphasis on their psychological correlates.

Truth-Telling At the extremes, cultures that put a high value on autonomy consider the need for truth telling as self-evident, while cultures in which the patient is tightly embedded in a wider family unit consider truth-telling an exercise in maleficence. The spreading breakdown in close kinship ties and the steady improvement of modern cancer treatments are combining to increase truth-telling in growing segments of the world. However, local cultural deviance continues to arouse strong objections to it.

Informed Consent In the United States, informed consent is legally required for both conventional and experimental treatment. Given the unique toxicity and noncurative nature of much cancer treatment, this does not seem unreasonable, and it is spreading to other Western countries. However, it comes at some psychological cost. Anxiety reactions and occasional psychiatric decompensations are seen when patients feel overburdened by demands to make decisions. These often occur in predisposed individuals, whose premorbid adjustment was nevertheless good. Patients respond to active interventions, including support, medication, behavioral techniques, and active environmental manipulation of both home and treatment setting. These interventions usually suffice to help patients make decisions on their own behalf and undergo treatment, but posttreatment relapses may occur and are resistant to therapy.

Terminal Care Decisions Modern society is unequipped to cope with the life-and-death decisions spawned by technology. During the buoyant 1950s and 1960s, public enthusiasm about cardiopulmonary resuscitation was supported by the medical profession. It was quickly endowed with exaggerated, quasi-magical power and became a ritualized right rather than an optional medical treatment. That practice played into the paternalistic therapeutic activism characteristic of many physicians. The 1970s and early 1980s saw a countermovement. First the right to refuse treatment was established, thanks in large part to synergy between the consumer movement and the bioethics movement with its emphasis on patient autonomy. Next, the legality of do-not-resuscitate orders and the moral equivalence of stopping and not starting treatment were established. The medical profession is less enthusiastic than the public, perhaps because practitioners are familiar with the emotional ambiguities that inevitably surround death and must repeatedly experience them. Mechanisms are now in place which encourage competent patients to state their wishes concerning the terminal care period through the use of health proxies and advanced directives. Such mechanisms culminated in the 1991 Federal Patient Self-Determination Act (PSDA), but their use continues to be limited to about 20 percent of surveyed populations, unless very pointed, labor-intensive routines are put in place to encourage patients to prepare them. Such programs are under intense investigation, along with attempts to understand patients and surrogate decision-making processes.

At the bedside patients and their families vacillate between a suspicious, self-protective stance and a less conscious but strongly motivated, needy, and dependent one. These behaviors may appear erratic and paradoxical to medical staff who do not understand the emotional agendas being expressed. Caregivers are not immune to defensiveness and confusion as they try to rise above the doctor-bashing which has become commonplace. Federal mandates and regulations cannot resolve the emotional ambiguities of this difficult time.

With incompetent patients who have left no directive or who were never competent, active legal and ethical debates are continuing. Legally sanctioned behaviors vary with the jurisdiction. Psychiatric consultants must be very clear about these issues in their area. The local branch of one's professional society usually has an ethics committee, which can be consulted.

Euthanasia and Physician-Assisted Suicide Cancer patients have been central to the euthanasia and assisted-suicide debate. The legal rules governing physician behavior are unclear and constantly changing under the impact of precedent-setting court decisions and new legislation. Physician-assisted suicide had been legal in Australia's Northern Territory until it was overruled by the Federal Parliament. It has been accepted in the Netherlands, where it is regulated without being formally legalized, an ambiguous state of affairs that is unworkable in larger heterogeneous societies. Furthermore, longitudinal studies have pointed out a rising incidence of euthanasia as opposed to assisted suicide, in the face of a constant total number of assisted deaths, leading some to ask whether the Dutch are on a slippery slope.

In the United States, euthanasia remains unacceptable, but physician-assisted suicide is garnering increasing support. Two federal circuit courts of appeals have supported it. One decriminalized it on the basis of equal protection under the law, equating it to the available right to discontinue life-preserving treatment. The other legalized it on the basis of liberty and privacy rights. Both decisions were halted by injunctions and were reviewed by the United States Supreme Court. In June 1997 the Court denied a constitutional right to assisted suicide and opened the door to a state-by-state process of continuing experimentation. Oregon voters promptly voted in a law permitting physician-assisted suicide under carefully defined conditions. At the end of one year, the right had been exercised by eight patients. For some it was eight too many, for others it was few enough to prove that the law would not be abused. Meanwhile, the practical and emotional dilemmas will only multiply as regulations, laws, and initiatives proliferate. Some commentators pointed out that the Court had implied a right to active, effective pain management and palliative care. It has not yet been tested in the courts, but doubtless will be in the future.

Since 1982 a presidential commission, supported by major Catholic and Protestant authorities has affirmed the moral acceptability of withholding extraordinary measures and of stopping them later. They also support “the double effect,” namely, the unintentional possible hastening of death in the process of improving comfort. Intent is the important variable, meaning that one cannot deliver a large bolus of morphine that renders an alert patient deeply comatose or dead, but it is appropriate and humane to titrate morphine doses upward at a rate that maintains good pain relief regardless of potential respiratory impairment. In the habituated patient without primary respiratory failure, pain relief from opioids is usually achieved before respiratory depression occurs, making terminal struggle over opioids an unnecessary torment.

Despite this, the reasoning that surrounds the double effect remains controversial, with one faction using it to justify the legalization of assisted suicide and another calling it euthanasia or even murder. The moral situation is even less clear when non–terminally ill patients ask for help in dying. The physician who actually performs the act is practicing active euthanasia, which is against the law and against the medical code of ethics. But the role of the physicians who provide information on how to die or knowingly allow patients to hoard prescriptions is also under intense debate. Derek Humphrys' suicide handbook *Final Exit*, was on the best seller list for several months, underlining public hunger for knowledge in this area and making moot the issue of the medical role in providing information to many.

Proponents of legalization emphasize dignity and autonomy, pointing to Dutch studies that name this as the most frequent reason for help-in-dying requests. Opponents point to the lack of good pain management and other palliative care, citing American and Canadian studies that found depression and poor symptom control to be the major factors underlying patient suicidality. Given severe retrenchment of health care expenditures, with politicians, insurance companies, and managed care corporations calling the tune, there is cause for concern even among individuals who have no philosophical or moral objection to assisted suicide. African-Americans are far more opposed to legalizing assisted suicide than whites.

This controversy is emblematic of the moral and emotional malaise of the postmodern era and surfaces in the practice of psychiatrists, whether or not they are directly involved with dying patients. They must explore their own feelings to prevent their confusion from warping the treatment. Whatever personal conclusion they reach and whatever the outcome of the debate, psychiatrists should always keep the following fact uppermost in their mind and remind their medical colleagues, that a dying human being whose physical, emotional, and spiritual needs are being effectively attended to, seldom exercises the option to commit suicide.

Investigational Treatment Since the Nuremberg trials, and the Helsinki declaration, the moral requirement for informed consent from research subjects has been clearly spelled out and buttressed by regulations and institutions in the United States. Critics feel it is honored in letter more than in spirit, but competent patients systematically suppress information given to them, to create the illusion of an old-fashioned paternalistic relationship; hence the situation remains ambiguous despite the efforts of lawyers and bioethicists to rationalize it.

Critics of clinical trials claim that randomization is incompatible with the doctor's basic responsibility to the patient. Some patients find randomization intolerable and refuse to participate or later demand to break the code. Most patients find trials with a placebo-versus-treatment design emotionally more difficult to understand and tolerate than one with two treatment arms. Overall, patient's reactions are defined less by the protocol than by their relationship to the physician. Many patients seek experimental treatment with desperate intensity, peddling influence to enter limited protocols or pleading to use untested agents that have not shown enough efficacy to warrant clinical trials. Other patients participate in clinical trials out of altruistic motives. Alternatives to randomized clinical trials have been suggested, but they are

unwieldy and less powerful than the trials. Any solution requires well-designed trials (Table 25.11-23).

A sound clinical trial must
-Ask a useful question
-Have the power to answer it
-Have an objective review of the methodological and ethical issues
-Have a condition of equipoise (i.e., no treatment arm is known to be inferior to any of the others.)
-Have a mechanism for premature closure

Table 25.11-23 Characteristics of an Ethically Sound Clinical Trial

The role of the commercialization of scientific knowledge and of the media in promoting premature, exaggerated claims contribute heavily to consumer anguish as hopes rise with the first headlines, only to founder in subsequent months as more thoughtful voices make themselves heard or results fail to be reproduced. Savvy patients often outwit themselves as they learn about numerous protocols in different academic and commercial institutions and agonize about whether they are missing the very one that would save them.

Surrogate Decision Making Current legal doctrine specifies that surrogates must use substituted judgment (i.e., do what the patient would have wanted). Family members are presumed best equipped to carry out this charge, by virtue of their close association with the patient. However, experienced clinicians know that family members often respond to their own needs, once patients can no longer express their own, but they usually do not confront this issue unless surrogates are incompetent or clearly acting against the patient's interest. Psychiatry often plays a major role in furthering negotiations, developing compromises, and arranging treatment for the surrogate. However, these situations are often insoluble because existing laws make no provisions for incompetence in surrogates except via adversarial proceedings, which are painful and often destructive. The psychiatrist can still play a useful role in helping caregivers cope with their frustration.

Consent in Pediatrics All pediatric consents are third-party consents that carry the possibility of conflicts between parent and child. The parent may make a decision that is not in the interests of the child, as in the refusal of lifesaving treatment. The courts have tended to overrule parental authority in such cases. Parent and child may disagree, especially adolescents, although disagreements occur with school-age children as well, presenting staff with painful problems. Psychiatric intervention may help resolve the conflict, if the consultant does not impose personal beliefs, but the pain of watching a child caught between his need to please his parents and his right to the best available treatment does not always have a satisfactory solution. Legal recourse is used only after all attempts at conflict resolution have been unsuccessful.

Resource Allocation and Managed Care A basic tenet of the medical profession is that the physician attends solely to the patient's welfare, excluding other considerations. That tenet has not formally changed, but in fact, physician autonomy has been eroded by economic and political interests, and medical decision making is now seriously constrained by third parties with a profit-making agenda. Forced early discharges, limitations on expensive treatments, and the notorious gag rule are the result. The well-publicized refusal of managed care companies to pay for bone marrow transplants may represent only the tip of the iceberg.

Sexuality Cancer patients hide their sexual concerns because they are embarrassed and recognize that their doctor may be embarrassed; but they are usually eager for information, which is seldom provided. Formal observations on sexual dysfunction related to cancer type are sparse for women (breast cancer excepted) and men and inconsistent for several reasons. First, early studies did not stratify well by diagnosis, stage, or treatment. Except for obvious sexual ablations, dysfunction relates to type of treatment as much as to site. For example, testicular cancer with lymph node dissection has a high incidence of dysfunction. Absent that dissection, patients should have normal erection and orgasm—despite loss of ejaculation—but in fact, about 20 percent of men experience sexual performance problems on a psychosexual basis. The sexual impairments associated with prostate, bladder, and rectal cancers matched the amount of postsurgical sympathetic nerve damage rather than gross anatomical change. Addition of hormonal therapy or surgical castration to prostate cancer regimens results in near total cessation of activity, regardless of anatomy. Any course of radiation or chemotherapy can result in some sexual dysfunction, with radiation causing a high rate of dyspareunia. Patients with nondisfiguring cancers like leukemias and lymphomas have an unexpectedly large and persistent decrease of psychosexual functioning.

Second, evidence continues to accumulate showing that the incidence and severity of sexual dysfunction increase over time and that spontaneous remissions or stabilization does not occur, even in the presence of stable or improved physical states. Early studies had variable and usually short follow-ups, accounting for inconsistencies. Dysfunction is greater in younger patients across all diagnoses and is particularly high for cancers of breast, head, and neck and other physically disfiguring cancers. Significant psychiatric morbidity ensues and is only beginning to be studied.

Finally, one problem may be artifactual, because many texts are written by nonpsychiatric physicians who focus on the anatomically and physiologically possible, rather than on psychological factors. Patients report two- to threefold drops in level of sexual activity after treatment, for no clear physical reason.

Current research design is likely to define dysfunction more carefully, select the study population by both cancer diagnosis and treatment regimen, include partner assessment, extend follow-up much longer, and include interventions in the study design.

In an ideal world sexual concerns should be routinely addressed before treatment, with a baseline assessment that models open communication from the start. Patients need detailed information about what problems to expect and their reversibility. The information should be combined with reassurance that some form of sexual expression is always possible. If there is a spouse or sexual partner, early joint involvement is beneficial.

After the initial treatment period, patients should again be queried about sexual concerns. Follow-up clinic appointments are a good time to advertise workshops, support groups, and information sessions. A flexible format, with a mix of information, emotional ventilation, and focused problem-solving has been well received by several types of cancer patients. Emotional concerns include lowered self-esteem, negative body image, fear of rejection, anxiety, and depression and frequently create self-perpetuating cycles. Severe reactions and antecedent problems call for treatment. Recent studies reinforce the observation that psychological and relational factors play a large (often the largest) role in determining the degree of posttreatment recovery of sexual functioning. Given the neglect of sexual issues characteristic of much medical treatment, psychiatrists and other mental health professionals will continue to be the first to hear about them. They need to know the basic anatomy and physiological potential of a patient's condition and should refer the patient for further workup and treatment if needed (it often is). Psychological treatment includes couple psychotherapy and sex therapy. Sexual rehabilitation involves an adaptation of sex therapy principles and can be very helpful. It is based on the desire-arousal-orgasm model of sexual response and requires a phase-specific diagnosis. Treatment of late-phase dysfunction is quite effective if there is no anatomical interdiction. Early-phase dysfunction is more difficult to treat and benefits from a specialized referral. Table 25.11-24 summarizes the main treatment issues.

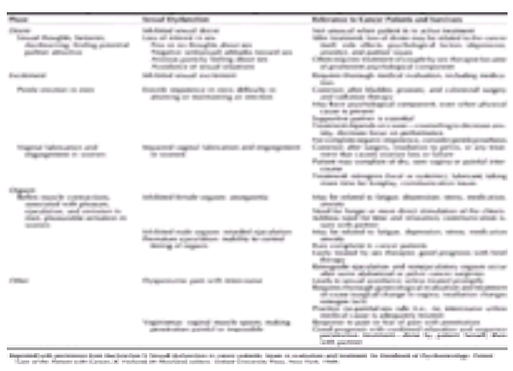

Table 25.11-24 Application of the Triphasic Model to Assessment of Sexual Dysfunction in Cancer Patients

Cancer Survivors At least 8 million Americans are cancer survivors. Many of them can be presumed cured, but they will never be the same. Their existence is a tribute to the human intellect; their resiliency, a tribute to the human spirit. But these partial victories should not blind one to subjective distress and residual problems in this traumatized population.

Most survivors are adolescents and young adults cured of childhood cancers and leukemia or lymphomas. Breast cancer survivors are another large group, but colon, cervix, head and neck, testicular, and thyroid cancers also figure among those in which early diagnosis and good treatment can result in cure.

In early studies, survivors were believed to be free of psychological residue because many of them used denial and emphasized positive beliefs such as having learned deeper values and being grateful for life. Recent studies of leukemia/lymphoma survivors and breast cancer patients, using the Brief Psychiatric Symptom Inventory, have shown a level of psychiatric symptomatology one standard deviation above the norm, or halfway between normal controls and psychiatric patients. Psychosexual functioning has been found to be notably impaired. Many survivors have posttraumatic stress symptoms that overlap with, but are not identical to, patients with persistent conditioned nausea and vomiting.

Becoming a survivor as opposed to being a cancer patient is both a real and symbolic transition of great complexity. Some of the coping techniques that enabled the survivor to be a good patient (e.g., the ability to regress, to be more passive, and to be dependent) must now be jettisoned, and a new mantle of action must be assumed. The survivor's environment may be out of step. Families may continue to require an untoward degree of dependency or may demand an instant transition to a preillness level of behavior.

With more-visible disfigurement and greater disability comes a greater impact on intrapsychic and interpersonal adjustment. When the face, voice, breasts, or sexual organs are affected or when the patient must use an appliance or prosthesis, a substantial psychological burden overlies the physical impairment. But even with no obvious deformity, survivors feel damaged, vulnerable, and sensitive to any abnormal signs or symptoms in their bodies. Their awareness of death seems to last indefinitely and is comparable to the altered self and world view seen in trauma victims. Thus, survivors' increased somatic complaints have both psychological and physiological determinants.

Delayed Consequences of Treatment Four categories have major psychological impact.

1. Infertility problems, premature ovarian failure, and interference with sexual response are particularly distressing if patients have not been educated and prepared to face them. But evidence indicates persistent patient denial even in the face of preparation, such as sperm banking. Intervention should include endocrinological, gynecological or urological, and medical evaluation and treatment. Psychotherapy, couple therapy, group therapy, veteran patient programs, and self-help programs can all be used to good effect.
2. Pituitary, thyroid, and other endocrine failures occur as a consequence of radiation therapy. Patients with these problems often present with psychiatric symptoms. Patients treated before or during puberty suffer from short stature due to lack of growth hormone. Chronic fatigue is a common symptom that calls for patient and family education, since it is often given an unjustified psychological label.
3. Survivors have increased vulnerability to late organ failure and secondary malignancies and to the chronic anxiety that this vulnerability generates. If such a complication comes to pass, it finds the survivor less able to cope and more prone to a posttraumatic response.
4. In a frightened, superstitious world, survivors face social rejection, employment discrimination, and serious insurance problems. Survivors well enough to return to work plateau in their careers because they are passed over for advancement by employers who fear a recurrence or because they are averse to moving due to having become uninsurable.

Predictors of poor coping include previous psychiatric problems, lack of social supports, and stage of disease at diagnosis. In treating cancer survivors psychotherapeutically, one should strive for a detailed understanding of the patient's experience. When the content is anxiety provoking to the therapist, it is sometimes overlooked, leading to poorer outcomes even in the hands of seasoned therapists. Full knowledge is required to understand when the trauma response is primary and when it is a shield for deeper psychodynamic issues. Lingering too sympathetically on the trauma may deprive the patient of the opportunity to grow beyond it. Yet, failing to be sufficiently empathic in understanding its impact is obviously unproductive. Many survivor programs offer workshops, lectures, and groups for patients, couples, and families. The National Coalition of Cancer Survivors (NCCS) is emblematic of the possibilities for self-awareness and psychological and political empowerment.

PSYCHOLOGICAL PROBLEMS OF FAMILIES

Research on the family of the cancer patient is an active and exciting field, especially because of the increasing integration of family therapy concepts. Some findings are disease specific, but many can serve as a paradigm for understanding the impact of any major illness on the family.

Psychological Reciprocity Awareness of the powerful reciprocity of emotional states and behaviors between cancer patient and family members is well established from numerous studies of parents, spouses, and siblings that document levels of distress and functional impairment that can rival or even exceed that of the patient. More disturbingly, primary caregivers have been noted to worsen over time in the face of stabilization or improvement in the patient. Finally, studies of families after bereavement or cancer survival show a significant incidence of impaired functioning over extended periods of time and, again, a worsening over time in the distressed families. These findings have some urgency, since most families will experience cancer at some time and it will probably be a drawn-out, chronic ordeal. High-risk families can be identified early and significantly helped by professional intervention.

Family Evaluation Families can be evaluated from several points of view. The most traditional one is to examine how well the family is taking care of the patient. Medical staff are quite sensitive to this and will often call for help when families fail in this area. Another approach is to scan for psychopathology in family members. If the family member is acutely symptomatic and is visible to the treatment team, a consultation will follow, but absent members will go untreated.

Categories of family support include

1. Providing emotional support and containment. Family members are expected, and expect themselves, to contain their own reactions and support the patient.
2. Sharing responsibility for decision making. Family members often carry the lion's share in researching and selecting options, with or without patient approval. This goes hand in hand with an enormous and universally reported need for information.
3. Concrete caretaking. In today's budget-conscious climate and vanishingly short hospital stays, an ever-increasing amount of care is being thrown onto the family. This is not acknowledged, hence families receive little help or training.
4. Meeting financial costs. Even under socialized medicine, families absorb massive expenses and suffer significant downward mobility.
5. Absorbing social costs. In one study, 25 to 30 percent of primary caregivers lost their jobs, and more than half of the remaining moved to lower-paying jobs to accommodate their need for flexibility.
6. Maintaining stability. The patient's role and contribution must be replaced, a difficult task in the case of young mothers or breadwinners. The new demands must be folded into ongoing functioning. Some members develop increased emotional needs that must be met. And all the standard family functions, emotional nurturing, feeding, clothing, sheltering, educating, and socializing, must continue unabated.
7. Adapting to change. It has been said change may be the only constant during a cancer illness. But it is useful to divide events into acute and chronic phases. An acute event is met with effective mobilization of family members, but psychologically, they may be reacting quite asynchronously, with the denial of some and the pessimism of others causing significant friction. Members may protect themselves, under the guise of protecting each other, by colluding in a conspiracy of silence that can rigidify and be hard to change later. There is a universal need for information, to decrease uncertainty, to help the family problem solve effectively, and to ensure better communication, cohesion, and emotional containment. In the chronic phases the family must return to developmental and maintenance tasks, which may expose conflicts between the patient's continuing needs and the needs of others. Initial mobilization is replaced with a paradoxical increase in psychological symptoms. Families isolate themselves, even when outside support is available, and may put major decisions on hold.

Family-Centered Approaches A new and powerful method of evaluation uses a family-centered approach to examine how the family sustains itself and copes with

the illness, while still meeting the needs of all its members. Four concepts are important for understanding the impact of the illness and devising interventions that will not be instantly neutralized for the sake of family homeostasis.

1. Developmental stages: Families go through developmental stages with specific tasks at each stage. Cancer disrupts the tasks at any point, sometimes permanently if no help is offered. Any intervention must be compatible with helping the family carry out its phase-specific tasks.
2. Family structure: One must understand how a family is organized, to understand the caregiving dynamics and intervene in ways that will reinforce the family rather than threaten and destabilize it.
3. Family history, beliefs, and myths: Every family is permeated by stories that dictate unconscious responses to illness, dependency, loss, and other fundamental life experiences. They underlie behaviors that seem idiosyncratic or bizarre to untrained observers and must be factored into treatment. Explaining them to the treatment team minimizes scapegoating and polarization.
4. Family style of interaction: Good communication among members is the best predictor of good outcomes, with family cohesion a close second. Theoretically too much cohesion should be deleterious to individual development, but most studies have found that during a serious illness, high cohesion remains a positive factor.

Nontraditional Families Divorced or blended families, single-parent families, homosexual families, and families that are ethnically, culturally, or religiously discrepant from the ambient medical culture experience many of the problems described above but also have specific characteristics that are being more systematically recognized.

Staff-Family Interface During a life-threatening illness such as cancer, the medical staff come to play an enormous role in the family dynamics, invading the family system to create a new ad hoc hybrid system. That hybrid is the milieu in which consultation requests are generated. It must be understood and used for any intervention to be effective.

Guidelines for Intervention While most families show generosity, courage, and resiliency, as many as 25 percent might need intervention, and more might well benefit. Of those, a much smaller number require formal family therapy, which must be done with a realistic understanding of the medical facts and the medical milieu. Most families manage with short-term crisis interventions designed with an accurate understanding of the family factors described above and a commitment to the family as a whole, not just selected members. The staff-family conference deserves special mention. It can be a powerful mutative event that resolves what had seemed very knotty problems.

PSYCHOLOGICAL ISSUES FOR STAFF

Anatomy of Stress The stress on caregivers has been documented in studies across many settings and many countries. Some stress factors are comparable to those found in other high-technology, high-morbidity areas of medical care outlined in Table 25.11-25. Of recent note are the massive downsizing and cost-ratcheting sweeping medical institutions as they are being turned over to commercial entities, creating severe individual hardships and serious ethical problems in the delivery of care. Communication problems between doctors and patients lead not only to patient dissatisfaction, but also to lower job satisfaction and self-esteem. The following stressors are more particular to the oncology setting: the negative aura that still surrounds it, even in the AIDS era; the toxic nature of treatment and its inevitable adverse effects; the occupational hazards surrounding chemotherapeutic and radioactive agents, and the resistant infections to which immunocompromised patients are prone; the ambiguity of many treatment decisions, which often breeds intrastaff conflict and hostility; the unsettled social and ethical climate that surrounds palliative care and terminal care decisions today; and the extreme emotional reactions engendered by cancer and projected onto staff in the form of overvaluation, ingratiation, and covert bargaining, followed by disillusionment and anger.

High morbidity, high mortality
Complex technology used under high pressure
High frequency of life-and-death decisions
Terminal-care issues
Third-party conflicts
Interstaff conflicts
Limelight medicine (medical care administered under the impact of unusual publicity or public interest)
Response to severe debilitation and disfigurement
Response to difficult patients (excessive dependence, anger, uncooperativeness)
Response to suicidal ideation
Issue of inflicting pain as part of treatment

Table 25.11-25 Staff Stresses Common to High-Stress Medical Settings

One must add the staff's own reactions to cancer. At a conscious level, caregivers depend on their intellectual grasp of the situation and make a point of rejecting myth and superstition. They are proud of their ability to function under pressure with reliable emotional controls and to offer something in all situations, even hopeless ones. Yet, at an unconscious level, covert adaptations exist that are idiosyncratic and irrational, often determined by historical precedent, and resistant to change. They include superstitious beliefs, stubborn fears, and feelings. Their eruption into awareness makes the worker feel embarrassed and inadequate. Hence the feelings are kept secret, and the caregivers believe they alone have them. Thus, staff workers isolate themselves from one another. Outside the workplace, staff isolation may be reinforced by family, friends, and a society that avoids reminders of a frightening topic. Caregivers are not singled out personally but are discouraged from talking about their work and risk being shunned if they do not accept this taboo.

Clinical Spectrum of Staff Responses

Normal Adaptation and Coping Staff undergo a developmental process when they begin to work intensively with cancer patients. A very high initial level of dysphoria, anxiety, sadness, and numbing recedes over the first few months, displaced by the need to demonstrate competence and ability to survive. Over the next few months, existential issues are allowed to surface, and staff members shape a deeper adaptation that engages their whole personality. Formal support is not necessary, but informal support and peer-group interactions are important for successful resolution.

Adjustment Reaction Adjustment reactions may occur during the formative stages of providing cancer care, but they also overtake staff members at any point in their careers when a personal loss resonates with their work (cancer in self or loved ones in particular). These reactions are acute but time limited and respond well to support or a brief change of venue. Rarely is psychiatric intervention needed. Sometimes adjustment does not improve with time, exposing an underlying psychiatric disorder, often preexisting and precipitated by work stresses. Psychiatric evaluation is indicated and may result in transfer to a less emotionally stressful situation.

Supportive Interventions for Cancer Staff Staff support interventions generally fall into three categories: organizational, individual, and group. Organizational issues include leaders who model realistic expectations and monitor overinvolvement in themselves as well as others. A team approach encourages sharing difficult tasks, prevents a sense of being indispensable, promotes staff cohesion, and eases time off and vacations. Open communications and good orientation procedures are important. Individual responses include peer support, supervisor support, access to an employee assistance program, and other confidential psychological support or psychiatric evaluation. Positive reports about the benefits of staff support groups in many forms and many settings continue to appear despite the paucity of rigorous outcomes studies. The group must not be perceived as undermining unit norms or leadership. Structure must be provided as needed to alleviate staff anxiety, while still allowing unscheduled topics and feelings to be aired. Therapy issues must be avoided, and discussions should clearly flow from work-based topics. An active area of new and productive intervention is the development of group-based, workshop formats for improving communication. Many have been described and found helpful; more are under development.

CANCER IN THE PSYCHOTHERAPIST

Unlike degenerative diseases with their linear course and associated impairments, cancer may have an episodic course with no loss of cognitive functioning. It inevitably forces a blurring of psychological, and later overt, boundaries in therapy. An all-but-intolerable burden is placed on doctor and patient when therapists with

cancer continue treatment too long because of their own need to deny their fate. This suggests that difficult as it is, the therapist's most ethical course of action is to set a fixed termination date that allows patients to transfer to someone else while the therapist is still alive and well enough to negotiate the termination. This may be asking too much of an individual in whom denial is both the main coping mechanism and the only impairment. The help of colleagues is invaluable at this time.

CANCER IN CHILDREN

Magnitude of the Problem Cancer is second only to accidents as a cause of death in children. The overall survival rate is about 60 percent, but it may be higher for Wilms' tumors, Hodgkin's disease, and certain leukemias. These outcomes are bought at the cost of long, intensive treatments that put patient and family under severe stress.

Child Patient Sick children are benefitting from social and legal trends toward empowering them. They are being informed more honestly and their cooperation is being thoughtfully enlisted. Like adults, children know or intuit a great deal without being told and are relieved by open communication. Its provision is complicated by the need to be age appropriate and is more painful because of adult vulnerability to suffering in the young. As a result, adult denial often prevails, and children respond by increased behavioral symptoms or withdrawal.

Discussion About Diagnosis and Prognosis A child can hardly remain oblivious, with endless clinic visits, repeated chemotherapies, flagrant symptoms such as hair loss, repeated exposure to other patients, and statements of people around them. Studies note that perception outweighs reality, hence intrusive procedures can loom larger than prognosis, especially for younger children. The developmental stages of death awareness in healthy children are well described but are probably not applicable to children with cancer nor to other children who have been exposed to death in an untimely and personally threatening way that results in earlier and keener awareness. Thus, discussions are clearly indicated, but they must follow the child's lead, probing and responding to the child's sources of anxiety and remaining reassuring about care and comfort if they cannot be so about outcome. Children who received truthful information have been found to have less subsequent anxiety than those who did not.

Psychiatric Diagnosis and Treatment A syndrome-oriented approach to diagnosis is not useful with children. It is more important to know the child's previous developmental profile and to assess current symptomatology, arrests, or regressions. But in a few situations diagnosis is important. Preexisting disorders are aggravated by cancer and must be monitored and treated throughout. The stress of cancer can make a mild disorder manifest for the first time. Anxiety, depression, and delirium occur routinely in children and respond well to treatment. Anxiety is ubiquitous. Behavioral interventions are the first line of treatment, but some situations may require the use of anxiolytics. Benzodiazepines are used but can cause a disinhibition syndrome that may be mistaken for more anxiety. The use of sublingual alprazolam (Xanax) allows a rapid effect in children who cannot swallow. Mild depressive symptoms are common and rarely progress to severe, retarded depression with vegetative symptoms that respond to low doses of antidepressant medication. Desipramine is contraindicated because of several reports of sudden death. Delirium is common in very ill children and is often mistaken for psychosis, which it can resemble. Antipsychotics are helpful. Pediatric psycho-oncologists should be quicker to use drugs than child psychiatrists, but they should start with small doses, watch closely for adverse effects, and try to taper as quickly as possible. Further studies will be welcome.

Pain Management Children are even more undermedicated than adults, and some caregivers still doubt that neonates and infants feel pain. Therefore, as-needed dosing in children always results in serious undermedication. Very young children cannot make their complaints known clearly. Older children often make complaints in the context of a normal regression, which is then used to disqualify the complaints. Exhausted, critically ill children, given relief from suffering, may enjoy opioids in a way that upsets some parents and caretakers.

Management of Stressful and Painful Procedures Recent work on posttraumatic stress disorder in children reinforces the principle that aggressive prophylactic relief during stressful procedures is important not only for current comfort, but also for long-term adaptation. Poorly managed painful procedures not only brutalize the child, but also result in anticipatory fear of pain, loss of trust and cooperativeness, phobias, and posttraumatic symptoms that do not improve over time. Multimodal behavioral methods for use by both parents and staff are widely and effectively used. Painful medical and or surgical procedures should always be eased by the use of pharmacotherapy up to and including general anesthesia.

Family Involvement The families of pediatric patients are even more vulnerable than those of adults because of the child's total dependency and the biological, emotional, and social factors that make families uniquely responsible. No intervention has any hope of success if it does not address the family as much as the child. In one study, mothers had a greater rate of posttraumatic symptoms than their children.

Staff Problems The human species survives in part because the helpless young elicit nurturing responses from adults. This principle is strongly in evidence on pediatric oncology units. The staff's reward is a deep sense of engagement and meaning; the price they pay is relentless pain held at bay by a variety of mechanisms. The maintenance of staff morale, the prevention of dysfunctional norms, the support of faltering members, and the defusing of unconscious competitive feelings toward parents are important ways of contributing to the well-being of all participants.

Team Approach The multidisciplinary approach to patient care is most widely implemented in pediatric cancer patients than in adults. Child psychiatrists can play a useful role and, where the model is not in place, are in good position to help organize it. Local teachers and clergy should be involved, and community resources should be used to help families reintegrate when they return home.

PATIENTS AT GENETIC RISK FOR CANCER

The advent of DNA technology and sophisticated epidemiological studies have permitted identification of many healthy individuals at high genetic risk for developing cancer. This work is at the forefront of basic research and is paradigmatic of the ambiguous interplay between basic research, commercial interests, clinical practice, and social policy. More and more cancers are being found to have a genetic component (Table 25.11-26). Among the best studied are breast cancers, of which about 5 percent are hereditary and associated with an increased incidence of ovarian cancer, 25 percent are familial, and the rest are assumed to be sporadic. Hereditary forms have also been identified for colon cancer, retinoblastoma, Wilms' tumors, and melanoma. The Li-Fraumeni syndrome identifies families in which a mutation of the p53 gene on chromosome 17 is associated with the incidence of several early-onset tumors, particularly breast and soft tissue sarcomas.

Bilateral acoustic neuroma
Bladder cancer
Breast cancer
Colorectal cancer
Familial renal cell carcinoma
Gastric carcinoma
Multiple endocrine neoplasia (type 2A)
Neuroblastoma
Ovarian cancer
Small cell lung cancer
Uveal melanoma
Wilms' tumor

Table 25.11-26 Selected Human Cancers Associated With Recessive Chromosomal Abnormalities

High-risk individuals have chronic anxiety, lowered self-esteem, and problems concerning marriage and child-bearing. Their self-estimates of risk are usually much higher than their real risk, even for those in the highest risk bracket. Some show no increased psychological distress when found to be carriers, perhaps because, like human immunodeficiency virus (HIV)-infected individuals, their anticipation amounts to near certainty. Previously unsuspecting carriers do show increased distress, while those who decline testing remain anxious throughout. High risk and high anxiety often go hand in hand with denial and poor health maintenance behaviors such as avoiding breast self-examination and surveillance testing. A group therapy intervention with educational and expressive components has been effective in reducing psychological distress, normalizing risk estimation, and improving health behaviors. Individual educational and supportive interventions have shown promise. Some form of psychological intervention should be a regular part of the surveillance programs that have been developed in many centers. Similarly, psychological support is

crucial to deciding whether to enter surveillance trials, have prophylactic mastectomy, and above all whether or not to have testing. One study has shown that while only 71 percent of high-risk women would undergo testing for breast cancer, as many as 42 percent of average-risk women wished to undergo it as well. On the other hand, intention is not always translated into practice for the high-risk group. Testing is rapidly moving from an experimental procedure offered in a research context to a commercial enterprise. In response to this, the field of genetic counseling is undergoing exponential growth. But it does not include long-term support, other than occasional booster sessions; hence, mental health professionals will continue to provide the help needed to cope with later psychological repercussions.

The consequences of testing go far beyond the psychological distress of the individual. Cooperation of unwilling family members may be required, and unwelcome knowledge forced upon them. Marital, sibling, and parent-child relations may suffer, and whole families may be exposed to insurance and job discrimination in today's world of thoroughly eroded privacy. The individuals involved must not be given false reassurances by eager researchers or naive mental health professionals, but well-informed counselors can provide essential information and problem-solving techniques. The broader social issues are in other hands, in recognition of which, 5 percent of the budget for the human genome project is going to the study of the ethical, legal, and social implications of genetic knowledge, through the so-called ELSI office.

CANCER RISK AND SURVIVAL

The role of psychosocial factors in altering cancer risk and survival fascinates the public, but the discussion is often blighted by wishful thinking and genuine confusion. Cancer risk and survival are often conflated, and great emphasis is placed on the direct role of the individual's psychoneuroimmune mechanisms in preventing or curing cancer, while ignoring many psychologically mediated effects that are far stronger and better established. The common denominator behind all these distortions is the deeply grounded wish to believe that all human beings have within themselves the power to prevent or cure cancer. A well-designed study in which cancer mortality in a group of Chinese women showed a significant drop during a holiday honoring older women, followed by a compensatory peak after the holiday, does lend some encouragement to these views, but there is enough distortion and overinterpretation abroad that psychiatrists must know the current state-of-the-art to clarify their own thinking and better understand their patients.

Cancer Biology The natural history of a given cancer begins when changes in a cell's DNA establish the potential for this cell to become malignant. This cancer initiation precedes by many years (anywhere from 3 to 30) the second event, known as cancer promotion, in which growth suppression is lost and malignant multiplication begins. This again precedes by months to years the appearance of clinical symptoms. Finally, there is a greatly variable period between the appearance of any clinical symptoms and the seeking of care. Cancer risk can relate to the risk of initiation or the risk of promotion. Cancer survival is measured from time of diagnosis, but this ignores the important factor of delayed diagnosis for which initial disease staging is a partial but incomplete solution. With new knowledge have come opportunities to explore the role of psychosocial factors that propel a given cancer through all stages of biological development.

Psychosocial Factors One attempt at clarifying the multifaceted impact of psychosocial factors on cancer is to think in terms of the external and internal loops. The *external loop* refers to ways in which psychological, behavioral, and socioenvironmental factors affect the person's behavior and lifestyle and hence cancer risk. Even there, the actual behaviors must be teased out from their psychological determinants. The *internal loop* refers to the ways in which the person's psychological status affects cancer risk and survival via changes in the internal milieu. This effect can be mediated in many ways, such as neurological, immune, and endocrinologic mechanisms individually and in varying relations to each other.

Psychologically Mediated Environmental Factors By far the largest role in the development of cancer is played by environmental insults such as radiation, viruses, and chemicals acting cumulatively over time on each individual's predetermined complement of potentially cancer-causing genes. Exposure to injury in turn results from social and psychological factors over which the individual has variable control. By far the greatest contributors of psyche to cancer incidence are personal lifestyle and habits. Smoking cessation, abstinence from alcohol, more exercise, and better eating habits would probably decrease the incidence of cancer in the United States by 50 percent overall. The greatest contributor to decreased survival is poor use of screening, since early diagnosis is still the best predictor of prolonged survival. These facts are unequivocal, yet they leave the public, the media, and many policymakers remarkably passive in comparison to the excitement generated by other, far less significant and less proven psychological factors. Recent developments in which individuals and state governments may succeed in recovering medical costs from tobacco companies seemed to herald a sea change, although the settlements negotiated by the government and the tobacco companies have been seen by many as inadequate.

Methodological Considerations The ways of studying the role of psychosocial variables all involve large populations over long periods of time. The first is the case-control study, in which a group of patients is matched to a control group and differences between the two groups are identified. The index population is usually unrepresentative of broader populations, and the matching is incomplete; hence it is unlikely that the findings can be generalized to larger unselected populations unless the effects are large enough to be inescapable and easily verified. More reliable is the retrospective method, in which a cohort is opportunistically identified at a late point in time, and factors related to cancer are sought retrospectively. The index population is equally unrepresentative, but these are essential pilot studies pointing the way to later larger ones. The latter can be designed prospectively, with sophisticated methods of controlling for known confounding variables, but the task remains methodologically daunting. In semiprospective studies, patients are assessed in the prebiopsy stage and at various later times, to compare positive and negative biopsy groups. But, breast cancer patients correctly predicted their biopsy results more frequently than lung cancer patients, and all of them had greater than chance accuracy, casting doubt on the significance of pre- and postbiopsy self-reports. Even crisper facts such as negative life events can be of uncertain significance because individual reports vary with the subject's current mood and chronic disposition.

Current Findings All this notwithstanding, over 50 psychosocial factors have been claimed to play a role in cancer initiation or promotion. Some of them are surviving critical scrutiny, and the field continues to be deservedly active and exciting. Stress was initially thought to be significant, but later studies disproved this in most situations. However, stress plus passive coping styles may have a negative impact on the progression of virus-induced tumors such as cancer of the cervix, an effect that may be immunologically mediated. These account for about 5 percent of human cancers. No impact for bereavement has been demonstrated except for two studies that showed a small increase in diagnoses that washed out after 1 year, too short a time to support a role for bereavement in the development of cancer.

On the other hand, several recent studies have shown that social support is a significant positive survival factor, a fact that has important implications for mental health professionals. Social class has a variable effect on cancer risk, with some cancers labeled “cancers of poverty” and others “cancers of affluence.” But class has an unequivocal negative effect on cancer survival, probably because lower-class individuals are less knowledgeable about, and less able to avoid, toxic exposures and unhealthy lifestyles and lack access to good medical care. A crucial, hard-to-measure factor is the mix of mistrust, exhaustion, fatalism, and despair that leads the poor and the discriminated-against to underutilize even what little is available to them.

Race is also a strong predictor of decreased survival, but the effect decreases after correction for social class and shows great variability within racial groups. The effectiveness of interventions aimed at improving lifestyle and health behaviors has often been disappointing, usually because the complexity of the problem is underestimated, unrealistically short-term results are being demanded, or both. A few encouraging studies have been described: one that used an understanding of the role of peer pressure to affect adolescent smoking, and another that combined the provision of health care with the provision of food to the very poor. These interventions are cost-effective in the long run, but the up-front cost is high enough that they often lack reliable funding. Managed care institutions have claimed to put more emphasis on preventive care as a counterweight to their drastic curtailing of available medical care, but the population turnover is too great, their lack of open accountability is thus far notorious, and many are going out of business.

Internally Mediated Risk and Survival Factors Recent developments in psychoneuroendocrine-immunology have confirmed the feedback loop between feelings and perceptions on the one hand and neurological, endocrine, and immune changes on the other. In small part these update classic psychosomatic concepts. But more urgently, in this area of research recent developments lend theoretical support to current popular beliefs about “the power of the mind over the body.” A rereading of William James' 1902 book *The Varieties of Religious Experience* should disabuse any reader from thinking that these convictions represent anything new, either in their mood-enhancing effects or their potential for abuse and backlash. What is new is contemporary science's ability to explore the physiological underpinnings of these age-old and cherished human beliefs.

Personality Traits, Feeling States, and Coping Styles There are conflicting results on the role of personality in cancer prevalence and survival, beyond what is mediated through risk-avoidant behavior. Studies are handicapped by the absence of comprehensive prognostic indicator profiles. This becomes more urgent as more tumor markers such as prostate-specific antigen (PSA) come into use and as more prognostic tumor markers such as estrogen receptors in breast cancer are defined. These indicators may someday define subgroups of patients in whom the role of psychological factors may be very clear. A few centers have refined their research design over many years to allow a few conclusions. No strong relationship has been established between personality style and disease outcome. This may be due to the inadequacy of personality typologies as well as the difficulty of differentiating between state and trait when observing an individual in crisis. The well-known type A personality (driven and quick to anger) was studied mainly in reference to cardiovascular disease, although one study found a 1.5 times greater risk of cancer, likely related to smoking. Evidence for the role of its opposite, type C personality, is much flimsier than the enthusiasm with which it was received. Long-standing psychiatric

symptoms such as chronic neuroticism have not been proved to be related to disease outcome. Feeling states such as level of distress or anxiety have not been found to have any predictive value. An association between passive coping styles and poor disease outcomes was demonstrated in many studies using measures of helplessness and hopelessness, “fighting spirit,” stoic acceptance, and anxious preoccupation. The role of denial remains open and points again to the complexity of what is being measured. Affective denial in the face of an effective coping style may have the opposite impact from that of effective denial associated with a passive coping style.

Immune Mechanisms Now that measurements of immune function are available, numerous studies are showing small, but statistically significant, differences in bereavement, disease states, and many kinds of stress. In cancer, a conditioned negative immune response has been found with chemotherapy. An improved immune response was seen following a group intervention in melanoma patients, and differences have been found in the families of cancer patients depending on their coping effectiveness. More work needs to be done to establish the clinical significance of these preliminary findings observed in very small samples.

Endocrine Mechanisms The discovery that breast cancers with estrogen-sensitive receptors are associated with a better outcome is of clinical use when receptor typing is done on biopsy specimens to guide subsequent management. Since the receptors respond to emotional mediation through the hypothalamic-pituitary axis, a relationship to emotional states and psychological adjustment can be postulated, although studies have shown conflicting results.

Effect of Psychological Interventions The direct effect of psychological interventions on cancer risk through internally mediated mechanisms has not been studied and may never be fully disentangled from the large, well-known, externally mediated effects on lifestyle and health behaviors. However, studies of the effect on cancer survival have produced significant results. Over 20 intervention studies with patients in traditional treatment and 3 studies of alternative therapies have shown clear improvement in quality of life and no effect on mortality. One well-designed, widely known study was thought to show a significantly increased survival time (>18 months) in a small sample of women with metastatic cancer after a group intervention designed to address pain control, interpersonal relationships, and general illness-coping behaviors. The study is small, but large replications are under way. However, a subsequent paper studied the outcome figures for a large sample of women in the same geographic area and in the whole state and found that the control group did more poorly, while the intervention group reflected the larger norms. Several replication studies are under way. Another widely discussed intervention study demonstrated improved quality of life and improved immune parameters in early melanoma patients who had received a time-limited group therapy intervention with an educational and problem-solving emphasis. In a follow-up study, the intervention group had a longer relapse-free interval than the control group. Publication of a longer follow-up period is expected. It is not accidental that both of these studies involved a group intervention that provided a close social group and promoted more-active coping behavior, two of the factors already observed to have a positive effect on survival.

Discussion Given the unequivocal improvement in quality of life shown by psychosocial intervention studies, their continued use and further development is an obvious imperative. If they also turn out to affect disease outcome, the health care delivery system should be reexamined and adapted to maximize the effect. The extent to which their effect on quality of life has been undervalued by a medical establishment that prizes small improvements in survival so highly, speaks to fundamental differences between the medical and the mental health establishments and between doctors and the public.
