ABOUT THE EDITORS

BENJAMIN J. SADOCK, M.D.

Benjamin James Sadock, M.D., is the Menas S. Gregory Professor of Psychiatry and Vice Chairman of the Department of Psychiatry at the New York University (NYU) School of Medicine. He was graduated from Union College, received his Doctor of Medicine degree from New York Medical College, and did his internship at Albany Hospital. He completed his residency at Bellevue Psychiatric Hospital and then entered military service where he served as assistant chief and acting chief of neuropsychiatry at Sheppard Air Force Base, Texas. He has held faculty and teaching appointments at Southwestern Medical School and Parkland Hospital in Dallas, and at New York Medical College, St. Luke's Hospital, the New York State Psychiatric Institute, and Metropolitan Hospital in New York City. He joined the faculty of the NYU School of Medicine in 1980 and served in various positions: director of medical student education in psychiatry, co-director of the Residency Training Program in Psychiatry, and director of Graduate Medical Education. Currently, Dr. Sadock is director of Student Mental Health Services, psychiatric consultant to the Admissions Committee and co-director of Continuing Education in Psychiatry at the NYU School of Medicine. He is on the staff of Bellevue Hospital and Tisch Hospital and is consultant psychiatrist at Lenox Hill Hospital. Dr. Sadock is a diplomate of the American Board of Psychiatry and Neurology and served as an assistant and associate examiner for the board for over a decade. He is a Fellow of the American Psychiatric Association, a Fellow of the American College of Physicians, a Fellow of the New York Academy of Medicine, and a member of Alpha Omega Alpha Honor Society. He is active in numerous psychiatric organizations and is president and founder of the NYU-Bellevue Psychiatric Society. Dr. Sadock was a member of the National Committee in Continuing Education in Psychiatry of the American Psychiatric Association, served on the Ad Hoc Committee on Sex Therapy Clinics of the American Medical Asso ciation, was delegate to the Conference on Recertification of the American Board of Medical Specialists, and was a representative of the American Psychiatric Association's Task Force on the National Board of Medical Examiners and the American Board of Psychiatry and Neurology. In 1985 he received the Academic Achievement Award from New York Medical College. He is author or editor of over 100 publications, a book reviewer for psychiatric journals, and lectures on a broad range of topics in general psychiatry. Dr. Sadock maintains a private practice for diagnostic consultations, psychotherapy, and pharmacotherapy. He has been married to Virginia Alcott Sadock, M.D., clinical professor of psychiatry at NYU School of Medicine, since completing his residency. Dr. Sadock enjoys opera, skiing, and traveling, and is an avid fly-fisherman.

VIRGINIA A. SADOCK, M.D.

Virginia Alcott Sadock, M.D., joined the faculty of the New York University (NYU) School of Medicine in 1980 where she is currently clinical professor of psychiatry and attending psychiatrist at Tisch Hospital and Bellevue Hospital. She is director of the Program in Human Sexuality and Sex Therapy at the NYU Medical Center, one of the largest treatment and training programs of its kind in the United States. She is the author of over 50 articles and chapters on sexual behavior and was the developmental editor of *The Sexual Experience*, published by Williams & Wilkins—one of the first major textbooks on human sexuality. She serves as referee and book reviewer for several medical journals including the *American Journal of Psychiatry* and the *Journal of the American Medical Association*. She has had a long-standing interest in the role of women in medicine and psychiatry and was a founder of the Committee on Women in Psychiatry of the New York County District Branch of the American Psychiatric Association. She is active in academic matters, has served as an assistant and associate examiner for the American Board of Psychiatry and Neurology for over 15 years, and was also a member of the test committee in psychiatry for both the American Board of Psychiatry and the Psychiatric Knowledge and Self-Assessment Program (PKSAP) of the American Psychiatric Association. She served as chairperson of the Committee on Public Relations. New York County District Branch of the American Psychiatric Association and also participated in the National Medical Television Network series *Women in Medicine* and the PBS television documentary *Women and Depression*. She has been vice-president of the Society of Sex Therapy and Research, a regional council member of the American Association of Sex Education Counselors and Therapists, and is president of the Alumni Association of Sex Therapists. She lectures extensively both in this country and abroad on sexual dysfunction, relational problems, and dep ression and anxiety disorders. She is a Fellow of the American Psychiatric Association, a Fellow of the New York Academy of Medicine and a diplomate of the American Board of Psychiatry and Neurology. Dr. Sadock was graduated from Bennington College, received her M.D. from New York Medical College, and trained in psychiatry at Metropolitan Hospital. She lives in Manhattan with her husband, Dr. Benjamin Sadock, where she maintains an active psychiatric practice that includes individual psychotherapy, couples and marital therapy, sex therapy, psychiatric consultation, and pharmacotherapy. They have two children, James and Victoria, both physicians. In her leisure time Dr. Sadock enjoys theater, film, reading fiction, and travel.

CONTRIBUTORS

Henry David Abraham, M.D.
Clinical Associate Professor of Psychiatry, Brown University School of Medicine; Chief of Alcohol and Drug Treatment Services, Butler Hospital, Providence, Rhode Island; Lecturer in Psychiatry, Harvard Medical School; Consultant in Psychiatry, Massachusetts General Hospital, Boston, Massachusetts.
11.7. Hallucinogen-Related Disorders

Russell L. Adams, Ph.D.
Professor of Psychiatry and Behavioral Science, University of Oklahoma College of Medicine; Director of University Hospital Neuropsychology Assessment Laboratory; Director of Psychology Internship and Post Doctoral Neuropsychology Training Program, University of Oklahoma Health Sciences Center, Oklahoma City, Oklahoma.
7.5. Personality Assessment: Adults and Children

W. Stewart Agras, M.D., F.R.C.P.(C)
Professor of Psychiatry and Behavioral Sciences, Stanford University School of Medicine; Director of Stanford University Psychiatric Clinics, Stanford, California.
3.3. Learning Theory

Hagop S. Akiskal, M.D.
Professor of Psychiatry, University of California at San Diego School of Medicine, La Jolla, California; Director of Outpatient Psychiatric Services, San Diego Veterans Affairs Healthcare System, San Diego, California.
14.1. Mood Disorders: Introduction and Overview
14.6. Mood Disorders: Clinical Features

George S. Alexopoulos, M.D.
Professor of Psychiatry, The Joan and Sanford I. Weill Medical College of Cornell University, New York, New York; Director of Cornell Institute of Geriatric Psychiatry, New York Hospital-Cornell Medical Center, Westchester Division, White Plains, New York.
51.3d. Geriatric Psychiatry: Mood Disorders

Anne Alonso, Ph.D.
Clinical Professor of Psychology, Harvard Medical School; Director of Center for Psychoanalytic Studies at the Massachusetts General Hospital, Boston, Massachusetts; Professor, The Fielding Institute, Santa Barbara, California.
30.4. Group Psychotherapy, Combined Individual and Group Psychotherapy

Kenneth Z. Altshuler, M.D.
Stanton Sharp Professor of Psychiatry and Chairman, Department of Psychiatry, University of Texas Southwestern Medical School, Dallas, Texas.
30.10. Other Methods of Psychotherapy

Lisa Amaya-Jackson, M.D.
Assistant Professor of Psychiatry and the Behavioral Sciences, Duke University School of Medicine; Director of Trauma Evaluation, Treatment and Research Program, Center for Child and Family Health, Durham, North Carolina.
46.2. Posttraumatic Stress Disorder in Children and Adolescents

Daniel G. Amen, M.D.
Director of Amen Clinic for Behavioral Medicines, Fairfield, California.
2.13. Neuroimaging in Clinical Practice

George W. Arana, M.D.
Professor of Psychiatry and Behavioral Sciences, Associate Dean of College of Medicine, Medical University of South Carolina; Director of Mental Health Service, Ralph H. Johnson Veterans Affairs Medical Center, Charleston, South Carolina.
31.9. Barbiturates and Similarly Acting Substances
31.14. Chloral Hydrate

Lesley M. Arnold, M.D.
Assistant Professor of Psychiatry, Director of Division of Psychosomatic Research, University of Cincinnati College of Medicine, Cincinnati, Ohio.
25.7. Psychocutaneous Disorders

J. Hampton Atkinson, Jr., M.D.
Adjunct Professor of Psychiatry, University of California at San Diego School of Medicine, La Jolla, California; Staff Psychiatrist, San Diego Veterans Affairs Healthcare System, San Diego, California.
2.8. Neuropsychiatric Aspects of HIV Infection and AIDS

F. M. Baker, M.D., M.P.H.
Professor of Psychiatry, University of Hawaii John A. Burns School of Medicine; Chief of Inpatient Psychiatry, Hawaii State Hospital, Kaneohe, Hawaii.
51.6e. Geriatric Psychiatry: Minority Issues

Glen B. Baker, Ph.D.
Professor of Psychiatry, Co-Director of Neurochemical Research Unit, University of Alberta Faculty of Medicine and Dentistry, Edmonton, Alberta, Canada.
31.20. Monoamine Oxidase Inhibitors

Lorian Baker, Ph.D.
Former Research Professor of Child Psychiatry, University of California at Los Angeles School of Medicine, Los Angeles, California.
35.1. Reading Disorder
35.2. Mathematics Disorder
35.3. Disorder of Written Expression and Learning Disorder Not Otherwise Specified
36. Motor Skills Disorder: Developmental Coordination Disorder

James C. Ballenger, M.D.
Professor of Psychiatry and Chairman, Department of Psychiatry and Behavioral Sciences, Director of Institute of Psychiatry, Medical University of South Carolina, Charleston, South Carolina.
31.9. Barbiturates and Similarly Acting Substances
31.10. Benzodiazepine Receptor Agonists and Antagonists
31.12. Buspirone
31.14. Chloral Hydrate

Jay M. Baraban, M.D., Ph.D.
Associate Professor of Neuroscience Psychiatry, and Behavioral Sciences, Johns Hopkins University School of Medicine, Baltimore, Maryland.
1.8. Intraneuronal Signaling Pathways

Ida Sue Baron, Ph.D.
Clinical Associate Professor of Pediatrics, Georgetown University School of Medicine and Health Sciences, Washington, D.C.

7.6. Neuropsychological and Intellectual Assessment of Children

William W. Beatty, Ph.D.
Professor of Psychiatry and Behavioral Science, University of Oklahoma College of Medicine, Oklahoma City, Oklahoma.
2.7. Neuropsychiatric Aspects of Multiple Sclerosis and Other Demyelinating Disorders

Linda Beauclair, M.D.
Assistant Professor of Psychiatry
McGill University Faculty of Medicine, Montreal, Quebec, Canada.
31.24. Selective Serotonin-Noradrenaline Reuptake Inhibitors

Aaron T. Beck, M.D.
Professor Emeritus of Psychiatry and Director of Psychopathology Research Center, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania.
30.6. Cognitive Therapy

Anne E. Becker, M.D., Ph.D.
Assistant Professor of Medical Anthropology and Psychiatry
Harvard Medical School, Boston, Massachusetts.
4.1. Anthropology and Psychiatry

Joseph H. Beitchman, M.D.
Professor of Psychiatry and Public Health Science, University of Toronto Faculty of Medicine; Head of Child and Family Studies Centre, Clarke Institute of Psychiatry, Centre for Addiction and Mental Health, Toronto, Ontario, Canada.
37.1. Expressive Language Disorder
37.2. Mixed Receptive-Expressive Language Disorder
37.3. Phonological Disorder
37.4. Stuttering
37.5. Communication Disorder Not Otherwise Specified

Marilyn B. Benoit, M.D.
Clinical Associate Professor of Psychiatry, Georgetown University School of Medicine and Health Sciences, Washington, D.C.
49.3. Foster Care

Kate A. Berg, Ph.D.
Co-Director of Office of Bioethics and Special Populations Research, National Human Genome Research Institute, National Institutes of Health, Bethesda, Maryland.
28.4. Genetic Counseling

Sarah L. Berga, M.D.
Associate Professor of Obstetrics, Gynecology, Reproductive Sciences, and Psychiatry, University of Pittsburgh School of Medicine; Attending Physician, Magee-Women's Hospital, Pittsburgh, Pennsylvania.
28.2. Psychiatry and Reproductive Medicine

R. Lindsey Bergman, Ph.D.
Clinical Instructor of Psychiatry and Biobehavioral Science, University of California at Los Angeles School of Medicine; Associate Director of Child and Adolescent Obsessive-Compulsive Disorder and Anxiety Program, UCLA Neuropsychiatric Institute and Hospital, Los Angeles, California.
46.1. Obsessive-Compulsive Disorder in Children

William Bernet, M.D.
Associate Professor of Psychiatry, Vanderbilt University School of Medicine; Medical Director of Psychiatric Hospital at Vanderbilt, Nashville, Tennessee.
49.4. Child Maltreatment

Garth Bissette, Ph.D.
Professor of Psychiatry, University of Mississippi School of Medicine, Jackson, Mississippi.
1.6. Neuropeptides: Biology and Regulation

Ira B. Black, M.D.
Professor and Chair, Department of Neuroscience and Cell Biology, University of Medicine and Dentistry of New Jersey Robert Wood Johnson Medical School, Piscataway, New Jersey.
1.7. Neurotrophic Factors

Deborah Blacker, M.D., Sc.D.
Assistant Professor of Psychiatry, Harvard Medical School; Assistant Professor of Epidemiology, Harvard School of Public Health; Clinical Staff, Massachusetts General Hospital; Boston, Massachusetts.
7.8. Psychiatric Rating Scales

Barry Blackwell, M.D., F.R.C.Psych.
Clinical Professor of Psychiatry, University of Wisconsin Medical School, Milwaukee Campus, Milwaukee, Wisconsin.
27.1. Treatment Compliance

Ray Blanchard, Ph.D.
Associate Professor of Psychiatry, University of Toronto Faculty of Medicine; Head of Clinical Sexology Program, Clarke Institute of Psychiatry, Centre for Addiction and Mental Health, Toronto, Ontario, Canada.
19.3. Gender Identity Disorders

Dan G. Blazer, II, M.D., Ph.D.
J.P. Gibbons Professor of Psychiatry and Behavioral Sciences, Professor of Community and Family Medicine and Dean of Medical Education, Duke University School of Medicine, and Durham, North Carolina.
14.2. Mood Disorders: Epidemiology

Bennett Blum, M.D.
Clinical Instructor of Geriatric Psychiatry, University of California at Los Angeles School of Medicine; Director of Forensic Gero-Psychiatry Division, Park Dietz and Associates, Newport Beach, California.
51.6b. Geriatric Psychiatry: Forensic Issues

Michael P. Bogenschutz, M.D.
Assistant Professor of Psychiatry, University of New Mexico School of Medicine; Clinical Director of Dual Diagnosis Treatment Program, Mental Health Center, University of New Mexico Health Sciences Center, Albuquerque, New Mexico.
9.1. Classification of Mental Disorders

Kyle Brauer Boone, Ph.D.
Associate Professor-in-Residence, University of California at Los Angeles School of Medicine, Los Angeles, California; Director of Neuropsychological Services,

Department of Psychiatry, Harbor-UCLA Medical Center, Torrance, California.
51.2d. Geriatric Psychiatry: Neuropsychological Evaluation

Neil W. Boris, M.D.
Assistant Professor of Community Health Sciences, Tulane University School of Public Health and Tropical Medicine; Assistant Professor of Pediatrics, Psychiatry, and Neurology, Tulane University School of Medicine, New Orleans, Louisiana.
44.1. Reactive Attachment Disorder of Infancy and Early Childhood

Soo Borson, M.D.
Professor of Psychiatry and Behavioral Sciences, University of Washington School of Medicine; Director of Geropsychiatry Services and Director of University of Washington Medical Center Alzheimer's Disease Research Center, Seattle, Washington.
51.3a. Geriatric Psychiatry: Psychiatric Problems in the Medically Ill;
51.3b. Geriatric Psychiatry: Sleep Disorders

H. Stefan Bracha, M.D.
Research Physician, National Center for Posttraumatic Stress Disorder, Honolulu Veterans Affairs Medical and Regional Office Center, Honolulu, Hawaii.
2.13. Neuroimaging in Clinical Practice

Olga Brawman-Mintzer, M.D.
Assistant Professor of Psychiatry and Behavioral Sciences, Medical University of South Carolina, Charleston, South Carolina.
31.12. Buspirone

Kirk J. Brower, M.D.
Associate Professor of Psychiatry, Director of Alcohol Research Center, University of Michigan Medical School, Ann Arbor, Michigan.
11.13. Anabolic-Androgenic Steroid Abuse

Kelly D. Brownell, Ph.D.
Professor of Psychology, Master of Silliman College, Yale University; Professor of Epidemiology and Public Health and Director of Clinical Training, Director of Yale Center for Eating and Weight Disorders, Yale University School of Medicine, New Haven, Connecticut.
25.3. Obesity

Robert W. Buchanan, M.D.
Associate Professor of Psychiatry
University of Maryland School of Medicine, Baltimore, Maryland; Chief of Outpatient Research Program, Maryland Psychiatric Research Center, Catonsville, Maryland.
12.1. Schizophrenia: Introduction and Overview

Oscar G. Bukstein, M.D., M.P.H.
Associate Professor of Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania.
49.11. Adolescent Substance Abuse

Jack D. Burke, Jr., M.D., M.P.H.
Professor of Psychiatry and Head, Department of Psychiatry and Behavioral Science, Texas A & M University College of Medicine; Chairman, Department of Psychiatry, Scott and White Memorial Hospital and Clinic, Temple, Texas.
5.1. Epidemiology

Vivien K. Burt, M.D., Ph.D.
Associate Professor of Psychiatry and Biobehavioral Sciences, University of California at Los Angeles School of Medicine; Director of Women's Life Center, UCLA Neuropsychiatric Institute and Hospital; Medical Director, Mental Health Clinic, West Los Angeles Veterans Affairs Ambulatory Care Center, Los Angeles, California.
22. Impulse-Control Disorders Not Elsewhere Classified

Juan Bustillo, M.D.
Assistant Professor of Psychiatry, University of New Mexico School of Medicine, Albuquerque, New Mexico.
12.9. Schizophrenia: Psychosocial Treatment

Eric D. Caine, M.D.
John Romano Professor of Psychiatry and Chair, Department of Psychiatry, University of Rochester School of Medicine and Dentistry, Rochester, New York.
10. Delirium, Dementia, and Amnestic and Other Cognitive Disorders

Robert Jean Campbell, III, M.D.
Clinical Professor of Psychiatry, The Joan and Sanford I. Weill Medical College of Cornell University; Medical Director, New York Gracie Square Hospital; Attending Psychiatrist, New York Hospital, New York, New York.
52.2. Managed Care

Robert Cancro, M.D., Med.D.Sc.
Lucius N. Littauer Professor of Psychiatry and Chairman, Department of Psychiatry, New York University School of Medicine; Director of Department of Psychiatry, Tisch Hospital, New York, New York; Director of Nathan Kline Institute for Psychiatric Research, Orangeburg, New York.
12.7. Schizophrenia: Clinical Features

Dennis P. Cantwell, M.D.***
Joseph Campbell Professor of Child Psychiatry, Department of Psychiatry and Biobehavioral Sciences, University of California at Los Angeles School of Medicine, Los Angeles, California.
35.1. Reading Disorder;
35.2. Mathematics Disorder;
35.3. Disorder of Written Expression and Learning Disorder Not Otherwise Specified
36. Motor Skills Disorder: Developmental Coordination Disorder

William T. Carpenter, Jr., M.D.
Professor of Psychiatry and Pharmacology, University of Maryland School of Medicine, Baltimore, Maryland; Director of Maryland Psychiatric Research Center, Catonsville, Maryland.
12.1. Schizophrenia: Introduction and Overview

Christine K. Cassel, M.D.
Professor of Psychiatry and Chairman, Department of Geriatrics and Adult Development, Mount Sinai School of Medicine, New York, New York.
51.6c. Geriatric Psychiatry: Ethical Issues

Irene Chatoor, M.D.
Professor of Psychiatry and Behavioral Sciences, George Washington University School of Medicine and Health Sciences; Interim Chair and Director of Infant Psychiatry, Children's National Medical Center, Washington, D.C.
41. Feeding and Eating Disorders of Infancy and Early Childhood

Guy Chouinard, M.D., M.Sc.
Professor of Psychiatry, McGill University Faculty of Medicine; Professor of Psychiatry, University of Montreal Faculty of Medicine; Director of Clinical Psychopharmacology Unit, Allan Memorial Institute; Head of Clinical Psychopharmacology Inpatient Unit, Fernand-Seguin Research Centre, Louis-H. Lafontaine Hospital, Montreal, Quebec, Canada.
31.24. Selective Serotonin-Noradrenaline Reuptake Inhibitors

Tiffany W. Chow, M.D.
Clinical Instructor of Neurology, University of California at Los Angeles School of Medicine; Director of Frontotemporal Dementia Clinic, UCLA Neuropsychiatric Institute and Hospital, Los Angeles, California.
2.1. Neuropsychiatry: Clinical Assessment and Approach to Diagnosis

Domenic A. Ciraulo, M.D.
Professor of Psychiatry and Chairman, Boston University School of Medicine; Psychiatrist-in-Chief, Boston Medical Center; Chief of Psychiatry Service, Veterans Affairs Boston Clinic, Boston, Massachusetts.
11.12. Sedative-, Hypnotic-, or Anxiolytic-Related Abuse

James L. Claghorn, M.D.
Clinical Associate Professor of Psychiatry, University of Texas Medical School at Houston, Houston, Texas.
31.19. Mirtazapine

C. Robert Cloninger, M.D.
Wallace Renard Professor of Psychiatry, Washington University School of Medicine, Saint Louis, Missouri.
24. Personality Disorders

Barbara J. Coffey, M.D.
Assistant Professor of Psychiatry, Harvard Medical School, Boston, Massachusetts; Director of Tourette's Clinic, Director of Pediatric Psychopharmacology Clinic, McLean Hospital, Belmont, Massachusetts.
48.6. Pediatric Psychopharmacology

Lee S. Cohen, M.D.
Associate Professor of Psychiatry, Harvard Medical School; Director of Perinatal and Reproductive Psychiatry, Clinical Research Program, Clinical Psychopharmacology Unit, Department of Psychiatry, Massachusetts General Hospital, Boston, Massachusetts.
13.4. Postpartum Psychiatric Syndromes

Calvin A. Colarusso, M.D.
Clinical Professor of Psychiatry and Director of Child Psychiatry Residency Training Program, University of California at San Diego School of Medicine, La Jolla, California; Training and Supervising Analyst, San Diego Psychoanalytic Institute, San Diego, California.
50. Adulthood

Ralph Colp, Jr., M.D.
Assistant Professor of Clinical Psychiatry, Columbia University College of Physicians and Surgeons; Senior Attending Psychiatrist, St. Luke's-Roosevelt Hospital Center, New York, New York.
55.1. History of Psychiatry

Philip M. Coons, M.D.
Professor of Psychiatry, Indiana University School of Medicine; Attending Psychiatrist, Indiana University Hospitals, Indianapolis, Indiana.
18.2. Dissociative Fugue

Jeremy D. Coplan, M.D.
Associate Professor of Clinical Psychiatry, Columbia University College of Physicians and Surgeons; Associate Director of Biological Studies Unit, New York State Psychiatric Institute, New York, New York.
15.3. Anxiety Disorders: Biochemical Aspects

G. Rees Cosgrove, M.D., F.R.C.S.(C)
Associate Professor of Surgery, Harvard Medical School, Boston, Massachusetts.
31.32. Neurosurgical Treatments

Jorge Alberto Costa e Silva, M.D.
Professor of Psychiatry and Director of International Center for Mental Health Policy and Research, New York University School of Medicine; Director of Division of Mental Health and Prevention of Substance Abuse, World Health Organization, Geneva, Switzerland.
55.2. World Aspects of Psychiatry

Paul T. Costa, Jr., Ph.D.
Clinical Professor of Psychiatry, Georgetown University School of Medicine and Health Sciences, Washington, D.C.; Associate Professor of Medical Psychology, Johns Hopkins University School of Medicine; Chief of Laboratory of Personality and Cognition, Gerontology Research Center, National Institute on Aging, National Institutes of Health, Baltimore, Maryland.
6.4. Approaches Derived From Philosophy and Psychology

Nancy S. Cotton, Ph.D.
Instructor of Psychology, Department of Psychiatry, Harvard Medical School, Boston, Massachusetts.
32.3. Normal Adolescence

Thomas J. Crowley, M.D.
Professor of Psychiatry, University of Colorado School of Medicine; Director of Division of Substance Dependence, University of Colorado Health Sciences Center, Denver, Colorado.
11.8. Inhalant-Related Disorders

Jan L. Culbertson, Ph.D.
Associate Professor of Pediatrics and Clinical Associate Professor of Psychiatry and Behavioral Sciences, University of Oklahoma College of Medicine; Director of Neuropsychology Services, Child Study Center, Children's Hospital of Oklahoma, Oklahoma City, Oklahoma.
7.5. Personality Assessment: Adults and Children

Jeffrey L. Cummings, M.D.
Augustus S. Rose Professor of Neurology and Professor of Psychiatry and Biobehavioral Science, University of California at Los Angeles School of Medicine, Los Angeles, California.
2.1. Neuropsychiatry: Clinical Assessment and Approach to Diagnosis

John F. Curry, Ph.D.
Associate Professor of Psychiatry and Behavioral Sciences, Duke University School of Medicine; Associate Professor of Psychology, Duke University, Durham, North Carolina.

3.2. Extending Piaget's Approach to Intellectual Functioning

David Gordon Daniel, M.D.
Clinical Professor of Psychiatry and Behavioral Sciences, George Washington University School of Medicine and Health Sciences, Washington, D.C.
2.6. Neuropsychiatric Aspects of Movement Disorders

Garrett C. Daum, M.D.
Assistant Clinical Professor of Psychiatry and Biobehavioral Sciences, University of California at Los Angeles School of Medicine; Medical Director of Outpatient Geriatric Psychiatry Programs, West Los Angeles Veterans Affairs Ambulatory Care Center, Los Angeles, California.
51.4j. Geriatric Psychiatry: Cognitive-Behavioral Therapy

John M. Davis, M.D.
Gilman Professor of Psychiatry, University of Illinois at Chicago College of Medicine, Chicago, Illinois.
31.2. Pharmacokinetics and Drug Interactions

Kenneth L. Davis, M.D.
Esther and Joseph Klingenstein Professor of Psychiatry and Chairman, Department of Psychiatry, Mount Sinai School of Medicine, New York, New York.
31.15. Cholinesterase Inhibitors

Lori L. Davis, M.D.
Assistant Professor of Psychiatry, University of Alabama School of Medicine, Birmingham, Alabama.
28.3. Premenstrual Dysphoric Disorder

Mark DeAntonio, M.D.
Assistant Clinical Professor of Psychiatry and Biobehavioral Sciences, University of California at Los Angeles School of Medicine; Director of Inpatient Adolescent Service, UCLA Neuropsychiatric Institute and Hospital, Los Angeles, California.
48.8. Child Psychiatry: Residential and Inpatient Treatment

Charles DeBattista, M.D., D.M.H.
Clinical Fellow in Affective Disorders, Department of Psychiatry and Behavioral Sciences, Stanford University School of Medicine, Stanford, California.
31.33. Other Pharmacological and Biological Therapies

Rebecca F. Detweiler, Ph.D.
Assistant Professor of Speech-Language Pathology, University of Toronto, Toronto, Ontario, Canada.
37.5. Communication Disorder Not Otherwise Specified

Lynn H. Deutsch, D.O.
Clinical Assistant Professor of Psychiatry, Georgetown University School of Medicine and Health Sciences; Medical Officer, District of Columbia Commission on Mental Health Services, Saint Elizabeth's Campus, Washington, D.C.
7.7. Medical Assessment and Laboratory Testing in Psychiatry

Stephen I. Deutsch, M.D., Ph.D.
Professor and Associate Chairman of Clinical Neurosciences, Department of Psychiatry, Georgetown University School of Medicine and Health Sciences; Chief of Psychiatry Service, Veterans Affairs Medical Center, Washington, D.C.
7.7. Medical Assessment and Laboratory Testing in Psychiatry

Leah J. Dickstein, M.D.
Professor of Psychiatry and Associate Chair for Academic Affairs, Director of Division of Attitudinal and Behavioral Medicine, Department of Psychiatry and Behavioral Sciences, University of Louisville School of Medicine; Staff Psychiatrist, University of Louisville Hospital, Louisville, Kentucky.
27.5. Other Additional Conditions That May Be a Focus of Clinical Attention

Joel E. Dimsdale, M.D.
Professor of Psychiatry, University of California at San Diego School of Medicine, La Jolla, California.
25.9. Stress and Psychiatry

Nancy S. Downs, M.D.
Assistant Clinical Professor of Psychiatry, Associate Director of Residency Training, University of California at San Diego School of Medicine, La Jolla, California.
28.5. Death, Dying, and Bereavement

Martin J. Drell, M.D.
Professor of Clinical Psychiatry and Head of Infant, Child, and Adolescent Psychiatry, Louisiana State University Medical School; Clinical Director of New Orleans Adolescent Hospital, New Orleans, Louisiana.
49.5. Children's Reaction to Illness and Hospitalization

Jennifer J. Dunkin, Ph.D.
Assistant Professor of Psychiatry and Director of Geriatric Psychology and Biobehavioral Sciences Fellowship Program, University of California at Los Angeles School of Medicine, Los Angeles, California.
51.2c. Psychological Changes with Normal Aging

Elisabeth M. Dykens, Ph.D.
Associate Professor of Psychiatry and Biobehavioral Sciences, University of California at Los Angeles School of Medicine; Attending Psychiatrist, UCLA Neuropsychiatric Institute and Hospital, Los Angeles, California.
34. Mental Retardation

James C. Edmondson, M.D., Ph.D.
Clinical Assistant Professor of Neurology, State University of New York at Brooklyn College of Medicine; Assistant Attending, Department of Neurology, Brooklyn Hospital Center; Assistant Attending, Department of Neurology, Long Island College Hospital, Brooklyn, New York.
2.11. Neuropsychiatric Aspects of Neuromuscular Disease;
2.12. Neuropsychiatric Aspects of Child Neurology
28.6. Chronic Pain and the Placebo Effect

Michael F. Egan, M.D.
Director of Clinical Research, Neuroscience Research Center at Saint Elizabeth's Hospital, and Acting Branch Chief of Clinical Research Services Branch, National Institute of Mental Health, National Institutes of Health, Washington, D.C.
2.6. Neuropsychiatric Aspects of Movement Disorders;
12.4. Schizophrenia: Neurobiology

John Richard Elpers, M.D.
Professor of Clinical Psychiatry and Biobehavioral Sciences, University of California at Los Angeles School of Medicine, Los Angeles, California; Vice Chairman, Department of Psychiatry for Planning and Development, and Director of Ambulatory Psychiatric Services, Harbor-UCLA Medical Center, Torrance, California.

52.1. Public Psychiatry

Norbert B. Enzer, M.D.
Professor of Psychiatry and Interim Associate Dean for Community Programs and Graduate Medical Education, Michigan State University College of Human Medicine, East Lansing, Michigan.
49.15. Psychiatric Prevention in Children and Adolescents

Brenda R. Erickson, M.D.
Former Assistant Professor of Psychiatry, University of Nevada School of Medicine, Reno, Nevada.
13.1. Schizoaffective Disorder, Schizophreniform Disorder, and Brief Psychotic Disorder

Spencer Eth, M.D.
Professor of Psychiatry, New York Medical College; Vice Chairman and Clinical Director, Department of Psychiatry, St. Vincents Hospital, New York, New York.
51.6b. Geriatric Psychiatry: Forensic Issues

Dwight L. Evans, M.D.
Professor of Psychiatry, Chair of Department of Psychiatry, Professor of Medicine, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania.
25.10. Behavior and Immunity

Brian Anthony Fallon, M.D., M.P.H.
Associate Professor of Clinical Psychiatry, Columbia University College of Physicians and Surgeons; Attending Psychiatrist, New York State Psychiatric Institute, New York, New York.
2.9. Neuropsychiatric Aspects of Other Infectious Diseases

Beverly J. Fauman, M.D.
Associate Professor of Psychiatry, University of Maryland School of Medicine; Senior Psychiatrist, Walter P. Carter Center, University of Maryland Medical System, Baltimore, Maryland.
29.2. Other Psychiatric Emergencies

Jan Fawcett, M.D.
Stanley G. Harris, Sr., Professor of Psychiatry and Chairman, Department of Psychiatry, Rush Medical College; Director, Rush Institute for Mental Well-Being, Chicago, Illinois.
31.27. Sympathomimetics

Marc D. Feldman, M.D.
Associate Professor of Psychiatry, Vice Chairman for Clinical Services, Medical Director of Center for Psychiatric Medicine, and Director of Division of Adult Psychiatry, Department of Psychiatry and Behavioral Neurobiology, University of Alabama School of Medicine, Birmingham, Alabama.
17. Factitious Disorders

S. Shirley Feldman, Ph.D.
Senior Research Scientist, Division of Child Psychiatry and Child Development, Stanford University School of Medicine; Associate Director of Human Biology Program at Stanford University, Stanford, California.
49.7. Childhood or Adolescent Antisocial Behavior

Eileen B Fennell, Ph.D.
Professor of Clinical and Health Psychology, University of Florida; Professor of Neurology, University of Florida College of Medicine, Gainesville, Florida.
7.6. Neuropsychological and Intellectual Assessment of Children

Wayne S. Fenton, M.D.
Associate Clinical Professor of Psychiatry and Behavioral Sciences, George Washington University School of Medicine and Health Sciences, Washington, D.C.; Director of Research, Chestnut Lodge Hospital, Rockville, Maryland.
12.10. Schizophrenia: Individual Psychotherapy

Calvin J. Flowers, M.D.
Research Fellow, Department of Psychiatry and the Behavioral Sciences, University of Southern California School of Medicine, Los Angeles County and USC Medical Center, Los Angeles, California.
31.5. b-Adrenergic Receptor Antagonists

Charles V. Ford, M.D.
Professor of Psychiatry, Director of Neuropsychiatry Clinic, Department of Psychiatry and Behavioral Neurobiology, University of Alabama School of Medicine, Birmingham, Alabama.
17. Factitious Disorders

Victor M. Fornari, M.D.
Associate Professor of Clinical Psychiatry, New York University School of Medicine, New York, New York; Associate Chairman for Education and Training, Department of Psychiatry, North Shore University Hospital, Manhasset, New York.
49.10. Child Psychiatry: Identity Problem and Borderline Disorders

Sydney Frederick-Osborne, Ph.D.
Postdoctoral Fellow, Department of Psychiatry, University of California at San Francisco School of Medicine, San Francisco, California.
1.11. Psychoneuroendocrinology

Nelson B. Freimer, M.D.
Associate Professor of Psychiatry, University of California at San Francisco School of Medicine, San Francisco, California.
1.18. Genetic Linkage Analysis of the Psychiatric Disorders

M. Gerard Fromm, Ph.D.
Director of Therapeutic Community Program, Austen Riggs Center, Stockbridge, Massachusetts; Faculty, Massachusetts Institute for Psychoanalysis, Cambridge, Massachusetts.
30.9. Eriksonian Clinical Theory and Psychiatric Treatment

Abby J. Fyer, M.D.
Professor of Clinical Psychiatry, Columbia University College of Physicians and Surgeons; Attending Psychiatrist, New York State Psychiatric Institute, New York, New York.
15.4. Anxiety Disorders: Genetics

Glen O. Gabbard, M.D.
Bessie Walker Callaway Distinguished Professor of Psychoanalysis and Education, Karl Menninger School of Psychiatry, The Menninger Clinic; Clinical Professor of Psychiatry, University of Kansas School of Medicine, Wichita, Kansas; Director of Topeka Institute for Psychoanalysis, Topeka, Kansas.
6.1. Psychoanalysis
14.5. Mood Disorders: Psychodynamic Aspects;

15.5. Anxiety Disorders: Psychodynamic Aspects;
30.1. Psychoanalysis and Psychoanalytic Psychotherapy;
30.12. Combined Psychotherapy and Pharmacotherapy

Steven J. Garlow, M.D., Ph.D.
Assistant Professor of Psychiatry and Behavioral Sciences, Emory University School of Medicine, Atlanta, Georgia.
31.22. Nefazodone
31.29. Trazodone

Thomas R. Garrick, M.D.
Professor of Psychiatry and Biobehavioral Sciences, University of California at Los Angeles School of Medicine; Staff Psychiatrist, West Los Angeles Veterans Affairs Ambulatory Care Center, Los Angeles, California.
25.6. Endocrine and Metabolic Disorders

Nori Geary, Ph.D.
Associate Research Professor of Psychiatry, The Joan and Sanford I. Weill Medical College of Cornell University, New York, New York; Research Professor, E. W. Bourne Behavioral Research Laboratory, New York Hospital-Cornell Medical Center, Westchester Division, White Plains, New York.
1.20. Appetite

J. Christian Gillin, M.D.
Professor of Psychiatry, University of California at San Diego School of Medicine, La Jolla, California; Director of Mental Health Clinical Research Center, San Diego Veterans Affairs Healthcare System, San Diego, California.
1.19. Basic Science of Sleep

Michael J. Gitlin, M.D.
Clinical Professor of Psychiatry and Biobehavioral Sciences, University of California at Los Angeles School of Medicine; Director of Mood Disorders Program and Medical Director of Schizophrenia Aftercare Clinic, UCLA Neuropsychiatric Institute and Hospital, Los Angeles, California.
8. Clinical Manifestations of Psychiatric Disorders

Robert N. Golden, M.D.
Professor of Psychiatry and Chair, Department of Psychiatry, University of North Carolina School of Medicine, Chapel Hill, North Carolina.
31.11. Bupropion

Marion Zucker Goldstein, M.D.
Associate Professor of Psychiatry, State University of New York at Buffalo School of Medicine and Biomedical Sciences; Director of Division of Geriatric Psychiatry, University Psychiatry Practice, Erie County Medical Center, Buffalo, New York.
51.6f. Geriatric Psychiatry: Gender Issues;
51.6g. Geriatric Psychiatry: Elder Abuse, Neglect, and Exploitation

Daniel Goleman, Ph.D.
Former Science Editor, *New York Times*, New York, New York.
3.6. Emotional Intelligence

Maureen Fulchiero Gordon, M.D.
Assistant Clinical Professor of Psychiatry and Biobehavioral Sciences, University of California at Los Angeles School of Medicine, Los Angeles, California.
32.2. Normal Child Development

Jack M. Gorman, M.D.
Professor of Psychiatry, Columbia University College of Physicians and Surgeons, New York, New York.
15.1. Anxiety Disorders: Introduction and Overview

Irving I. Gottesman, Ph.D., F.R.C.Psych.(Hon)
Sherell J. Aston Professor, Departments of Psychology and Pediatrics (Medical Genetics), University of Virginia School of Medicine, Charlottesville, Virginia.
1.17. Population Genetic Methods in Psychiatry

Gary L. Gottlieb, M.D., M.B.A.
Professor of Psychiatry, Harvard Medical School, Boston, Massachusetts.
51.5a. Geriatric Psychiatry: Financial Issues

Igor Grant, M.D., F.R.C.P.(C)
Professor of Psychiatry, University of California at San Diego School of Medicine, La Jolla, California; Chief of Ambulatory Care for Psychiatry and Staff Psychiatrist, San Diego Veterans Affairs Healthcare System, San Diego, California.
2.8. Neuropsychiatric Aspects of HIV Infection and AIDS;
5.2. Statistics and Experimental Design

Jack A. Grebb, M.D.
Clinical Professor of Psychiatry, New York University School of Medicine, New York, New York.
1.1. Neural Sciences: Introduction and Overview;
31.1. General Principles of Psychopharmacology

Richard Green, M.D., J.D.
Visiting Professor of Psychiatry, Imperial College School of Medicine; Head of Gender Identity Clinic, Charing Cross Hospital, London, England; Professor of Psychiatry Emeritus, University of California at Los Angeles School of Medicine, Los Angeles, California; Senior Research Fellow, Institute of Criminology, and Affiliated Lecturer, Faculty of Law, University of Cambridge, Cambridge, England.
19.3. Gender Identity Disorders

Marcia Greenleaf, Ph.D.
Assistant Professor of Psychology, Department of Psychiatry, Albert Einstein College of Medicine of Yeshiva University, Bronx, New York.
30.3. Hypnosis

Stanley I. Greenspan, M.D.
Clinical Professor of Psychiatry and Behavioral Sciences and Pediatrics, George Washington University School of Medicine and Health Sciences; Supervising Child Psychoanalyst, Washington Psychoanalytic Institute, Washington, D.C.
3.2. Extending Piaget's Approach to Intellectual Functioning

John H. Greist, M.D.
Clinical Professor of Psychiatry, University of Wisconsin Medical School; Distinguished Senior Scientist. Co-Director of Lithium Information Center, Madison Institute of Medicine, Madison, Wisconsin.
31.18. Lithium

Roland R. Griffiths, Ph.D.

Professor of Psychiatry and Behavioral Sciences, Department of Neurosciences, Johns Hopkins University School of Medicine, Baltimore, Maryland.
11.4. Caffeine-Related Disorders

Lawrence S. Gross, M.D.
Associate Professor of Clinical Psychiatry and Behavioral Sciences, University of Southern California School of Medicine; Director of Outpatient Psychiatry, Cedars-Sinai Medical Center, Los Angeles, California.
31.8. Antihistamines

George T. Grossberg, M.D.
Samuel W. Fordyce Professor of Psychiatry and Chairman, Department of Psychiatry, Saint Louis University School of Medicine, Saint Louis, Missouri.
51.4g. Geriatric Psychiatry: Electroconvulsive Therapy

Peter B. Gruenberg, M.D.
Associate Clinical Professor of Psychiatry and Biobehavioral Sciences, University of California at Los Angeles School of Medicine, Los Angeles, California.
54.2. Ethics in Psychiatry

Frederick G. Guggenheim, M.D.
Marie Wilson Howells Professor of Psychiatry and Chair, Department of Psychiatry and Behavioral Sciences, University of Arkansas for Medical Sciences, Little Rock, Arkansas.
16. Somatoform Disorders

Raquel E. Gur, M.D., Ph.D.
Professor of Psychiatry and Director of Neurospsychiatry, Department of Psychiatry, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania.
12.3. Schizophrenia: Brain Structure and Function

Ruben C. Gur, Ph.D.
Professor of Psychiatry and Director of Neuropsychology, Department of Psychiatry, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania.
12.3. Schizophrenia: Brain Structure and Function

Alan S. Gurman, Ph.D.
Professor of Psychiatry, Director of Couple-Family Clinic, Chief Psychologist, University of Wisconsin Medical School, Madison, Wisconsin.
30.5. Family Therapy and Couple Therapy

Kathleen Y. Haaland, Ph.D.
Professor of Psychiatry, University of New Mexico School of Medicine; Staff Psychologist, Albuquerque Veterans Affairs Medical Center, Albuquerque, New Mexico.
7.4. Clinical Neuropsychology and Intellectual Assessment of Adults

Katherine A. Halmi, M.D.
Professor of Psychiatry, The Joan and Sanford I. Weill Medical College of Cornell University, New York, New York; Director of Eating Disorders Program, New York Hospital-Cornell Medical Center, Westchester Division, White Plains, New York.
20. Eating Disorders

M. Jackuelyn Harris, M.D.
Associate Professor of Psychiatry, University of California at San Diego School of Medicine, La Jolla, California; Co-Director of Geriatric Psychiatry Program, San Diego Veterans Affairs Healthcare System, San Diego, California.
51.3f. Geriatric Psychiatry: Schizophrenia and Delusional Disorders

Jennifer F. Havens, M.D.
Assistant Professor of Clinical Psychiatry, Columbia University College of Physicians and Surgeons; Director of Special Needs Clinic, Pediatric Psychiatry, Columbia-Presbyterian Medical Center, New York, New York.
49.6. Child Psychiatry: Psychiatric Sequelae of HIV and AIDS

Donald P. Hay, M.D.
Associate Professor of Psychiatry, Director of Geriatric Pscychiatry Programs, University of Colorado Health Sciences Center, Denver, Colorado.
51.4g. Geriatric Psychiatry: Electroconvulsive Therapy

Stephaine L. Heard, M.D.
Clinical Assistant Professor of Psychiatry, Michigan State University College of Human Medicine, Kalamazoo Center for Medical Studies, Kalamazoo, Michigan.
49.15. Psychiatric Prevention in Children and Adolescents

A. Scott Henderson, M.D., D.Sc., F.R.A.C.P., F.R.A.N.Z.C.P., F.R.C.P., F.R.C.Psych.
Professor, Australian National University; Director of National Health and Medical Research Council, Psychiatric Epidemiology Research Centre, Canberra, Capital Territory, Australia.
51.1b. Geriatric Psychiatry: Epidemiology of Psychiatric Disorders

Victoria C. Hendrick, M.D.
Assistant Professor of Psychiatry and Biobehavioral Sciences, Director of Pregnancy and Postpartum Mood Disorders Program, University of California at Los Angeles School of Medicine, Los Angeles, California.
25.6. Endocrine and Metabolic Disorders

Hugh C. Hendrie, M.B., Ch.B.
Albert E. Sterne Professor of Psychiatry and Chairman, Department of Psychiatry, Indiana University School of Medicine, Indianapolis, Indiana.
51.6d. Geriatric Psychiatry: Sociocultural Issues

Stephen P. Herman, M.D.
Associate Clinical Professor of Psychiatry, Mount Sinai School of Medicine, New York, New York.
49.12. Forensic Child and Adolescent Psychiatry

Jerry D. Heston, M.D.
Associate Professor of Psychiatry, University of Tennessee at Memphis College of Medicine; Medical Director of Child and Adolescent Day Treatment Services, University of Tennessee Medical Center, Memphis, Tennessee.
48.7. Child Psychiatry: Partial Hospital and Ambulatory Behavioral Health Services

Euthymia D. Hibbs, Ph.D.
Chief of Child and Adolescent Psychosocial Treatment Research, Child and Adolescent Treatment and Preventive Intervention Research Branch, Division of Services and Intervention Research, National Institute of Mental Health, National Institutes of Health, Rockville, Maryland; Adjunct Associate Professor of Psychiatry; George Washington University School of Medicine and Health Sciences, Washington, D.C.
48.2. Child Psychiatry, Short-Term Psychotherapy

Robert M. A. Hirschfeld, M.D.
Titus H. Harris Distinguished Professor of Psychiatry and Chair, Department of Psychiatry and Behavioral Sciences, University of Texas Medical School at Galveston,

Galveston, Texas.
14.9. Mood Disorders: Psychotherapy

Max Hirshkowitz, Ph.D.
Associate Professor of Psychiatry, Associate Director of Sleep Disorders Center, Baylor College of Medicine; Director of Sleep Research Center, Houston Veterans Affairs Medical Center, Houston, Texas.
21. Sleep Disorders

Robert M. Hodapp, Ph.D.
Associate Professor of Education and Psychological Studies in Education, University of California at Los Angeles, Los Angeles, California.
34. Mental Retardation

Ralph E. Hoffman, M.D.
Associate Professor of Psychiatry, Yale University School of Medicine; Medical Director, Yale Psychiatric Institute, New Haven, Connecticut.
12.6. Schizophrenia: Psychodynamic to Neurodynamic Theories

Jimmie C. Holland, M.D.
Professor of Psychiatry, The Joan and Sanford I. Weill Medical College of Cornell University; Chief of Psychiatry Services and Wayne E. Chapman Chair in Psychiatric Oncology, Memorial Sloan-Kettering Cancer Center, New York, New York.
25.11. Psycho-Oncology

Eric Hollander, M.D.
Professor of Psychiatry, Director of Psychopharmacology
Mount Sinai School of Medicine, New York, New York.
18.5. Dissociative Disorders Not Otherwise Specified

Nancy L. Hornstein, M.D.
Attending Staff, Condell Medical Center, Libertyville, Illinois; Attending Staff, Victory Memorial Hospital, Waukegan, Illinois.
49.8. Dissociative Disorders in Children and Adolescents

Thomas B. Horvath, M.D., F.R.A.C.P.
Professor of Psychiatry, Baylor College of Medicine; Chief of Staff, Houston Veterans Affairs Medical Center, Houston, Texas.
51.5c. Geriatric Psychiatry: Veterans Affairs Medical Centers and Psychogeriatric Services

Ewald Horwath, M.D., M.Sc.
Associate Clinical Professor of Psychiatry, Columbia University College of Physicians and Surgeons; Director of Intensive Care Unit, Washington Heights Community Service, New York State Psychiatric Institute, New York, New York.
15.2. Anxiety Disorders: Epidemiology

Kenneth I. Howard, Ph.D.
Professor of Psychology, Northwestern University, Evanston, Illinois; Professor of Psychiatry, Northwestern University Medical School, Chicago, Illinois.
30.11. Evaluation of Psychotherapy

Charles Campbell Hughes, Ph.D.*
Professor of Anthropology, University of Utah; Professor of Family and Preventative Medicine, University of Utah School of Medicine, Salt Lake City, Utah.
13.3. Acute and Transient Psychotic Disorders and Culture-Bound Syndromes

John R. Hughes, M.D.
Professor of Psychiatry, Psychology, and Family Practice, University of Vermont School of Medicine, Burlington, Vermont.
11.9. Nicotine-Related Disorders

Thomas M. Hyde, M.D., Ph.D.
Special Expert in Neurology, Neurology Consultation Service, Clinical Brain Disorders Branch, National Institute of Mental Health Neuroscience Center at Saint Elizabeth's Hospital, National Institutes of Health, Washington, D.C.
12.4. Schizophrenia: Neurobiology

Steven E. Hyman, M.D.
Director of National Institute of Mental Health, National Institutes of Health, Bethesda, Maryland.
1.10. Basic Molecular Neurobiology

Robert B. Innis, M.D., Ph.D.
Professor of Psychiatry and Pharmacology, Director of Neurochemical Brain Imaging Program, Yale University School of Medicine, New Haven, Connecticut.
1.15. Principles of Neuroimaging: Radiotracer Techniques

Keith E. Isenberg, M.D.
Associate Professor of Psychiatry, Washington University School of Medicine; Research Associate Professor, Saint Louis College of Pharmacy; Director of Electroconvulsive Therapy (ECT) Service, Barnes-Jewish Hospital, Saint Louis, Missouri.
1.9. Basic Electrophysiology
31.31. Electroconvulsive Therapy

Rolf G. Jacob, M.D.
Associate Professor of Psychiatry and Otolaryngology, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania.
30.2. Behavior Therapy

Ari B. Jaffe, M.D.
Clinical Instructor of Psychiatry, New York University School of Medicine, New York, New York.
11.10. Opioid-Related Disorders

Jerome H. Jaffe, M.D.
Clinical Professor of Psychiatry
University of Maryland School of Medicine, Baltimore, Maryland.
11.1. Substance-Related Disorders: Introduction and Overview;
11.3. Amphetamine (or Amphetamine-like)-Related Disorders;
11.6. Cocaine-Related Disorders;
11.10. Opioid-Related Disorders

Philip G. Janicak, M.D.
Professor of Psychiatry
Medical Director of the Psychiatric Clinical Research Center, University of Illinois at Chicago College of Medicine, Chicago, Illinois.
31.2. Pharmacokinetics and Drug Interactions

Lissy F. Jarvik, M.D., Ph.D.
Professor Emeritus of Psychiatry and Biobehavioral Sciences, University of California at Los Angeles School of Medicine; Distinguished Physician (Emeritus), UCLA Neuropsychiatric Institute and Hospital, Staff Psychiatrist, West Los Angeles Veterans Affairs Ambulatory Care Center, Los Angeles, California.
51.1a. Geriatric Psychiatry: Introduction;
51.2a. Psychiatric Examination of the Older Patient;
51.4a. Geriatric Psychiatry: Treatment of Psychiatric Disorders: Introduction and Overview

James W. Jefferson, M.D.
Clinical Professor of Psychiatry, University of Wisconsin Medical School; Distinguished Senior Scientist, Co-Director of Lithium Information Center, Madison Institute of Medicine, Madison, Wisconsin.
31.18. Lithium

Dilip V. Jeste, M.D.
Professor of Psychiatry and Neuroscience, University of California at San Diego School of Medicine, La Jolla, California; Director of Geriatric Psychiatry Clinical Research Center, San Diego Veterans Affairs Healthcare System, San Diego, California.
51.3f. Geriatric Psychiatry: Schizophrenia and Delusional Disorders

Russell T. Joffe, M.D.
Professor of Psychiatry and Chair, Department of Psychiatry, McMaster University Faculty of Health Sciences; Psychiatrist-in-Chief, Hamilton Psychiatric Hospital, Hamilton, Ontario, Canada.
31.28. Thyroid Hormones

Carla J. Johnson, Ph.D.
Associate Professor of Speech-Language Pathology, University of Toronto, Toronto, Ontario, Canada.
37.1. Expressive Language Disorder;
37.2. Mixed Receptive-Expressive Language Disorder;
37.3. Phonological Disorder

Ricardo E. Jorge, M.D.
Associate Research Scientist, Department of Psychiatry, University of Iowa College of Medicine; Attending Psychiatrist, University of Iowa Hospitals and Clinics, Iowa City, Iowa.
2.5. Neuropsychiatric Aspects of Traumatic Brain Injury

Allan M. Josephson, M.D.
Professor of Psychiatry and Chief of Psychiatry and Health Behavior, Section of Child, Adolescent, and Family Psychiatry, Medical College of Georgia; Director of Clinical Services for Psychiatry, Medical College of Georgia Hospital and Clinics, Augusta, Georgia.
48.5. Child Psychiatry: Family Therapy

Robert M. Kaplan, Ph.D.
Professor of Family and Preventive Medicine and Chief of Division of Health Care Sciences, University of California at San Diego School of Medicine, La Jolla, California.
5.2. Statistics and Experimental Design

Craig N. Karson, M.D.
Professor of Psychiatry and Pathology, University of Arkansas for Medical Sciences; Chief of Staff, John L. McClellan Memorial Hospital, Little Rock, Arkansas.
1.16. Principles of Neuroimaging: Magnetic Resonance Techniques

Julia E. Kasl-Godley, Ph.D.
Research Associate, Department of Psychiatry, University of California at Los Angeles School of Medicine, Los Angeles, California.
51.2c. Psychological Changes With Normal Aging

Ira R. Katz, M.D., Ph.D.
Professor of Psychiatry, University of Pennsylvania School of Medicine; Director of Section of Geriatric Psychiatry, Philadelphia Veterans Affairs Medical Center, Philadelphia, Pennsylvania.
51.6a. Geriatric Psychiatry: Psychiatric Aspects of Long-Term Care

Jeffrey William Katzman, M.D.
Assistant Clinical Professor of Psychiatry, University of New Mexico School of Medicine; Acting Chief of Albuquerque Veterans Affairs Medical Center, Albuquerque, New Mexico.
22. Impulse-Control Disorders Not Elsewhere Classified

Paul E. Keck, Jr., M.D.
Professor of Psychiatry, University of Cincinnati College of Medicine, Cincinnati, Ohio.
31.7b. Valproate

Francis J. Keefe, Ph.D.
Adjunct Professor of Psychiatry and Biobehavioral Sciences, Duke University School of Medicine, Durham, North Carolina.
25.9. Stress and Psychiatry

Samuel J. Keith, M.D.
Professor of Psychiatry and Chairman, Department of Psychiatry, University of New Mexico School of Medicine, Albuquerque, New Mexico.
12.9. Schizophrenia: Psychosocial Treatment;
13.1. Schizoaffective Disorder, Schizophreniform Disorder, and Brief Psychotic Disorder

Jeffrey E. Kelsey, M.D., Ph.D.
Assistant Professor of Psychiatry and Behavioral Sciences, Director of Mood and Anxiety Disorders Clinical Trials Program, Emory University School of Medicine, Atlanta, Georgia.
31.25a. Selective Serotonin Reuptake Inhibitors: Introduction and Overview;
31.25b. Citalopram;
31.25c. Fluoxetine;
31.25d. Fluvoxamine;
31.25e. Paroxetine;
31.25f. Sertraline

John R. Kelsoe, M.D.
Associate Professor of Psychiatry, University of California at San Diego School of Medicine, La Jolla, California.
14.3. Mood Disorders: Genetics

Kenneth S. Kendler, M.D.
Professor of Psychiatry and Human Genetics, Virginia Institute for Psychiatric and Behavioral Genetics, Medical College of Virginia at Virginia Commonwealth

University, Richmond, Virginia.
12.5. Schizophrenia: Genetics

Sidney H. Kennedy, M.D.
Professor of Psychiatry, University of Toronto Faculty of Medicine; Head of Mood and Anxiety Disorders Program, Centre for Addiction and Mental Health, Toronto, Ontario, Canada.
31.20. Monoamine Oxidase Inhibitors

Ronald C. Kessler, Ph.D.
Professor of Sociology, Department of Health Care Policy, Harvard Medical School, Boston, Massachusetts.
4.2. Sociology and Psychiatry

Bryan H. King, M.D.
Professor of Psychiatry and Pediatrics, Dartmouth Medical School, Hanover, New Hampshire; Director of Child and Adolescent Psychiatry, Children's Hospital at Dartmouth, Dartmouth Hitchock Medical Center, Lebanon, New Hampshire.
34. Mental Retardation

Deborah A. King, Ph.D.
Associate Professor of Psychiatry (Psychology), University of Rochester School of Medicine and Dentistry; Staff Psychologist and Director of Geriatric Psychiatry Services, Strong Memorial Hospital, Rochester, New York.
51.4k. Interventions and Consultation With Families of Older Adults

Robert A. King, M.D.
Professor of Child Psychiatry, Medical Director of Tic Disorder/Obsessive-Compulsive Disorder Specialty Clinic, Yale Child Study Center, Yale University School of Medicine; Associate Director of Child Psychiatry Consultation-Liaison Service in Pediatrics, Yale-New Haven Hospital, New Haven, Connecticut.
33. Psychiatric Examination of the Infant, Child, and Adolescent

Darrell G. Kirch, M.D.
Professor of Psychiatry and Health Behavior and Dean, Schools of Medicine and Graduate Studies, Medical College of Georgia, Augusta, Georgia.
28.4. Genetic Counseling

Thomas J. Kiresuk, Ph.D.
Professor of Health Psychology, Department of Psychiatry, University of Minnesota Medical School; Chief Clinical Psychologist, Hennepin County Medical Center; Director of Center for Addiction and Alternative Medicine Research, Minneapolis Medical Research Foundation, Minneapolis, Minnesota.
28.8. Alternative and Complimentary Health Practices

Laurel J. Kiser, Ph.D., M.B.A.
Professor of Psychiatry, University of Tennessee at Memphis College of Medicine; Executive Director of Child and Adolescent Day Treatment Services, University of Tennessee Medical Center, Memphis, Tennessee.
48.7. Child Psychiatry: Partial Hospital and Ambulatory Behavioral Health Services

Herbert D. Kleber, M.D.
Professor of Psychiatry, Director of Division on Substance Abuse, Department of Psychiatry, Columbia University College of Physicians and Surgeons; Executive Vice President and Medical Director, National Center on Addiction and Substance Abuse at Columbia University, New York, New York.
31.23. Opioid Agonists

Arthur Kleinman, M.D.
Presley Professor of Medical Anthropology and Psychiatry, Chairman, Department of Social Medicine, Harvard Medical School, Boston, Massachusetts; Professor of Social Anthropology, Harvard University, Cambridge, Massachusetts.
4.1. Anthropology and Psychiatry

Ami Klin, Ph.D.
Harris Associate Professor of Child Psychology and Psychiatry, Yale University School of Medicine, New Haven, Connecticut.
38. Pervasive Developmental Disorders

Alex Kopelowicz, M.D.
Assistant Professor of Psychiatry and Biobehavioral Sciences, University of California at Los Angeles School of Medicine, Los Angeles, California; Director of San Fernando Mental Health Center, Mission Hills, California.
52.4. Psychiatric Rehabilitation

Kathryn J. Kotrla, M.D.
Assistant Professor of Psychiatry and Behavioral Sciences, Baylor College of Medicine; Chief of Psychiatry, Ben Taub General Hospital, Houston, Texas.
1.3. Developmental Neurobiology

Peter D. Kramer, M.D.
Clinical Professor of Psychiatry, Brown University School of Medicine, Providence, Rhode Island.
55.3. The Future of Psychiatry

Ronald F. Krasner, M.D.
Assistant Professor of Psychiatry, Director of Psychiatric Education, and Vice Chairman, Department of Psychiatry and Behavioral Sciences, Northwestern University Medical School, Chicago, Illinois.
30.11. Evaluation of Psychotherapy

Suchitra Krishnan-Sarin, Ph.D.
Assistant Professor of Psychiatry, Yale University School of Medicine, New Haven, Connecticut.
31.21. Naltrexone

Robert Kroll, Ph.D.
Assistant Professor of Speech-Language Pathology, University of Toronto; Assistant Professor of Psychiatry, University of Toronto Faculty of Medicine; Director of Speech Foundation of Ontario Stuttering Centre; Toronto, Ontario, Canada.
37.4. Stuttering

Anand Kumar, M.D.
Associate Professor of Psychiatry and Biobehavioral Sciences, University of California at Los Angeles School of Medicine; Attending Psychiatrist, Geriatric Service, UCLA Neuropsychiatric Institute and Hospital, Los Angeles, California.
51.2f. Geriatric Psychiatry: Neuroimaging: Special Issues

Lawrence A. Labbate, M.D.
Associate Professor of Psychiatry and Behavioral Sciences, Medical University of South Carolina; Director of Outpatient Mental Health Service, Ralph H. Johnson Veterans Affairs Medical Center, Charleston, South Carolina; Associate Professor of Clinical Psychiatry, Uniformed Services University of the Health Sciences F. Edward Hébert School of Medicine, Bethesda, Maryland.

31.9. Barbiturates and Similarly Acting Substances
31.14. Chloral Hydrate

Asenath LaRue, Ph.D.
Professor of Psychiatry, University of New Mexico School of Medicine, Albuquerque, New Mexico.
7.4. Clinical Neurology and Intellectual Assessment of Adults

John Lauriello, M.D.
Assistant Professor of Psychiatry, University of New Mexico School of Medicine, Albuquerque, New Mexico.
12.9. Schizophrenia: Psychosocial Treatment;
13.1. Schizoaffective Disorder, Schizophreniform Disorder, and Brief Psychotic Disorder

Eleanor P. Lavretsky, M.D., Ph.D.
Research Psychopharmacologist, UCLA Neuropsychiatric Institute and Hospital, Los Angeles, California.
51.2a. Psychiatric Examination of the Older Patient

Helen Lavretsky, M.D.
Assistant Professor of Psychiatry, University of California at Los Angeles School of Medicine, Los Angeles, California.
51.4e. Geriatric Psychiatry: Psychopharmacology: Antipsychotic Drugs

Lawrence W. Lazarus, M.D.
Assistant Professor of Psychiatry, Director of Geropsychiatry Fellowship Program, Rush Medical College, Chicago, Illinois.
51.4i. Geriatric Psychiatry: Individual Psychotherapy

Paul Leber, M.D.
Associate Clinical Professor of Psychiatry and Behavioral Science, George Washington University School of Medicine and Health Sciences, Washington, D.C.; Former Director, Division of Neuropharmacological Drug Product, Center for Drug Evaluation and Research, Food and Drug Administration, Rockville, Maryland.
31.3. Drug Development and Approval Process in the United States

Jay L. Lebow, Ph.D.
Senior Therapist and Research Consultant, Family Institute, Northwestern University, Evanston, Illinois.
30.5. Family Therapy and Couple Therapy

Barry D. Lebowitz, Ph.D.
Chief of Adult and Geriatric Treatment and Preventive Intervention, National Institute of Mental Health, National Institutes of Health, Rockville, Maryland; Adjunct Faculty, Department of Psychiatry, Georgetown University School of Medicine and Health Sciences, Washington, D.C.
51.5d. Community Services for the Elderly Psychiatric Patient

Marguerite S. Lederberg, M.D.
Clinical Professor of Psychiatry, The Joan and Sanford I. Weill Medical College of Cornell University; Attending Psychiatrist, Memorial Sloan-Kettering Cancer Center, New York, New York.
25.11. Psycho-Oncology

Sing Lee, M.D.
Associate Professor of Psychiatry, Chinese University of Hong Kong, Hong Kong, China; Lecturer of Social Medicine, Harvard Medical School, Boston, Massachusetts.
9.2. International Psychiatric Diagnosis

Heinz E. Lehmann, M.D.*
Professor Emeritus of Psychiatry, McGill University Faculty of Medicine, Montreal, Quebec, Canada; Deputy Commissioner for Research, Office of Mental Health, Albany, New York.
12.7. Schizophrenia: Clinical Features

Fredda L. Leiter, M.D.
Clinical Instructor of Psychiatry and Biobehavioral Sciences, University of California at Los Angeles School of Medicine; Attending Psychiatrist, UCLA Neuropsychiatric Institute and Hospital, Los Angeles, California.
51.4a. Geriatric Psychiatry: Treatment of Psychiatric Disorders: Introduction and Overview

Henrietta L. Leonard, M.D.
Professor of Psychiatry and Human Behavior, Brown University School of Medicine; Director of Training, Child and Adolescent Psychiatry Residency Program and Combined Pediatrics-Psychiatry-Child Psychiatry Residency Program, Rhode Island Hospital, Providence, Rhode Island.
46.4. Selective Mutism

Ira M. Lesser, M.D.
Professor of Psychiatry and Biobehavioral Sciences, University of California at Los Angeles School of Medicine, Los Angeles, California; Director of Residency Training, Vice Chair for Academic Affairs, Department of Psychiatry, Harbor-UCLA Medical Center, Torrance, California.
51.3c. Geriatric Psychiatry: Anxiety Disorders

Molyn Leszcz, M.D., F.R.C.P.(C)
Assistant Professor of Psychiatry, Head of Psychotherapy Program, University of Toronto Faculty of Medicine, Toronto, Ontario, Canada.
51.4l. Geriatric Psychiatry: Group Therapy

Eric S. Levine, Ph.D.
Assistant Professor of Pharmacology, University of Connecticut School of Medicine, Farmington, Connecticut.
1.7. Neurotrophic Factors

Stephen B. Levine, M.D.
Clinical Professor of Psychiatry
Case Western Reserve University School of Medicine, Clinical Staff, University Hospitals of Cleveland, Cleveland, Ohio; Co-Director of The Center for Marital and Sexual Health, Beachwood, Ohio.
19.2. Paraphilias

David A. Lewis, M.D.
Professor of Psychiatry and Neuroscience, University of Pittsburgh School of Medicine; Associate Director for Basic Research, Western Psychiatric Institute and Clinic, Pittsburgh, Pennsylvania.
1.2. Functional Neuroanatomy

Owen Lewis, M.D.
Associate Clinical Professor of Psychiatry, Columbia University College of Physicians and Surgeons; Director of Residency Education in Child Psychiatry, New York State Psychiatric Institute, New York, New York.

48.1. Child Psychiatry: Individual Psychodynamic Psychotherapy

Robert Paul Liberman, M.D.
Professor of Psychiatry and Biobehavioral Sciences, University of California at Los Angeles School of Medicine; Director of Clinical Research Center for Serious Mental Illnesses, Los Angeles, California.
52.4. Psychiatric Rehabilitation

Keh-Ming Lin, M.D., M.P.H.
Professor of Psychiatry and Biobehavioral Sciences, University of California at Los Angeles School of Medicine, Los Angeles, California.
13.3. Acute and Transient Psychotic Disorders and Culture-Bound Syndromes

Mark S. Lipian, M.D., Ph.D.
Assistant Clinical Professor of Psychiatry and Biobehavioral Sciences, University of California at Los Angeles School of Medicine, Los Angeles, California; Associate Clinical Professor of Psychiatry and Human Behavior, University of California at Irvine College of Medicine, Irvine, California; Medical Director of Conditional Release Program of Orange County, Santa Ana, California.
27.2. Malingering

Mack Lipkin, Jr., M.D.
Professor of Clinical Medicine and Director of Division of Primary Care, New York University School of Medicine, New York, New York.
28.1. Primary Care and Psychiatry

Richard J. Loewenstein, M.D.
Medical Director, Trauma Disorders, Sheppard Pratt Health System, Baltimore, Maryland.
18.3. Dissociative Identity Disorder

Joan L. Luby, M.D.
Assistant Professor of Psychiatry (Child), Director of Preschool and Infant Clinic, Department of Psychiatry, Washington University School of Medicine, Saint Louis, Missouri.
44.2. Stereotypic Movement Disorder of Infancy and Disorders of Infancy and Early Childhood Not Otherwise Specified

R. Bruce Lydiard, Ph.D., M.D.
Professor of Psychiatry and Behavioral Sciences, Director of Psychopharmacology Unit and Clinical Psychopharmacology Research Division, Medical University of South Carolina, Charleston, South Carolina.
31.12. Buspirone

Jeffrey M. Lyness, M.D.
Assistant Professor of Psychiatry, University of Rochester School of Medicine and Dentistry, Rochester, New York.
10. Delirium, Dementia, and Amnestic and Other Cognitive Disorders

Wayne Macfadden, M.D.
Clinical Assistant Professor of Psychiatry, University of Pennsylvania School of Medicine; Chief of Inpatient Dual Diagnosis Unit, Philadelphia Veterans Affairs Medical Center, Philadelphia, Pennsylvania.
11.5. Cannabis-Related Disorders

Robert T. Malison, M.D.
Assistant Professor of Psychiatry, Yale University School of Medicine, New Haven, Connecticut.
1.15. Principles of Neuroimaging: Radiotracer Techniques

Facundo F. Manes, M.D.
Research Fellow, Department of Psychiatry, University of Iowa College of Medicine, Iowa City, Iowa.
2.3. Neuropsychiatric Aspects of Brain Tumors

Myrl R. S. Manley, M.D.
Associate Professor of Clinical Psychiatry, Director of Medical Student Education in Psychiatry
New York University School of Medicine, New York, New York.
7.1. Psychiatric Interview, History, and Mental Status Examination

Theo C. Manschreck, M.D., M.P.H.
Professor of Psychiatry and Human Behavior, Director of Laboratory for Clinical and Experimental Psychopathology, Director of Division of Public Psychiatry, Director of Schizophrenia and Related Psychosis Research, Brown University School of Medicine, Providence, Rhode Island.
13.2. Delusional Disorder and Shared Psychotic Disorder

John S. March, M.D., M.P.H.
Associate Professor of Psychiatry and Director of Programs in Pediatric Anxiety Disorders and Psychopharmacology, Division of Child and Adolescent Psychiatry, Department of Psychiatry, Duke University School of Medicine; Associate Professor of Psychology: Social and Health Sciences, Duke University, Durham, North Carolina.
48.3. Child Psychiatry: Cognitive-Behavioral Psychotherapy

Stephen R. Marder, M.D.
Professor of Psychiatry and Biobehavioral Sciences, University of California at Los Angeles School of Medicine; Director of Mental Health Services and Chief of Psychiatry, West Los Angeles Veterans Affairs Ambulatory Care Center, Los Angeles, California.
12.8. Schizophrenia: Somatic Treatment;
31.17. Dopamine Receptor Antagonists (Typical Antipsychotics);
31.26. Serotonin-Dopamine Antagonists

Deborah B. Marin, M.D.
Assistant Professor of Psychiatry and Geriatrics, Mount Sinai School of Medicine; Director of Division of Geriatric Psychiatry, Mount Sinai Medical Center, New York, New York.
51.6c. Geriatric Psychiatry: Ethical Issues

John C. Markowitz, M.D.
Associate Professor of Psychiatry, The Joan and Sanford I. Weill Medical College of Cornell University, New York, New York.
30.7. Interpersonal Psychotherapy

Carol A. Mathews, M.D.
Research Fellow, Department of Psychiatry, University of California at San Francisco School of Medicine, San Francisco, California.
1.18. Genetic Linkage Analysis of the Psychiatric Disorders

Richard E. Mattison, M.D.
Clinical Professor of Psychiatry and Director of School Consultation, Department of Psychiatry and Behavioral Science, State University of New York at Stony Brook School of Medicine, Stony Brook, New York.

49.14. School Consultation

Jeffrey E. Max, M.B.B.Ch.
Associate Professor-In-Residence, University of California at San Diego School of Medicine, La Jolla, California; Director of Neuropsychiatric Research, Children's Hospital and Health Center, San Diego, California.
2.5. Neuropsychiatric Aspects of Traumatic Brain Injury

Jon M. McClellan, M.D.
Assistant Professor of Psychiatry and Behavioral Sciences, University of Washington School of Medicine, Seattle, Washington; Medical Director, Child Study and Treatment Center, Lakewood, Washington.
47. Early-Onset Schizophrenia

James T. McCracken, M.D.
Professor-in-Residence of Psychiatry and Biobehavioral Sciences, University of California at Los Angeles School of Medicine; Director of Division of Child and Adolescent Psychiatry, UCLA Neuropsychiatric Institute and Hospital, Los Angeles, California.
39.1. Attention-Deficit Disorders
42. Tic Disorders

Robert R. McCrae, Ph.D.
Research Psychologist, Personality, Stress and Coping Section, Gerontology Research Center, National Institute on Aging, National Institutes of Health, Baltimore, Maryland.
6.4. Approaches Derived From Philosophy and Psychology

John Stephen McDaniel, M.D.
Associate Professor of Psychiatry and Behavioral Sciences, Department of Psychiatry and Behavioral Sciences, Emory University School of Medicine, Atlanta, Georgia.
25.1. History, Classification, and Current Trends in Psychosomatic Medicine

Susan L. McElroy, M.D.
Professor of Psychiatry, University of Cincinnati College of Medicine, Cincinnati, Ohio.
31.7b. Valproate

Thomas H. McGlashan, M.D.
Professor of Psychiatry, Yale University School of Medicine; Executive Director, Yale Psychiatric Institute, New Haven, Connecticut.
12.6. Schizophrenia: Psychodynamic to Neurodynamic Theories;
12.10. Schizophrenia: Individual Psychotherapy

James J. McGough, M.D.
Associate Clinical Professor of Psychiatry and Biobehavioral Sciences, Division of Child and Adolescent Psychiatry, University of California at Los Angeles School of Medicine; Associate Director of Outpatient Service, UCLA Neuropsychiatric Institute and Hospital, Los Angeles, California.
27.4. Borderline Intellectual Functioning and Academic Problem

Michael T. McGuire, M.D.
Professor of Psychiatry and Biobehavioral Sciences, University of California at Los Angeles School of Medicine; Attending Psychiatrist, UCLA Neuropsychiatric Institute and Hospital, Los Angeles, California.
4.3. Evolutionary Biology and Psychiatry

Kevin F. McKenna, M.D., Ph.D.
Clinical Associate Professor of Psychiatry, University of Alberta Faculty of Medicine and Dentistry, Edmonton, Alberta, Canada.
31.20. Monoamine Oxidase Inhibitors

William T. McKinney, Jr., M.D.
Helen and Norman Asher Professor of Psychiatry and Behavioral Sciences, Northwestern University Medical School; Director of The Asher Center for the Study and Treatment of Depressive Disorders; Clinical Staff, Northwestern Memorial Hospital, Chicago, Illinois.
5.4. Animal Research and Its Relevance to Psychiatry

Claude Mellins, Ph.D.
Assistant Professor of Clinical Psychology in Psychiatry, Columbia University College of Physicians and Surgeons; Research Scientist, HIV Center for Clinical and Behavioral Studies, New York State Psychiatric Institute; Co-Director of Speech Needs Clinic, Pediatric Psychiatry, Columbia-Presbyterian Medical Center, New York, New York.
49.6. Child Psychiatry: Psychiatric Sequelae of HIV and AIDS

Mario F. Mendez, M.D., Ph.D.
Associate Professor of Neurology, Psychiatry, and Biobehavioral Sciences, University of California at Los Angeles School of Medicine; Director of Neurobehavioral Unit, West Los Angeles Veterans Affairs Ambulatory Care Center, Los Angeles, California.
2.4. Neuropsychiatric Aspects of Epilepsy

W. Walter Menninger, M.D.
J. Cotter Hirschberg Professor and Former Dean, Karl Menninger School of Psychiatry and Mental Health Sciences, Chief Executive Officer of The Menninger Foundation and Clinic; Clinical Professor of Psychiatry, University of Kansas School of Medicine, Kansas City, Kansas; Instructor, Topeka Institute for Psychoanalysis, Topeka, Kansas.
52.3. Role of the Psychiatric Hospital in the Treatment of Mental Illness

James R. Merikangas, M.D.
Lecturer of Psychiatry, Yale University School of Medicine; Attending in Neurology, Yale-New Haven Hospital, New Haven, Connecticut.
2.10. Neuropsychiatric Aspects of Headache

Kathleen Ries Merikangas, Ph.D.
Professor of Epidemiology and Psychiatry and Director of Geriatric Epidemiology Research Unit, Yale University School of Medicine, New Haven, Connecticut.
2.10. Neuropsychiatric Aspects of Headache

Jonathan M. Meyer, M.D.
Adjunct Assistant Professor of Psychiatry, Oregon Health Sciences University School of Medicine, Portland, Oregon.
31.6. Anticholinergics and Amantadine

Juan E. Mezzich, M.D., Ph.D.
Professor of Psychiatry, Mount Sinai School of Medicine; Director of Division of Psychiatric Epidemiology and International Center for Mental Health, Mount Sinai Medical Center, New York, New York.
9.2. International Psychiatric Diagnosis;
13.3. Acute and Transient Psychotic Disorders and Culture-Bound Syndromes;

23. Adjustment Disorders

Edwin J. Mikkelson, M.D.
Associate Professor of Psychiatry, Harvard Medical School; Medical Director, Mentor Clinical Care; Consultant, Massachusetts Department of Mental Retardation, Boston, Massachusetts.
43. Elimination Disorders

Andrew H. Miller, M.D.
Associate Professor of Psychiatry and Behavioral Sciences and Emory University School of Medicine, Atlanta, Georgia.
1.12. Immune System and Central Nervous System Interactions

Marvin J. Miller, M.D.
Assistant Professor of Psychiatry, Indiana University School of Medicine; Staff Psychiatrist, Larue Carter Memorial Hospital, Indianapolis, Indiana.
7.9. Computer-Based Testing of the Psychiatric Patient

Mark J. Mills, J.D., M.D.
Clinical Professor of Psychiatry and Biobehavioral Sciences, University of California at Los Angeles School of Medicine, Los Angeles, California.
27.2. Malingering

Klaus Minde, M.D., F.R.C.P.(C)
Professor of Psychiatry and Pediatrics and Chairman, Division of Child Psychiatry, McGill University Faculty of Medicine; Director of Department of Psychiatry, Montreal Children's Hospital, Montreal, Quebec, Canada.
49.1. Psychiatric Aspects of Day Care

Paul C. Mohl, M.D.
Professor of Psychiatry, University of Texas Southwestern Medical School; Director of Psychiatric Residency Training, University of Texas Southwestern Medical Center, Dallas, Texas.
6.3. Other Psychodynamic Schools

Steven O. Moldin, Ph.D.
Chief of Genetics Research Branch, Division of Basic and Clinical Neuroscience Research, National Institute of Mental Health, National Institutes of Health, Rockville, Maryland.
1.17. Population Genetic Methods in Psychiatry

Constance A. Moore, M.D.
Associate Professor of Psychiatry and Director of Sleep Disorders Center, Baylor College of Medicine; Director of Sleep Diagnostic Center, Houston Veterans Affairs Medical Center, Houston, Texas.
21. Sleep Disorders

Michael G. Moran, M.D.
Associate Professor of Psychiatry, University of Colorado School of Medicine; Director of Adult Psychosocial Medicine, National Jewish Medical and Research Center, Denver, Colorado.
25.5. Respiratory Disorders

James Morrison, M.D.
Clinical Professor of Psychiatry, Temple University School of Medicine, Philadelphia, Pennsylvania; Chief of Staff, Coatesville Veterans Affairs Medical Center, Coatesville, Pennsylvania.
53.2. Examining Psychiatrists and Other Trainees

Rodrigo A. Muñoz, M.D.
Clinical Professor of Psychiatry, University of California at San Diego; Attending Psychiatrist, UCSD Medical Center; Attending Psychiatrist, Scripps Memorial Hospital, La Jolla, California; Attending Psychiatrist, Mercy Hospital and Medical Center, San Diego, California.
53.2. Examining Psychiatrists and Other Trainees

William E. Narrow, M.D., M.P.H.
Senior Advisor for Epidemiology, National Institute of Mental Health, National Institutes of Health, Bethesda, Maryland.
12.2. Schizophrenia: Epidemiology

J. Craig Nelson, M.D.
Professor of Psychiatry, Yale University School of Medicine; Director of Inpatient Psychiatry Service and Geriatric Psychiatry Programs, Yale-New Haven Hospital, New Haven, Connecticut.
31.30. Tricyclics and Tetracyclics

Charles B. Nemeroff, M.D., Ph.D.
Reunette W. Harris Professor of Psychiatry and Chairman, Department of Psychiatry and Behavioral Sciences, Emory University School of Medicine, Atlanta, Georgia.
1.6. Neuropeptides: Biology and Regulation;
31.22. Nefazodone;
31.25a. Selective Serotonin Reuptake Inhibitors: Introduction and Overview;
31.25b. Citalopram;
31.25c. Fluoxetine;
31.25d. Fluvoxamine;
31.25e. Paroxetine;
31.25f. Sertraline;
31.29. Trazodone

John C. Nemiah, M.D.
Professor of Psychiatry, Dartmouth Medical School, Hanover, New Hampshire; Clinical Staff, Mary Hitchcock Memorial Hospital, Lebanon, New Hampshire; Professor of Psychiatry Emeritus, Harvard Medical School, Boston, Massachusetts.
Introduction

Eric J. Nestler, M.D., Ph.D.
Jameson Professor of Psychiatry, Yale University School of Medicine, New Haven, Connecticut.
1.10. Basic Molecular Neurobiology

Jeffrey H. Newcorn, M.D.
Associate Professor of Psychiatry and Pediatrics, Mount Sinai School of Medicine; Director of Child and Adolescent Psychiatry, Mount Sinai Medical Center, New York, New York.
23. Adjustment Disorders

Dorian S. Newton, Ph.D.

Affiliate Member, San Francisco Psychoanalytic Institute, San Francisco, California; Director of Mills College Counseling and Psychological Services, Oakland, California.
6.2. Erik H. Erikson

Peter M. Newton, Ph.D.
Professor of Psychology, Wright Institute, Berkeley, California.
6.2. Erik H. Erikson

Cynthia T. M. H. Nguyen, M.D.
Postdoctoral Research Fellow, Department of Psychiatry and Behavioral Sciences, Stanford University School of Medicine, Stanford, California.
51.4d. Geriatric Psychiatry: Psychopharmacology: Antianxiety Drugs

Linda M. Nicholas, M.D.
Assistant Professor of Psychiatry, University of North Carolina School of Medicine, Chapel Hill, North Carolina.
31.11. Bupropion

Steven L. Nickman, M.D.
Clinical Assistant Professor of Psychiatry, Harvard Medical School; Assistant in Psychiatry, Massachusetts General Hospital, Boston, Massachusetts; Assistant in Psychiatry, McLean Hospital, Belmont, Massachusetts.
49.2. Adoption

Ruta Nonacs, M.D., Ph.D.
Instructor of Psychiatry, Harvard Medical School, Boston, Massachusetts.
13.4. Postpartum Psychiatric Syndromes

Grayson S. Norquist, M.D., M.S.P.H.
Director of Division of Services and Intervention Research, National Institute of Mental Health, National Institutes of Health, Rockville, Maryland.
12.2. Schizophrenia: Epidemiology

Ann E. Norwood, M.D.
Associate Professor of Psychiatry and Associate Chairman, Department of Psychiatry, Uniformed Services University of the Health Sciences F. Herbert School of Medicine, Bethesda, Maryland.
30.8. Brief Psychotherapy

H. George Nurnberg, M.D.
Professor of Psychiatry and Vice Chair for Clinical Programs, Department of Psychiatry, University of New Mexico School of Medicine; Medical Director, University of New Mexico Health Sciences Center, Albuquerque, New Mexico.
9.1. Classification of Mental Disorders

M. Kevin O'Connor, M.D.
Assistant Professor of Psychiatry, Mayo Foundation, Rochester, Minnesota.
25.8. Musculoskeletal Disorders

Stephanie S. O'Malley, Ph.D.
Associate Professor of Psychiatry, Director of Division of Substance Abuse Research, Yale University School of Medicine, New Haven, Connecticut.
31.21. Naltrexone

Mark Olfson, M.D., M.P.H.
Associate Professor of Clinical Psychiatry, College of Physicians and Surgeons of Columbia University; Attending Psychiatrist, New York State Psychiatric Institute, New York, New York.
5.3. Mental Health Services Research

Angel A. Otero-Ojeda, M.D.
Professor of Psychiatry, Havana University; Chairman, Executive Committee, Cuban Glossary of Psychiatry, Havana, Cuba.
9.2. International Psychiatric Diagnosis

Michael J. Owens, Ph.D.
Associate Professor of Psychiatry and Behavioral Sciences, Emory University School of Medicine, Atlanta, Georgia.
1.6. Neuropeptides: Biology and Regulation;
31.22. Nefazodone

Ken A. Paller, Ph.D.
Assistant Professor of Psychology, Northwestern University, Evanston, Illinois.
3.4. Biology of Memory

Laszlo A. Papp, M.D.
Associate Professor of Clinical Psychiatry, Columbia University College of Physicians and Surgeons; Director of Biological Studies Unit, New York State Psychiatric Institute, New York, New York; Director of Anxiety Disorders Program, Long Island Jewish-Hillside Medical Center, Queens, New York.
15.7. Anxiety Disorders: Somatic Treatment

Carmine M. Pariante, M.D.
Medical Research Council Clinical Training Fellow, Section of Clinical Neuropharmacology, Institute of Psychiatry, London, United Kingdom.
1.12. Immune System and Central Nervous System Interactions

Barbara L. Parry, M.D.
Professor of Psychiatry, University of California at San Diego School of Medicine, La Jolla, California; Director of Psychiatric Emergency Room, UCSD Medical Center, San Diego, California.
28.2. Psychiatry and Reproductive Medicine

Caroly S. Pataki, M.D.
Associate Clinical Professor of Psychiatry and Biobehavioral Sciences and Associate Director of Training and Education for Child and Adolescent Psychiatry, University of California at Los Angeles School of Medicine; Attending Psychiatrist, UCLA Neuropsychiatric Institute and Hospital, Los Angeles, California.
32.1. Child Psychiatry: Introduction and Overview;
45. Mood Disorders and Suicide in Children and Adolescents

Robert H. Paul, Ph.D.
Fellow, Department of Psychiatry and Behavioral Sciences, University of Oklahoma College of Medicine, Oklahoma City, Oklahoma.
2.7. Neuropsychiatric Aspects of Multiple Sclerosis and Other Demyelinating Disorders

Bradley D. Pearce, Ph.D.
Assistant Professor of Psychiatry and Behavioral Sciences, Department of Psychiatry and Behavioral Sciences, Emory University School of Medicine, Atlanta,

Georgia.
1.12. Immune System and Central Nervous System Interactions

David Pelcovitz, Ph.D.
Clinical Associate Professor of Psychology in Psychiatry, New York University School of Medicine, New York, New York; Chief Psychologist, Division of Child and Adolescent Psychiatry, North Shore University Hospital, Manhasset, New York.
49.10. Child Psychiatry: Identity Problem and Borderline Disorders

William H. Pelham, Ph.D.
Professor of Psychology and Director of Clinical Training, State University of New York at Buffalo, Buffalo, New York.
30.2. Behavior Therapy

Bradley S. Peterson, M.D.
House Jameson Assistant Professor in Child Psychiatry, Yale University School of Medicine, New Haven, Connecticut.
33. Psychiatric Examination of the Infant, Child, and Adolescent

John M. Petitto, M.D.
Associate Professor of Psychiatry, Neuroscience, and Pharmacology, University of Florida College of Medicine, Gainesville, Florida.
25.10. Behavior and Immunity

Cynthia R. Pfeffer, M.D.
Professor of Psychiatry, The Joan and Sanford I. Weill Medical College of Cornell University, New York, New York.
48.10. Psychiatric Treatment of Adolescents

Kemuel L. Philbrick, M.D.
Assistant Professor of Psychiatry, Mayo Foundation, Rochester, Minnesota.
25.8. Musculoskeletal Disorders

Edmond Hsin-tung Pi, M.D.
Executive Vice Chair, Department of Psychiatry, King/Drew University of Medicine and Science, Los Angeles, California.
31.4. Medication-Induced Movement Disorders

John Piacentini, Ph.D.
Assistant Professor-in-Residence of Psychiatry and Biobehavioral Science, University of California at Los Angeles School of Medicine; Director of Child and Adolescent Obsessive-Compulsive Disorder and Anxiety Program, UCLA Neuropsychiatric Institute and Hospital, Los Angeles, California.
46.1. Obsessive-Compulsive Disorder in Children

Daniel S. Pine, M.D.
Associate Professor of Clinical Psychiatry, Division of Child and Adolescent Psychiatry, College of Physicians and Surgeons of Columbia University; Attending Psychiatrist, New York State Psychiatric Institute, New York, New York.
15.6. Anxiety Disorders: Clinical Features

Bruce G. Pollock, M.D., Ph.D.
Professor of Psychiatry and Pharmacology, University of Pittsburgh School of Medicine; Director of Geriatric Psychopharmacology Program, Western Psychiatric Institute and Clinic, Pittsburgh, Pennsylvania.
51.4b. Geriatric Psychiatry: Psychopharmacology: General Principles

Harrison G. Pope, Jr., M.D.
Professor of Psychiatry, Harvard Medical School, Boston, Massachusetts; Chief of Biological Psychiatry Laboratory, McLean Hospital, Belmont, Massachusetts.
11.13. Anabolic-Androgenic Steroid Abuse;
31.7b. Valproate

Robert M. Post, M.D.
Chief of Biological Psychiatry Branch, National Institute of Mental Health, National Institutes of Health, Bethesda, Maryland.
14.8. Mood Disorders: Treatment of Bipolar Disorders;
31.13. Calcium Channel Inhibitors

Karl H. Pribram, M.D., Ph.D.
Director of Center for Brain Research and Informational Sciences, Radford University, Radford, Virginia; Professor Emeritus, Stanford University, Stanford, California.
3.5. Brain Models of Mind

Patricia N. Prinz, Ph.D.
Professor of Biobehavioral Nursing and Health Systems, University of Washington School of Nursing; Adjunct Professor of Psychiatry, University of Washington School of Medicine, Seattle, Washington.
51.3b. Geriatric Psychiatry: Sleep Disorders

David B. Pruitt, M.D.
Professor of Psychiatry and Vice Chairman, Department of Psychiatry, University of Tennessee at Memphis College of Medicine, Memphis, Tennessee.
48.7. Child Psychiatry: Partial Hospital and Ambulatory Behavioral Health Services

Andres J. Pumariega, M.D.
Professor of Psychiatry and Chair, Department of Psychiatry and Behavioral Sciences, James H. Quillen College of Medicine, East Tennessee State University, Johnson City, Tennessee.
48.9. Child Psychiatry: Community-Based Treatments

Frank W. Putnam, M.D.
Chief of Unit on Developmental Traumatology, National Institute of Mental Health, National Institutes of Health, Bethesda, Maryland; Professor of Pediatrics, Ohio State University College of Medicine and Public Health; Professor of Psychiatry, University of Cincinnati College of Medicine, Cincinnati, Ohio.
18.3. Dissociative Identity Disorder

Denisa Radoi-Andraous, M.D.
Assistant Professor of Psychiatry, University of Montreal Faculty of Medicine, Montreal, Quebec, Canada.
31.24. Selective Serotonin-Noradrenaline Reuptake Inhibitors

Scott L. Rauch, M.D.
Associate Professor of Psychiatry, Harvard Medical School; Associate Chief of Psychiatry for Neuroscience Research, Massachusetts General Hospital, Boston, Massachusetts.
31.32. Neurosurgical Treatments

Darrel A. Regier, M.D., M.P.H.
Associate Director for Epidemiology and Health Policy Research, National Institute of Mental Health, National Institutes of Health, Bethesda, Maryland; Clinical

Professor of Psychiatry, Georgetown University School of Medicine and Health Sciences, Washington, D.C.
5.1. Epidemiology

Edward L. Reilly, M.D.
Professor of Psychiatry and Director of Residency Training, University of Texas Medical School at Houston; Director of Mental Sciences Institute, University of Texas-Houston Health Science Center, Houston, Texas.
1.14. Applied Electrophysiology

Eric M. Reiman, M.D.
Professor, Associate Head of Psychiatry
University of Arizona College of Medicine, Tucson, Arizona; Scientific Director of Positron Emission Tomography Center, Good Samaritan Regional Medical Center; Director of Arizona Alzheimer's Disease Research Center, Phoenix, Arizona.
51.2e. Geriatric Psychiatry: Neuroimaging: Overview

Perry F. Renshaw, M.D., Ph.D.
Research Director, Brain Imaging Center, McLean Hospital, Boston, Massachusetts.
1.16. Principles of Neuroimaging: Magnetic Resonance Techniques

Victor I. Reus, M.D.
Professor of Psychiatry, University of California at San Francisco School of Medicine; Director of Psychiatry, Langley Porter Psychiatric Institute, San Francisco, California.
1.11. Psychoneuroendocrinology

Charles F. Reynolds, III, M.D.
Professor of Psychiatry, University of Pittsburgh School of Medicine; Director of Mental Health Clinical Research Center for the Study of Late-Life Mood Disorders, Western Psychiatric Institute and Clinic, Pittsburgh, Pennsylvania.
51.4c. Geriatric Psychiatry: Psychopharmacology: Antidepressants and Mood Stabilizers

Robert G. Robinson, M.D.
The Paul W. Penningroth Professor of Psychiatry and Head, Department of Psychiatry, University of Iowa College of Medicine, Iowa City, Iowa.
2.2. Neuropsychiatric Aspects of Cerebrovascular Disorders;
2.3. Neuropsychiatric Aspects of Brain Tumors;
2.5. Neuropsychiatric Aspects of Traumatic Brain Injury

Robert M. Rohrbaugh, M.D.
Assistant Clinical Professor of Psychiatry, Yale University School of Medicine, New Haven, Connecticut; Director of Education in Psychiatry, Connecticut Veterans Affairs Healthcare System, West Haven, Connecticut.
51.3g. Geriatric Psychiatry: Personality Disorders

Richard B. Rosse, M.D.
Associate Professor of Psychiatry, Georgetown University School of Medicine and Health Sciences; Chief of Georgetown University Teaching Unit, Veterans Affairs Medical Center, Washington, D.C.
7.7. Medical Assessment and Laboratory Testing in Psychiatry

Bruce J. Rounsaville, M.D.
Professor of Psychiatry, Yale University School of Medicine, New Haven, Connecticut.
31.21. Naltrexone

Alec Roy, M.D.
Professor of Psychiatry, New Jersey Medical School, University of Medicine and Dentistry of New Jersey, Newark, New Jersey; Assistant Chief of Psychiatry for Substance Abuse, East Orange Campus of the Veterans Affairs New Jersey Health Care System, East Orange, New Jersey.
29.1. Suicide

Teresa A. Rummans, M.D.
Associate Professor of Psychiatry, Mayo Foundation, Rochester, Minnesota.
25.8. Musculoskeletal Disorders

A. John Rush, M.D.
Professor of Psychiatry, Betty Jo Hay Distinguished Chair in Mental Health, and Rosewood Corporation Chair in Biomedical Science, University of Texas Southwestern Medical School, Dallas, Texas.
14.7. Mood Disorders: Treatment of Depression;
30.6. Cognitive Therapy

Sheila Ryan, C.S.W.
Program Director of Special Needs Clinic, Pediatric Psychiatry, Columbia-Presbyterian Medical Center, New York, New York.
49.6. Child Psychiatry: Psychiatric Sequelae of HIV and AIDS

Joel Sadavoy, M.D., F.R.C.P.(C)
Associate Professor of Psychiatry and Head, Division of General Psychiatry, University of Toronto Faculty of Medicine; Psychiatrist-in-Chief, Mount Sinai Hospital; Clinical Director, Joint General Psychiatry Program, Mount Sinai Hospital and Centre for Addiction and Mental Health, Toronto, Ontario, Canada.
51.4h. Geriatric Psychiatry: Psychosocial Treatments: General Principles
51.4i. Geriatric Psychiatry: Individual Psychotherapy

Benjamin J. Sadock, M.D.
Menas S. Gregory Professor of Psychiatry and Vice Chairman, Department of Psychiatry, New York University School of Medicine; Attending Psychiatrist, Tisch Hospital; Attending Psychiatrist, Bellevue Hospital Center; Consultant Psychiatrist, Lenox Hill Hospital, New York, New York.
7.2. Psychiatric Report and Medical Record;
7.3. Signs and Symptoms in Psychiatry

Virginia A. Sadock, M.D.
Clinical Professor of Psychiatry and Director of Program in Human Sexuality and Sex Therapy, New York University School of Medicine; Attending Psychiatrist, Tisch Hospital; Attending Psychiatrist, Bellevue Hospital Center, New York, New York.
19.1a. Normal Human Sexuality and Sexual Dysfunctions

Rafael J. Salin-Pascual, M.D., Ph.D.
Professor of Psychiatry and Physiology, Department of Physiology, Universidad Nacional Autonomona de Mexico, Mexico City, Mexico.
1.19. Basic Science of Sleep

Steven C. Samuels, M.D.
Assistant Professor of Psychiatry, Mount Sinai School of Medicine; Director of Outpatient Geriatric Psychiatry Program, Department of Psychiatry, Mount Sinai Medical Center, New York, New York.

31.15. Cholinesterase Inhibitors

Ofra Sarid-Segal, M.D.
Assistant Professor of Psychiatry, Boston University School of Medicine; Staff Psychiatrist, Department of Veterans Affairs Outpatient Clinic, Boston, Massachusetts.
11.12. Sedative-, Hypnotic-, or Anxiolytic-Related Abuse

Stephen M. Saunders, Ph.D.
Assistant Professor of Psychology, Marquette University, Milwaukee, Wisconsin.
30.11. Evaluation of Psychotherapy

S. Alan Savitz, M.D.
President and Chief Executive Officer, PacifiCare Behavioral Health, Laguna Hills, California.
51.5b. Geriatric Psychiatry: Managed Care

Alan F. Schatzberg, M.D.
Kenneth T. Norris Jr., Professor of Psychiatry and Chairman, Department of Psychiatry and Behavioral Sciences, Stanford University School of Medicine, Stanford, California.
31.33. Other Pharmacological and Biological Therapies

Stephen C. Scheiber, M.D.
Adjunct Professor of Psychiatry, Northwestern University Medical School, Chicago, Illinois; Adjunct Professor of Psychiatry, Medical College of Wisconsin, Milwaukee, Wisconsin; Executive Vice President American Board of Psychiatry and Neurology, Deerfield, Illinois; Senior Attending Physician, Evanston Hospital, Evanston, Illinois.
53.1. Graduate Psychiatric Education

Diane H. Schetky, M.D.
Associate Clinical Professor of Psychiatry, University of Vermont College of Medicine, Burlington, Vermont; Attending Psychiatrist, Maine Medical Center, Portland, Maine.
49.13. Ethical Issues in Child and Adolescent Psychiatry

Lon S. Schneider, M.D.
Professor of Psychiatry, Neurology, and Gerontology, University of Southern California School of Medicine, Los Angeles, California.
51.4f. Geriatric Psychiatry: Psychopharmacology: Antidementia Drugs

Richard S. Schottenfeld, M.D.
Professor of Psychiatry, Director of Substance Abuse Residency Training
Yale University School of Medicine; Director of Substance Abuse Treatment Unit and Associate Clinical Director of Addiction Services, Connecticut Mental Health Center, New Haven, Connecticut.
31.23. Opioid Agonists

Marc A. Schuckit, M.D.
Professor of Psychiatry, University of California at San Diego School of Medicine, La Jolla, California; Director of Alcohol Research Center, San Diego Veterans Affairs Healthcare System, San Diego, California.
11.2. Alcohol-Related Disorders

Mary E. Schwab-Stone, M.D.
Associate Professor of Child Psychiatry, Yale University School of Medicine, New Haven, Connecticut.
33. Psychiatric Examination of the Infant, Child, and Adolescent

Erich Seifritz, M.D.
Professor of Psychiatry, Psychiatric University Hospital, Basel, Switzerland.
1.19. Basic Science of Sleep

Alberto C. Serrano, M.D.
Professor of Psychiatry, University of Hawaii John A. Burns School of Medicine; Director of Consortium of Education and Training, Kapi'olani Medical Center for Women and Children, Honolulu, Hawaii.
48.4. Child Psychiatry: Group Psychotherapy

Richard P. Shank, Ph.D.
Senior Research Fellow, CNS Drug Discovery, Robert Wood Johnson Pharmaceutical Research Institute, Spring House, Pennsylvania.
1.5. Amino Acid Neurotransmitters

Edward R. Shapiro, M.D.
Medical Director and Chief Executive Officer, Austen Riggs Center, Stockbridge, Massachusetts; Director of Erik H. Erikson Institute for Education and Research of the Austen Riggs Center; Associate Clinical Professor of Psychiatry, Harvard Medical School, Boston, Massachusetts.
30.9. Eriksonian Clinical Theory and Psychiatric Treatment

Peter A. Shapiro, M.D.
Associate Professor of Clinical Psychiatry, Columbia University College of Physicians and Surgeons; Assistant Director, Consultation-Liaison Psychiatry Service, Columbia-Presbyterian Medical Center, New York, New York.
25.4. Cardiovascular Disorders

M. Tracie Shea, Ph.D.
Associate Professor of Psychiatry and Human Behavior and Director of Clinical Assessment and Training Unit, Brown University School of Medicine; Staff Psychologist, Providence Veterans Affairs Medical Center, Providence, Rhode Island.
14.9. Mood Disorders: Psychotherapy

Javaid I. Sheikh, M.D., M.B.A.
Associate Professor of Psychiatry, Stanford University School of Medicine, Stanford, California; Chief of Psychiatry, Palo Alto Veterans Affairs Health Care System, Palo Alto, California.
51.4d. Geriatric Psychiatry: Antianxiety Drugs

Cleveland G. Shields, Ph.D.
Associate Professor of Family Medicine and Psychiatry, University of Rochester School of Medicine and Dentistry; Family Therapist, Highland Hospital; Family Therapist, Strong Memorial Hospital, Rochester, New York.
51.4k. Interventions and Consultation With Families of Older Adults

Daniel J. Siegel, M.D.
Associate Professor of Clinical Psychiatry and Biobehavioral Sciences, University of California at Los Angeles School of Medicine; Medical Director of Infant and Preschool Service, UCLA Neuropsychiatric Institute and Hospital, Los Angeles, California.

3.1. Perception and Cognition

Daphine Simeon, M.D.
Assistant Professor of Psychiatry and Director of Medical Student Education in Psychiatry, Mount Sinai School of Medicine, New York, New York.
18.5. Dissociative Disorders Not Otherwise Specified

Robert I. Simon, M.D.
Clinical Professor of Psychiatry and Director of Program in Psychiatry and Law, Georgetown University School of Medicine, Washington, D.C.
54.1. Legal Issues in Psychiatry

George M. Simpson, M.D.
Professor of Research Psychiatry and Director of Clinical Research, Department of Psychiatry and the Behavioral Sciences, University of Southern California School of Medicine, Los Angeles County and USC Medical Center, Los Angeles, California.
31.4. Medication-Induced Movement Disorders;
31.5. b-Adrenergic Receptor Antagonists;
31.6. Anticholinergics and Amantadine;
31.8. Antihistamines

Gary W. Small, M.D.
Professor of Psychiatry and Biobehavioral Sciences, Director of Geriatric Psychiatry and Psychology Fellowship Program, Director of Center on Aging, University of California at Los Angeles School of Medicine, Los Angeles, California.
51.1a. Geriatric Psychiatry: Introduction;
51.3e. Geriatric Psychiatry: Alzheimer's Disease and Other Dementias

Buster D. Smith, M.D.
Clinical Associate in Psychiatry, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania.
51.6a. Geriatric Psychiatry: Psychiatric Aspects of Long-Term Care

Gerard P. Smith, M.D.
Professor of Psychiatry, The Joan and Sanford I. Weill Medical College of Cornell Univerity; Attending Psychiatrist (Behavioral Science), New York Hospital, New York, New York.
1.20. Appetite

Thomas E. Smith, M.D.
Assistant Professor of Psychiatry, New York, New York.
52.4. Psychiatric Rehabilitation

Virginia L. Smith-Swintosky, Ph.D.
Senior Scientist, CNS Drug Discovery, Robert Wood Johnson Pharmaceutical Research Institute, Spring House, Pennsylvania.
1.5. Amino Acid Neurotransmitters

Solomon H. Snyder, M.D.
Distinguished Service Professor of Neuroscience, Pharmacology, Molecular Sciences, and Psychiatry, Johns Hopkins University School of Medicine, Baltimore, Maryland.
1.21. Future Directions in Neuroscience and Psychiatry

Michael E. Spagna, Ph.D.
Associate Professor of Special Education, California State University at Northridge, Northridge, California.
35.1. Reading Disorder;
35.2. Mathematics Disorder;
35.3. Disorder of Written Expression and Learning Disorder Not Otherwise Specified;
36. Motor Skills Disorder: Developmental Coordination Disorder

David Spiegel, M.D.
Professor of Psychiatry and Behavioral Sciences, Stanford University School of Medicine, Stanford, California.
30.3. Hypnosis

Herbert Spiegel, M.D.
Special Lecturer in Psychiatry, Columbia University College of Physicians and Surgeons, New York, New York.
30.3. Hypnosis

Larry R. Squire, Ph.D.
Professor of Psychiatry and Neurosciences, University of California at San Diego School of Medicine; Professor of Psychology, University of California at San Diego, La Jolla, California; Research Career Scientist, San Diego Veterans Affairs Healthcare System, San Diego, California.
3.4. Biology of Memory

Sergio E. Starkstein, M.D., Ph.D.
Director of Neuropsychiatry, FLENI, Buenos Aires, Argentina.
2.2. Neuropsychiatric Aspects of Cerebrovascular Disorders

Murray B. Stein, M.D.
Associate Professor of Psychiatry, University of California at San Diego School of Medicine, La Jolla, California.
25.9. Stress and Psychiatry

Terry S. Stein, M.D.
Professor of Psychiatry, Michigan State University College of Human Medicine, East Lansing, Michigan.
19.1b. Homosexuality and Homosexual Behavior

Marlene Steinberg, M.D.
Associate Professor of Psychiatry, University of Massachusetts Medical School, Worcester, Massachusetts; Research Affiliate, Department of Psychiatry, Yale University School of Medicine, New Haven, Connecticut.
18.1. Dissociate Amnesia;
18.4. Depersonalization Disorder

Hans Steiner, M.D.
Professor of Psychiatry and Behavioral Sciences, Stanford University School of Medicine; Director of Training, Division of Child Psychiatry and Human Development, Stanford, California.
40. Disruptive Behavior Disorders;
49.7. Childhood or Adolescent Antisocial Behavior

Alan Stoudemire, M.D.

Professor of Psychiatry and Behavioral Sciences, Emory University School of Medicine, Atlanta, Georgia.
25.1. History, Classification, and Current Trends in Psychosomatic Medicine

Eric C. Strain, M.D.
Associate Professor of Psychiatry and Behavioral Science, Johns Hopkins School of Medicine, Baltimore, Maryland.
11.4. Caffeine-Related Disorders

James J. Strain, M.D.
Professor of Psychiatry, Mount Sinai School of Medicine; Director of Division of Behavioral Medicine and Consultation-Psychiatry, Mount Sinai Medical Center, New York, New York.
23. Adjustment Disorders;
25.12. Consultation-Liaison Psychiatry

Joel E. Streim, M.D.
Associate Professor of Psychiatry, University of Pennsylvania School of Medicine; Director of Geriatric Psychiatry Fellowship Program, Ralston-Penn Center, Philadelphia, Pennsylvania.
51.6a. Geriatric Psychiatry: Psychiatric Aspects of Long-Term Care

Gregory M. Sullivan, M.D.
Postdoctoral Fellow, Department of Psychiatry, Columbia University College of Physicians and Surgeons; Clinical Assistant in Psychiatry, Columbia-Presbyterian Medical Center, New York, New York.
15.3. Anxiety Disorders: Biochemical Aspects

David L. Sultzer, M.D.
Associate Clinical Professor of Psychiatry and Biobehavioral Sciences, University of California at Los Angeles School of Medicine; Director of Gero-Neuropsychiatry Division, West Los Angeles Veterans Affairs Ambulatory Care Center, Los Angeles, California.
51.4e. Geriatric Psychiatry: Psychopharmacology: Antipsychotic Drugs

Norman Sussman, M.D.
Clinical Professor of Psychiatry, New York University School of Medicine; Director of Psychopharmacology Research and Consultation Service, Bellevue Hospital Center, New York, New York.
31.7c. Other Anticonvulsants;
31.16. Clonidine

Dragan M. Svrakic, M.D., Ph.D.
Assistant Professor of Psychiatry, Washington University School of Medicine, Saint Louis, Missouri.
24. Personality Disorders

Rex M. Swanda, Ph.D.
Adjunct Assistant Professor of Psychiatry, University of New Mexico School of Medicine; Staff Psychologist, Veterans Affairs Medical Center, Albuquerque, New Mexico.
7.4. Clinical Neuropsychology and Intellectual Assessment of Adults

Carrie Sylvester, M.D., M.P.H.
Associate Professor of Psychiatry, Behavioral Sciences, and Pediatrics and Director of Education in Child and Adolescent Psychiatry, Northwestern University School of Medicine; Attending Psychiatrist, Children's Memorial Hospital; Attending Psychiatrist, Northwestern Memorial Hospital, Chicago, Illinois.
46.3. Separation Anxiety Disorder and Other Anxiety Disorders

Kenneth Tardiff, M.D., M.P.H.
Professor of Psychiatry and Public Health, The Joan and Sanford I. Weill Medical College of Cornell University; Attending Psychiatrist and Medical Director of Payne Whitney Clinic, New York Hospital, New York, New York.
27.3. Adult Antisocial Behavior and Criminality

Laurence H. Tecott, M.D., Ph.D.
Assistant Professor of Psychiatry, University of California at San Francisco School of Medicine, San Francisco, California.
1.4. Monoamine Neurotransmitters

Michael E. Thase, M.D.
Professor of Psychiatry, University of Pittsburgh School of Medicine; Research Director of Division of General Adult Psychiatry, Western Psychiatric Institute and Clinic, Pittsburgh, Pennsylvania.
14.4. Mood Disorders: Neurobiology

Armin Paul Thies, Ph.D.
Associate Clinical Professor of Psychology, Yale University School of Medicine, New Haven, Connecticut.
33. Psychiatric Examination of the Infant, Child, and Adolescent

Mauricio Tohen, M.D., Dr.P.H.
Associate Clinical Professor of Psychiatry, Harvard Medical School, Boston, Massachusetts.
31.7a. Carbamazepine

Alan Trachtenberg, M.D., M.P.H.
Adjunct Associate Professor of Community Medicine and Health Care Sciences, George Washington University School of Medicine and Health Sciences, Washington, D.C.; Medical Director, Office of Pharmacologic and Alternative Therapies, Center for Substance Abuse Treatment, Substance Abuse and Mental Health Services Administration, United State Public Health Service, Rockville, Maryland.
28.8. Alternative and Complimentary Health Practices

Alfonso Troisi, M.D.
Professor of Psychopathology, University of Rome Tor Vergata, Rome, Italy.
4.3. Evolutionary Biology and Psychiatry

Manuel Trujillo, M.D.
Professor of Clinical Psychiatry and Vice Chairman of Psychiatry, New York University School of Medicine; Director of Psychiatry, Director of Division of Cultural Psychiatry, Bellevue Hospital Center, New York, New York.
4.4. Cultural Psychiatry

Roy E. Twyman, M.D.
Associate Professor of Neurology and Pharmacology, University of Utah School of Medicine, Salt Lake City; Director, Global CNS Research and Development, Robert Wood Johnson Pharmaceutical Research Institute, Spring House, Pennsylvania.
1.5. Amino Acid Neurotransmitters

Jurgen Unützer, M.D., M.P.H.

Assistant Professor-in-Residence, University of California at Los Angeles School of Medicine, Los Angeles, California.
51.3a. Geriatric Psychiatry: Psychiatric Problems in the Medically Ill

Robert J. Ursano, M.D.
Professor of Psychiatry and Neuroscience and Chairman, Department of Psychiatry, Uniformed Services University of the Health Sciences F. Edward Hébert School of Medicine, Bethesda, Maryland.
30.8. Brief Psychotherapy

Jerome V. Vaccaro, M.D.
Associate Clinical Professor Psychiatry and Biobehavioral Sciences, University of California at Los Angeles School of Medicine, Los Angeles, California.
51.5b. Geriatric Psychiatry: Managed Care

Bessel A. van der Kolk, M.D.
Professor of Psychiatry, Boston University School of Medicine, Boston, Massachusetts; Chief of Trauma Center, HRI Hospital, Brookline, Massachusetts.
28.7. Physical and Sexual Abuse of Adults

Daniel P. van Kammen, M.D., Ph.D.
Professor of Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania; Director of Global Clinical Research and Development, Robert Wood Johnson Pharmaceutical Research Institute, Springhouse, New Jersey.
31.17. Dopamine Receptor Antagonists (Typical Antipsychotics);
31.26. Serotonin-Dopamine Antagonists

William W. Van Stone, M.D.
Emeritus Clinical Associate Professor of Psychiatry and Behavioral Sciences, Stanford University School of Medicine, Stanford, California; Chief of Treatment Services, Mental Health and Behavioral Sciences Services, Veterans Affairs Medical Center, Washington, D.C.
51.5c. Geriatric Psychiatry: Veterans Affairs Medical Centers and Psychogeriatric Services

Johan M. F. Verhulst, M.D.
Associate Professor of Psychiatry and Behavioral Sciences, University of Washington School of Medicine, Seattle, Washington.
26. Relational Problems

Jeff Victoroff, M.D.
Associate Professor of Clinical Neurology, University of Southern California School of Medicine, Los Angeles, California; Director of Neurobehavior, Co-Director of Geriatric Neurology Clinic, Director Near Medicine Clinic, Rancho Los Amigos Medical Center, Downey, California.
51.2b. Central Nervous System Changes With Normal Aging

Michael V. Vitiello, Ph.D.
Professor of Psychiatry and Behavioral Sciences, University of Washington School of Medicine; Adjunct Professor of Psychology, and Biobehavioral Nursing and Health Systems, University of Washington School of Nursing, Seattle, Washington.
51.3b. Geriatric Psychiatry: Sleep Disorders

Fred R. Volkmar, M.D.
Harris Associate Professor of Child Psychiatry, Pediatrics, and Psychology, Yale University School of Medicine, New Haven, Connecticut.
38. Pervasive Developmental Disorders

Thomas A. Wadden, Ph.D.
Professor of Psychology and Director of Weight and Eating Disorders Program, Department of Psychiatry, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania.
25.3. Obesity

Thomas A. Wehr, M.D.
Chief of Clinical Psychobiology Intramural Research Program, National Institute of Mental Health, National Institutes of Health, Bethesda, Maryland.
1.13. Chronobiology

Daniel R. Weinberger, M.D.
Chief of Clinical Brain Disorders Branch, National Institute of Mental Health, National Institutes of Health, Bethesda, Maryland.
1.3. Developmental Neurobiology

Myron F. Weiner, M.D.
Professor of Psychiatry and Vice Chair, Department of Psychiatry, University of Texas Southwestern Medical School; Chief of Geropsychiatry, University of Texas Southwestern Medical Center, Dallas, Texas.
6.3. Other Psychodynamic Schools

Myrna M. Weissman, Ph.D.
Professor of Epidemiology in Psychiatry, Columbia University College of Physicians and Surgeons; Chief of Division of Clinical and Genetic Epidemiology, New York State Psychiatric Institute, New York, New York.
15.2. Anxiety Disorders: Epidemiology;
30.7. Interpersonal Psychotherapy

Lawrence A. Welkowitz, Ph.D.
Assistant Professor of Psychology, Keene State College, Keene, New Hampshire.
15.8. Anxiety Disorders: Psychological Treatments

Paul H. Wender, M.D.
Distinguished Professor of Psychiatry, University of Utah School of Medicine, Salt Lake City, Utah.
39.2. Adult Manifestations of Attention-Deficit Disorders

Louis J. West, M.D.*
Professor of Psychiatry and Biobehavioral Sciences, University of California at Los Angeles School of Medicine, Los Angeles, California

28.9. Nonprofessional Therapies, Quacks, and Cults

Tonya Jo Hanson White, M.D.
Assistant Professor of Psychiatry, University of Iowa College of Medicine; Attending Psychiatrist, Eating Disorders Clinic, University of Iowa Hospital and Clinics, Iowa City, Iowa.
49.5. Children's Reaction to Illness and Hospitalization

Robert L. Williams, M.D.
Professor Emeritus of Psychiatry, Baylor College of Medicine, Houston, Texas.

21. Sleep Disorders

G. Terence Wilson, Ph.D.
Professor of Psychology, Rutgers University, Piscataway, New Jersey.
3.3. Learning Theory

Eve J. Wiseman, M.D.
Associate Professor of Psychiatry and Behavioral Sciences, University of Arkansas for Medical Sciences; Chief of Special Treatment Section, John L. McClellan Memorial Hospital, Little Rock, Arkansas.
51.3h. Geriatric Psychiatry: Drug and Alcohol Abuse

Steven S. Wolf, M.D.
Co-Director of Neurology Consultation Service, National Institute of Mental Health Neuroscience Center at Saint Elizabeth's Hospital, National Institutes of Health; Director of Neurology Service, District of Columbia Commission on Mental Health Services, Washington, D.C.
2.6. Neuropsychiatric Aspects of Movement Disorders

George E. Woody, M.D.
Clinical Professor of Psychiatry, University of Pennsylvania School of Medicine; Chief of Substance Abuse Treatment Unit, Philadelphia Veterans Affairs Medical Center, Philadelphia, Pennsylvania.
11.5. Cannabis-Related Disorders

Joseph C. Wu, M.D.
Associate Professor of Psychiatry, Clinical Director of Brain Imaging Center, University of California at Irvine College of Medicine, Irvine, California.
2.13. Neuroimaging in Clinical Practice

Lyman C. Wynne, M.D., Ph.D.
Professor of Psychiatry Emeritus, University of Rochester School of Medicine and Dentistry, Rochester, New York.
51.4k. Interventions and Consultation With Families of Older Adults

Joel Yager, M.D.
Professor of Psychiatry and Vice Chair for Education, Department of Psychiatry, University of New Mexico School of Medicine, Albuquerque, New Mexico.
8. Clinical Manifestations of Psychiatric Disorders

Alayne Yates, M.D.
Professor of Child and Adolescent Psychiatry, University of Hawaii John A. Burns School of Medicine; Director of Division of Child and Adolescent Psychiatry, Kapi'olani Medical Center for Women and Children, Honolulu, Hawaii.
49.9. Child Psychiatry: Gender Identity and Sexual Issues

William R. Yates, M.D.
Professor of Psychiatry and Family Medicine, Chairman of Department of Psychiatry, University of Oklahoma College of Medicine-Tulsa, Tulsa, Oklahoma.
25.2. Gastrointestinal Disorders

Kimberly A. Yonkers, M.D.
Associate Professor of Psychiatry, Obstetrics, and Gynecology, University of Texas Southwestern Medical School, Dallas, Texas.
28.3. Premenstrual Dysphoric Disorder

Carlos A. Zarate, Jr., M.D.
Assistant Professor of Psychiatry, University of Massachusetts Medical School; Director of Bipolar and Psychotic Disorders Program, University of Massachusetts Medical Center, Worcester, Massachusetts.
31.7a. Carbamazepine

Elsa M. Zayas, M.D.
Instructor, Director of Geriatric Consultation, Department of Psychiatry, Director of Partial Hospitalization Program, Saint Louis University School of Medicine, Saint Louis, Missouri.
51.4g. Geriatric Psychiatry: Electroconvulsive Therapy

Charles H. Zeanah, M.D.
Professor of Psychiatry and Chair of Division of Child and Adolescent Psychiatry, Tulane University School of Medicine, New Orleans, Louisiana.
44.1. Reactive Attachment Disorder of Infancy and Early Childhood

Sidney Zisook, M.D.
Professor of Psychiatry and Director of Residency Training, University of California at San Diego School of Medicine, La Jolla, California; Attending Psychiatrist, San Diego Veterans Affairs Healthcare System, San Diego, California.
28.5. Death, Dying, and Bereavement

Rebecca K. Zoltoski, Ph.D.
Assistant Professor of Biological Sciences, Illinois College of Optometry, Chicago, Illinois.
1.19. Basic Science of Sleep

Charles F. Zorumski, M.D.
Professor of Psychiatry and Neurobiology, Washington University School of Medicine; Attending Psychiatrist, Barnes-Jewish Hospital, Saint Louis, Missouri.
1.9. Basic Electrophysiology;
31.31. Electroconvulsive Therapy

Stephen R. Zukin, M.D.
Director of Division of Clinical and Services Research, National Institute on Drug Abuse, National Institutes of Health, Bethesda, Maryland; Clinical Professor of Psychiatry, Albert Einstein College of Medicine of Yeshiva University, Bronx, New York.
11.11. Phencyclidine (or Phencyclidine-like)-Related Disorders

PREFACE

This seventh edition of *Kaplan and Sadock's Comprehensive Textbook of Psychiatry* is being published on the threshold of the twenty-first century. For over 30 years it has helped educate generations of psychiatrists, other physicians, and mental health professionals from all fields—psychology, social work, and nursing, among others. Its goal has always been to foster professional competence and ensure the highest quality of care based upon humanistic and scientific principles. The textbook has earned a reputation both in the United States and around the world, as a reliable, consistent, and accurate compendium of psychiatric knowledge. We believe this millennium edition meets the high standards set by its predecessors.

EDITORSHIP

The task of continuing the *Comprehensive Textbook of Psychiatry* without the collaboration of Harold I. Kaplan, M.D. (1927–1998), was made possible with the able assistance of Virginia A. Sadock, M.D., who was often referred to as the "unsung heroine" of this and other *Kaplan and Sadock* books. Her role was described in the preface of the last edition of the textbook as follows:

> We especially want to thank Virginia Alcott Sadock. M.D., Clinical Professor of Psychiatry and Director of Graduate Education in Human Sexuality at New York University School of Medicine. As in all our previous books, she has served as an assistant to the editors and actively participated in every editorial decision. Her enthusiasm, sensitivity, comprehension, and depth of psychiatric knowledge were of immeasurable importance to the editors. She has ably represented not only the viewpoint of women in medicine and psychiatry but has also made many contributions to the content of this textbook. We are deeply appreciative of her outstanding help and assistance.

She now joins as coeditor of the *Comprehensive Textbook of Psychiatry* for this edition and those to follow.

TEACHING SYSTEM

This textbook forms one part of a comprehensive system developed to facilitate the teaching of psychiatry and the behavioral sciences. At the head of the system is *Comprehensive Textbook of Psychiatry*, which is global in depth and scope. It is designed for and used by psychiatrists, behavioral scientists, and all workers in the mental health field. *Kaplan and Sadock's Synopsis of Psychiatry* is a relatively brief, highly modified, original, and current version useful for medical students, psychiatric residents, practicing psychiatrists, and mental health professionals. The *Concise Textbook of Clinical Psychiatry,* derived from the *Synopsis*, emphasizes clinical psychiatry and includes extensive case studies useful for students and clinical practitioners from all fields. Another part of the system is *Study Guide and Self-Examination Review for Kaplan and Sadock's Synopsis of Psychiatry,* which consists of over 1600 multiple-choice questions and answers including detailed case histories. It is designed for students of psychiatry and for clinical psychiatrists who require a review of the behavioral sciences and general psychiatry in preparation for a variety of examinations. The questions are modeled after and consistent with the format used by the United States Medical Licensing Examination. Other parts of the system are the pocket handbooks: *Pocket Handbook of Clinical Psychiatry, Pocket Handbook of Psychiatric Drug Treatment, Pocket Handbook of Emergency Psychiatric Medicine,* and *Pocket Handbook of Primary Care Psychiatry*. These books cover the diagnosis and treatment of psychiatric disorders, psychopharmacology, psychiatric emergencies, and primary care psychiatry, respectively, and are compactly designed and concisely written to be carried in the pocket of clinical clerks and practicing physicians, whatever their specialty, to provide a quick reference. Finally, *Comprehensive Glossary of Psychiatry and Psychology* provides simply written definitions for psychiatrists and other physicians, psychologists, students, other mental health professionals, and the general public.

Taken together, these books create a multiple approach to the teaching, study, and learning of psychiatry.

CHANGES IN THIS EDITION

New Contributors A tradition of inviting a certain number of new authors to write sections written by prior authors began with the second edition of the textbook. That was done for the same reasons as in other great textbooks of medicine—to ensure a fresh approach to each topic and to keep the *Comprehensive Textbook of Psychiatry* vital and current. Over 60 percent of the contributors to this edition are new. The editors are deeply grateful to the more than 1500 psychiatrists and behavioral scientists who contributed to previous editions, all of whom maintained the highest standards of scholarship. Many of their sections remain classics in the field and are accessible to the interested reader. We especially wish to thank John Nemiah, M.D., editor emeritus of the *American Journal of Psychiatry*, for agreeing to write the Introduction. He has contributed to every edition of this book since its beginning.

Major Changes in This Edition Almost every chapter in this edition has been completely rewritten or revised, and many new sections have been added. Some of the major additions to the text-book and other highlights are listed below.

Neural Science, Neuropsychiatry, and Behavioral Neurology A major expansion in the chapters covering neural science, neuropsychiatry, and behavioral neurology reflects the rapid advances in these fields. New sections include Developmental Neurobiology, Neurotrophic Factors, Appetite, and expanded sections on radiotracing imaging and magnetic resonance imaging. Also added to this edition are sections on Neuropsychiatric Aspects of Neuromuscular Diseases, Neuropsychiatric Aspects of Traumatic Brain Injury, Neuropsychiatric Aspects of Brain Tumors, and a special section on Psychiatric Aspects of Child Neurology. Recent advances are included in Genetic Linkage Analysis of Psychiatric Disorders, Neuropsychiatric Aspects of HIV and AIDs, and Neuropsychiatric Aspects of Other Infectious Diseases. These sections chapters were completely revised and updated.

Psychological, Sociocultural, and Experimental Sciences The sections Perception and Cognition, Learning Theory, and Brain Models of Mind were extensively revised. Recent advances are included in Biology of Memory and a new section Emotional Intelligence has been added. Evolutionary Biology and Psychiatry is included in a separate section for the first time. Health Services Research and Outcomes Research in Psychiatry was added to the chapter on experimental methods, and the section Epidemiology is thoroughly updated. The chapter Theories of Personality and Psychopathology has been revised, and the section Psychoanalysis is updated to reflect changing theories in the field.

Clinical Psychiatry A newly written version of Psychiatric Interview, History, and Mental Status was prepared for this edition. The section Psychiatric Report was expanded to include the medical record and third-party documentation requirements. Signs and Symptoms in Psychiatry was revised to include a glossary of psychiatric terms. A new section, Computer-Based Testing of the Psychiatric Patient, is included in this edition.

Anxiety Disorders is greatly expanded with newly written sections that include Introduction and Overview, Epidemiology, Biochemical Aspects, Genetics, Psychodynamic Aspects, Clinical Features, Somatic Treatment, and Psychological Treatments.

The chapter Substance-Related Disorders was expanded to include the separate sections Caffeine-Related Disorders and Nicotine-Related Disorders and a new section Anabolic-Androgenic Steroid Abuse. The treatment of depressive disorders has been enlarged to include the separate sections Psychotherapy, Treatment of Bipolar Disorders, and Treatment of Depressive Disorders. The dissociative disorders are now covered in five new sections: Dissociative Amnesia, Dissociative Fugue. Dissociative Identity Disorder (formerly called multiple personality disorder), Depersonalization Disorder, and Dissociative Disorders Not Otherwise Specified. The coverage of attention-deficit/hyperactivity disorder now includes a new section. Adult Manifestations of Attention-Deficit/Hyperactivity Disorder. Other new sections include Primary Care Psychiatry and Cults, Quacks, and Nonprofessional Therapies. A new section, Alternative and Complementary Health Practices, is included for the first time in a major psychiatric textbook.

All sections dealing with clinical disorders have been thoroughly updated and follow a similar outline, which includes an introduction and definition of the disorder; a history of the disorder including comparative nosology, epidemiology, and etiology; diagnosis and clinical features; pathology and laboratory examination; differential diagnosis; and course and prognosis. Treatment strategies for all clinical disorders are presented eclectically to include biological, pharmacological, psychosocial, and psychotherapeutic approaches. The area of psychiatric treatment has been expanded with the addition of three new sections: Interpersonal Therapy. Eriksonian Clinical Theory and Psychiatric Treatment, and Combined Psychotherapy and Psychopharmacotherapy.

Because of the increased importance of certification and qualifications of physicians generally, the editors included a new section. Examining Psychiatrists and Other Trainees. The chapter Ethics and Forensic Psychiatry is completely updated and a new section, World Aspects of Psychiatry, was written to reflect the fact that mental

illness is a worldwide problem that requires global solutions.

A new section on Chronic Pain and the Placebo Effect is included to reflect the editors' belief that psychiatrists be involved in the emerging clinical specialties of palliative care and pain control. In the Spring of 1999, the American Board of Psychiatry and Neurology (ABPN) and the American Board of Physical Medicine and Rehabilitation (ABPMR) joined the American Board of Anesthesiology (ABA) in recognition of pain management as an interdisciplinary subspecialty. The respective Boards have agreed on a single standard of certification.

Geriatric Psychiatry The chapters on geriatric psychiatry continue to expand in each edition, and we thank Lissy Jarvik, M.D., for her extraordinary help over the years as contributing editor of this section. With the assistance of Gary Small, M.D., she helped coordinate the content of this important subspecialty. Both the editors and the field of psychiatry owe her a debt of gratitude. We especially wish to thank Dr. Small for integrating the many sections in this chapter into a coherent whole. New sections written by new contributors in geriatric psychiatry for this edition include Special Issues in Neuroimaging, Psychopharmacology: General Principles, Antidepressants and Mood Stabilizers, Antianxiety Drugs, Antipsychotic Drugs, and Antidementia Drugs. Other new sections include Psychosocial Treatment: General Principles, Cognitive Behavior Therapy, Gender Issues, and the section Health Care Delivery Systems, which includes the separate subsections Medicare and Medicaid and Managed Care. All the geropsychiatry sections were revised and updated.

Child and Adolescent Psychiatry The editors owe a great debt to Dennis Cantwell, M.D. (1939–1997), who served as contributing editor to the child and adolescent psychiatry section. He was responsible for organizing and inviting the contributors to this chapter—all of whom he valued as experts in their respective fields. The editors wish to dedicate this area of the *Comprehensive Textbook of Psychiatry* to his memory and as a testimonial to this outstanding and much admired child psychiatrist. Dr. Cantwell had been assisted by Caroly Pataki, M.D., who was able to step into the breach to complete the work he had begun. We thank her deeply for her efforts.

Many new sections covering child and adolescent psychiatry were added to this edition. New sections written by new contributors include Obsessive-Compulsive Disorder in Children, Posttraumatic Stress Disorder in Children, Short-term Psychotherapy, Cognitive and Behavioral Therapy, Family Therapy, Psychiatric Sequela of HIV and AIDS, Dissociative Disorders, Gender Identity and Sexual Issues, Adolescent Substance Abuse, Forensic Child and Adolescent Psychiatry, Ethical Issues in Child and Adolescent Psychiatry, School Consultation, Community-Based Treatments, and Psychiatric Prevention.

Psychopharmacology The editors continue to use the unique format of discussing drugs used in the treatment of mental disorders on a pharmacological basis rather than under the rubric of antidepressant, antipsychotic, and the like. Thus the clinician can use a psychotherapeutic drug on the basis of its pharmacological activity, which may make it equally effective in depression, anxiety, and other disorders as well as being specific for a particular condition.

A thoroughly updated section General Principles of Psychopharmacology was written for this edition, and two new sections, Drug Development and Approval and Pharmacokinetics and Drug Interactions, were added. New sections on classes of drugs with unique pharmacological properties were written, including Cholinesterase Inhibitors and Other Anticonvulsants. The most recently developed drugs are covered in detail, and all discussions of other drugs have been thoroughly updated.

New Format This seventh edition uses color for the first time to highlight figures, tables, and case studies and to help differentiate the 10th revision of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) and fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) diagnostic criteria. Like all *Kaplan and Sadock* books, this edition includes color plates of major psychiatric drugs and their various dosage forms including those recently released. This edition is heavily illustrated; photographs enhance the learning experience and keep the reader from being lost in a sea of type.

Following the style of other major medical textbooks, internal literature citations were eliminated, and the number of references at the end of each section reduced. Contributors were asked to limit themselves to 30 to 40 major books, monographs, and review articles and to include current references where possible; thus some citation lists are not as long as some of the authors would have wished. In addition, 1999 references were added by the editors to alert the reader to the most current literature. Contributors were also asked to note the five most important references with an asterisk.

Case histories are cited extensively to add clarity to the clinical disorders. They are derived from the DSM-IV and ICD-10 casebooks and the clinical and research experience of the contributors. We wish to thank the American Psychiatric Association (APA) and the World Health Organization (WHO) for permission to use some of their material.

DSM-IV AND ICD-10

In 1994 DSM-IV was published by the APA. DSM-IV contains the official nomenclature used by psychiatrists and other mental health professionals; thus DSM-IV terminology is used throughout the *Comprehensive Textbook*. In the year 2000, according to treaties between the United States and WHO, DSM-IV classifications must be identical with those used by ICD-10. Accordingly, this is the first U.S. textbook to include the definitions and diagnostic criteria of mental disorders used in ICD-10. Readers can find tables comparing the DSM-IV and ICD-10 diagnostic criteria in Chapter 10.

The psychiatric disorders discussed in this textbook are consistent with the nosology in DSM-IV; however, some of our contributors maintain reservations about the changes introduced into the various editions of DSM. In several sections of the book the reader will find these objections clearly stated. DSM-IV is a diagnostic and statistical manual; it is *not* and never claimed to be a textbook. Unfortunately, it is used as a text by some groups, including insurance companies who believe it to be a comprehensive source of information about mental illness.

As future editions of DSM appear—and the editors believe they are in the offing—the *Comprehensive Textbook of Psychiatry* will continue to allow room for dissent, before and especially after every new edition of the manual appears. It will continue to provide a forum for discussion, evaluation, criticism, and disagreement, while duly acknowledging the official nomenclature.

THE CONTINUING CRISIS IN THE FUTURE OF PSYCHIATRY

The last edition of the *Comprehensive Textbook of Psychiatry,* published in 1995, included the following commentary on the crisis of the future of psychiatry. This crisis continues and is far from resolution.

The introduction of the American Health Security Bill (the Clinton plan) in 1993 served as a catalyst for dramatic change in the delivery of health care in the United States even though the bill was not enacted into law. In the vanguard of change were the insurance companies and the health maintenance organizations (HMOs), which are, in the main, managed care programs run by large profit-seeking corporations. Managed care has had serious and adverse effects on the practice of psychiatry. For example, most managed mental health care (MMHC) plans restrict the number of outpatient visits for psychotherapy to a small and unpredictable number of sessions, usually 5 to 20 a year. Although some types of psychotherapy can be conducted within that framework, other types (insight oriented) require frequent visits over an extended period. Before a patient can be referred to a psychiatrist, many HMOs require that the patient see a primary care physician (the so-called gatekeeper), sometimes for several weeks; during that time, the doctor may prescribe pharmacotherapy about which he or she may have limited knowledge. Drugs, rather than psychotherapy, become the treatment of choice even though many studies have found the superior efficacy of psychotherapy used in conjunction with drugs in the treatment of most mental disorders, particularly depressive disorders and schizophrenia. Persons who are emotionally well make fewer general medical visits than do persons with emotional disorders. Providing timely psychotherapy results in savings in the overall cost of general medical care.

Many HMOs require preauthorization by a panel of so-called behavioral health experts. This panel requires information about the intimate and private details of a person's life to authorize therapy. If the patient or doctor refuses to comply, permission for psychiatric treatment is usually denied. And even if the patient is permitted to enter therapy, the psychiatrist must send frequent written reports to the HMO about the treatment, which breaches the confidentiality and trust of the doctor-patient relationship. Patients usually must be treated by psychiatrists who are enrolled in their particular HMO. They forfeit the right to see a doctor of their own choosing. In the traditional fee-for-service system patients can seek treatment from any psychiatrist they choose and can seek a second or even a third opinion if they so desire. In an HMO the patient does not have these options. Capitation, another method of payment used by HMOs, is untested in psychiatry and may mean "de-capitation" of the field.

HMOs use from 15 to 30 percent of their revenues to pay for marketing, administration, and the distribution of profits to owners and investors—money that

would otherwise be available for clinical care, research, and medical education. Health care in America is being “corporatized,” and HMOs reap profits by often eliminating laboratory tests, referrals to specialists, and reducing length of hospital stay to questionable and dangerous proportions. For example, patients with major psychiatric disorders are being forced out of the hospital, often against their will and against the recommendation of their psychiatrists. HMOs also increase their profit margin by paying lower fees to doctors, and since the HMOs control the supply of patients, price control rules the system.

The issue of financial liability is another area of danger to doctors who work for HMOs. Psychiatrists (and other physicians) who sign contracts with HMOs must agree to accept complete liability if any adverse effects to the patient occur during the course of treatment. Consider this example: A psychiatrist wants to hospitalize a potentially suicidal patient, but the HMO refuses to pay for hospitalization or limits the number of days allowed in the hospital to fewer than the psychiatrist deems necessary. The psychiatrist can be sued for malpractice if the patient ultimately commits suicide because of premature hospital discharge mandated by the HMO. The HMO accepts no liability for any adverse outcome based on their decisions. The only alternative is for the psychiatrist to treat the patient for no fee or for the patient to pay for treatment out-of-pocket. Neither option is satisfactory.

Currently, the future of psychiatric treatment is of concern. Unfortunately, prejudice toward mental illness still exists in many quarters—political policy makers, insurance companies, the general public, and, sadly, the medical profession itself. Psychiatry and medicine are at a crossroad. It would be tragic to take the path that discards and negates the humanism that psychiatry has brought to medicine and the great advances that have been made over the past hundred years by Sigmund Freud and other great psychiatric clinicians and researchers.

A new concept of medical services as *market driven* now dominates the health care industry and will do so for the foreseeable future. Paradoxically, the role of government must increase to regulate this new industry whose preoccupation is the *cost* of health care. For example, some states recently passed legislation allowing patients to sue health maintenance organizations (HMOs). Ultimately the U.S. Congress will become the arbiter between the consumers of health care (patients), the providers (physicians and other health professionals), and the payers (insurance companies and HMOs). In this sense, society and the body politic will determine the nature and quality of health care in the United States.

Physicians, especially psychiatrists, have a special obligation to be informed about sociopolitical issues affecting the physical and psychological well-being of their patients. The spirit of the Hippocratic oath written over 2000 years ago continues to inspire the ethics of the medical profession: *To act for the good of my patients according to my ability and my judgment*. As medicine changes, physicians (and other health care professionals) are the last stronghold for humanitarian and compassionate care that stresses the inherent dignity and worth of each person.

CONTRIBUTING AND SECTION EDITORS

In the preparation of this textbook we have been helped immensely by our distinguished section and contributing editors.

The section editors worked closely with the authors and suggested modifications when necessary. We are deeply appreciative of their efforts. They include Hagop S. Akiskal, M.D., who covered the area of mood disorders; Jack M. Gorman, M.D., who covered anxiety disorders; Katherine A. Haaland, Ph.D., who covered neuropsychological assessment; Jerome Jaffe, M.D., who covered substance-related disorders; Samuel Keith, M.D., who covered schizophrenia and other psychotic disorders; Caroly Pataki, M.D., who covered child and adolescent disorders; Gary W. Small, M.D., who covered geriatric psychiatry; and Alan Stoudemire, M.D., who covered psychosomatic medicine.

The contributing editors kept us apprised of new advances in the field and helped obtain contributors with expertise in their respective areas. We thank them for their help and cooperation. They include Glen Gabbard, M.D., who contributed to the areas of psychodynamics and psychoanalysis; Lissy Jarvik, M.D., who contributed to geriatric psychiatry; Joel Yager, M.D., who contributed to clinical psychiatric disorders; and the late Dennis Cantwell, M.D., who contributed to child and adolescent psychiatry. Our special thanks are extended to Jack Grebb, M.D., a past coauthor of *Kaplan and Sadock’s Synopsis of Psychiatry* who, as contributing editor, assisted us in many editorial decisions, particularly in the area of biological psychiatry.

Together this admirable and distinguished group of men and women helped integrate an immense amount of material into a balanced and consistently styled work. The editors and the field of psychiatry owe them a debt of gratitude for their outstanding help.

ACKNOWLEDGMENTS

In addition to our contributing and section editors mentioned above, we want to extend our appreciation to Justin Hollingsworth, who served as project editor in New York and helped us immensely. He was ably assisted by Linda Kenevich. Margaret Cuzzolino, David Abramson, and Angela Barbuscia, all of whom worked with alacrity. Our editors Anne Schwartz and Radhika Rao Gupta provided invaluable assistance.

We especially want to thank our dear friend Nancy Barrett Kaplan, who gave us her complete support throughout this project. Over the years she has been an invaluable source of encouragement and understanding. Others who helped us were Norman Sussman, M.D., Victoria Sadock, M.D., James Sadock, M.D., Chris Marra, D.O., and Ben Hammer, M.D.

We take this opportunity to acknowledge those who have translated this and other *Kaplan and Sadock* books into foreign languages. Current translations include Croatian, French, German, Greek, Indonesian, Italian, Japanese, Polish, Portuguese, Russian, Spanish, and Turkish, in addition to a special Asian and international student edition.

The staff at Lippincott Williams & Wilkins was most efficient. We especially wish to thank Katey Millet, developmental editor, who was extraordinarily helpful and who has been an inspiration to us all. We also thank Susan Gay, former vice-president and publisher of Williams & Wilkins, for her encouragement and support over the years and we want to welcome Charley Mitchell.

Robert Cancro, M.D., Professor and Chairman of the Department of Psychiatry at New York University School of Medicine, participated as Senior Contributing Editor of this edition. Dr. Cancro’s commitment to psychiatric education and psychiatric research is recognized throughout the world. He has been a source of great inspiration to the editors and contributed immeasurably to this and previous editions. He is a much valued and highly esteemed colleague, and it is very special privilege to work closely with him. Dr. Cancro has developed a department that represents the very best in American psychiatry. Our collaboration and association with this outstanding American educator has contributed immeasurably to the ideas and directions shaping this textbook.

Finally, we want to express our deepest thanks to our contributors who were extraordinarily cooperative in every aspect of this textbook.

NYU School of Medicine, New York, New York

Benjamin James Sadock, M.D.

Virginia Alcott Sadock, M.D.

INTRODUCTION: TWO FACES OF PSYCHIATRY

JOHN C. NEMIAH, M.D.

Over 30 years have elapsed since the publication of the first edition of *Comprehensive Textbook of Psychiatry* (CTP-I). In comparison with its successors, it was a modest work of only some 1600 pages contained within the covers of a single volume. Equally striking is the difference in its contents from what the modern reader will find in this seventh edition of this now classic text. CTP-I, in line with the standard diagnostic manual of its day, referred to “psychiatric reactions” rather than to “disorders” and construed their causes and treatment in psychological terms. Twelve pages, for example, ere devoted to the “psychological treatment” of schizophrenia in contrast to a mere two-and-a-half to its “organic treatment.” “Serotonin” had but a single entry in the index, “dopamine” was not listed at all, and only a handful of pages were allotted to the budding clinical experience with the use of chloropromazine and the antidepressants. It needs only the most cursory glance at the pages of the latest edition to discover what dramatic changes 30 years have wrought. “Psychiatric reactions” are now full-fledged illnesses, their cause and treatment are seen as being primarily biological in nature, and psychological factors are minor actors on the clinical stage.

A shift of outlook of such magnitude occurs, of course, for many reasons. It is notable, however, that similar shifts have happened before in the development of psychiatric theory and practice, and the brief account that follows of a curious chapter of psychiatric history may, therefore, give us useful insights into the nature and implications of the changes that have taken place in our own era.

“The 11th of August,” wrote Frank Podmore in *From Mesmer to Christian Science*,

> should be observed as a day of humiliation in the civilised world, for on that date in 1784 a Commission, consisting of the most distinguished representatives of Science in the most distinguished capital in Europe, pronounced the rejection of a pregnant scientific discovery—a discovery possibly rivaling in permanent significance all the contributions to the physical sciences made by the two most famous members of the Commission—Lavoisier and Benjamin Franklin.

The oft-told events to which Podmore alludes may be quickly recounted. In the early 1770s the Viennese physician Franz-Anton Mesmer had developed a remarkable treatment for human illness that became a highly popular therapeutic procedure among the citizens of Paris after he established a clinical practice in that ity in 1778. Indeed, so thronged was Mesmer's clinic with patients from all levels of society that a commission of inquiry was established by the authorities to examine his procedures and their results.

Mesmer's explanation of the pathogenesis of human discases was based on his concept of the nature and function of what be called “animal magnetism.” There exists, he proposed, an invisble fluid spread throughout the universe with properties similar to mineral magnetism whose steady flow through the bodies of living beings sustains their healthy physiological functioning. However, as the result of a pathological blockage of that flow, a localized organ dysfunction occurs that is manifested in the symptoms of a specific bodily disease. Treatment was aimed at restoring the normal flow of the fluid by overcoming the blockage. That was accomplished by the production of a powerful surge of fluid in the patient's body by a magnetic therapist, who induced the flow of magnetic fluid by repetitious passes of his hands over the patient's thorax and abdomen. The same therapeutic effect could be produced in several patients at once by placing them in contact with the *baquet*, a large, circular wooden tub filled with “magnetized” water. The high drama of such a group treatment is evident in the commissioners' description of a typical clinical session in their final report.

> The patients are arranged in large numbers in several rows around the baquet and are exposed to the therapeutic flow of the magnetic fluid over several channels at once—by its transmission over the iron rods protruding from the baquet, by a long cord entwined around their bodies connecting the patients to one another, through the fluid's transmission to their neighbors by the mutual contact of their thumbs, and by the sounds of a piano or a pleasing voice that spreads it through the atmosphere. Patients are also magnetized directly when the magnetist passes his fingers or an iron wand over their faces, over the back or top of their heads, or over the diseased parts of their bodies. It is particularly to be noted that magnetization is produced by contact with the magnetist's hands as be applies pressure to the upper and lower abdomen for a long stretch of time, often several hours in duration.
>
> The patients present a spectacle of wide-ranging conditions and behavior. Some are calm and tranquil and have no untoward sensations. Other are coughing and spitting, or suffer from mild pains and complain of localized or generalized burning accompanied by bouts of sweating. Yet others are agitated and wracked by convulsions that are notable for their frequency, duration, and violence. Moreover, when one patient has a convulsion, many others follow suit. The Commissioners have witnessed some seizures that lasted more than three hours and were accompanied by the violent expectoration of a foul, viscous fluid, sometimes flecked with blood. The convulsions are further characterized by precipitous involuntary movements of all the limbs and the entire body, by a construction of the throat, by spasmodic jerks in the hypochondrium and the epigastric region, by a dimming and clouding of vision, by piercing shrieks, tears and hiccoughs, and by immoderate laughter. All of these events are preceded or followed by a state of languor, dreaminess, and prostration, and even by drowsiness.

After extensive observations of these remarkable phenomena the commissioners proceeded to investigate the nature of the animal magnetism alleged to be their cause. In a series of clever experiments, whose design might well be admired by modern investigators, they determined conclusively that there was no evidence whatsoever for the existence of a magnetic fluid, and that the dramatic, often wildly violent behavior attributed to it was entirely due to the effect of imagination and imitation on suggestible patients in a group setting.

The commissioners in the concluding paragraph of their report wrote.

> We have determined that the magnetic fluid cannot be detected by any of the five senses and that it has no effect whatsoever either on the Commissioners themselves or on the patients they exposed to it. They have ascertained that the practice of compressing or touching the body brings about changes that are rarely favorable and arouses excitations of the imagination that are invariably vexatious. Finally, they have demonstrated by definitive experiments that imagination without magnetism produces convulsions and that magnetism without imagination produces nothing. Therefore, the Commissioners have unanimously concluded regarding the question of the existence and the effectiveness of animal magnetism that there is no evidence whatsoever of a magnetic fluid and that such a non-existent fluid is consequently without useful effect. They have further determined that the observable violent results of public treatment are the product of touching, of an aroused imagination, and of an instinctive tendency automatically to imitate whatever strongly impresses the senses. At the same time, the Commissioners feel obliged to add the important observation that the practice of touching and the repetitious arousal of the imagination designed to bring on the magnetic crisis can be injurious. Furthermore, the public spectacle of these crises is equally dangerous because of that element of imitativeness that nature appears to have designed as a basic law. As a consequence, public treatment employing magnetism can in the long run have only disastrous effects.

Such, then, were the commissioners' conclusions and recommendations to which Podmore took such vigorous objection. It was not so much their denial of the existence of Mesmer's magnetic fluid that troubled him as the fact that having recognized the central importance of imagination and suggestion in producing the therapeutic convulsions (and the cures that frequently followed them), the commissioners then proceeded to dismiss magnetic phenomena as being the result of mere imagination and to condemn treatment as harmful. Mesmer's magnetic fluid, Podmore agreed,

> was a chimera and Mesmer . . . perhaps three parts a charlatan, [but] his claim to our remembrance lies in this—that he wrested the privilege of healing from the Churches and gave it to mankind as a universal possession. In rejecting that gift for themselves and their successors to the third and fourth generation, Bailly and his colleagues rejected more than they knew.

If Podmore's charges against the commissioners are perhaps a bit overblown, he does point to an arresting fact: Having skillfully demonstrated the fallacy of Mesmer's hypothesis of a physical magnetic fluid, the commissioners perceptively recognized the psychological basis for the patients' dramatic response to magnetic procedures and for the significant number of genuine cures that resulted from their application. But having made that discovery, far from being intrigued by such a remarkable finding and advising its further exploration, they dismissed it as not only being nugatory but as resulting in dangerous clinical practices that should be

curtailed.

The conclusions of the commissioners' report seem to have had little or no effect on the continued development of animal magnetism. Indeed, although the French Revolution temporarily slowed its progress, it became a vigorous movement throughout France in the early decades of the nineteenth century, spread beyond French borders to the rest of the Continent, crossed the Channel to England, and ultimately reached the United States.

The large number of individuals engaged in the clinical application of animal magnetism (or “mesmerism,” as it came to be called) ignored the commissioners' evidence against the existence of a magnetic fluid and held fast to Mesmer's mechanistic view that it was the active agent in the response to magnetic treatment. The discovery in 1785 by the Marquis de Puységur of the phenomenon of somnambulistic trance (which thereafter replaced seizures as the primary response to magnetic passes) did not alter adherence to the fluidic hypothesis. Nor was it in any way modified by the proposal of Alexandre Bertrand in the 1820s that the magnetic fluid was indeed nonexistent and that the effects of mesmeric treatment were entirely due to the psychological agency of suggestion. Not until the 1840s did the first serious challenge to the fluidic hypothesis arise.

In the late autumn of 1841 James Braid, an English surgeon in Manchester, attended a public demonstration of magnetism by the traveling French mesmerist, Charles Lafontaine. Impressed, despite his initial skepticism, by what he observed, Braid embarked upon a series of mesmeric experiments of his own. In the course of these he ultimately discovered that he could produce all the phenomena of mesmeric trance by merely arousing the idea of them in his subjects' minds. Hypnosis (as Braid termed it) was, he proposed, a process arising entirely within the hypnotic subject and set in motion by the hypnotist's verbal instructions. Braid's procedures made it clear that neither a magnetic fluid nor any other external physical agency was responsible for the observed phenomena, but that they resulted from those very psychological agencies of suggestion and imagination that had been so vigorously belittled and rejected by the French commission a half-century earlier.

Although Braid's studies made no immediate impact on his English colleagues, by a curious turn of fate his ideas returned across the Channel to France where they caught the attention of the French physician Eugene Azam. Azam is perhaps best remembered for his description of the phenomenon of “double consciousness” in his famous patient, Félida X, but he was also notable for the fact that, as Charcot wrote, “he was the first person in France to verify Braid's findings by his own experiments.” Indeed, Azam's publication in 1860 of a description of Braid's hypnotic experiments helped set the stage for three important developments in France during the ensuing decade.

1. Charcot's major interest in the nature and clinical application of hypnosis, which led to its extensive use at the Salpêtrière in Paris, gave the subject a legitimacy it had not had before. From being a phenomenon viewed by most of the orthodox scientific and medical world as mere quackery, if not outrightly fraudulent, with the blessing of a person of Charcot's academic and scientific reputation it became for the first time in its history a sanctioned procedure worthy of clinical application and serious study. The major thrust of Charcot's research was aimed at the clinical application of hypnosis to patients with major hysterical disorders. In this context, he came to the conclusion that hypnosis and hysteria were closely related phenomena whose manifestations were the result of poorly defined pathological processes in the central nervous system. Charcot, that is, held to a physical rather than a psychological view of the hypnotic process.
2. At the same time that Charcot's studies were under way in Paris, Hippolyte Bernheim in Nancy had joined with Ambroise Liábeault, a general practitioner in the neighboring countryside, in a study of the medical uses of therapeutic hypnotism. Influence by their reading of Bertrand and Braid. Liábeault and Bernheim advanced the hypothesis that the basic factor in the production of hypnotic phenomena was the subject's psychological state of suggestibility. Suggestibility, they held, was an entirely normal trait that was to be found to a greater or lesser degree in the vast majority of human beings; and it was, furthermore, the primary agency in affecting cures by hypnotic therapy. It is evident from the nature of their views that Liábeault and Bernheim, and the so-called Nancy School that gathered around them, were completely at odds with Charcot and the “Salpêtrière School” with regard to every aspect of therapeutic hypnosis. Nor is it surprising that a protracted controversy raged between them, ultimately to be settled in favor of Bernheim and his colleagues.
3. Although Pierre Janet came from a background of philosophical rather than medical studies, it is evident that he was thoroughly familiar with the literature of clinical hypnosis. “M. Despine,” he wrote in 1889 in his first major publication. *L'Automatisma Psychologioue*,

   has maintained that psychology has no application whatsoever to somnambulism and that it can be explained only by physiology. In fact, far from explaining it, it cannot even be defined in physiological terms. Many authors, such as Bertrand and Braid, and more recently Gurney and Bernheim, have distinguished themselves by having recognized that somnambulism is a psychological phenomenon and can be defined only by its uniquely psychological characteristics.

It was with this intellectual background and predilection for psychological concepts that in the early 1880s Janet embarked on the hypnotic investigation of hysterical patients that led to his important discovery of psychological dissociation and psychological automatism—a discovery that led him to formulate the psychological explanation of hysterical symptoms as originating from dissociated traumatic memories and to his use of hypnotic suggestion in their treatment.

Almost simultaneously with Janet, Sigmund Freud, stimulated by his observations of Charcot's work at the Salpêtrière and Bernheim's practice in Nancy, began his own investigation of hysterical patients in conjunction with Josef Breuer. Like Janet (with whose early studies he was familiar) Freud focused his attention on the role of unconscious traumatic memories in the production of hysterical symptoms. He went beyond Janet, however, in pointing to the important psychogenic role of the unconscious painful feelings associated with the traumatic memories and the necessity for their conscious expression in the course of therapy. With these original formulations Freud laid the groundwork for the concepts of psychological conflict and psychic structure that became the hallmark of psychoanalytic theory and practice.

While Janet and Freud were thus pursuing the medical aspects of dissociation and hypnosis, a less well known group of lay investigators, working in London under the aegis of the recently created Society for Psychical Research, were studying the nature and extent of hypnotic and dissociative phenomena in normal subjects. Particularly prominent among these investigators was Frederic W. H. Myers, one of the first of their contemporaries to recognize and publicize the significance of Freud's and Janet's early findings. Myers's own investigations led him to a demonstration of the presence of dissociative elements in a variety of unusual but not necessarily pathological phenomena, such as artistic creation, nonpsychotic hallucinations, automatic writing, medium trance-states, and spirit possession. His postulate of a “subliminal mind” expanded the scope and meaning of the process of dissociation far beyond the narrower pathological concept of clinical investigators. So impressed was William James by Myers's contributions that (as he wrote in a eulogy published after Myers's death in 1901) he “was disposed to think it a probability that Frederic Myers will always be remembered in psychology as the pioneer who staked out a vast tract of mental wilderness and planted the flag of genuine science upon it.”

James himself, of course, was a major player in the explorations of the reaches of the mind, and his *The Varieties of Religious Experience* remains a classic contribution to the psychology of religion. His profound interest in and commitment to the development of depth-psychology is evident throughout his writings. As he commented in the volume just mentioned,

> I cannot but think that the most important step forward that has occurred in psychology since I have been a student of that science is the discovery . . . that, in certain subjects at least, there is not only the consciousness of the ordinary field . . . but an addition thereto in the shape of a set of memories, thoughts, and feelings which are extra-marginal and outside of the primary consciousness altogether. . . . I call this the most important step forward because, unlike the other advances which psychology has made, this discovery has revealed to us an entirely unsuspected peculiarity in the constitution of human nature.

It is evident that as it evolved 100 years ago the study of psychology, both normal and abnormal, was satisfying, rewarding, and stimulating for those engaged in it. Moreover, they were optimistic about its future and looked forward confidently to further explorations and major discoveries in the still uncharted land of the unconscious. As the philosopher Henri Bergson wrote at the dawn of the twentieth century,

> To explore the most sacred depths of the unconscious, to labor in . . . the subsoil of consciousness, that will be the principal task of psychology in the century which is opening. I do not doubt that wonderful discoveries await it, as important perhaps as have been in the preceding centuries the discoveries of the physical and natural sciences.

Brave words! Bold predictions! And yet how widely off the mark they appear in the face of modern developments in psychiatry, especially on the North American continent as it approaches the new millennium. Our current major emphasis on the biological, neurological, and phenomenological aspects of psychiatric disorders is a far cry from the prominent concern with their psychological attributes among investigators 100 years ago. The briefest perusal of our contemporary psychiatric literature will readily indicate the extent of that difference. The space current major psychiatric publications allot to the elucidation of the unconscious, of psychological conflict, and of psychodynamic processes is miniscule compared with that devoted to the description of psychiatric syndromes and their neurobiological underpinnings. It is clear that there have been major changes in the conception of psychiatric illness over the course of the century now ending—changes whose

details are within the memory of many living psychiatrists and need be only briefly reviewed.

From the earlist years of the twentieth century. American psychiatry was significantly guided by two major influences—the psychobiological concepts of Adolf Meyer and the psychoanalytic theories of Freud. Both strongly underscored the vital importance of including psychosocial factors in the clinical understanding and treatment of psychiatric illnesses. The intellectual stimulation and the therapeutic optimism aroused by that humanistic approach brought psychiatrists away from their isolation in asylums for the insane back into the mainstream of medicine. By midcentury, the number of physicians choosing the practice of psychiatry was beginning to swell; general hospitals throughout the country were opening psychiatric inpatient units and outpatient clinics, and under the banners of “psychosomatic medicine” and “consultation-liaison psychiatry,” psychiatric clinicians and investigators were applying their psychological knowledge and procedures beyond the realm of psychiatric disorders to an exploration of the psychosocial aspects of the conventional medical and surgical illnesses as well.

At the height of this movement. Carl Binger, for many years the editor-in-chief of the journal *Psychosomatic Medicine*, wrote in *The Two Face of Medicine*,

> The principal contribution of psychiatry to medicine lies in its humanizing influence. It has kept man himself as the center of its concern rather than his enzymes or the chains of proteins of which he is composed. It has thus far managed to escape the automation that threatens to swallow up clinical medicine. . . . Our view is the holistic view. . . . We are less preoccupied with machine processed data than are those in other medical disciplines. The unprocessed reality of our world is . . . the human animal in his [inner] environment . . . which we approach through a study of personality. This latter has become of paramount importance not only for psychiatry but in the management of all sick people.

Binger's comments should make starkly clear the magnitude of the revolution that has occurred in the three decades since their utterance. The scientific advances in the knowledge of brain structure and function that have been achieved since that time, the development of effective psychopharmacotherapeutic agents, and the radical revision of the concept of psychiatric disorders and their diagnosis have now to a large degree supplanted attention to the clinical applications of psychodynamic understanding. However, no matter how strongly the biological view of psychiatric disease dominates the current scene, it constitutes only a cross-sectional view of a more extended historical process.

A look backward over the past 200 years reveals an interesting pattern in the evolution of ideas about mind and body and their role in the production of illness. Mesmer, of course, was not aware that his animal magnetism and the conditions he treated with it would evolve into the modern discipline of psychiatry. Indeed, he viewed his procedure as a contribution to the general practice of medicine and ascribed the therapeutic effect of his magnetic treatment to the direct mechanical action of a physical magnetic fluid on the patient's bodily organs. His materialistic hypothesis persisted as the accepted view for some 70 years until it was at last superseded by the psychological hypothesis of suggestion that emerged from the experiments and writings of James Braid. As the discipline of psychiatry gradually crystallized from those early clinical studies, it was dominated by psychological theories in one form or another for nearly a century until they were replaced by the biological hypotheses now in the ascendancy.

A historical perspective, in other words, reveals a curious alternation between psychological and biological explanations of illness. History, moreover, makes evident the fact that although one outlook may be dominant, it is not necessarily exclusive. On the contrary, its obverse is always to be found in a small but devoted minority. Indeed, throughout the two centuries that began with Mesmer, whatever the prevailing theoretical view of psychiatric illness, there has been, as Stanley Jackson has demonstrated, a constant demand for psychological understanding and treatment, while at the same time the quest for biological knowledge has continued at a steady pace.

History shows as well that there has always been a degree of antagonism between the proponents of the psychological and the biological view of psychiatric phenomena. The reasons for this seeming incompatibility are not entirely clear, but perhaps it has something to do with differences in human temperament. As Samuel Taylor Coleridge long ago suggested, each of us is born either an Aristotelian or a Platonist—each of us, that is, inherently prefers either to limit knowledge to what is ascertainable by the five senses alone or to include within its compass the psychological insights derived from introspection, intuition, and inspiration. Thus, among psychiatrists, there are those who would restrict the understanding of psychiatric disease to their biological aspects alone and those who would include their intangible, but no less real, psychological components as well.

The inherent tendency toward misunderstanding and antagonism between the proponents of these separate views hardly gives logical grounds for concluding that the concepts and practical clinical procedures associated with each are mutually exclusive, or even incompatible. On the contrary, biological and psychological knowledge each have vital contributions to make to the understanding and treatment of psychiatric disease. To borrow Binger's metaphor, they are the two faces of psychiatry, and both are essential for the fullest development of psychiatry as a discipline.

That is not to say, however, that any one individual can become completely familiar with both of these basic pathways to knowledge. A mere glance at the overwhelming wealth of information contained in this new edition of CTP demonstrates the impossibility of that feat. Instead of straining after the unattainable, each of us must choose that portion of the whole that is of most interest and master that more limited domain. At the same time, we must move outside our own parochial perceptions and predilections to a genuine understanding and appreciation of the pursuits of those who are following different pathways from our own. It is a major virtue of the volumes in hand that they greatly facilitate that task. The various contributors to their pages have delineated aspects of one or the other of the two faces of psychiatry with a clarity and precision that will enable their readers to achieve a broader vision of the nature and treatment of psychiatric disorders. Therein lies the basis for the ultimate integration of our knowledge of body and mind.

SUGGESTED CROSS-REFERENCES

The neural sciences are discussed in Chapter 1, neuropsychiatry in Chapter 2, and biological therapies in Chapter 3. Psychoanalytic theories and other psychological theories are covered in Chapter 6, and psychological therapies are covered in Chapter 30. The history and future of psychiatry is discussed in Chapter 55.

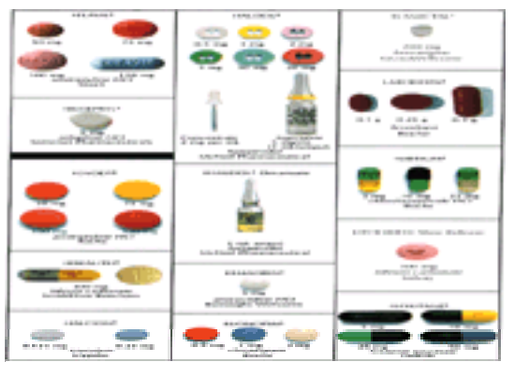
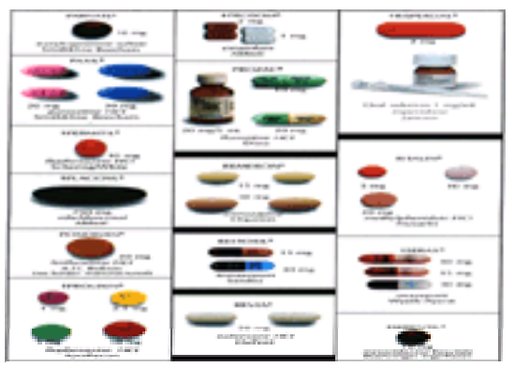
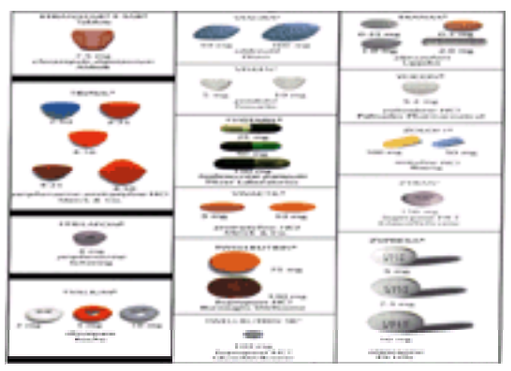
DRUGS USED IN PSYCHIATRY

This guide contains color reproductions of some commonly prescribed major psychotherapeutic drugs. This guide mainly illustrates tablets and capsules. A † symbol preceding the name of the drug indicates that other doses are available. Check directly with the manufacturer. (*Although the photos are intended as accurate reproductions of the drug, this guide should be used only as a quick identification aid.*)







Textbook of Psychiatry

COLOR PLATES

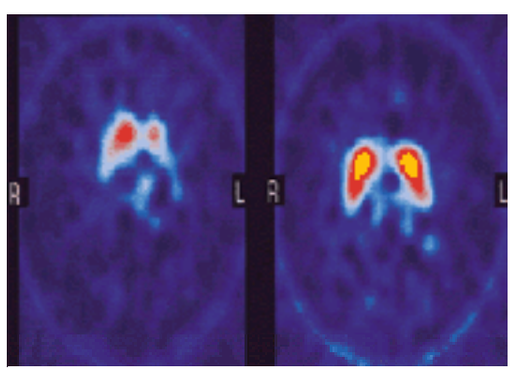


FIGURE 1.15–4 SPECT images of the distribution of [^{123}I]b-CIT (cocaine-iodo-tropane) in a healthy subject and a patient with Parkinson's disease. [^{123}I]b-CIT is a radiolabeled cocaine analogue and is a probe of dopamine transporters in the striatum. These transporters are located presynaptically on terminals of dopamine neurons projecting from the substantia nigra to the striatum. These transverse images show a high density of dopamine transporters in striatum and a marked reduction of these sites in an age- and sex-matched patient with idiopathic Parkinson's disease. The transporters are lost because the entire dopaminergic neuron, including its terminal projections in the striatum, degenerate in this disorder. (Courtesy of John Seibyl, Yale University.)

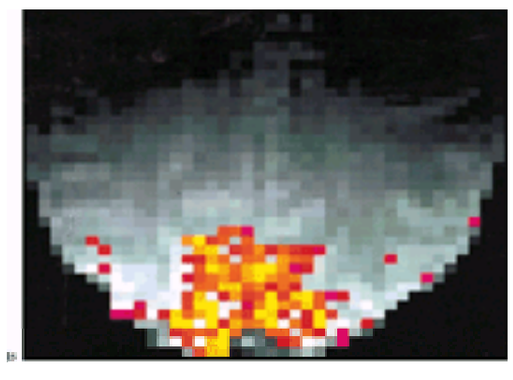

FIGURE 1.16–6 fMRI studies of photic stimulation. **A**, Change in image signal intensity in a single pixel during four alternating, 30-second epochs of flash photic stimulation. **B**, Activation maps demonstrating statistically significant increases in image signal intensity in primary visual cortex. Image data is acquired with a surface coil placed at the back of the head, thus explaining the decrease in image intensity with increasing distance from the occipital pole of the head. (Courtesy of Jonathan M. Levin, M.D., and Luis C. Maas.)

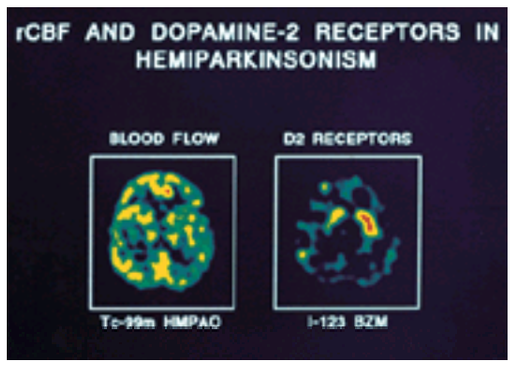

FIGURE 2.6–2 Regional cerebral blood flow, visualized with Technetium-99m HMPAO (**left panel**), and dopamine D_2-receptor binding, visualized with ^{123}I-iodobenzamide (I-123 BZM) (**right panel**), in a patient with hemiparkinsonism. Individuals with Parkinson's disease may present with markedly asymmetric symptoms. In this case, I-123 BZM uptake is markedly increased in the basal ganglia contralateral to the affected limb, whereas blood flow is unaffected. The increased uptake reflects increased D_2-receptor availability, either because of receptor upregulation or depletion of competing dopamine for the D_2 sites. (Courtesy of Michael Knable, D.O., and Daniel R. Weinberger, M.D.)

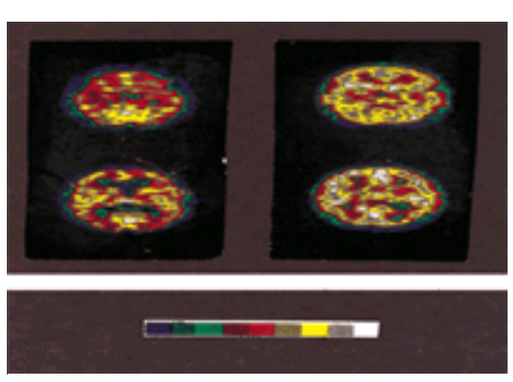

FIGURE 2.9–1 Transverse views obtained with Technetium-99m HMPAO SPECT. The two views on the left are of the brain of an adolescent with Lyme encephalopathy and demonstrate moderate heterogeneous hypoperfusion. The views on the right are of the brain of an adolescent without encephalopathy and demonstrate a normally perfused scan. The color spectrum scale, from purple to white, represents low to normal perfusion.

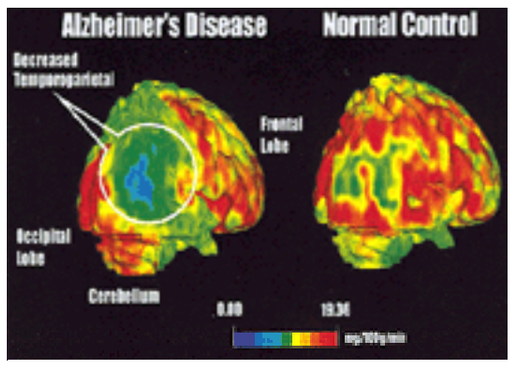

FIGURE 2.13–2 Three-dimensional PET FDG images demonstrate markedly lower glucose metabolism in temporoparietal region in patient with Alzheimer's disease than in normal control.

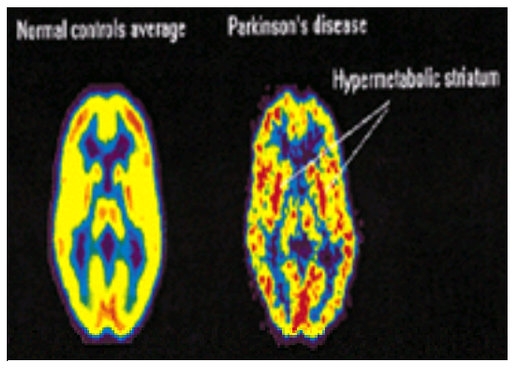

FIGURE 2.13–3 Transaxial section of PET FDG demonstrates hypermetabolism in striatum in patient with Parkinson's disease compared with normal control average image.

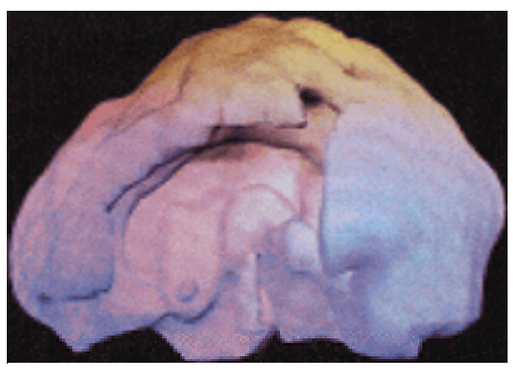

FIGURE 2.13–4 Stroke. Left side surface view shows marked decreased left frontal, temporal, and parietal lobe. (Note: SPECT cortical surface images are rendered by setting the threshold at 55%, looking at most active 45% of brain activity; SPECT active images are rendered by setting blue color threshold set at 55%, looking at average brain activity in the brain compared to red [or white] threshold set at 85%, looking at the most active 15% of brain activity.)

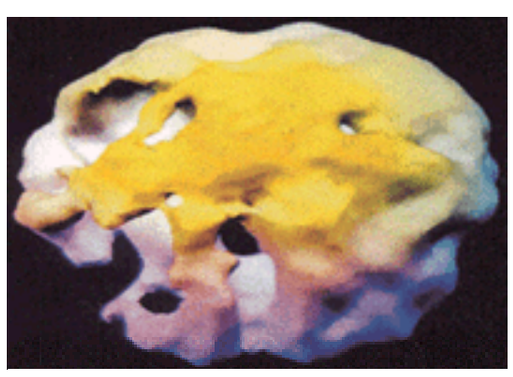

FIGURE 2.13–5 Two right hemisphere strokes with depression as presenting symptom. Top-down surface view shows marked decreased right frontal, temporal, and parietal lobe.

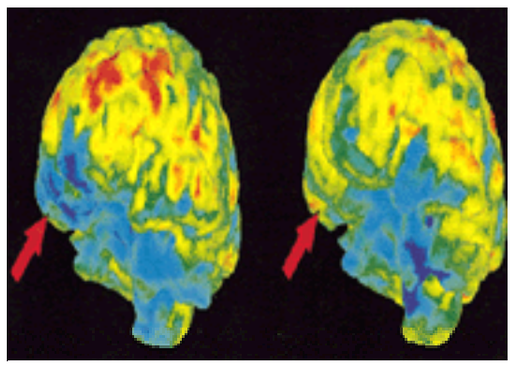

FIGURE 2.13–6 Three-dimensional PET FDG images demonstrate lower orbitofrontal metabolism in orbital frontal lobe syndrome in patient secondary to traumatic brain injury than in normal control.

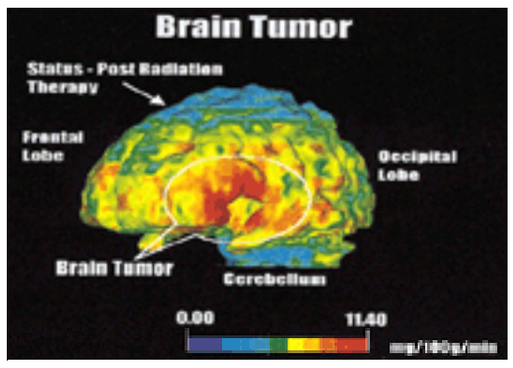

FIGURE 2.13–7 Three-dimensional PET FDG image demonstrate hypermetabolism in region of brain tumor in frontal cortex and decreased metabolism in parietal cortex secondary to postradiation injury.

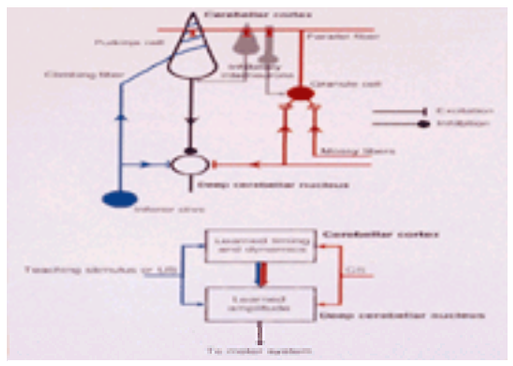

FIGURE 3.4–2 A schematic diagram of the circuitry of the mammalian cerebellum (**top**). In the classically conditioned blink response, input from the air-puff unconditioned stimulus and input from the auditory conditioned stimulus comes in through parallel pathways to the cerebellar cortex and to the deep cerebellar nucleus, and plasticity occurs in both pathways (**bottom**). FIGURE 3.4–5 PET and MRI scans in a patient with Korsakoff's syndrome. Neural dysfunction was evident as reduced glucose utilization in multiple cortical regions in the frontal and parietal lobes, and in the cingulate. Functional neuroimaging can reveal brain dysfunction that might otherwise not be evident if limited to structural neuroimaging results. In Korsakoff's syndrome, the memory impairment probably reflects a disruption of thalamocortical circuitry. (Reprinted with permission from Paller KA, Acharya A, Richardson BC, Plaisant O, Shimamura AP, Reed BR, Jagust WJ: Functional neuroimaging of cortical dysfunction in alcoholic Korsakoff's syndrome. J Cogn Neurosci *9:*277, 1997.)

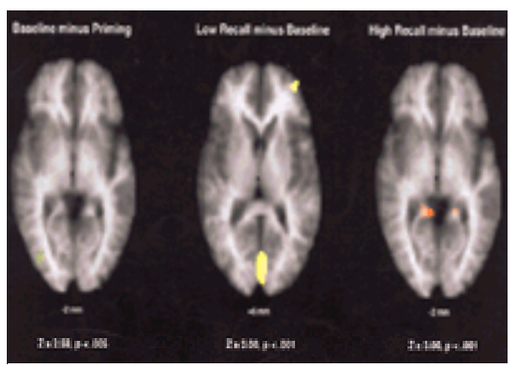

FIGURE 3.4–9 PET activations superimposed over averaged transverse MRI scans with the distance shown representing the distance from the line connecting the anterior and posterior commissure. Words were studied under strong or weak learning conditions (high recall or low recall) and then both declarative memory (cued recall) and nondeclarative memory (priming) were tested. The Baseline minus Priming subtraction showed an area of decreased blood flow (green) in right visual association cortex thought to be related to the greater ease of processing primed words. The Low Recall minus Baseline subtraction showed an area of increased blood flow (yellow) in secondary visual cortex and left prefrontal cortex thought to be related to the effort involved in deliberate, effortful retrieval. The High Recall minus Baseline subtraction showed a region of increased blood flow (red) in bilateral hippocampal regions thought to be related to successful retrieval of recently acquired information. (Reprinted with permission from Schacter DL, Alpert NM, Savage CR, Rauch SL, Albert MS: Conscious recollection and the human hippocampal formation: Evidence from positron emission tomography. Proc Natl Acad Sci USA *93:*321, 1996. ©1996 National Academy of Sciences, U.S.A.)

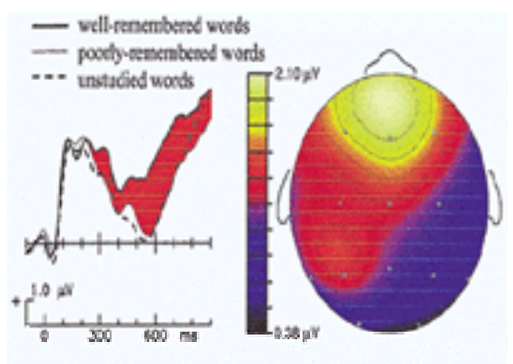

FIGURE 3.4–10 Brain potentials showing a differential response based on the extent to which subjects engaged in recollection following word presentations. Potentials shown at the left were recorded from a frontal scalp electrode. Measurements from multiple electrodes over the 400- to 800-ms latency range were used to

generate the topographical map at the right, showing that the neural correlate of recollection was broadly distributed across the scalp, with largest responses over frontal cortex. (Adapted with permission from Paller KA, Kutas M: Brain potentials during memory retrieval provide neurophysiological support for the distinction between conscious recollection and priming. J Cogn Neurosci *4:*375, 1992.)

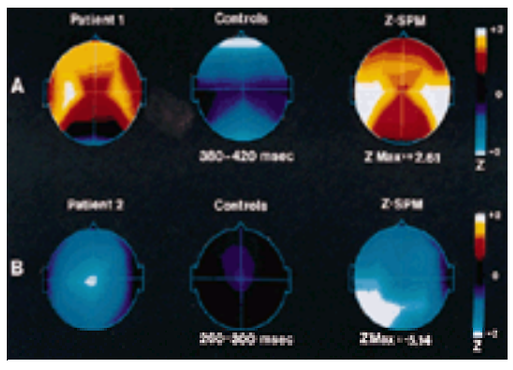

FIGURE 11.7–3 Illustrative cases of quantitative EEG abnormalities in hallucinogen persisting perception disorder (flashback). **Patient 1:** A 26-year-old computer programmer used LSD at the age of 18 on 15 occasions; 31 months later the patient experienced the abrupt onset of intense, LSD-like set of visual and affective disturbances lasting all night. At 25 he suffered the spontaneous onset of hourly flashing white lights centrally and black dots in his peripheral fields, which have continued for the past 10 years. Topographic brain maps are shown during the 380–420 msec epoch of the visually evoked potential in row **A**. The upper left map represents the subject's data. The upper middle map shows control subjects for the same poststimulus latency epoch. The right upper image is a significance probability map (SPM) showing *Z*-scores resulting from a comparison of the data from the left and middle upper maps. The patient shows an enhancement in the visually evoked signal involving both temporal regions of the cerebrum. **Patient 2:** A 23-year-old musician used LSD on 16 occasions over a 4-month period at the age of 20. Within 2 months he began to notice a progressive, continuous visual disorder characterized by flashes of color, persisting afterimages, haloes around objects, a grainy texture to the sky, and the lingering trails of objects as they passed through his visual field. The graininess in the visual field interfered with night vision. Topographic brain mapping is illustrated during the 260–300 msec epoch of auditory evoked potentials in row **B**. Note the region of reduced electrical activity in the left posterior temporal region in the lower right map. (Reprinted with permission from Abraham HD, Duffy FH: Stable quantitative EEG difference in post-LSD visual disorder by split-half analysis: Evidence for disinhibition. Psychiatry Res *67:*173, 1996.)

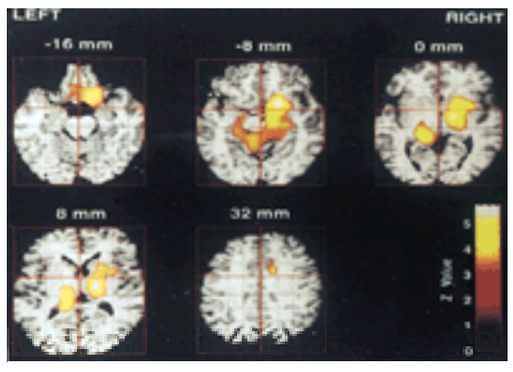

FIGURE 12.1–1 Axial sections demonstrating brain areas with significantly increased activity during auditory verbal hallucinations in the group study. Functional PET results (threshold at $Z > 3.09$, $P < 0.001$, by reference to the unit normal distribution) are displayed in color, superimposed upon a single structural T1-weighted magnetic resonance imaging (MRI) scan that has been transformed into the Talairach space for anatomical reference. Section numbers refer to the distance from the anterior commissure-posterior commissure line, with positive numbers being superior to the line. The areas of activation extend into the amygdala bilaterally, and into the right orbitofrontal cortex. Although these regions of extension are consistent with the limbic paralimbic component of activity during hallucinations, and may contribute to drive and affect in this context, definitive statements cannot be made in the absence of discrete maxima. (Reprinted with permission from Silbersweig DA, Stern E, Frith C, Cahill C, Holmes A, Grootoonk S, Seaward J, McKenna P, Chua SE, Schnorr L, et al: A functional neuroanatomy of hallucinations in schizophrenia. Nature *378:*1769, 1995.)

CHAPTER 1. NEURAL SCIENCES

1.1 NEURAL SCIENCES: INTRODUCTION AND OVERVIEW

JACK A. GREBB, M.D.

The first two chapters of this textbook—Neural Sciences and Neuropsychiatry and Behavioral Neurology—provide the reader a very complete primer and reference resource on the biological basis of normal behaviors and mental illnesses. Both chapters focus on the human brain, which is the biological substrate for all of our emotions, cognitive abilities, and behaviors—that is, everything we feel, think, and do. This chapter describes the basic biology of the brain and presents information on the interactive systems within the brain, the imaging of brain function, and the genetics of mental illnesses. Chapter 2, Neuropsychiatry and Behavioral Neurology, focuses on the neuropsychiatric aspects of the more classical neurological diseases, the study of which provides valuable information regarding how identified lesions in the nervous system are associated with disorders of affect, cognition, and behavior.

NEUROANATOMY

Functional neuroanatomy (discussed in Section 1.2) is the study of interacting and interdependent neurons, groups of neurons (e.g., nuclei), and brain regions. The three neural systems of most interest in psychiatry are the thalamocortical system, the basal ganglia, and the limbic system. In the 1970s, the thalamus was a focus of psychiatric research; however, the thalamus and its interactions with the cerebral cortex have primary importance in the sensory, motor, and associative functions of the brain. Moreover, the thalamus and its interactions with the cerebellar cortex are now known to be involved in cognition. The basal ganglia, once thought of only as part of the motor system, is now known to be a complex system within itself, and plays a key role in the cognitive functions of the brain. In contrast to the thalamus and basal ganglia, the limbic system has long been associated with psychiatric symptoms because of its clear involvement in the experience and expression of emotions.

The rapidly expanding understanding of the adult human brain in recent years has allowed more questions to be asked about the developing human brain (Section 1.3). Because psychiatric disorders that become symptomatic only in adulthood may be caused by genetic or environmental events that occur during conception or early in development, the study of human brain development has the potential to provide neurobehavioral scientists with a breakthrough in understanding mental illnesses.

NEUROTRANSMITTERS

There are four broad classes of neurotransmitter and neuromodulator substances in the brain: monoamines, amino acids, peptide neurotransmitters, and the much more recently discovered neurotrophins (also known as *neurotrophic factors*). Two additional neurotransmitters that do not fit into these four major classes are the gas nitric oxide and the purine-related neurotransmitters adenosine and adenosine triphosphate (ATP). Any single neuron can release multiple different types of neurotransmitters or neuromodulators, and also have receptors for multiple different receptor types and subtypes, thus making each individual neuron capable of exquisite integration and modulation of incoming and outgoing signals. There are five classic monoamine neurotransmitters, which are serotonin, the three catecholamines (epinephrine, norepinephrine, and dopamine), acetylcholine, and histamine (Section 1.4). The monoamine neurotransmitters, although present in only a small percentage of neurons localized in small nuclei of the brain, have enormous impact on total brain functioning because the diffuse projections of axons from these monoaminergic neurons can affect virtually every brain region. In contrast to the monoamine neurotransmitters, the amino acid neurotransmitters are widely distributed in the brain, and it is possible to conceptualize the brain as reflecting the balance between the excitatory amino acid glutamate, and the inhibitory amino acid g-aminobutyric acid (GABA) (Section 1.5). In contrast to the relatively small number of different monoamine and amino acid neurotransmitters, over one hundred different neuropeptide neurotransmitters have already been identified (Section 1.6). Because virtually all existing drugs for psychiatric conditions act through monoamine or amino acid neurotransmitter systems, the development of drugs that would have specific agonist or antagonist properties on neuropeptide systems offers great hopes for the development of new pharmacological treatments.

The first neurotrophic factor, nerve growth factor (NGF), was discovered by the Nobel Prize laureate, Rita Levi-Montalcini. The neurotrophic factors are polypeptides (i.e., proteins), and thus have the same basic structure as the neuropeptide neurotransmitters. Less is known about neurotrophic factors than about the more classic neurotransmitter substances, but neurotrophic factors can be conceptualized as differing from neuropeptide neurotransmitters in having longer-term regulatory functions (Section 1.7). The identification of additional neurotrophic factors and neurotrophic factor receptors provides researchers with many new hypotheses for disease etiologies and new hopes for disease interventions. Clinical trials of specific neurotrophic factors (e.g., brain-derived neurotrophic factor [BDNF], ciliary neurotrophic factor [CNTF]) in neurological diseases have already been conducted on neurodegenerative diseases such as amyotrophic lateral sclerosis.

Nitric Oxide Nitric oxide (NO) acts in the brain as both an intraneuronal second messenger and as a neurotransmitter. NO is formed from the amino acid arginine by the actions of NO synthase. NO and NOS synthase have been described in the brain. NO synthase is present in discrete regions of the brain, particularly the striatum, hypothalamus, basal forebrain, and cerebellum. The best understood pathway resulting in the generation of NO begins with activation of the *N*-methyl-D aspartate (NMDA) subtype of the glutamate receptor. Activation of the NMDA receptor results in the influx of calcium into the neuron, and the calcium-mediated activation of NO synthase, which generates NO from arginine. Intraneuronal NO then acts on the iron molecule contained in guanylyl cyclase and results in the formation of cyclic guanylyl monophosphate (cGMP), a potent second-messenger molecule. Because of its gaseous properties, NO can also diffuse to adjacent neurons, in which it can also result in the formation of cGMP. Unlike other neurotransmitters, NO is not stored in synaptic vesicles and is not necessarily released only on depolarization. Its receptors are iron and possibly other reactive metals, and not the conventional protein neurotransmitter receptors. Currently available data suggest that NO may be involved in some aspects of learning and memory. In addition, inhibitors of NO synthase may be effective in reducing ischemic damage after cerebrovascular events.

Adenosine and ATP Adenosine is a purine and ATP is synthesized from adenosine. P_1 receptors, which have a high affinity for adenosine, and P_2 receptors, which have a high affinity for ATP, have been found in the brain. The P_1 receptors are blocked by xanthines, such as caffeine and theophylline. Three subtypes of the P_1 receptor are the adenosine A_1, A_2 and A_3 receptors, all of which are G protein-linked receptors. Adenosine is concentrated in discrete regions of the brain and appears to have the general effect of inhibiting the release of most other neurotransmitters. This property has led to research activities to study adenosine analogues for use as anticonvulsants or sedatives. ATP is stored along with catecholamines in synaptic vesicles, and is released when the catecholamines are released. ATP preferentially acts on P_2 receptors, and data show that at least one function of ATP is the excitatory activation of sodium-potassium and calcium ion channels. A small body of evidence suggests that nucleotides and nucleosides may have trophic actions on glial and neuronal cells.

s-Receptors Another molecule that does not fit easily into the general scheme is the s-receptor, for which a natural ligand has not been identified, although in the past the sigma receptor was erroneously thought to be the primary receptor for phencyclidine (PCP, also known as “angel dust”). The previous association between s-receptors and PCP and the discovery that a number of antipsychotic drugs bind with high affinities to the s-receptors have caused researchers and pharmaceutical companies to develop sigma antagonists as potential antipsychotic compounds. So far, however, clinical trials with these compounds have not been successful.

SIGNAL TRANSDUCTION AND MOLECULAR GENETICS

The process of *chemical neurotransmission* refers strictly to the release of a neurotransmitter by a presynaptic neuron, the travel of that neurotransmitter across some space (e.g., the synaptic cleft), and the binding of that neurotransmitter to its specific receptor on a postsynaptic neuron (or an autoreceptor on a presynaptic neuron). The process of *signal transduction,* however, refers to the process by which an electrical signal (e.g., the action potential) in the presynaptic neuron is translated into a chemical signal (e.g., the release of a neurotransmitter), and the process by which the chemical signal (e.g., the interaction of a neurotransmitter and its receptor) is translated back into an electrical signal in the postsynaptic neuron. The study of intraneuronal signaling pathways and the regulation of neuronal ion channels

provides the basics for understanding signal transduction.

The initial step in intraneuronal signaling is most often the generation of second-messenger molecules (e.g., ATP) following the activation of a neurotransmitter receptor by its specific neurotransmitter (Section 1.8). In this schema, the first messenger is considered to be the neurotransmitter, peptide, or hormone that activated the receptor. The generation of the second messenger, however, can lead to a cascade of intraneuronal third, fourth, and more messenger molecules. One example of this cascade is the process of protein phosphorylation, which is a reversible, posttranslational modification of a protein. The deletion or the addition of one or more phosphate groups to a protein results in a change in the function of that protein. Thus, protein phosphorylation can serve as a type of molecular on-off switch for protein function. Protein phosphorylation more often modulates the function of a protein than it turns a specific function completely on or off. The identification of multiple biochemical steps, such as protein phosphorylation, offers researchers novel opportunities to identify pathophysiological processes as well as to develop therapeutic approaches.

Although psychiatrists and other mental health professionals may be more familiar with neurotransmitters and intraneuronal messengers than with ion channels, it is the balance between external and internal concentrations of ions that actually fuels the activities of the brain (Section 1.9). This balance is achieved by a wide array of ion channels, some of which are regulated by neurotransmitters and others by voltage gradients directly. Many of the drugs of interest in psychiatry act directly on ion channels. The benzodiazepines act on GABA type A ($GABA_A$) receptors that are chloride ion channels. Phencyclidine acts on the NMDA subtype of glutamate receptors that are calcium ion channels. Nicotine, the active ingredient in tobacco, acts on nicotinic acetylcholine receptors that are sodium and potassium ion channels. As with the neurotransmitter receptors, the delineation of ion channel subtypes and the modulation of ion channel function by processes such as protein phosphorylation are among the most active areas of neuropsychiatric and neuropharmacological research.

Driving the development of the brain as well as the daily maintenance and regulation of brain function is the process of genetic expression (Section 1.10). The basic process of genetics involves the transcription of deoxyribonucleic acid (DNA) into ribonucleic acid (RNA) and the translation of RNA into a protein. A complex system of regulation exists for transcription and translation, and the newly discovered molecules and pathways for this regulation are sites of investigation for discoveries in the etiology, pathophysiology, and treatment of mental disorders. Alterations in gene expression occur both during development and in adulthood and may be the bases for abnormal and normal development, and for abnormal and normal adaptation to stress. Psychiatric research in the twenty-first century is likely to investigate neurotrophic factors and molecular genetics.

INTEGRATION AND TIME

In addition to the central nervous system, the human body contains two other systems that have complex, internal communicative networks—the endocrine system and the immune system. Mostly because of the discoveries of the involved molecular signals, it is now known that these three systems are integrated with each other, which has given birth to the sciences of psychoneuroendocrinology (Section 1.11) and psychoneuroimmunology (Section 1.12). The interactions between the neuroendocrine and central nervous systems can most easily be seen in the psychiatric symptoms that can accompany some hormonal disorders (e.g., depression in Cushing's syndrome), and also in the identification of disorders of neuroendocrine regulation as potential markers for state or trait variables in psychiatric conditions.

In addition to the property of internal communication, another property shared by the neuroendocrine, immune, and central nervous systems is that they undergo regular changes with time. The study of these changes with time and disorders of time regulation are encompassed in the field of chronobiology (Section 1.13).

IMAGING BRAIN FUNCTION

Although X-rays and computed tomography (CT) can provide images of the skull, these are often of more interest to neurologists and neurosurgeons than to psychiatrists because psychiatry is more focused on the function of the brain itself. The first approach to be developed for measuring and imaging brain function was the field of applied electrophysiology, using the tools of electroencephalography (EEG) and evoked potentials (EPs) (Section 1.14). More recently, computerized approaches to these data have yielded more sophisticated analyses and presentations of information. The recent development of magnetoencephalography may expand the ability of this field to measure the activity of deeper brain structures.

Of most value in psychiatric research today for the visualization of brain function are the modalities of positron emission tomography (PET) and single photon emission computed tomography (SPECT), utilizing either radiotracer techniques (Section 1.15) or the differing magnetic resonance properties of the molecules in the brain (Section 1.16). These techniques can measure and visualize brain function during increasingly shorter time periods, allowing researchers to ask increasingly specific questions about specific brain regions and neural networks and their relationship to specific emotional, cognitive, and behavioral states and activities.

APPLIED GENETICS

The application of the techniques of population genetics to the study of mental illness provided some of the first objective data that mental illnesses were biological illnesses, thereby helping to destigmatize these human conditions. The use of population genetic methods in psychiatric research continues to yield important data and insights into mental illnesses (Section 1.17). The tools of population genetics have been more recently supplemented by the application of molecular neurobiological tools to this discipline, and the ability to study specific genetic linkages among individuals and groups of individuals (Section 1.18). The application of these techniques can lead to the identification of a specific gene or genes as causative agents for specific mental disorders. The example of the discovery of the gene for Huntington's disease is described in a subsequent chapter (Section 1.21).

SLEEP AND APPETITE

Sleep and appetite are just two examples of complex behaviors that are the observable results of the summations of neural processes. Sleep (Section 1.19) and appetite (Section 1.20) are regulated by specific brain regions and specific neurotransmitters, modulated by intraneuronal signals and ion channels, affected by the immune and neuroendocrine systems, altered with time, visualizable through brain-imaging techniques, subject to genetic regulation, and often affected by neurological or psychiatric disorders. Other complex brain activities such as perception, cognition, and memory are described elsewhere in this textbook.

SUGGESTED CROSS-REFERENCES

Neuropsychiatry and behavioral neurology are discussed in Chapter 2; the neuropsychological and psychiatric aspect of AIDS are discussed in Section 2.8; the neurochemical, viral, and immunological studies of schizophrenia are discussed in Section 12.4; the biochemical aspects of mood disorders are discussed in Section 14.3; biological therapies are discussed in Chapter 31; and Alzheimer's disease is discussed in Section 51.3. The future of psychiatry is discussed in Section 55.3.

1.2 FUNCTIONAL NEUROANATOMY

DAVID A. LEWIS, M.D.

The normal affective, cognitive, and behavioral processes that are disturbed in different psychiatric disorders arise because of specific patterns of activation in networks of neurons that are distributed through the central nervous system. These patterns of activation are mediated by the connections among specific brain structures. Consequently, understanding the neurobiological bases for psychiatric disorders requires an appreciation of the major principles governing the functional organization of these structures and connections in the human brain. The thalamocortical, basal ganglia, and limbic systems are of particular relevance to neuropsychiatric disorders.

Those systems are formed by extensive and highly specific connections among certain anatomical structures, and the activation of those multiple connections gives rise to distinct behaviors, cognitive abilities, and emotional states. Thus, knowledge of the anatomical organization of the functional systems is crucial for the development and testing of hypotheses regarding the biological bases of the signs and symptoms of neuropsychiatric disorders.

PRINCIPLES OF BRAIN ORGANIZATION

Cells The human brain contains approximately 10^{11} nerve cells or *neurons*. In general, neurons are composed of four morphologically identified regions (Fig. 1.2-1): (1) the cell body or *soma*, which contains the nucleus and can be considered the metabolic center of the neuron; (2) the *dendrites,* processes that arise from the cell body, branch extensively, and serve as the major recipient zones of input from other neurons; (3) the *axon,* a single process that arises from a specialized portion of the cell body (the *axon hillock*) and conveys information to other neurons; and (4) the *axon terminals,* fine branches near the end of the axon that form contacts *(synapses)* generally with the dendrites or the cell bodies of other neurons, release neurotransmitters, and thereby provide a mechanism for interneuronal communication.

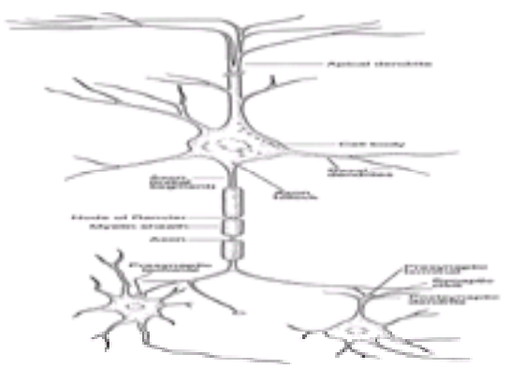

FIGURE 1.2-1 Drawing of the major features of a typical neuron. (Adapted from Kandel ER: Nerve cells and behavior. In *Principles of Neural Science,* ed 3, E Kandel, J Schwartz, T Jessell, editors. Elsevier, New York, 1991.)

The majority of neurons in the human brain are considered to be multipolar in that they give rise to a single axon and several dendritic processes. Although there are a number of classification schemes for neurons in different brain regions, almost all neurons can be considered either projection or local circuit neurons. *Projection neurons* have long axons and convey information from the periphery to the brain (sensory neurons), from one brain region to another, or from the brain to effector organs (motor neurons). In contrast, *local circuit neurons* or *interneurons* have short axons and process information within distinct regions of the brain.

Neurons can also be classified according to the neurotransmitters they contain (e.g., the dopamine neurons of the substantia nigra). Identification of neurons by their neurotransmitter content in anatomical studies provides a means for correlating the structure of a neuron with certain aspects of its function. However, neurotransmitters have defined effects on the activity of neurons, whereas complex brain functions, such as those disturbed in psychiatric disorders, are mediated by the coordinated activity of ensembles of neurons. Thus, the effects of neurotransmitters (or of pharmacological agents that mimic or antagonize the action of neurotransmitters) on behavioral, emotional, or cognitive states must be viewed within the context of the neural circuits that they influence.

In addition to neurons, the brain also contains several types of *glial* cells, which are at least ten times more numerous than the neurons. Although glial cells are not directly involved in information processing, they play several important roles in the nervous system. *Oligodendrocytes* and *Schwann cells*, found in the central and peripheral nervous systems, respectively, are relatively small cells that wrap their membranous processes around axons in a tight spiral. The resulting *myelin sheath* facilitates the conduction of action potentials along the axon. *Astrocytes,* the most numerous class of glial cells, appear to serve a number of functions, including participation in the formation of the blood-brain barrier, removal of certain neurotransmitters from the synaptic cleft, buffering of the extracellular potassium (K^+) concentration, and, given their close contact with both neurons and blood vessels, possibly a nutritive function as well. The third class of glial cells, the *microglia*, are actually derived from macrophages and function as scavengers, eliminating the debris resulting from neuronal death and injury.

Architecture Neurons and their processes form groupings in a number of different ways, and those patterns of organization can be evaluated by several approaches. The pattern of distribution of the neurons, called *cytoarchitecture,* is revealed by aniline dyes that stain ribonucleotides, Nissl substance, in the nucleus and the cytoplasm of neuronal cell bodies. The Nissl stains demonstrate the relative size and packing density of the neurons and consequently reveal, for example, the organization of the neurons into the different layers of the cerebral cortex. In certain pathological states, such as Alzheimer's disease, neuronal degeneration and loss results in striking changes in the cytoarchitecture of some brain regions (Fig. 1.2-2).

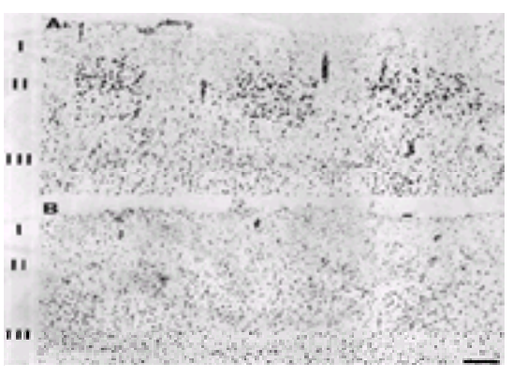

FIGURE 1.2-2 Nissl-stained sections of the superficial layers of the intermediate region of human entorhinal cortex. In the control brain **(A)**, layer II contains clusters or islands of large, intensely stained neurons. In Alzheimer's disease **(B)**, these layer II neurons are particularly vulnerable to degeneration, and their loss produces a

marked change in the cytoarchitecture of the region. Roman numerals indicate the location of the cortical layers. Calibration bar (200 μm) applies to **A** and **B**.

Other types of histological techniques, such as silver stains, selectively label the myelin coating of axons and, consequently, reveal the *myeloarchitecture* of the brain. For example, certain regions of the cerebral cortex—such as area MT, a portion of the temporal cortex involved in processing visual information—can be identified by a characteristic pattern of heavy myelination in the deep cortical layers. The progression of myelination is highly region-specific, may not be complete for years after birth, and may be a useful anatomical indicator of the functional maturation of brain regions.

Immunohistochemical and other related techniques—which identify the location of neurotransmitters, their synthetic enzymes, or other molecules within neurons—can be used to determine the *chemoarchitecture* of the brain (Fig. 1.2-3B). In some cases, these techniques reveal striking regional differences in the chemoarchitecture of the brain that are difficult to detect in cytoarchitecture.

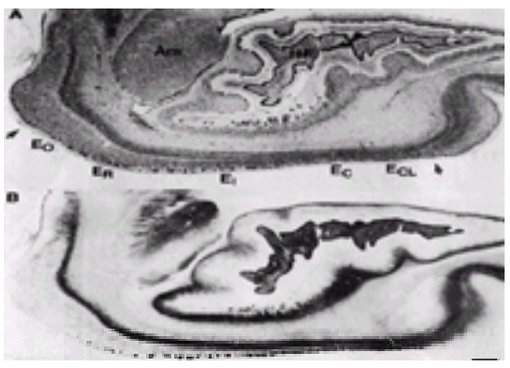

FIGURE 1.2-3 Adjacent sagittal sections through the medial temporal lobe of the human brain labeled to reveal the cytoarchitecture (**A**—Nissl stain) and chemoarchitecture (**B**—nonphosphorylated neurofilament protein immunoreactivity) of the entorhinal cortex. Arrows indicate the rostral (left) and caudal (right) borders of the entorhinal cortex, and letters indicate some of its subdivisions. Calibration bar (2 mm) applies to both panels. (Reprinted with permission from Beall MJ, Lewis DA: Heterogeneity of layer II neurons in human entorhinal cortex. J Comp Neurol *321:*241, 1992.)

Connections Every function of the human brain is a consequence of the activity of specific neural circuits. The circuits form as a result of several developmental processes. First, each neuron extends an axon, either after it has migrated to its final location or, in some cases, before. The growth of an axon along distinct pathways is guided by molecular cues from its environment and eventually leads to the formation of synapses with specific target neurons. Although the projection of axons is quite precise, some axons initially produce an excessive number of axon branches or *collaterals* and thus contact a broader set of targets than are present in the adult brain. During later development the connections of particular neurons are focused by the pruning or elimination of axonal projections to inappropriate targets.

Within the adult brain the connections among neurons or neural circuits follow several important principles of organization. First, many but not all connections between brain regions are *reciprocal;* that is, each region tends to receive input from those regions to which it sends axonal projections. In some cases the axons arising from one region may directly innervate the reciprocating projection neurons in another region; in other cases local circuit interneurons are interposed between the incoming axons and the projection neurons that furnish the reciprocal connections. For some projections the reciprocating connection is indirect, passing through one or more additional brain regions and synapses before innervating the initial brain region.

Second, many neuronal connections are either divergent or convergent in nature. A *divergent* system involves the conduction of information from one neuron or a discrete group of neurons to a much larger number of neurons that may be located in diverse portions of the brain. The locus ceruleus, a small group of norepinephrine-containing neurons in the brainstem that sends axonal projections to the entire cerebral cortex and other brain regions, is an example of a divergent system. In contrast, the output of multiple brain regions may be directed toward a single area, forming a convergent system.

Third, the connections among regions may be organized in a hierarchical or parallel fashion or both. For example, visual input is conveyed in a *serial* or *hierarchical* fashion through several populations of neurons in the retina to the lateral geniculate nucleus, to the primary visual cortex, and then progressively to the multiple visual association areas of the cerebral cortex. Within the hierarchical scheme, different types of visual information (e.g., motion, form) may be processed in a parallel fashion through different portions of the visual system.

Finally, regions of the brain are specialized for different functions. For example, lesions of the left inferior frontal gyrus (Broca's area, Fig. 1.2-4A) produce a characteristic impairment in speech production. However, speech is a complex faculty that depends not only on the integrity of Broca's area but also on the distributed processing of information across a number of brain regions through divergent and convergent, serial and parallel interconnections. Thus, the role of any particular brain region or group of neurons in the production of specific behaviors or in the pathophysiology of a given neuropsychiatric disorder cannot be viewed in isolation but must be considered within the context of the neural circuits connecting those neurons with other brain regions.

FIGURE 1.2-4 Photographs of the lateral **(top)** and medial **(bottom)** of the left hemisphere of a human brain indicating the location of major surface landmarks. F indicates frontal lobe, O indicates occipital lobe, P indicates parietal lobe, T indicates temporal lobe, Th indicates thalamus, cc_G indicates the genu of the corpus callosum, cc_S indicates the splenium of the corpus callosum.

Distinctiveness of the Human Brain The human brain is substantially larger than the brains of other primate species and certain areas of the human brain have expanded disproportionately. For example, the prefrontal cortex has been estimated to occupy only 3.5 percent of the total cortical volume in cats and 11.5 percent in monkeys but close to 30 percent of the much larger cortical volume of the human brain. Conversely, the relative representation of other regions is decreased in the human brain; for example, the primary visual cortex accounts for only 1.5 percent of the total area of the cerebral cortex in humans, but in monkeys a much greater proportion (17 percent) of the cerebral cortex is devoted to that region. Thus, the distinctiveness of the human brain is attributable both to its size and to the differential expansion of certain regions, particularly those areas of the cerebral cortex devoted to higher cognitive functions.

The expansion and the differentiation of the human brain is associated with substantial differences in the organization of certain elements of neural circuitry. For example, when compared with rodents, the dopaminergic innervation of the human cerebral cortex is much more widespread and regionally specific. The primary

motor cortex and certain posterior parietal regions receive a dense dopamine innervation in both monkeys and humans, but those areas receive little dopamine input in rats. These types of species differences indicate that there are limits to the accuracy of the generalizations made about human brain function when studies on rodents or even nonhuman primates are used as the basis for the inference. However, direct investigation of the organization of the human brain is obviously restricted and complicated by a number of factors. As indicated above, the expansion of the human brain is associated with the appearance of additional regions of the cerebral cortex. For example, the entorhinal cortex of the medial temporal lobe is sometimes considered to be a single cortical region, yet in the human brain the cytoarchitecture and the chemoarchitecture of that cortex differs substantially along its rostral-caudal extent (Fig. 1.2-3). It is tempting to identify those regions by their location relative to other structures, but sufficient interindividual variability exists in the human brain to make such a topological definition unreliable. In the case of the entorhinal cortex, the location of its different subdivisions relative to adjacent structures, such as the amygdala and the hippocampus, varies somewhat across human brains. Therefore in all studies, particularly those using the human brain, areas of interest must be defined such that investigators can accurately identify the same region in all cases.

An additional limitation to the study of the human brain concerns the changes in morphology and biochemistry that can occur during the interval between the time of death and the freezing or fixation of brain specimens. In addition to the influence of the known postmortem interval, such changes may begin to occur during the agonal state preceding death. When comparing aspects of the organization of the human brain with that of other species, the researcher must try to account for changes that may have occurred in the human brain as a result of postmortem delay or agonal state. Furthermore, in the study of disease states appropriate controls must be used because differences in neurotransmitter content or other characteristics among cases could be a result of factors other than the disease state. Studies of the human brain in vivo—using such imaging techniques as positron emission tomography, magnetic resonance imaging, and magnetic resonance spectroscopy—circumvent many of those problems but are limited by a level of resolution that is insufficient for the study of many aspects of human brain organization.

STRUCTURAL COMPONENTS

Major Brain Structures In the early stages of the development of the human brain, three primary vesicles can be identified in the neural tube: the *prosencephalon,* the *mesencephalon,* and the *rhombencephalon* (Table 1.2-1). Subsequently, the prosencephalon divides to become the *telencephalon* and the *diencephalon*. The telencephalon gives rise to the cerebral cortex, the hippocampal formation, the amygdala, and some components of the basal ganglia. The diencephalon becomes the thalamus, the hypothalamus, and several other related structures. The mesencephalon gives rise to the midbrain structures of the adult brain. The rhombencephalon divides into the *metencephalon* and the *myelencephalon*. The metencephalon gives rise to the pons and the cerebellum; the medulla is the derivative of the myelencephalon.

Primary Vesicles	Secondary Vesicles	Brain Components
Prosencephalon	Telencephalon	Cerebral cortex
		Hippocampus
		Amygdala
		Striatum
	Diencephalon	Thalamus
		Hypothalamus
		Epithalamus
Mesencephalon	Mesencephalon	Midbrain
Rhombencephalon	Metencephalon	Pons
		Cerebellum
	Myelencephalon	Medulla

Table 1.2-1 Derivatives of the Neural Tube

The cerebral cortex of each hemisphere is divided into four major regions; the *frontal, parietal, temporal*, and *occipital* lobes (Fig. 1.2-4). The frontal lobe is located anterior to the central sulcus and consists of the primary motor, premotor, and prefrontal regions. The primary somatosensory cortex is located in the anterior parietal lobe; in addition, other cortical regions that are related to complex visual and somatosensory functions are located in the posterior parietal lobe. The superior portion of the temporal lobe contains the primary auditory cortex and other auditory regions; the inferior portion contains regions devoted to complex visual functions. In addition, some regions of the superior temporal sulcus receive a convergence of input from the visual, somatosensory, and auditory sensory areas. The occipital lobe consists of the primary visual cortex and other visual association areas.

Beneath the outer mantle of the cerebral cortex are a number of other major brain structures, such as the caudate nucleus, the putamen, and the globus pallidus (Fig. 1.2-5 and Fig. 1.2-6). Those structures are components of the basal ganglia, a system involved in the control of movement. The hippocampus and the amygdala, which are components of the limbic system, are located deep in the medial temporal lobe (Fig. 1.2-6 and Fig. 1.2-7). In addition, the derivatives of the diencephalon, such as the thalamus and the hypothalamus, are prominent internal structures; the thalamus is a relatively large structure composed of a number of nuclei that have distinct patterns of connectivity with the cerebral cortex (Fig. 1.2-6 and Fig. 1.2-7). In contrast, the hypothalamus is a much smaller structure that is involved in autonomic and endocrine functions.

Ventricular System As the neural tube fuses during development, the cavity of the neural tube becomes the ventricular system of the brain. It is composed of two C-shaped *lateral ventricles* in the cerebral hemispheres that can be further divided into five parts: the anterior horn (which is located in the frontal lobe), the body of the ventricle, the inferior or temporal horn in the temporal lobe, the posterior or occipital horn in the occipital lobe, and the atrium (Fig. 1.2-8). The *foramina of Monro* (interventricular foramina) are the two apertures that connect the two lateral ventricles with the *third ventricle,* which is found on the midline of the diencephalon. The *cerebral aqueduct* connects the third ventricle with the *fourth ventricle* in the pons and the medulla.

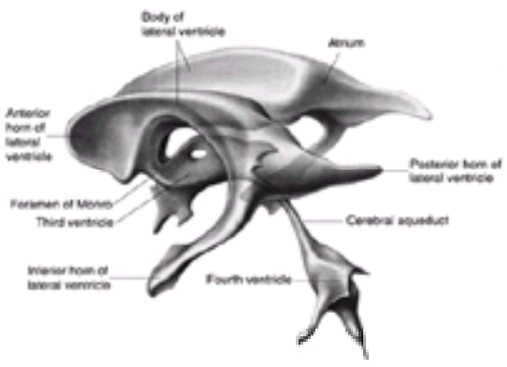

FIGURE 1.2-8 Drawing of a cast of the ventricular system of the human brain. The C shape of the lateral ventricles within the cerebral hemispheres is shown. (Adapted from Nieuwenhuys R, Voogd J, van Huijzen C: *The Human Central Nervous System: A Synopsis and Atlas,* ed 3. Springer, New York, 1988.)

The ventricular system is filled with cerebrospinal fluid (CSF), a colorless liquid containing low concentrations of protein, glucose, and potassium and relatively high concentrations of sodium and chloride. The majority (70 percent) of the CSF is produced at the choroid plexus located in the walls of the lateral ventricles and in the roof of both the third and fourth ventricles. The *choroid plexus* is a complex of ependyma, pia, and capillaries that invaginate the ventricle. In contrast to other parts of the brain, the capillaries in the choroid plexus are fenestrated, which allows substances to pass out of the capillaries and through the pia mater. The ependymal or choroid epithelial cells, however, have tight junctions between cells to prevent the leakage of substances into the CSF; that provides what is sometimes referred to as the *blood-CSF barrier*. In other parts of the brain, the endothelial cells of the capillaries exhibit tight junctions that prevent the movement of substances from the blood to the brain; that is referred to as the *blood-brain barrier*.

The CSF is produced constantly and circulates through the lateral ventricles to the third ventricle and then to the fourth ventricle. The CSF then flows through the medial and lateral apertures to the cisterna magna and pontine cistern and finally travels over the cerebral hemispheres to be absorbed by the arachnoid villi and released into the superior sagittal sinus. Disruptions in the flow of the CSF usually cause some form of hydrocephalus; for example, if an intraventricular foramen is occluded, the associated lateral ventricle becomes enlarged, but the remaining components of the ventricular system remain normal.

Several functions are attributed to the CSF: it serves to cushion the brain against trauma, to maintain and control the extracellular environment, and to spread endocrine hormones. Since the CSF bathes the brain and is in direct communication with extracellular fluid, it is possible to measure the amount of certain compounds in the CSF as a correlate of the amount of that substance in the brain. For example, concentrations of homovanillic acid (HVA), a metabolite of the neurotransmitter dopamine, are thought to reflect functional activity of that neurotransmitter. Thus, the concentration of HVA in samples of the CSF taken in a lumbar puncture may provide a picture of brain dopaminergic function. However, because the CSF bathes the entire brain, the concentrations of HVA in CSF may not be a valid indicator of the activity of dopamine neurons in any particular brain area. Consequently, caution must be exercised in interpreting the findings of investigations that rely on CSF measurements as indicators of neurotransmitter activity.

FUNCTIONAL BRAIN SYSTEMS

The relation between the organizational principles and the structural components of the human brain are illustrated in three functional systems—the thalamocortical, basal ganglia, and limbic systems.

Thalamocortical Systems

Thalamus The largest portion of the diencephalon consists of the *thalamus,* a group of nuclei that serve as the major synaptic relay station for the information reaching the cerebral cortex. On an anatomical basis the thalamic nuclei can be divided into six groups: anterior, medial, lateral, reticular, intralaminar, and midline nuclei. A thin Y-shaped sheet of myelinated fibers, the *internal medullary lamina,* delimits the anterior, medial, and lateral groups of nuclei (Fig. 1.2-9). In the human thalamus the anterior and medial groups each contain a single large nucleus, the *anterior* and *medial dorsal nuclei*. The lateral group of nuclei can be further subdivided into dorsal and ventral tiers. The dorsal tier is composed of the *lateral dorsal,* the *lateral posterior,* and the *pulvinar nuclei;* the ventral tier consists of the *ventral anterior,* the *ventral lateral,* the *ventral posterior lateral,* and the *ventral posterior medial nuclei*. The lateral group of nuclei are covered by the *external medullary lamina,* another sheet of myelinated fibers. Interposed between those fibers and the internal capsule is a thin group of neurons forming the *reticular nucleus* of the thalamus. The *intralaminar nuclei,* the largest of which is the *central median nucleus,* are located within the internal medullary lamina. The final group of thalamic nuclei, the *midline nuclei*, cover portions of the medial surface of the thalamus. The midline nuclei of each hemisphere may fuse to form the interthalamic adhesion, which is variably present.

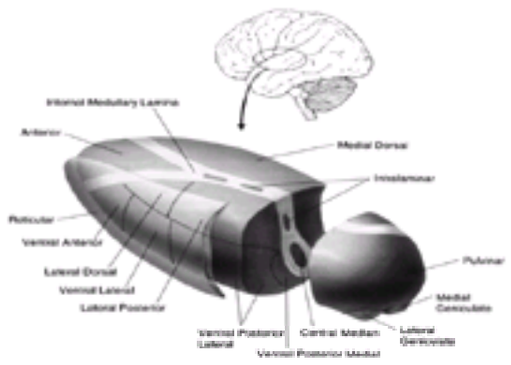

FIGURE 1.2-9 Drawing of the nuclei of the thalamus as seen on the left side of the brain. (Adapted with permission from Kelly JP: The neural basis of perception and movement. In *Principles of Neural Science,* ed 3, ER Kandel, JH Schwartz, TM Jessell, editors. Elsevier, New York, 1991.)

Thalamic nuclei can also be classified into several groups based on the pattern and information content of their connections (Table 1.2-2). For example, *relay nuclei* project to and receive input from specific regions of the cerebral cortex. Those reciprocal connections apparently allow the cerebral cortex to modulate the thalamic input it receives. *Specific relay nuclei* process input either from a single sensory modality or from a distinct part of the motor system. For example, the lateral geniculate nucleus receives visual input from the optic tract and projects to the primary visual area of the occipital cortex. As summarized in Figure 1.2-10, neurons of the thalamic relay nuclei furnish topographically organized projections to specific regions of the cerebral cortex, although some cortical regions receive input from more than one nucleus.

Type	Nuclei	Principal Afferent Inputs	Major Projection Sites
Specific relay	Anterior	Mamillary body of hypothalamus	Cingulate cortex
	Ventral anterior	Globus pallidus	Premotor cortex
	Ventral lateral	Dentate nucleus of cerebellum	Motor, premotor cortices
	Ventral posterior lateral	Medial lemniscal and spinothalamic pathways	Somatosensory cortex
	Ventral posterior medial	Sensory nuclei of trigeminal nerve	Somatosensory cortex
	Medial geniculate	Inferior colliculus	Auditory cortex
	Lateral geniculate	Optic tract	Visual cortex
Association relay	Lateral dorsal	Unknown	Cingulate cortex
	Lateral posterior	Superior colliculus	Parietal cortex
	Pulvinar	Superior colliculus	Temporal, parietal, occipital cortices
	Medial dorsal	Amygdala and hypothalamus	Prefrontal cortex
Diffuse projection	Midline	Reticular formation, hypothalamus	Basal forebrain, cortex
	Intralaminar	Reticular formation, spinothalamic tract, globus pallidus	Basal ganglia, cortex
	Reticular	Cerebral cortex, thalamus	Thalamus

* This table does not include the cortical inputs to each thalamic nucleus.

Table 1.2-2 Connections of Thalamic Nuclei*

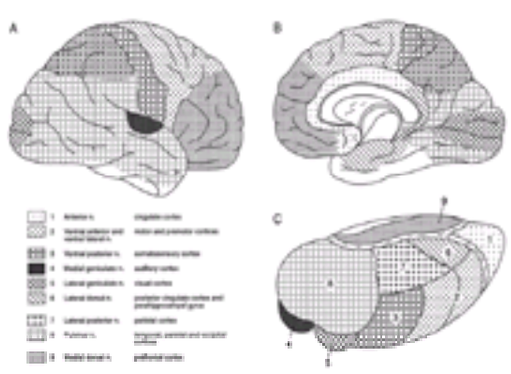

FIGURE 1.2-10 Schematic drawings of the lateral **(A)** and medial **(B)** surfaces of the right cerebral hemisphere and the right thalamus **(C)**. Shading patterns depict the cortical projection zones of some thalamic relay nuclei. (Adapted from Burt AM: *Textbook of Neuroanatomy*. Saunders, Philadelphia, 1993.)

In contrast, *association relay nuclei* receive highly processed input from more than one source and project to larger areas of the association cortex. or example, the medial dorsal thalamic nucleus receives input from the hypothalamus and the amygdala and is reciprocally interconnected with the prefrontal cortex and certain premotor and temporal cortical regions. In contrast to relay nuclei, *diffuse-projection nuclei* receive input from diverse sources and project to widespread areas of the cerebral cortex and to the thalamus. The divergent nature of the cortical connections of those nuclei indicates that they may be involved in regulating the level of cortical excitability and arousal. Finally, the reticular nucleus is somewhat unique in that it receives input from collaterals of the axons that reciprocally connect other thalamic nuclei and the cerebral cortex. Each portion of the reticular nucleus then projects to that thalamic nucleus from which it receives input. The pattern of connectivity may indicate that the reticular nucleus samples both cortical afferent and efferent activity and then uses that information to regulate thalamic function.

Cerebral Cortex The *cerebral cortex* is a laminated sheet of neurons, several millimeters thick, that covers the cerebral hemispheres. More that 90 percent of the total cortical area consists of the *neocortex,* which has a six-layered structure (at least at some point during development). The remainder of the cerebral cortex is referred to as the *allocortex* and consists of the *paleocortex* and the *archicortex*, regions that are restricted to the base of the telencephalon and the hippocampal formation, respectively.

Within the neocortex, the two major neuronal cell types are the pyramidal and stellate or nonpyramidal neurons. *Pyramidal neurons*, which account for approximately 60 percent of all neocortical neurons, usually have a characteristically shaped cell body that gives rise to a single apical dendrite that ascends vertically toward the cortical surface. In addition, the neurons have an array of short dendrites that spread laterally from the base of the cell. The dendrites of pyramidal neurons are coated with short protrusions, called *spines,* that are the sites of most of the excitatory inputs to these neurons. Most pyramidal cells are projection neurons that are thought to use excitatory amino acids as neurotransmitters. In contrast, *nonpyramidal cells* are generally small, local-circuit neurons, many of which use the inhibitory neurotransmitter g-aminobutyric acid (GABA). These neurons can be divided into distinct functional subclasses based on their biochemical and morphological features (Fig. 1.2-11). For example, the chandelier class of GABA neurons contains the calcium-binding protein parvalbumin, and exerts powerful inhibitory control over pyramidal neurons through synaptic inputs to the axon initial segment of pyramidal cells. In contrast, double bouquet cells contain the calcium-binding protein calbindin and provide inhibitory synapses to the dendritic shafts of pyramidal neurons, as well as to other local circuit neurons.

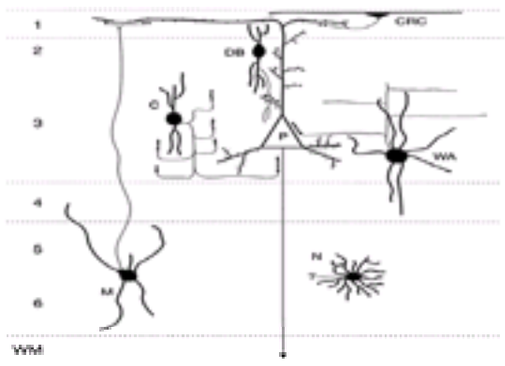

FIGURE 1.2-11 Schematic drawings of different morphological subclasses of GABA-containing local circuit neurons in the primate prefrontal cortex. As illustrated, the axons of some subclasses of GABA neurons selectively target different portions of pyramidal neurons (P). C indicates chandelier neuron, CRC indicates Cajal-Retzius cell, DB indicates double-bouquet cell, M indicates Martinotti cell, N indicates neurogliaform neuron. (Adapted with permission from Condé F, Lund JS, Jacobowitz DM, Baimbridge KG, Lewis DA: Local circuit neurons immunoreactive for calretinin, calbindin D-28k or parvalbumin in monkey prefrontal cortex: Distribution and morphology. J Comp Neurol *341:*95, 1994.)

Neocortical neurons are distributed across six layers of the neocortex; those layers are distinguished by the relative size and packing density of their neurons (Fig. 1.2-12 and Fig. 1.2-13). Each cortical layer tends to receive particular types of inputs and to furnish characteristic projections. For example, afferents from thalamic relay nuclei terminate primarily in deep layer III and layer IV, whereas corticothalamic projections originate mainly from layer VI pyramidal neurons. These laminar distinctions provide important clues for dissecting possible pathophysiological mechanisms in psychiatric disorders. For example, reports of decreased somal size and diminished spine density on deep-layer pyramidal neurons in the prefrontal cortex of schizophrenic subjects suggests that these changes may be related to abnormalities in afferent projections from the medial dorsal thalamic nucleus. Consistent with this interpretation, the number of neurons in the medial dorsal nucleus has been reported to be decreased in schizophrenia.

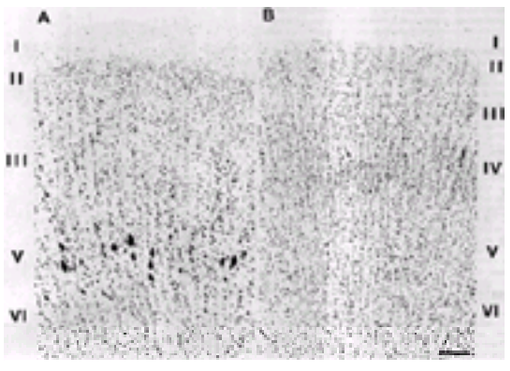

FIGURE 1.2-12 Nissl-stained sections of **(A)** Brodmann's area 4 (primary motor cortex) and **(B)** area 41 (primary auditory cortex) from a control human brain. Roman numerals indicate the cortical layers. Marked differences in neuronal size and packing density across the layers of the two regions are evident. Calibration bar (200 μm) applies to **A** and **B**.

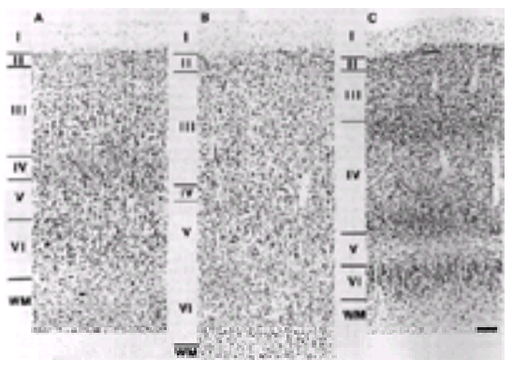

FIGURE 1.2-13 Nissl-stained sections of **(A)** Brodmann's area 46 (dorsolateral prefrontal cortex), **(B)** area 9 (dorsomedial prefrontal cortex) and **(C)** area 17 (primary visual cortex) from a control human brain. Roman numerals indicate the cortical layers. Note the marked differences in laminar organization between the prefrontal and visual areas, but the more subtle differences between the two prefrontal regions. Calibration bar (200 µm) applies to **A-C**.

In addition to the horizontal laminar structure, many aspects of cortical organization have a vertical or columnar characteristic. For example, the apical dendrites of pyramidal neurons and the axons of some local-circuit neurons have a prominent vertical orientation, indicating that those neural elements may sample the input to or regulate the function of neurons in multiple layers, respectively. Afferent inputs to the neocortex from other cortical regions also tend to be distributed across cortical layers in a columnar fashion. Finally, physiological studies in the somatosensory and visual cortices have shown that neurons in a given column respond to stimuli with particular characteristics, whereas those in adjacent columns respond to stimuli with different features.

The neocortex can be divided into two general types of regions. Regions with a readily identifiable six-layer appearance are known as the *homotypical cortex* and are found in association regions of the frontal, temporal, and parietal lobes. In contrast, some regions of the neocortex do not retain a six-layer appearance. Those regions, called the *heterotypical cortex*, include the primary motor cortex, which lacks a defined layer IV, and primary sensory regions, which exhibit an expanded layer IV. The neocortex can be further divided into discrete areas, each area having a distinctive architecture, a certain set of connections, and a role in particular brain functions. Most subdivisions of the human neocortex have been based on cytoarchitectural features; that is, subdivisions differ in the size, packing density, and arrangement of neurons across layers (Fig. 1.2-12 and Fig. 1.2-13). The most widely used system is that of Korbinian Brodmann (Fig. 1.2-14), who divided the cortex of each hemisphere into 44 numbered areas. Some of these numbered regions correspond closely to functionally distinct areas, such as area 4 (primary motor cortex in the precentral gyrus) and area 17 (primary visual cortex in the occipital lobe). In contrast, other Brodmann's areas appear to encompass several cortical zones that differ in their functional attributes. Although Brodmann's brain map has been extensively used in postmortem studies of psychiatric disorders, many of the distinctions among regions are quite subtle (Fig. 1.2-13A and Fig. 1.2-13B), and the locations of the boundaries between regions may vary among persons.

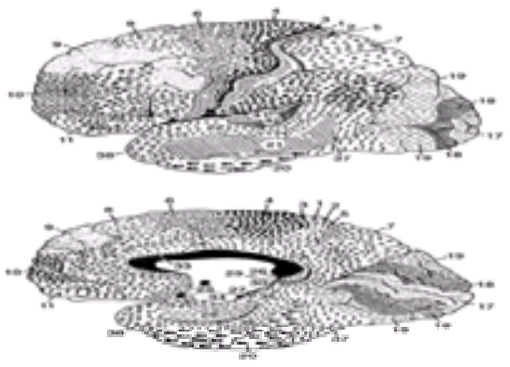

FIGURE 1.2-14 Drawing of the cytoarchitectonic subdivisions of the human brain as determined by Brodmann. **Top,** lateral view; **bottom,** medial view.

Although a given cortical area may receive other inputs, it is heavily innervated by projections from particular thalamic nuclei and from certain other cortical regions either in the same hemisphere *(association fibers)* or the opposite hemisphere *(commissural fibers)*. The patterns of connectivity make it possible to classify cortical regions into different types. *Primary sensory areas* are dominated by inputs from specific thalamic relay nuclei and are characterized by a topographic representation of visual space, the body surface, or the range of audible frequencies on the cortical surface of the primary visual, primary somatosensory, and primary auditory cortices, respectively. Those regions project in turn to nearby *unimodal association regions,* which are also devoted to processing information from a particular sensory modality. Output from those regions converges in *multimodal association areas,* such as the prefrontal cortex or the temporoparietal cortical regions. Neurons in those regions respond to complex stimuli and are thought to be mediators of higher cognitive functions. Finally, those regions influence the activity of the *motor areas* of the cerebral cortex that control behavioral responses.

Although this classification scheme of cortical regions is accurate in many respects, it fails to account for some of the known complexities of cortical information processing. For example, somatosensory input from the thalamus projects to several distinct, topographically organized maps in the cerebral cortex. In addition, information flow within the cortex is not confined to the serial processing route implied in the classification scheme but also involves parallel processing streams, such as sensory input from the thalamus to both the primary and association areas.

Although this discussion has not distinguished between the cerebral hemispheres, certain brain functions, such as language, are localized to one hemisphere (Fig. 1.2-15). The structural bases for the lateralization of function have not been determined, but some anatomical differences between the cerebral hemispheres have been observed. For example, a portion of the superior temporal cortex, called the *planum temporale,* is generally larger in the left hemisphere than in the right hemisphere. That cortical area, which is located close to the primary auditory cortex and includes the region called *Wernicke's area* (Fig. 1.2-4A), appears to be involved in receptive language functions that are localized to the left hemisphere. In addition, Brodmann's area 44, in the left inferior frontal cortex contains larger pyramidal neurons than the homotopic region of the right hemisphere, a difference that may contribute to the specialization of Broca's area for motor speech function.

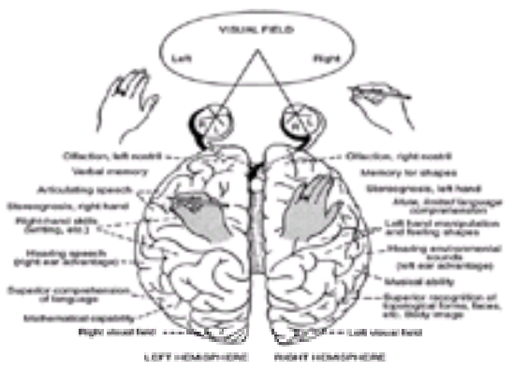

FIGURE 1.2-15 Drawing of the dorsal surface of the human brain showing the tendency for certain functions to be preferentially localized to one hemisphere. However, it is important to note that the intact brain may not be as lateralized as some studies (e.g., of patients with commissurotomies) suggest, that the degree of lateralization differs across individuals, and that in the intact brain it is rare that one hemisphere can mediate a function that the other hemisphere is completely unable to perform. (Reprinted with permission from Fuchs AF, Phillips JO: Association cortex. In *Textbook of Physiology,* HD Patton, AF Fuchs, B Hillie, AM Scher, R Steiner, editors, vol 1, ed 21. Saunders, Philadelphia, 1989.)

Functional Circuitry The connections between the thalamus, the cortex, and certain related brain structures comprise three thalamocortical systems, each with different patterns of functional circuitry. Those three systems—sensory, motor, and association systems—are described separately here but are heavily interconnected.

THALAMOCORTICAL SENSORY SYSTEMS Several general principles govern the organization of the thalamocortical sensory systems. First, sensory receptors transduce certain stimuli in the external environment to neural impulses. The impulses ascend, often through intermediate nuclei in the spinal cord and the medulla, and ultimately synapse in specific relay nuclei of the thalamus.

Second, projections from peripheral sensory receptors to the thalamus and the cortex exhibit topography; that is, a particular portion of the external world is mapped onto a particular region of the brain. For example, in the somatosensory system, axons carrying information regarding a distinct part of the body synapse in a discrete part of the ventral posterior nucleus of the thalamus. Specifically, the ventral posterior medial nucleus receives inputs regarding the head, and the ventral posterior lateral nucleus receives inputs regarding the remainder of the body. The nuclei then project topographically to the primary somatosensory cortex, where several representations of the contralateral half of the body can be found. Those representations are distorted; regions heavily innervated by sensory receptors, such as the fingers, are disproportionately represented in the primary somatosensory cortex.

Third, in some cases, sensory inputs travel to the thalamus in a segregated manner according to the submodality of the information conveyed. The inputs are then processed in a parallel fashion; particular pathways may be exclusively devoted to processing a submodality. An example of such segregation is evident in the somatosensory system, where most fibers carrying tactile and proprioceptive information travel in the medial lemniscus, but pain and temperature information is conveyed to the ventral posterior thalamic nuclei through the spinothalamic tract. Although some tactile information is carried in the spinothalamic tract, the submodalities of pain and temperature are largely segregated from tactile and proprioceptive inputs as they ascend to the thalamus.

Finally, sensory pathways exhibit convergence; that is, primary sensory areas process sensory information and then project to unimodal association areas. Subsequently, the unimodal areas project to and converge in multimodal association areas. An illustration of convergence in sensory pathways is found in the somatosensory system. The primary somatosensory cortex, located in the anterior parietal lobe (Fig. 1.2-16), has been divided into four regions on the basis of cytoarchitecture. Each of the cytoarchitectonic regions—numbered 1, 2, 3a, and 3b by Brodmann—contains a topographical representation of the body. The regions are heavily interconnected, and all project to the next level of somatosensory processing in area S-II. That type of projection, from one level of processing to a more advanced level, is termed a *feedforward projection*. The reciprocal connection, from the more advanced processing level back to the simpler level, is called a *feedback projection*. Both projections have distinct patterns of laminar termination: feedforward projections originate in the superficial layers of cortex (layer III) and terminate in layer IV; feedback projections originate in layers III, V, and VI and terminate outside layer IV. Further processing of somatosensory information occurs in higher-order somatosensory areas, such as area 7b of the posterior parietal cortex, which receive feedforward projections from S-II. Lesions of the posterior parietal cortex reflect the complexity of the information processed there; after a person has sustained a posterior parietal lesion, the ability to understand the significance of sensory stimuli is impaired, and extreme cases result in contralateral sensory neglect and inattention. However, the processing of somatosensory information within

the cortex is clearly much more complex than what has been described here (Fig. 1.2-17).

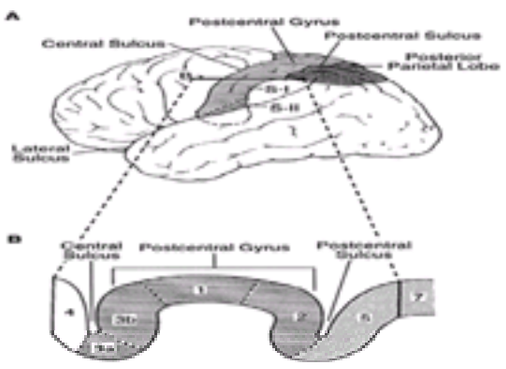

FIGURE 1.2-16 Drawing of the location of the somatosensory cortices in the human brain. **A:** Somatosensory cortices are located in the anterior and posterior parietal cortex. **B:** Primary somatosensory cortex (S-I) is divided into four cytoarchitectonic regions, as shown on the drawing of the section taken at the level depicted in **(A)**. Elsevier, New York, 1991.)

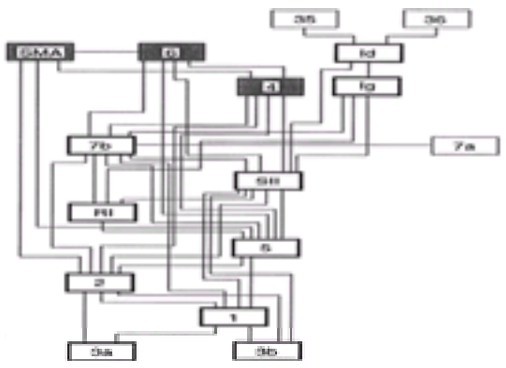

FIGURE 1.2-17 A proposed organizational scheme of the connectivity among cortical areas involved in somatosensory information processing. Hierarchical assignments were made on the basis of feedforward and feedback patterns of connections, as described in the text. (Reprinted with permission from Felleman DJ, Van Essen DC: Distributed hierarchical processing in the primate cerebral cortex. Cereb Cortex *1:*36, 1991.)

THALAMOCORTICAL MOTOR SYSTEMS The thalamocortical motor systems exhibit some unique organizational principles but also share many of the features present in the sensory systems. First, in contrast to sensory systems, which primarily ascend from sensory receptor to cortical association areas, motor systems descend from association and motor regions of the cortex to the brainstem and the spinal cord. For example, the corticospinal tract originates in layer V neurons of the premotor and primary motor cortices of the frontal lobe and terminates in the spinal cord to influence motor behavior.

Second, motor systems exhibit strong topography at both the thalamic and the cortical levels. For example, the corticospinal tract is organized so that a topographical representation of the contralateral half of the body is evident in the primary motor and premotor cortices. The representation of the body is disproportionate, with large regions of the motor cortex devoted to areas of the body involved in fine movement, such as the face and the hands.

Finally, there is a convergence of projections from several sensory association regions to the motor regions of the frontal cortex. For example, the premotor cortex receives a convergence of afferents from higher-order somatosensory and visual areas of the posterior parietal cortex, whereas afferents from the primary somatosensory cortex converge on the primary motor cortex. In addition to cortical input, the primary motor cortex receives afferents from the ventral lateral nucleus of the thalamus; that nucleus receives afferents predominantly from the cerebellum. The premotor cortex receives input from the ventral anterior thalamic nucleus, which receives much of its input from the globus pallidus.

THALAMOCORTICAL ASSOCIATION SYSTEMS The multimodal association areas of the cortex are organized according to several general principles. First, association regions receive a convergence of input from a variety of sources, including unimodal and multimodal association regions of the cortex, the association nuclei of the thalamus, and other structures. For example, the prefrontal cortex receives afferents from higher-order sensory cortices of the parietal and temporal lobes, the contralateral prefrontal cortex, the cingulate cortex of the limbic system, the medial dorsal nucleus of the thalamus, an association relay nucleus, and portions of the amygdala. The medial dorsal nucleus receives highly processed inputs from many sources, including some regions, such as the amygdala, that project directly to the prefrontal cortex. The redundant (direct and indirect) projections may serve to attach additional significance to certain inputs received by the prefrontal cortex. The significance of these inputs may also be influenced by their temporal and spatial coincidence with modulatory inputs from brainstem nuclei that utilize the monoamine neurotransmitters dopamine, norepinephrine, or serotonin. Interestingly, the density of the monoamine afferent systems differs substantially across cortical regions of the human brain (Fig. 1.2-18), suggesting that the relative influence of these systems differs with the functional characteristics of the cortical region.

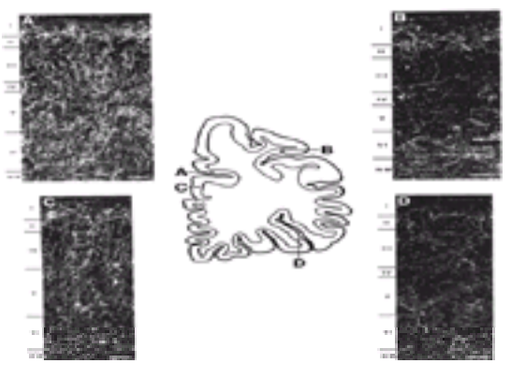

FIGURE 1.2-18 Photomicrographs illustrating the differential distribution of dopamine-containing axons in different regions of the human prefrontal **(A, B, D)** and anterior cingulate **(C)** cortices. The center panel represents a coronal section through the human prefrontal cortex at the level of the genu of the corpus callosum (cc), and the surrounding panels show the density of dopamine axons (white lines) at the indicated locations. Roman numerals indicate the cortical layers, and WM indicates white matter. Calibration bars equal 200 μm. (Reprinted with permission from Lewis DA: The catecholaminergic innervation of primate prefrontal cortex. J Neural Transm *36:*179, 1992.)

Second, the projections that terminate in multimodal association regions exhibit a topographical organization. Since the information conveyed in those projections is highly processed, it does not appear that the topographical organization of the afferents is a representation of the external world. Nonetheless, a distinct pattern is present in the afferents received by association areas. For example, different cytoarchitectonic regions of the medial dorsal nucleus project to discrete regions of the prefrontal cortex. In addition, some of the cortical afferents received by the prefrontal cortex are topographically organized; certain regions of the prefrontal cortex

predominantly receive highly processed information from one modality.

The patterns of connectivity are clearly related to some of the functional characteristics attributed to the prefrontal cortex. For example, in monkeys, lesions of the dorsolateral prefrontal cortex consistently produce an impairment in the monkey's ability to perform spatial delayed-response tasks. Those tasks require the monkey to maintain a spatial representation of the location of an object during a delay period in which the object is out of sight; it has been suggested that the prefrontal cortex plays a role in maintaining the spatial representation of the object. Such a function would require that the prefrontal cortex receive information regarding the location of objects in space; indeed, the dorsolateral prefrontal cortex is innervated by afferents from association regions of the parietal cortex that convey such information. Although the dorsolateral prefrontal cortex is necessary for the performance of delayed-response tasks in the monkey, it is not sufficient for the performance of the task. For example, lesions of the medial dorsal nucleus in the monkey result in similar impairments on the performance of spatial delayed-response tasks. Thus, the functions attributed to the prefrontal cortex are a result of the neural circuitry involving the region.

Knowledge of the integration of afferent inputs into the neural circuitry of certain prefrontal regions may also be important for understanding the nature of prefrontal cortical dysfunction in schizophrenia. Schizophrenic patients perform poorly on tasks that are known to be mediated by the prefrontal cortex. Those findings have been correlated with other measures to suggest, albeit indirectly, that the dopamine projections to the prefrontal cortex are impaired in schizophrenia. For example, studies in nonhuman primates have shown that performance of delayed-response tasks, the same type of behaviors that are impaired in schizophrenic subjects, requires an appropriate level of dopamine input to the dorsolateral prefrontal cortex.

CEREBELLO-THALAMOCORTICAL SYSTEMS The cerebellum has traditionally been considered to be involved solely with motor control, regulating posture, gait, and voluntary movements. However, recent studies indicate that the cerebellum may also play an important role in the mediation of certain cognitive abilities through inputs to portions of the thalamus that project to association regions of the cerebral cortex.

The cerebellum is located in the posterior cranial fossa, inferior to the occipital lobes (Fig. 1.2-4). The external surface of the cerebellum, the cerebellar cortex, is composed of small folds, termed *folia,* separated by sulci. Viewed from the dorsal surface, the cerebellum contains a raised central portion, called the *vermis,* and lateral portions called the *cerebellar hemispheres* (Fig. 1.2-19). Located within the cerebellum are the deep cerebellar nuclei that are arranged as follows: the fastigial nucleus is located next to the midline; located slightly more lateral are the globose and emboliform nuclei; and the largest nucleus, the dentate, occupies the most lateral position. In general, the cerebellar cortex can be considered to process the inputs to the cerebellum, and the deep nuclei to process the outputs.

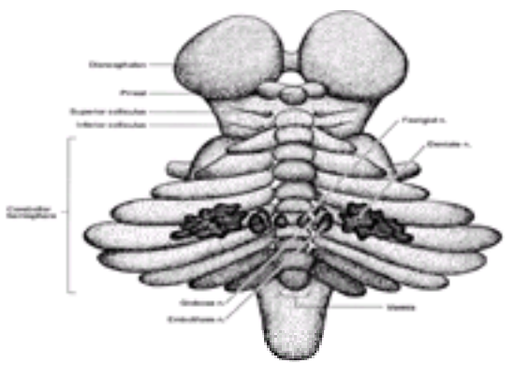

FIGURE 1.2-19 Schematic drawing of the dorsal view of the cerebellum showing the relative location and size of the cerebellar nuclei situated deep within the cerebellum. (Adapted from Hendelman WJ: *Student's Atlas of Neuroanatomy*. Saunders, Philadelphia, 1994.)

Although many portions of the cerebellum are interconnected with brain regions that regulate motor actions, from the standpoint of psychiatric illness the circuitry of the cerebellum involved in cognitive functions is of greatest interest. For example, the lateral cerebellar cortex and the dentate nucleus are markedly expanded in the primate brain. It has been suggested that these changes are associated with an increase in the size of cortical areas (especially the prefrontal regions) influenced by cerebellar output and an expanded role of the cerebellum in cognitive functions. Recent studies in nonhuman primates have shown that the dorsolateral prefrontal cortex receives inputs from two ipsilateral thalamic nuclei (medial dorsal and ventral lateral), which in turn receive inputs from the contralateral cerebellar dentate nucleus. The cells of the dentate nucleus involved in these connections are distinct from those that influence the motor and premotor regions of the cerebral cortex. Interestingly, functional imaging studies in schizophrenic subjects have revealed abnormal patterns of activation in the cerebellum, thalamus, and prefrontal cortex, suggesting that dysfunction of this circuitry might be associated with the disturbances in cognitive processes exhibited by these patients.

Basal Ganglia System The basal ganglia are a collection of nuclei that have been grouped together on the basis of their interconnections. These nuclei play an important role in regulating movement and in certain disorders of movement (dyskinesias), which include jerky movements (chorea), writhing movements (athetosis), and rhythmic movements (tremors). In addition, recent studies have shown that certain components of the basal ganglia play an important role in many cognitive functions.

Major Structures The basal ganglia are generally considered to include the *caudate nucleus,* the *putamen,* the *globus pallidus* (referred to as the *paleostriatum* or *pallidum*), the *subthalamic nucleus,* and the *substantia nigra* (Fig. 1.2-20). The term *striatum* refers to the caudate nucleus and the putamen together; the term *corpus striatum* refers to the caudate nucleus, the putamen, and the globus pallidus; and the term *lentiform nucleus* refers to the putamen and the globus pallidus together.

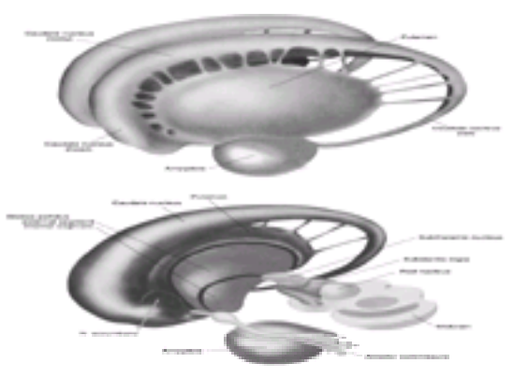

FIGURE 1.2-20 Schematic drawing of the isolated basal ganglia as seen from the dorsolateral perspective, so that the caudate nucleus is apparent bilaterally. In the bottom panel, the basal ganglia from the left hemisphere has been removed, exposing the medial surface of the right putamen and globus pallidus, as well as the subthalamic nucleus and substantia nigra. (Adapted from Hendelman WJ: *Student's Atlas of Neuroanatomy*. Saunders, Philadelphia, 1994.)

Although these nuclei are generally agreed to belong to the basal ganglia, some controversy exists concerning whether other nuclei should be included in the definition of the basal ganglia. Some investigators believe that additional regions of the brain have anatomical connections that are similar to other components of the basal ganglia and should, therefore, be included in the definition. Those additional regions are usually termed the *ventral striatum* and the *ventral pallidum*. The ventral striatum includes the nucleus accumbens (Fig. 1.2-20), which is the region where the putamen and the head of the caudate nucleus fuse, and the olfactory tubercle. The ventral pallidum is a region that receives afferents from the ventral striatum and includes but is not limited to a group of neurons termed the *substantia innominata* (Fig. 1.2-5). This section focuses on the structures generally accepted as belonging to the basal ganglia but also discusses additional structures when relevant to the functional anatomy of the system.

CAUDATE NUCLEUS The caudate nucleus is a C-shaped structure that is divided into three general regions. The anterior portion of the structure is referred to as the

head, the posterior region is the *tail*, and the intervening region is the *body* (Fig. 1.2-20). The caudate nucleus is associated with the contour of the lateral ventricles: the head lies against the frontal horn of the lateral ventricle, and the tail lies against the temporal horn (Fig. 1.2-5, Fig. 1.2-6, and Fig. 1.2-7). The head of the caudate nucleus is continuous with the putamen; the tail terminates in the amygdala of the temporal lobe.

PUTAMEN The putamen lies in the brain medial to the insula and is bounded laterally by the fibers of the external capsule and medially by the globus pallidus (Fig. 1.2-5 and Fig. 1.2-6); the putamen is continuous with the head of the caudate nucleus (Fig. 1.2-20). Although bridges of neurons between the caudate nucleus and the putamen show the continuity of the nuclei, the two structures are separated by fibers of the anterior limb of the internal capsule.

GLOBUS PALLIDUS In contrast to the caudate nucleus and the putamen, which are telencephalic in origin, the globus pallidus is derived from the diencephalon. The globus pallidus constitutes the inner component of the lentiform nucleus (Fig. 1.2-20, bottom panel); with the putamen it forms a conelike structure, with its tip directed medially (Fig. 1.2-5 and Fig. 1.2-6). The posterior limb of the internal capsule bounds the globus pallidus medially and separates it from the thalamus; the putamen borders the globus pallidus laterally. In the human the medial medullary lamina divides the globus pallidus into external (lateral) and internal (medial) segments (Fig. 1.2-5 and Fig. 1.2-6).

SUBTHALAMIC NUCLEUS The subthalamic nucleus (of Luys) is also derived from the diencephalon. The large-celled nucleus lies dorsomedial to the posterior limb of the internal capsule and dorsal to the substantia nigra (Fig. 1.2-6 and Fig. 1.2-20). Discrete lesions of the subthalamic nucleus in humans lead to hemiballism, a syndrome characterized by violent, forceful choreiform movements that occur on the side contralateral to the lesion.

SUBSTANTIA NIGRA The substantia nigra is present in the midbrain between the tegmentum and the basis pedunculi and is mesencephalic in origin (Fig. 1.2-6). The substantia nigra consists of two components: a dorsal cell-rich portion referred to as the *pars compacta* and a ventral cell-sparse portion called the *pars reticulata*. Most of the neurons in the pars compacta of the substantia nigra in humans are pigmented because of the presence of neuromelanin; those cells contain the neurotransmitter dopamine. The dendrites of the pars compacta neurons frequently extend into the pars reticulata, where they receive synapses from the neurons of the pars reticulata that use the inhibitory neurotransmitter GABA.

In rodents, the dopamine-containing neurons of the substantia nigra (A9 region) have been distinguished from those located in the ventral tegmental area (A10 region) and the retrorubral field (A8 region), but recent studies in monkey and human brains suggest that dopamine neurons can be more meaningfully parcellated at a functional level into dorsal and ventral tiers (Fig. 1.2-21). The dorsal tier is formed by a medially and laterally oriented band of neurons that includes the dopamine-containing cells that are (1) located in the medial ventral mesencephalon, (2) scattered dorsal to the dense cell clusters in the substantia nigra, and (3) distributed lateral and caudal to the red nucleus. The ventral tier is composed of the dopamine neurons that are densely packed in the substantia nigra and the cell columns that penetrate into the substantia nigra pars reticulata. Dorsal-tier dopamine neurons express relatively low concentrations of the messenger ribonucleic acids (mRNAs) for the dopamine transporter and the dopamine type 2 (D_2) receptor, contain the calcium-binding protein calbindin, and send axonal projections to the regions of the striatum that are dominated by input from limbic-related structures and association regions of the cerebral cortex. In contrast, ventral-tier neurons contain high concentrations of the mRNAs for the dopamine transporter and the D_2 receptor, typically lack calbindin, and send axonal projections to the sensorimotor regions of the striatum. Each of these features may contribute to the greater vulnerability of ventral-tier neurons to the pathology of Parkinson's disease, whereas dorsal tier neurons may be more likely to be involved in the pathophysiology of schizophrenia.

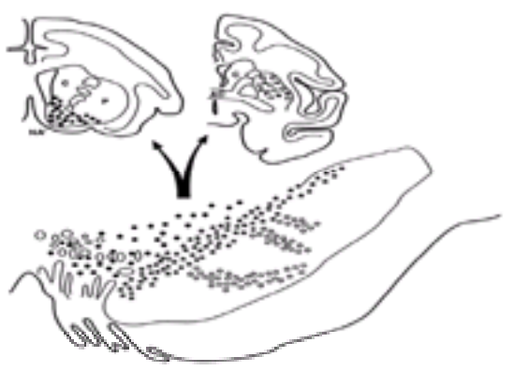

FIGURE 1.2-21 Schematic drawing of the topographic organization of dopamine-containing neurons in the mesencephalon and their projections to the ventral striatum and the sensorimotor-related dorsal striatum. All areas of the ventral striatum receive inputs from the dorsal tier neurons, with the shell region of the nucleus accumbens innervated almost exclusively by dorsal tier neurons (filled circles). In contrast, the ventral columns of cells (open circles) in the ventral tier send projections selectively to the sensorimotor-related striatum. The neurons of the densocellular zone (stars) of the ventral tier are unique in that they project to both the ventral and sensorimotor-related striatum. AC, anterior commissure; C, caudate nucleus; NA, nucleus accumbens; P, putamen. (Adapted from Lynda-Balta E, Haber SN: The organization of midbrain projections to the ventral striatum in the primate. Neuroscience *59:*625, 1994.)

Internal Organization The caudate nucleus and the putamen are frequently referred to together because of their common characteristics. For example, in the rodent these nuclei are a continuous structure, and in all mammals, they are composed of histologically identical cells. The majority of neurons in the striatum are medium-sized cells (10–20 μm in diameter) that possess spines on their dendrites; these so-called *medium spiny neurons* are known to send their axons out of the striatum. In addition to medium spiny neurons, medium-sized cells without spines (*medium aspiny neurons*) are present, as are large cells with and without spines (*large spiny neurons* and *large aspiny neurons*). With the exception of the medium and large spiny cells, most other striatal neurons are local circuit neurons.

Immunohistochemical and receptor-binding studies have shown a discontinuity in the distribution of certain neurotransmitter-related substances that form the functional circuitry of the basal ganglia. For example, in the striatum, zones that contain a low density of acetylcholinesterase enzymatic activity are surrounded by regions rich in acetylcholinesterase activity. The acetylcholinesterase-rich regions are referred to as the *matrix,* and the acetylcholinesterase-poor zones are termed either *striosomes* in the primate or *patches* in the rodent. The organization of several neuropeptide systems follows this system. For example, the distributions of enkephalin, substance P, and somatostatin immunoreactivity show the compartmentalization of the striatum. In addition, in the rodent certain subtypes of dopamine receptors are present predominantly in one compartment as compared with the other. In addition, the distribution of some afferent systems terminating in the striatum follows the striosome-matrix organization. For example, afferents from the thalamus terminate preferentially in the matrix rather than in the striosome.

Functional Circuitry Projections into, within, and out of the basal ganglia are topographically organized and maintain that topography throughout he processing circuits of the basal ganglia. The existence of such patterns of connectivity has resulted in the hypothesis that parallel, independent circuits in the basal ganglia process information from different regions of the brain and subserve separate complex functions.

INPUTS TO THE BASAL GANGLIA The striatum is the major recipient of the inputs to the basal ganglia. Three major afferent systems are known to terminate in the striatum: the corticostriatal, the nigrostriatal, and the thalamostriatal afferents (Fig. 1.2-22). The corticostriatal projection originates from all regions of the neocortex, arising primarily from the pyramidal cells of layers V and VI, which utilize the excitatory neurotransmitter glutamate. A topography governing corticostriatal projections has been found in the monkey. Afferents from the sensorimotor cortex terminate predominantly in the putamen; association regions of the cortex terminate preferentially in the caudate nucleus. The prefrontal regions, in particular, provide a heavy input to the head of the caudate nucleus. In addition, afferents from the limbic cortical areas and from the hippocampus and the amygdala terminate in the ventral striatum. The second major class of afferents utilize the neurotransmitter dopamine. In Figure 1.2-22, these projections are shown arising from the substantia nigra pars compacta, but as noted previously (Fig. 1.2-21), different portions of the striatum receive input from either the dorsal- or ventral-tier dopamine-containing neurons of the ventral mesencephalon. Electron microscopy studies have shown that many of the synapses formed by dopamine axon terminals on medium spiny neuron dendrites are immediately adjacent to the synapses provided by corticostriatal axons, suggesting that dopamine may play an important role in modulating the excitatory influence of cortical projections on striatal neurons. The third afferent system originates in the thalamus. The thalamic nuclei providing the projections are the intralaminar nuclei, particularly the central median nucleus.

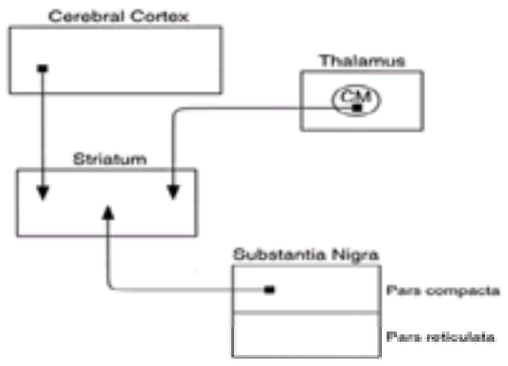

FIGURE 1.2-22 Diagram of the inputs to the basal ganglia system. Three major afferent systems have been identified: the corticostriatal, thalamostriatal, and nigrostriatal pathways.

Disruption of the input pathways of the basal ganglia has been associated with some movement disorders, such as Parkinson's disease, which is characterized by muscular rigidity, fine tremor, shuffling gait, and bradykinesia. The most consistent neuropathological feature of Parkinson's disease is a degeneration of the dopamine neurons in the substantia nigra pars compacta, accompanied by a loss of dopamine terminals in the striatum. Levodopa (Larodopa, Dopar), a precursor in the biosynthesis of dopamine, is used as a treatment for Parkinson's disease because of its ability to augment the release of dopamine from the remaining terminals. Conversely, the administration of dopamine receptor antagonists (so-called typical antipsychotics) agents in the treatment of schizophrenia is frequently associated with Parkinsonian features and other motor-system abnormalities; the fact that these agents are D_2-receptor antagonists is thought to explain their movement-related adverse effects.

INTERNAL PROCESSING The major processing pathways within the basal ganglia are summarized in Figure 1.2-23. Within the striatum, the subclass of medium spiny neurons that contain the neuropeptide substance P send inhibitory projections to the internal segment of the globus pallidus in what is termed the *direct pathway*. In contrast, the subpopulation of medium spiny neurons that contain the neuropeptide enkephalin provides inhibitory projections to the external segment of the globus pallidus, which in turn sends inhibitory afferents to the internal segment of the globus pallidus in what is termed the *indirect pathway*. The globus pallidus external also projects to the pars reticulata of the substantia nigra. The topography found in the afferent projections to the striatum appears to be maintained in that processing pathway. For example, the sensorimotor territories of the striatum project most heavily to the ventral portion of the globus pallidus, whereas association territories project to the dorsal regions of the globus pallidus.

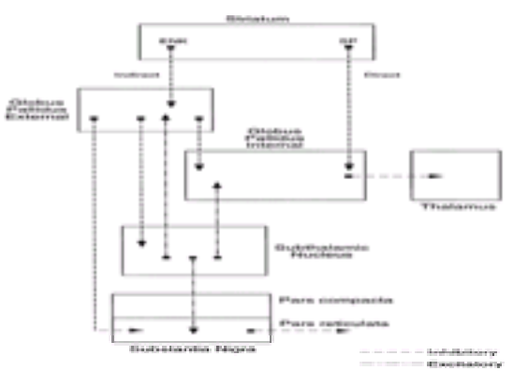

FIGURE 1.2-23 Diagram of the intrinsic circuitry of the basal ganglia. Substance P (SP)-containing striatal neurons send an inhibitory projection directly to the internal segment of the globus pallidus, whereas those containing enkephalin provide an inhibitory projection to GABA neurons in the external segment of the globus pallidus, which in turn project to the internal segment of the globus pallidus. The subthalamic nucleus receives a projection from the external segment of the globus pallidus and projects back to both segments. Finally, the subthalamic nucleus and globus pallidus external project to the substantia nigra pars reticulata.

The external segment of the globus pallidus also gives rise to an inhibitory projection that terminates in the subthalamic nucleus. In contrast, neurons in the subthalamic nucleus provide excitatory projections that terminate in both segments of the globus pallidus and in the pars reticulata. Although most connections within the basal ganglia are unidirectional, a reciprocal projection is found between the external segment of the globus pallidus and the subthalamic nucleus.

The intrinsic circuitry of the basal ganglia is disrupted by a severe loss of neurons in the striatum in Huntington's disease. This autosomal-dominant disorder is characterized by progressive chorea and dementia. Although the gene for Huntington's disease has been identified, how the excessive number of trinucleotide repeats in this gene leads to the selective degeneration of striatal cells is currently a matter of intense investigation. Interestingly, recent studies indicate that cortical neurons are also subject to degeneration in Huntington's disease.

OUTPUT OF BASAL GANGLIA The internal segment of the globus pallidus is the source of much of the output of the basal ganglia (Fig. 1.2-24). That segment of the globus pallidus provides a projection to the ventral lateral and ventral anterior nuclei of the thalamus and to the intralaminar thalamic nuclei—in particular, the central median nucleus. The pars reticulata of the substantia nigra also provides a projection to the ventral anterior and ventral lateral thalamic nuclei. Those portions of the ventral lateral and ventral anterior thalamic nuclei then project to the premotor and prefrontal cortices. As a result of the projections of the premotor and prefrontal cortices to the primary motor cortex, the basal ganglia are able to indirectly influence the output of the primary motor cortex. In addition, the cortical output of the basal ganglia exhibits marked convergence, that is, although the striatum receives afferents from all regions of the neocortex, the eventual output of the globus pallidus and the pars reticulata is largely conveyed through the thalamus to a much smaller portion of the neocortex, the premotor and prefrontal regions.

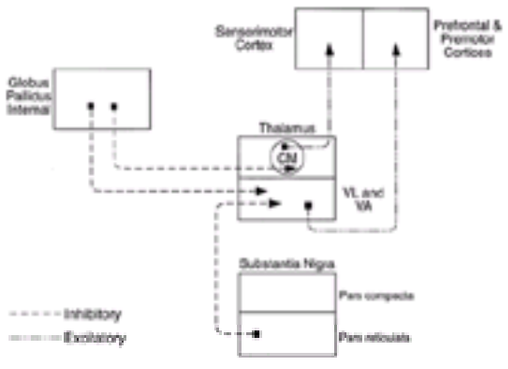

FIGURE 1.2-24 Diagram of the output of the basal ganglia system. The internal segment of the globus pallidus projects to the central median (CM), ventral lateral (VL), and ventral anterior (VA) nuclei of the thalamus. Those nuclei then project to sensorimotor, prefrontal, and premotor cortices. The substantia nigra pars reticulata also projects to the VL and VA nuclei.

The functional consequences of the neural circuitry of the basal ganglia can also be considered in the context of some of the neurotransmitters used (Fig. 1.2-23 and Fig. 1.2-24). Since the afferents from the cortex are thought to use glutamate, which is an excitatory neurotransmitter, cortical afferents presumably excite the

structures of the basal ganglia in which they terminate. Many of the processing pathways within the basal ganglia use the inhibitory neurotransmitter GABA. Finally, the output pathways of the basal ganglia—namely, the globus pallidus and the substantia nigra pars reticulata—use GABA as well. Thus, excitation from cortical afferents eventually disinhibits the target structures of the basal ganglia because of the back-to-back inhibitory pathways of the basal ganglia.

Historically, motor systems have been divided into pyramidal (corticospinal) and extrapyramidal (basal ganglia) components; that division is based on clinical findings suggesting that lesions of each system result in distinct motor syndromes. For example, lesions of the extrapyramidal system result in involuntary movements, changes in muscle tone, and slowness of movement; lesions of the pyramidal system lead to spasticity and paralysis. Because of these findings the pyramidal and extrapyramidal systems were thought to independently control voluntary and involuntary movement, respectively. However, for several reasons that division is no longer accurate. First, other structures of the brain outside the traditional pyramidal and extrapyramidal systems, such as the cerebellum, are involved in the control of movement. Second, the pyramidal and extrapyramidal systems are not independent—their neural circuits are interconnected. For example, the basal ganglia influence motor behavior through certain regions of the cerebral cortex, which then directly (through the corticospinal tract) or indirectly (through specific brainstem nuclei) produce motor activity.

Finally, although the basal ganglia are important in the control of movement, they also appear to be involved in other functions of the brain. For example, recent studies of the connections of the basal ganglia in nonhuman primates also support a role for these structures in cognitive functions. The dorsolateral prefrontal cortex has been shown to receive inputs from portions of the thalamus that are the targets of projections from specific locations within the internal segment of the globus pallidus, providing evidence for a distinct pallido-thalamo-cortical pathway. Thus, in addition to linking association regions of the cerebral cortex, such as the prefrontal and posterior parietal areas, with the control of motor activity in the primary motor cortex, some of the output of the basal ganglia appears to be directed back to regions of the prefrontal cortex. These findings suggest that “closed” loops exist between the prefrontal cortex and basal ganglia, which presumably have a cognitive rather than a motor function.

Limbic System The concept of the limbic system as a neural substrate for emotional experience and expression has a rich but controversial history. More than 100 years ago Pierre Broca applied the term “limbic” (from the Latin *limbus* for border) to the curved rim of the cortex, including the cingulate and the parahippocampal gyri, located at the junction of the diencephalon and the cerebral hemispheres (Fig. 1.2-25). In 1937, primarily on the basis of anatomical data James Papez postulated that these cortical regions were linked to the hippocampus, the mammillary body, and the anterior thalamus in a circuit that mediated emotional behavior (Fig. 1.2-26). That concept was supported by the work of Heinrich Klüver and Paul Bucy, who demonstrated that temporal lobe lesions, which disrupt components of the circuit, alter affective responses in nonhuman primates. In 1952, Paul MacLean coined the term *limbic system* to describe Broca's limbic lobe and related subcortical nuclei as the neural substrate for emotion.

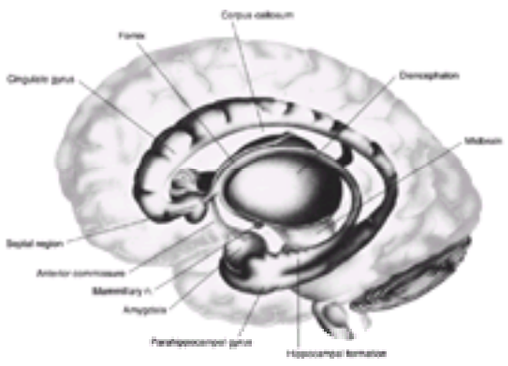

FIGURE 1.2-25 Schematic drawing of the major anatomical structures of the limbic system. Note that the cingulate and parahippocampal gyri form the “limbic lobe,” a rim of tissue located along the junction of the diencephalon and the cerebral hemispheres. (Adapted from Hendelman WJ: *Student's Atlas of Neuroanatomy*. Saunders, Philadelphia, 1994.)

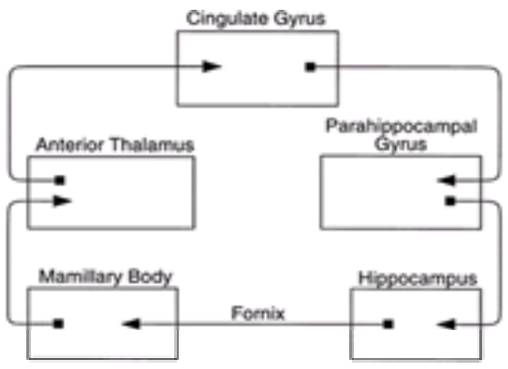

FIGURE 1.2-26 Diagram of the neural circuit for emotion as originally proposed by James Papez.

However, over the last 45 years it has become clear that some limbic structures (e.g., the hippocampus) are also involved in other complex brain processes such as memory. In addition, expanding knowledge of the connectivity of traditional limbic structures has made it increasingly difficult to define the boundaries of the limbic system. Despite those limitations, the concept of a limbic system may still be a useful way to describe the circuitry that relates certain telencephalic structures and their cognitive processes with the hypothalamus and its output pathways that control autonomic, somatic, and endocrine functions.

Major Structures There is no unanimity on which brain structures constitute the limbic system. This section includes the brain regions that are most commonly listed as components of the limbic system: the cingulate and parahippocampal gyri (limbic cortex), the hippocampal formation, the amygdala, the septal area, the hypothalamus, and related thalamic and cortical areas.

LIMBIC CORTEX The limbic cortex is composed of two general regions, the cingulate gyrus and the parahippocampal gyrus (Fig. 1.2-25). The *cingulate gyrus,* located dorsal to the corpus callosum, includes several cortical regions that are heavily interconnected with the association areas of the cerebral cortex. As the cingulate gyrus travels posteriorly, it becomes continuous (via the cingulum bundle of fibers in the white matter) with the *parahippocampal gyrus,* located in the medial temporal lobe, which contains several distinct cytoarchitectonic regions. One of the most important of those regions is the *entorhinal cortex,* which not only funnels highly processed cortical information to the hippocampal formation but is also a major output pathway from the hippocampal formation.

HIPPOCAMPAL FORMATION Three distinct zones—the dentate gyrus, the hippocampus, and the subicular complex—constitute the hippocampal formation, which is located in the floor of the temporal horn of the lateral ventricle (see Fig. 1.2-7). Those zones are composed of adjacent strips of cortical tissue that run in a rostral-caudal direction but fold over each other mediolaterally in a spiral fashion, resulting in a C-shaped appearance. The *dentate gyrus* is composed of three layers: an outer, acellular molecular layer, which faces the subarachnoid space of the hippocampal fissure; a middle layer composed of granule cells; and an inner polymorphic layer (Fig. 1.2-27). The granule cells extend their dendritic trees into the molecular layer and give rise to axons that form the mossy fiber projection to the hippocampus.

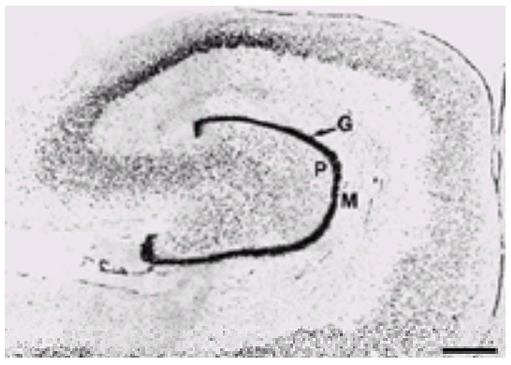

FIGURE 1.2-27 Nissl-stained coronal section through the dentate gyrus of the human hippocampal formation. Medial is to the left. M, molecular layer; G, granular layer; P, polymorphic layer. Calibration bar equals 1.0 mm.

The *hippocampus* is also a trilaminate structure composed of molecular and polymorphic layers and a middle layer that contains pyramidal neurons. On the basis of differences in cytoarchitecture and connectivity, the hippocampus can be divided into three distinct fields, which have been labeled CA3, CA2, and CA1. (*CA* is derived from the term *cornu ammonis* after the Egyptian deity Ammon, who was depicted with ram's horns, which some early investigators thought described the shape of the hippocampus.) The white matter adjacent to the polymorphic layer of the hippocampus is known as the *alveus*. The axons in that structure contribute to the fimbria, which at the caudal end of the hippocampus becomes the crus of the *fornix*. Those bilateral structures converge to form the body of the fornix, which travels anteriorly and then turns inferiorly to form the columns of the fornix, which pass through the hypothalamus into the mammillary bodies (Fig. 1.2-28). The *subicular complex* is generally considered to have three components—the presubicular, the parasubicular, and the subiculum—which together serve as transition regions between the hippocampus and the parahippocampal gyrus.

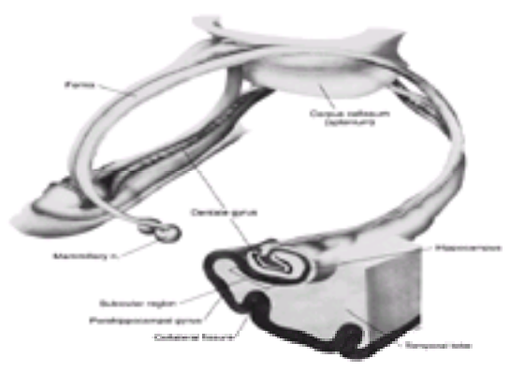

FIGURE 1.2-28 Schematic drawing of a cross-sectional view of the hippocampal formation and the path of the fornix running between that structure and the mammillary bodies. (Adapted from Hendelman WJ: *Student's Atlas of Neuroanatomy*. Saunders, Philadelphia, 1994.)

The components of the hippocampal formation have a distinct pattern of intrinsic connectivity that is largely unidirectional and provides for a specific flow of information (Fig. 1.2-29). The major input to the hippocampal formation arises from neurons in layers II and III of the entorhinal cortex that project through the *perforant path* (i.e., through the subiculum and the hippocampus) to the outer two thirds of the molecular layer of the dentate gyrus, where they synapse on the dendrites of granule cells. The mossy fiber axons of the granule cells then provide a projection to the pyramidal neurons of the CA3 field of the hippocampus. Axon collaterals from CA3 pyramidal neurons project within CA3 and, through the so-called Schäffer collaterals, to the CA1 field of the hippocampus. That region in turn projects to the subicular complex, which provides output to the entorhinal cortex, completing the circuit.

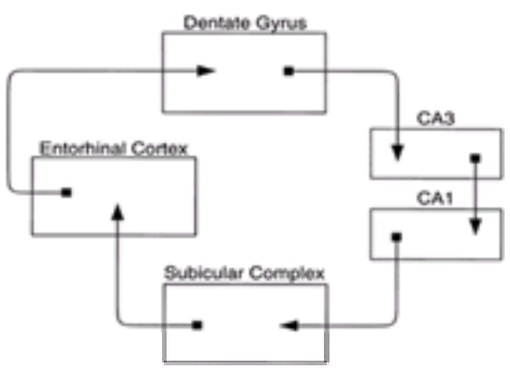

FIGURE 1.2-29 Diagram of the intrinsic neural circuitry of the hippocampal formation.

AMYGDALA Located in the medial temporal lobe just anterior to the hippocampal formation are a group of nuclei referred to as the *amygdala* (see Fig. 1.2-6). Those nuclei form several distinct clusters: the basolateral complex, the centromedial amygdaloid group, and the olfactory group, including the cortical amygdaloid nuclei. The *basolateral complex,* the largest of the three groups, differs from the remaining amygdaloid nuclei in a number of respects. Although the basolateral complex is not a laminated structure, its connectivity and some other anatomical characteristics are more similar to cortical regions than to the remaining amygdaloid nuclei. For example, the basolateral nuclei are directly and reciprocally connected with the temporal, insular, and prefrontal cortices. In addition, like some cortical regions, the basolateral complex shares bidirectional connections with the medial dorsal thalamic nucleus, and it receives projections from the midline and intralaminar thalamic nuclei. Finally, neurons of the basolateral complex with a pyramidal-like morphology appear to furnish projections to the striatum that use excitatory amino acids as neurotransmitters. Thus, on the basis of those anatomical characteristics, the basolateral complex can be said to function like a multimodal cortical region.

In contrast, the *centromedial amygdala* appears to be part of a larger structure that is continuous through the sublenticular substantia innominata with the bed nucleus of the stria terminalis. That larger structure, which has been termed the *extended amygdala*, consists of two major subdivisions. The central subdivision of the extended amygdala includes the central amygdaloid nucleus and the lateral portion of the bed nucleus of the stria terminalis. That subdivision is reciprocally connected with brainstem viscerosensory and visceromotor regions and with the lateral hypothalamus. In addition, it receives afferents from cortical limbic regions and the basolateral amygdaloid complex. In contrast, the medial subdivision of the extended amygdala, composed of the medial amygdaloid nucleus and its extension into the medial part of the bed nucleus of the stria terminalis, is distinguished by reciprocal connections with the medial or endocrine portions of the hypothalamus.

SEPTAL AREA The septal area is a gray matter structure located immediately above the anterior commissure (Fig. 1.2-30). The septal nuclei are reciprocally connected with the hippocampus, the amygdala, and the hypothalamus and project to a number of structures in the brainstem.

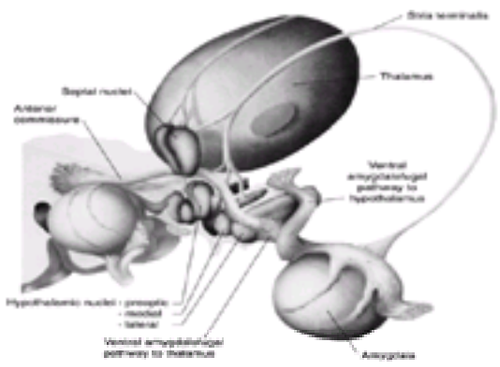

FIGURE 1.2-30 Schematic drawing of some components of the limbic system showing the major output pathways of the amygdala, the stria terminalis and the ventral amygdalofugal pathway. (Adapted from Hendelman WJ: *Student's Atlas of Neuroanatomy*. Saunders, Philadelphia, 1994.)

HYPOTHALAMUS The hypothalamus, a relatively small structure within the diencephalon, is a crucial component of the neural circuitry regulating not only emotions but also autonomic, endocrine, and some somatic functions. In addition to its relations with other components of the limbic system, it is interconnected with various visceral and somatic nuclei of the brainstem and the spinal cord, and it provides an output that regulates the function of the pituitary gland. On its inferior surface the hypothalamus is bounded rostrally by the optic chiasm and caudally by the posterior edge of the mammillary bodies. The area of the hypothalamus between those two structures, called the *tuber cinereum,* gives rise to the median eminence, which is continuous with the infundibular stalk and then the posterior lobe of the pituitary gland (Fig. 1.2-31). On the basis of these features the hypothalamus is subdivided from anterior to posterior into three zones: the supraoptic region, the tuberal region, and the mammillary region. (In addition, the preoptic area, a telencephalic structure located immediately anterior to the supraoptic region is usually considered part of the hypothalamus.) These three zones are also divided on each side into medial and lateral areas by the fornix as it travels through the body of the hypothalamus to the mammillary bodies. As shown in Table 1.2-3, the six parts of the hypothalamus contain different nuclei.

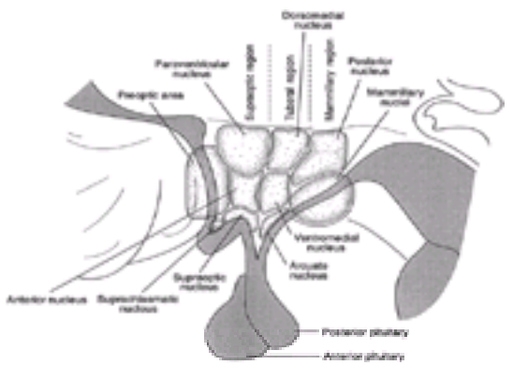

FIGURE 1.2-31 Schematic drawing of the nuclei in the medial hypothalamus. (Adapted from Burt AM: *Textbook of Neuroanatomy*. Saunders, Philadelphia, 1993.)

Region	Medial Area	Lateral Area
Supraoptic	Supraoptic nucleus Paraventricular nucleus Anterior nucleus Suprachiasmatic nucleus	Lateral nucleus Part of supraoptic nucleus
Tuberal	Dorsomedial nucleus Ventromedial nucleus Arcuate nucleus	Lateral nucleus Lateral tuberal nuclei
Mammillary	Mammillary body Posterior nucleus	Lateral nucleus

Table 1.2-3 Hypothalamic Nuclei

Those different nuclei subserve the diverse functions of the hypothalamus. For example, the *suprachiasmatic nucleus* receives both direct and indirect projections from the retina and appears to be important in the regulation of diurnal rhythms. The *supraoptic* and *paraventricular nuclei* contain large cells (magnocellular neurons) that send oxytocin and vasopressin-containing fibers to the posterior neural lobe of the pituitary. In addition, some neurons of the paraventricular nucleus project to the median eminence, where they release neuropeptides, such as corticotropin-releasing factor, into the portal blood system. These neuropeptides then control the synthesis and the release of anterior pituitary hormones. The paraventricular nucleus also gives rise to descending projections that regulate the sympathetic and parasympathetic autonomic areas of the medulla and the spinal cord.

Within the medial tuberal region of the hypothalamus, the *ventromedial* and *arcuate nuclei* also participate in the regulation of the anterior pituitary function. In addition, the ventromedial nucleus may play an important role in reproductive and ingestive behavior. The medial posterior section of the hypothalamus contains the *posterior nucleus* and the *mammillary bodies*. Within the mammillary bodies, the lateral and medial mammillary nuclei receive hippocampal input through the fornix (Fig. 1.2-28) and project to the anterior nuclei of the thalamus. The posterior nucleus shares reciprocal connections with the extended amygdala. That nucleus appears to be more developed in primates than in rodents, suggesting that it plays an important role in the human brain, one that has still to be clarified.

The lateral portions of the hypothalamus contain a relatively low density of neurons scattered among longitudinally running fibers of the medial forebrain bundle, which is interconnected with multiple regions of the forebrain, the brainstem, and the spinal cord.

Functional Circuitry The major structures of the limbic system are interconnected with each other and with other components of the nervous system in a variety of ways. However, several major output pathways of the limbic system are clearly defined. In one pathway (Fig. 1.2-32) highly processed sensory information from the cingulate, the orbital and temporal cortices, and the amygdala is transmitted to the entorhinal cortex of the parahippocampal gyrus and from there to the hippocampal formation. After traversing the intrinsic circuitry of the hippocampal formation, information is projected through the fornix either to the anterior thalamus, which in turn projects to the limbic cortex or to the septal area and the hypothalamus. Those latter two regions provide feedback to the hippocampal formation through the fornix. In addition, the mammillary bodies of the hypothalamus project to the anterior thalamus. Finally, the hypothalamus and the septal area project to the brainstem and the spinal cord.

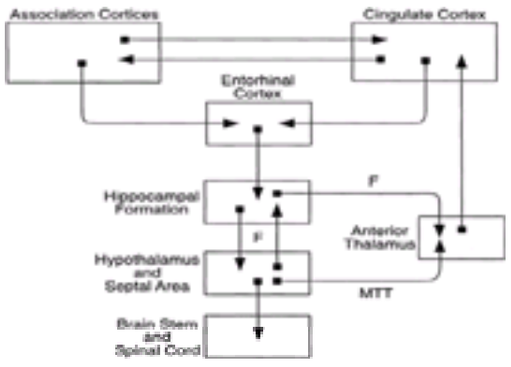

FIGURE 1.2-32 Functional neural circuitry of the limbic system. This diagram illustrates the manner in which the hippocampal formation and the anterior thalamus provide a mechanism for the integration of information between the cerebral cortex and the hypothalamus. F, fornix; MTT, mammillothalamic tract. (Adapted from Nolte J: *The Human Brain: An Introduction to Its Functional Anatomy,* ed 3. Mosby, St. Louis, 1993.)

Another major pathway within the limbic system centers on output from the amygdala (Fig. 1.2-33). Highly processed sensory information, primarily from the association regions of the prefrontal and temporal cortices, projects to the amygdala. Output from the amygdala is conducted through two main pathways (Fig. 1.2-30). A dorsal route, the *stria terminalis,* accompanies the caudate nucleus in an arch around the temporal lobe and contains axons that project primarily to the septal area and the hypothalamus. The second major output route, the *ventral amygdalofugal pathway* passes below the lenticular nucleus and contains fibers that terminate in a number of regions, including the septal area, the hypothalamus, and the medial dorsal thalamic nucleus. The medial dorsal nucleus in turn projects heavily to prefrontal and some temporal cortical regions.

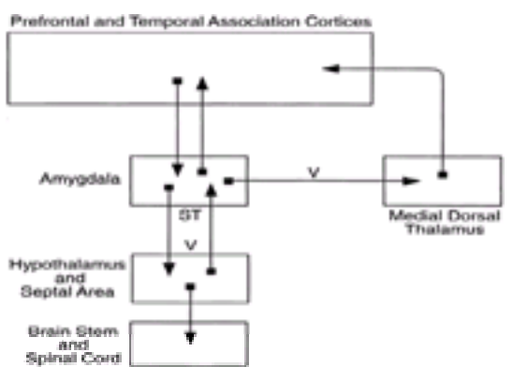

FIGURE 1.2-33 Functional neural circuitry of the limbic system. This diagram illustrates how the amygdala and the medial dorsal thalamus serve to integrate information processing between prefrontal and temporal association cortices and the hypothalamus. V, ventral amygdalofugal pathway; ST, stria terminalis. (Adapted from Nolte J: *The Human Brain: An Introduction to Its Functional Anatomy,* ed 3. Mosby, St. Louis, 1993.)

Both these pathways reveal how the limbic system is able to integrate the highly processed sensory and cognitive information content of the cerebral cortical circuitry with the hypothalamic pathways that control autonomic and endocrine systems. In addition, the limbic system interacts with components of the basal ganglia system (Fig. 1.2-34). For example, the ventral amygdalofugal pathway also projects to the nucleus accumbens (ventral striatum), the area where the head of the caudate nucleus fuses with the putamen (Fig. 1.2-20). That region sends efferents to the ventral palladium, an extension of the globus pallidus, which in turn projects to the medial dorsal thalamic nucleus. The pathway indicates that the functions of the basal ganglia extend beyond the regulation of motor activities and shows the necessity of considering the function or dysfunction of particular brain regions in the context of all aspects of their circuitry.

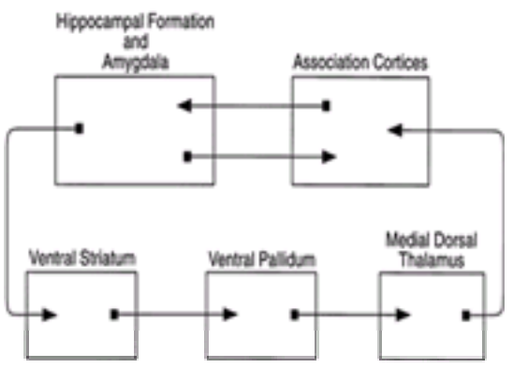

FIGURE 1.2-34 Functional neural circuitry of the limbic system. This drawing illustrates the interaction between the limbic system and certain components of the basal ganglia. (Adapted from Nolte J: *The Human Brain: An Introduction to Its Functional Anatomy,* ed 3. Mosby, St. Louis, 1993.)

1.3 DEVELOPMENTAL NEUROBIOLOGY

KATHRYN J. KOTRLA, M.D. AND DANIEL R. WEINBERGER, M.D.

Human behaviors, thoughts, and emotions reside in the interface between the mind and the brain. The mind is experienced; the brain is the substrate on which mind depends. Basic neuroscience research provides an impressive array of information about the brain. The genes and molecules required for normal brain formation and functioning are being discovered, as are the many neural networks that subserve different aspects of cognition, memory, and mood. The practicing psychiatrist does not need to know the details of neuronal connectivity and functioning. However, moving from a knowledge of the concepts of basic neuroscience to an understanding of the mind is within the domain of psychiatry and will impact psychiatric care substantially.

Three threads of basic neuroscience research are particularly important. Developmental neurobiology explores the mechanisms underlying prenatal and postnatal brain development. Psychiatric conditions like schizophrenia and autistic disorder are likely to have their origins in utero. Understanding development will illuminate the etiology of such disorders, and may suggest novel treatment and prevention strategies. During postnatal development there are critical periods in which the fine-tuning of cortical connections occurs. Understanding critical periods during early childhood may help to explain the lifelong difficulties of individuals who suffer trauma, abuse, or neglect in early life. Lastly, neuroscience is investigating the continued plasticity of the adult brain. Understanding how the adult brain changes with time and experience has implications for how psychiatric disorders change in their expression and treatment responsiveness over a lifetime.

PRENATAL DEVELOPMENT

The wonder of development is that a structure as complex as the human brain originates from a flat sheet of embryologic ectoderm. The final, formed brain shows remarkable order in its predictable cortical layering, its diversity of cortical areas, and the numerous networks linking specific cortical areas and subcortical structures. To have cells choosing to become a certain neuronal type, attaining the correct laminar position, finding the correct target, and expressing the correct neurotransmitters at first seems overwhelmingly difficult. However, the final, breathtakingly complex set of connections in the human brain depends on a series of much simpler decisions as neurons become progressively more restricted in the choices they make. These decisions require the subtle interplay of genetic and environmental factors; much has been learned at a molecular level about these processes. At first glance this information seems most relevant to mental retardation or autistic disorder, in which abnormal brain development results in lifelong disability. However, even schizophrenia is believed to originate in subtle aberrant brain development, and understanding it requires an understanding of its etiology.

Neurogenesis and Neural Identity The cerebral cortex possesses an orderly six-layered array of neuronal and glial cell types; layer I is the most superficial layer closest to the meninges, layer VI lies deeper, closest to white matter. Each layer has characteristic interconnections, with the superficial layers connecting with other cortical areas, and the deeper layers connecting to subcortical structures. Across the cortex there are microscopic variations in the appearance of the array, corresponding to areas of cortex with distinct functions, connections, receptors, and neurotransmitters (Fig. 1.3-1). Such complexity arises via a series of progressive restrictions in cell fate.

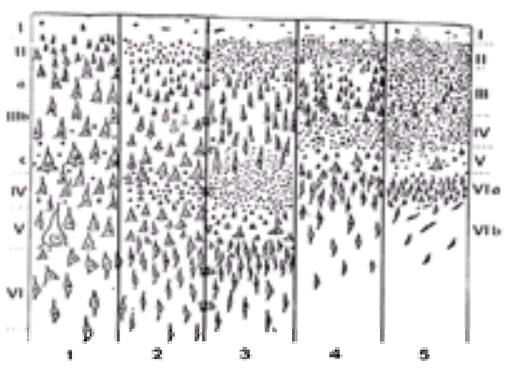

FIGURE 1.3-1 The cerebral cortex contains discrete areas with differing cytoarchitecture. This drawing shows the six layers of the cortex (I-VI). The five different panels illustrate marked differences in cortical structure in different brain areas. Note the variations in neuronal size and morphology. (Reprinted with permission from Carpenter MB, Sutin J: *Human Neuroanatomy,* ed 8. Williams & Wilkins, Baltimore, 1983.)

The initial decision to form a brain depends on the embryonic mesoderm inducing the overlying ectoderm to become nervous system. This sheet of ectoderm, the neural plate, invaginates to form the neural tube as cells are progressively determined to form forebrain, midbrain, and hindbrain even before any neurons have been generated.

On the inner surface of the neural tube there is a rapidly dividing pseudostratified epithelium that forms a ventricular zone. From the neural ectoderm arise neuroblasts, which are precursor cells located in the ventricular zone. Neuroblasts divide and produce a lineage of daughter cells that migrate into the developing cortex to form cortical neurons. In humans, cortical neurons are born from around gestational day 40 until day 125.

The first postmitotic neurons leave the neuroepithelium and accumulate beneath the pial surface to form the preplate. This is split by later-generated neurons, the cortical plate, into a superficial, marginal zone (future layer I) and a deep subplate zone. As cortical plate neurons are born, they populate layers VI through II of the adult cortex, between the marginal and subplate zones.

Normally, the six cortical layers are generated in an orderly sequence, with first-born neurons residing in the deeper cortical layers, and later-born neurons residing in more superficial layers. One early decision a neuron faces is to which cortical layer to belong. This decision is reached before the final cell division producing the daughter neuron, and is based on cues in the neuron's microenvironment, including previously generated cells. This was shown experimentally by transplanting younger cortex making deep-layer neurons into older cortex making superficial-layer neurons. If neuroblasts are transplanted before daughter neurons are born, the daughter neurons become superficial-layer neurons, consistent with the local environment. However, if the progenitor neuroblasts are transplanted closer to the daughter neurons' birth, the daughter neurons migrate to deep cortical layers, true to their original laminar fate. Laminar identity is probably marked molecularly, and this marker may be used during later neuronal migration and target finding.

The microenvironment may also provide other information about a neuron's fate, such as what kind of cortex to become. For example, limbic cortex is marked by a protein that distinguishes it from other cortical areas. Very soon after neurogenesis, the cells destined to form the prefrontal, cingulate, perirhinal, and hippocampal cortices are marked on their surfaces by a specific molecule, called *limbic system-associated membrane protein* (LAMP). The neocortex as a whole is also distinct from other forebrain regions in its expression of specific regulatory genes. Later differences in neocortical areas, like whether to become visual cortex or sensory cortex, are likely to be determined by epigenetic factors and afferent inputs.

Other localizing information, which may guide afferent ingrowth, seems to be provided around neurogenesis. Positional information in the neuroepithelium is probably imparted to preplate cells around the time they are generated; this information is used in the subplate to control the targeting of ingrowing thalamocortical axons, at

least in the neocortex. Abnormalities in the assignment of laminar identity or cortical area markers could result in disordered cortical layers or in the formation of incorrect afferent and efferent connections.

Neuronal Migration Once neurons are born in the ventricular zone, they migrate past earlier born neurons to assume their final laminar position. The formation of the six cortical layers is complete between gestational age 26 and 29 weeks. To reach their laminar location, neurons migrate along radial glial fibers that stretch from the ventricular to superficial surface, a journey that may take place over tens of millimeters. Neurons must travel through a complex, rapidly expanding zone containing afferents from the thalamus and other cortical areas (Fig. 1.3-2).

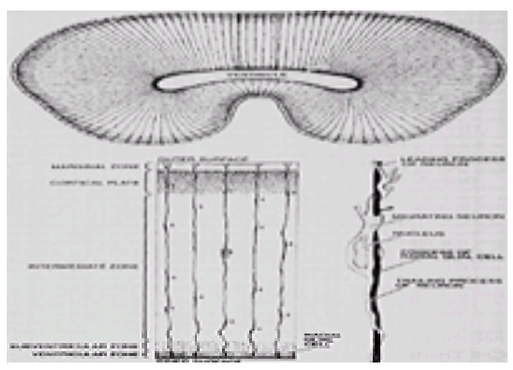

FIGURE 1.3-2 To form the cortex, neurons are born in the ventricular zone and migrate along radial glial cells to assume their position in the correct cortical layer. The upper figure clarifies the relationship between the ventricular surface, where neurons are born, and their final destination in the cortical plate. More detail is provided in the lower left drawing. This figure labels the ventricular zone, the large expanse of the intermediate zone through which the neuron migrates, and the final developing cortical layers in the cortical plate. The drawing on the lower right demonstrates the morphology of a migration neuron as it climbs along a radial glial cell through the intermediate zone. (Reprinted with permission from Maxwell Cowan W: The development of the brain. Sci Am *241:*124, 1979.)

During migration, there appear to be transient synapses and expression of neurotransmitters and neuromodulators, suggesting a chemical interaction between the migrating neurons and the embryonic environment, which influences the rate of neuronal migration. Also, contact interaction between migrating neurons and the surfaces of neighboring cells plays a crucial role in selecting migratory pathways, and in choosing to detach from the radial glial fiber and stop migrating. Stopping migration is probably an active process, and may depend on cell surface markers conferring laminar identity. The vast majority of neurons find the correct position; the small percentage of neurons that migrate to the wrong location mostly degenerate during the later phase of naturally occurring cell death.

Establishing Connections After finding the correct layer comes the intricate decision to establish connections between different brain regions. This process occurs between subcortical and cortical areas, within cortical areas, and between cortical areas. The final fate and functioning of neocortex are very dependent on the connections it establishes. How does a neuron extend its axon through the complex embryonic environment to find its correct target?

The leading edge of the axon, the growth cone, has an array of molecules on its surface. It interacts with molecules on other cells, axons, and the extracellular matrix in the embryonic environment. The molecules in the growth cone's environment are differentially adhesive or repellent. They cause the growth cone to grow where there are adhesive molecules and to avoid repulsive molecules that cause the growth cone to collapse. To choose among the number of possible pathways in the embryonic environment, the growth cone samples among the choices by means of its filopodia, and grows along specific pathways to which it is adherent or does not encounter repulsive molecules. There also appear to be diffusible gradients towards which some growth cones grow.

To illustrate the complexity of pathfinding, axons from the lateral geniculate nucleus, the visual thalamus, must navigate long distances to find the visual cortex, and then grow specifically into layer IV to synapse. Thalamic afferents presumably select their cortical targets based on molecular information on target cells or in the extracellular matrix. The subplate plays a crucial role during development, allowing afferents from thalamic neurons to wait under the developing cortex until layer IV neurons are born and migrate to their final location. In the absence of the subplate, ingrowing thalamic afferents grow past the visual cortex and fail to find their appropriate target.

Finding the appropriate cortical layer is likely to depend on laminar addresses conferred when neurons are born. For example, just as thalamic afferents to the visual cortex find layer IV, axons of layer III cortical neurons bypass layer IV to make specific connections with layer V. Even if layer V neurons are transplanted to foreign locations, they still send their axons to appropriate targets.

The molecules guiding pathway selection are being identified and characterized rapidly. One of the first discovered was the neural cell adhesion molecule (NCAM). NCAM is one of a family of molecules that mediates cell-cell or cell-substrate adhesion, and is found in many parts of the developing nervous system. Deficits in NCAM expression result in subtle cytoarchitectural abnormalities in specific brain areas. Similarly, growth-associated protein (GAP-43) is a molecule that plays a key role in guiding axon growth and modulating new connections. If GAP-43 is overexpressed, aberrant extra connections are formed in the hippocampus and other areas of the central nervous system and the peripheral nervous system. Conversely, in the absence of GAP-43, grossly abnormal connections are established.

However, there are molecules that provide more specific pathway selection information. The LAMP molecule, which marks the identity of limbic and prefrontal cortices, is needed for the formation of axon pathways between neurons in the prefrontal, cingulate, and limbic areas. It is also required for the thalamus to send correct inputs into these cortical areas, completing a network linking cortical and subcortical structures.

Cell Death Once cortical neurons are created and assume their connections, there is a period of naturally occurring cell death (*apoptosis*) in widespread areas. Apoptosis is a complex cellular process, including the expression of specific gene sequences, that ultimately leads to deoxyribonucleic acid (DNA) fragmentation and nuclear dissolution. It is distinctly different from necrosis in that cells are not damaged by external agents but die after the activation of an internal program. Also, apoptosis does not produce an inflammatory response like necrosis does. Neurons that make an adequate number of appropriate connections do not express the genes leading to apoptosis, presumably because of the trophic factors they receive from their connections, which prevent expression of the apoptotic program.

Apoptosis occurs mostly during the second half of gestation, and may result in the loss of 25 to 40 percent of the neurons in different cortical layers. The extent of cell death is controlled by influences from the neuron's synaptic targets, afferent input to the neurons, and local glial-derived and extracellular matrix molecules. If the amount of target or afferent input is diminished, more cell death results; similarly, if target or afferents are increased, the number of surviving neurons increases. Notably, even in adults neurons continue to depend on their efferent and afferent connections both for their survival and the maintenance of normal morphology and biosynthetic events.

Neuronal Differentiation and Neurotransmitter Selection The cues governing final neuronal phenotype and neurotransmitter selection also arise from multiple sources. These include previously generated neurons, glia, the extracellular matrix, various trophic factors, growth factors, and local neurotransmitters. One critical factor in neuronal differentiation appears to be cortical afferents. The differentiation of neurons in layers VI, V, and IV coincides with the ingrowth of thalamocortical fibers, that of layer III with the arrival of interhemispheric fibers, and that of layer II with the arrival of cortico-cortical fibers. Postsynaptic targets also produce differentiation factors, which alter gene expression in the presynaptic neuron and influence the choice of neurotransmitter and neuropeptides synthesized. A neuron's target can even influence which other cells connect with the neuron's dendrites. Because differentiation factors can be communicated through efferent and afferent connections, these factors regulate neuronal phenotype very precisely. They can influence the functioning of a limited number of neurons linked together in a network, without causing changes in the large numbers of nearby cells. Even in postembryonic, functional neurons, normal fluctuations in neuronal activity or hormone levels or an insult to the system can alter transmitter and neuropeptide expression.

Implications for Psychiatry What happens when the developmental plan goes awry? Aberrations in the formation of neural ectoderm or in the formation of neuroblasts are likely to result in gross abnormalities like anencephaly. A generalized failure of the migration of daughter neurons into cortical layers is seen in a lissencephalic brain, characterized by an agyric (smooth) cerebral surface. Mutations in certain cell adhesion molecules affect neural migration or axonal outgrowth, and are associated with inherited hydrocephalus. Such gross pathology is unlikely to result in an illness appreciated as psychiatric because children with these

disorders have severe mental retardation and neurological syndromes. Abnormalities of neural migration have been implicated in radiation exposure, fetal alcohol syndrome, epilepsy, reading disorder, autistic disorder, and schizophrenia. A relatively well-researched example is the radiation exposure during Hiroshima and Nagasaki, which caused a disruption of neural migration in fetuses exposed during midgestation (weeks 10 to 17). Postmortem examination showed massive heterotopia, attenuation of superficial cortical layers, and a reduction in cortico-cortical connections; epilepsy and mental retardation were frequent medical sequelae. However, given the intricate interplay of molecules and cells during development, the potential for even more subtle aberrations in cortical development and connections abounds.

Localized Abnormalities If abnormalities develop within certain neural networks, specific behavioral, cognitive, or mood symptoms recognized as a psychiatric disorder could conceivably result. Examples of localized abnormalities abound in developmental neurobiology. If monkeys are enucleated in utero, developing visual cortex diminishes in size, and surrounding cortical areas show abnormal cytoarchitecture; even localized neuronal morphologies and neurotransmitter receptor patterns show changes. Efferent connections can also be altered by abnormal afferent connections. If somatosensory input from the thalamus is routed to and synapses with visual cortex, primary visual cortical neurons retain a projection to the spinal cord, acting like somatosensory cortex.

Such subtle developmental anomalies are being discovered in many animal species. In the fruitfly, when a cell surface adhesion molecule is deleted genetically, the fly develops a characteristic set of behavioral dysfunction. The fly can walk and jump, but not fly; it has abnormal visual orientation and drinking behavior. This suggests that the molecule is crucial for the development of neural circuits controlling a subset of behavior.

There are mutant mice strains characterized by abnormal neural migration localized to the hippocampus. The hippocampus is divided into areas such as CA1, CA2, and CA3. The neurons of the hippocampus are generated during characteristic prenatal intervals in the ventricular zone lining the lateral ventricle. As in other cortical areas, the neurons migrate along primarily radial glial fibers to reach their final location. The migratory path followed by neurons destined for areas CA1 and CA2 is fairly direct. The path followed by neurons destined for area CA3, in contrast, is tortuous and lengthens during the migratory process because of hippocampal growth. One autosomal-dominant mutation, the hippocampal lamination defect mutation, affects only late-generated pyramidal cells destined for area CA3. In this mutation, this very discrete population of pyramidal cells stops in its migration and resides in an ectopic position below earlier-generated cells. This mutant demonstrates that heterotypic neuronal lamination can be limited to certain cell types in specific cortical areas.

Kallman's syndrome, an inherited human disorder characterized by hypogonadism and anosmia, is thought to result from the lack of a substrate adhesion molecule. During normal development, olfactory and gonadotropin-releasing hormone neurons migrate along a common pathway. In Kallman's syndrome this migration appears to be arrested, possibly because of a failure in neuronal interaction or synaptogenesis of olfactory neurons and their target in the olfactory bulb. Neuroanatomical findings include aplasia of the olfactory gyri and absent olfactory tracts and bulbs, which implies that an abnormality of a specific molecule causes dysfunction in discrete neuronal areas.

Neurodevelopmental Hypothesis of Schizophrenia Although future investigations may suggest that the seeds of other psychiatric illnesses are sown during development, the implications that abnormal brain development has for psychiatry are best illustrated in schizophrenia. The etiology of schizophrenia has been explored using in vivo neuroimaging, and postmortem neuropathological examinations. The neurodevelopmental hypothesis states that schizophrenia results from abnormal brain development, which manifests characteristic symptoms during early adulthood.

One dysfunctional neural network in schizophrenia links the association cortices of the frontal, parietal, and temporal lobes and the limbic cortex and subcortical structures. This network contains cortices that are the most evolutionarily advanced, and are critical to executive functioning, memory, and attention (Fig. 1.3-3) functions that are particularly impaired in persons with schizophrenia. Because these cerebral areas are well defined, it is possible to investigate their integrity, both with in vivo neuroimaging techniques and via postmortem neuropathological examinations.

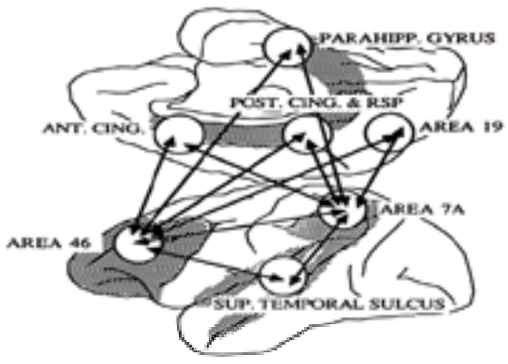

FIGURE 1.3-3 Cortical and subcortical areas are physically connected into discrete neural networks that subserve distinct aspects of cognition, affect, and behavior. A crucial goal of development is the establishment of the correct neural connections to form these networks. This drawing is a simplification of the multiple pathways connecting the frontal, parietal, and temporal cortices, areas involved in attention and memory, and implicated in schizophrenia. The hatched areas reveal inputs from one thalamic nucleus. (Reprinted with permission from Goldman-Rakic PS: Parallel distributed networks in primate association cortex. Annu Rev Neurosci *11:*143, 1988.)

NEUROIMAGING Imaging the brain with magnetic resonance imaging (MRI) allows for volumetric measurements of brain structures. In schizophrenia, reductions on the order of 10 to 15 percent are reported in overall temporal lobe size, in temporal lobe gray matter, and in specific mesial and lateral temporal lobe structures. Recent MRI studies suggest subtle volumetric reductions in widespread cortical areas, including the frontal and parietal secondary association areas, and in the thalamus.

Neuroimaging with single photon emission computed tomography (SPECT) and positron emission tomography (PET) can investigate the functioning of these brain regions in vivo. By imaging subjects during tasks, cerebral activity patterns reflect the functioning of neural networks necessary to perform the tasks. In numerous studies individuals with schizophrenia show dysfunction within frontal-parietal-temporal networks, even during different tasks that utilize these cerebral areas. An example is the Wisconsin Card Sorting Test, an abstract problem-solving test requiring attention and working memory. Monozygotic twins discordant for schizophrenia underwent PET blood flow scans while performing this test. In all but one pair the ill twin had relatively decreased prefrontal cerebral blood flow; the mesial temporal lobe limbic region in the ill twin was invariably hyperactive. In vivo studies do not speak to when or how the functional abnormality arose. However, finding functional consequences in cerebral areas defined as abnormal in neuropathological investigations is essential to correlate neurodevelopmental abnormalities with the clinical symptoms of schizophrenia.

NEUROPATHOLOGY Postmortem morphometric studies of brains from patients with schizophrenia are consistent with in vivo imaging studies. Schizophrenia is associated with enlarged ventricles and apparently focal decreases in the size of mesial temporal lobe structures, including the amygdala, hippocampus, parahippocampal gyrus, and entorhinal cortex. Similarly, reduced neuronal counts and decreased neuropil have been reported in selected cortical and periventricular regions. One crucial observation is the lack of gliosis in schizophrenia. A proliferation of glial cells is seen in most degenerative brain conditions and encephalopathies that arise after birth. This suggests that whatever causes the brain abnormalities in schizophrenia does so before the third trimester of gestation, when glial cells become responsive to injury.

Of considerable interest in understanding the developmental neurobiology of schizophrenia are studies exploring cortical cytoarchitecture, particularly in the networks showing in vivo dysfunction. In the entorhinal cortex of individuals with schizophrenia, heterotopic groups of neurons belonging to layer II are found displaced into layer III. This may indicate abnormal neuronal migration that results in heterotopic neuronal islands, and abnormal cytoarchitecture; unfortunately, not all studies replicate this finding. However, other investigators report reduced numbers of small neurons and abnormal neuronal aggregates in the anterior cingulate. Layer II of the prefrontal cortex of persons with schizophrenia shows reduced numbers of small neurons and higher densities of pyramidal neurons in layer V.

A neuron-specific stain for nicotinamide-adenine dinucleotide phosphate-diaphorase (NADPH-d) has been used to study brains from patients with schizophrenia. NADPH-d-staining cells are seen in cortex and in subcortical white matter and are likely to be the remnants of subplate neurons. In the prefrontal and lateral temporal

lobe cortex of some patients with schizophrenia these neurons are decreased in the cortex and its subjacent white matter, but are present in abnormally high numbers in deeper white matter. This is consistent with the hypothesis of aberrant neuronal migration in schizophrenia.

CONSEQUENCES OF ABNORMAL CYTOARCHITECTURE The number of studies exploring the extent, type, and location of cytoarchitectural abnormalities in schizophrenia is limited. Nevertheless, each positive finding implicates a failure of neurons assuming the correct laminar location, a process that occurs during the second trimester of intrauterine brain development. This could reflect a defect not only in migration, but in the ability to attract the correct afferents or make normal efferent connections.

If one area of cortex is abnormal, there will be ramifications in the organization and function of cortical and subcortical areas from which it receives afferents and to which it sends efferents. Because cortical areas depend on their afferent and efferent connections to survive cell death, the reports of reduced cell numbers in schizophrenia could be due to the effects of disordered cortex elsewhere. This is consistent with the subtle cortical volume reductions found in MRI studies of schizophrenia.

Not surprisingly, multiple postmortem biochemical and molecular abnormalities are also associated with schizophrenia. These include mesial temporal lobe abnormalities of choline acetyltransferase, glutamate decarboxylase, glutamate, aspartate, serotonin, neurotensin, and substance P. Abnormalities in receptor subtypes include k-opioid, b-adrenergic, serotonin (5-hydroxytryptamine [5-HT]) type 1A [HT_{1A}], $5\text{-}HT_2$, g-aminobutyric acid (GABA), as well as alterations in glutamate reuptake sites and adenylate cyclase. In the prefrontal cortex, reported abnormalities include serotonin reuptake sites and met-enkephalin, $5\text{-}HT_{1A}$ and $5\text{-}HT_2$ muscarinic cholinergic, glutamate and $GABA_A$ receptors.

Molecules crucial to normal brain development and postnatal plasticity are being investigated in schizophrenia. In brains of persons with schizophrenia abnormalities of NCAM have been reported. GAP-43 is essential for the initial establishment and reorganization of synaptic connections, and remains high throughout life in the limbic system and neocortex, areas involved in the processing and storage of information. In frontal cortex and visual association areas of persons with schizophrenia, levels of GAP-43 protein are increased, which is perhaps a reflection of the plasticity of inputs to prefrontal cortex. GAP-43 messenger ribonucleic acid (mRNA), a measure of intrinsic prefrontal efferent plasticity, is reduced. Levels of synaptophysin also are reduced; synaptophysin is a synaptic–vesicle-associated protein involved in neurotransmitter release that is used as a marker of presynaptic terminal density. Reduced synaptophysin mRNA concentrations are also found in specific regions of the mesial temporal lobe. Although the precise mechanisms controlling these molecular changes remain unknown, the results suggest abnormal synaptic connectivity.

If abnormal brain development causes schizophrenia, why does onset of symptoms occur in late adolescence or early adulthood? Frontal–lobe-linked networks, which appear to be dysfunctional in schizophrenia, undergo substantial postnatal maturation. Schizophrenic symptoms may not appear until a critical network is tested at a particular time in postnatal maturation. However, it should be noted that individuals destined to develop schizophrenia showed subtle but significant delays in early-childhood milestones like walking and speech development. This suggests that abnormalities are present virtually from birth, but that their clinical manifestations may vary over time.

EARLY POSTNATAL DEVELOPMENT

The early postnatal years are marked by a rapid maturation of cognitive, social, and behavioral abilities as infants progress from helplessness to autonomy, and children and adolescents develop more sophisticated ways of thinking. The information and abilities acquired by infants, children, and adolescents are staggering. The impact that these early years have on personality development and behavior is profound, longlasting, and at times, refractory to treatment interventions. The consequences of physical or emotional childhood trauma are seen in every psychiatric practice. For such dramatic cognitive, behavioral, and emotional changes, there must be an underlying neurobiological substrate. Neuroscience is exploring the structural and functional foundations of normal postnatal maturation and how it is impacted by the environment.

Postnatal Cortical Maturation The number of cortical synapses changes dramatically in early postnatal life. Newborn monkeys have approximately the same number of synapses as adult monkeys do. Synaptic density increases in the first few months of life until it is about 40 percent higher than adult values. Synaptic density remains high until adolescence when it decreases to adult levels, and then remains fairly constant throughout life. The pruning of cortical synapses appears to involve primarily excitatory connections. Local circuit interneurons, which are GABAergic, appear to maintain stable synapses from childhood into adulthood. This suggests that exuberant excitatory synaptic connections are selectively remodeled into adultlike connectivity by experience.

The maturation of neuronal structure was investigated by a postmortem examination of prefrontal cortex from 10 weeks' gestational age through adulthood. Neurons were stained, and their location and morphology was studied. Distinct cortical areas and layers assume adult morphology at different rates. The subplate has disappeared by birth in the visual and somatosensory cortices, but is present in the prefrontal cortex of the newborn and gradually declines during the first 6 months of life. It may continue to serve a role in the development of postnatal prefrontal cortico-cortical projections.

Many neuronal types alter their shape postnatally, corresponding to altered synaptic connections. In several cortical layers in the prefrontal cortex and other association cortices, pyramidal neurons continue dendritic outgrowth and spine formation throughout the first 2 postnatal years. Pyramidal neurons in layers III and V of the prefrontal cortex may not develop adultlike dendritic fields until adolescence. The pyramidal neurons of layer III are a major source of cortico-cortical connections, and they show intensive spine growth during early childhood, possibly as targets of thalamocortical and cortico-cortical fibers. Similarly, the interneurons that modulate pyramidal neurons show postnatal changes.

Implications for Psychiatry The continued maturation of prefrontal cortex in early life offers ample opportunities for childhood experience to permanently shape the cortex that controls thought, behavior, and mood. At a gross level, if the processes governing synaptic remodeling and maturation go awry, severe conditions can occur. Fragile X syndrome, the second most common inherited form of mental retardation, is associated with abnormal synapses. Individuals with fragile X show thin, elongated dendritic spines with smaller synaptic contacts, much like the appearance of immature synapses during normal neocortical development. However, environmental input to otherwise normal cortex can also produce dramatic changes in cortical structure and function.

Environmental Effects on Cortical Connections During early life the cortex is fine-tuning its connections dependent on patterns of neural activity caused by environmental input. An example is human infants with congenital cataracts. The cataracts must be removed before 4 to 6 months of age, or permanent visual impairment results. Also, if strabismus is not corrected by about 7 years of age, the squinting eye is permanently visually handicapped. The timing of these critical periods corresponds with the normal timing of exuberant synapse elimination. In the human visual cortex, synapse elimination begins at about 6 months and is complete by age 6 or 7 years.

The impact of left-hemisphere damage on language development reveals an analogous process. If the brain damage occurs before 8 years of age, language development may recover and seem normal; after 8 years of age, aphasia results. These clinical examples illustrate that the availability of exuberant synapses facilitates functional plasticity. Similarly, normal cortical language representation can be visualized using functional MRI. Individuals who learned two languages during infancy show similar cortical activity when exposed to either language. In contrast, individuals who learned a second language in early adulthood show distinct Broca's area representations of the native and second languages. This illustrates how cortical organization and plasticity is dependent on the time of the environmental influence. However, to more fully understand the mechanisms underlying this plasticity requires experimental animal models.

David Hubel and Torsten Wiesel described the impact of environmental manipulations on the visual system in cats and monkeys. Analogous to humans, there is a critical period during visual cortical development during which the cortex is exquisitely sensitive to changes in environmental input. Once the critical period passes, cortical abnormalities are irreversible. In contrast, adult visual cortex is much less sensitive to environmental input; a year of monocular lid closure in an adult cat leads to no detectable cortical effects. If one eyelid is sutured during the critical period, there is little visual input from that eye; if the eye is opened later, vision remains permanently impaired. This is reflected cortically by reduced representation from the sutured eye and expanded representation from the open eye (Fig. 1.3-4). In the lateral geniculate nucleus, the synaptic waystation between the retina and visual cortex, there is profound atrophy in the geniculate layers receiving input from the covered eye. In the visual cortex, the terminals from visually deprived afferents are smaller, have fewer mitochondria, and make immature-appearing synapses. GAP-43, a molecule implicated in axonal connectivity, has its highest expression in primary visual cortex during the critical period as synapses are remodeled.

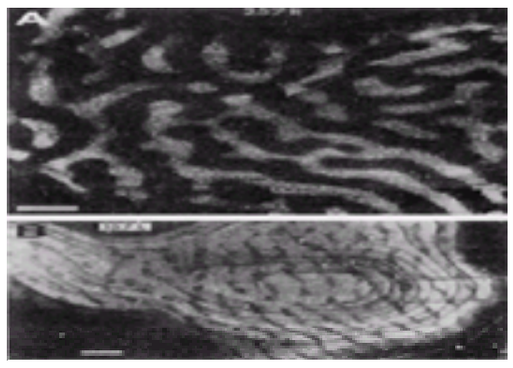

FIGURE 1.3-4 Early postnatal environmental inputs dramatically alter cortical structure. The top picture **(A)** shows an autoradiograph from layer IV of the primary visual cortex of a normal monkey. The light areas reveal inputs from one eye; the dark bands are inputs from the other eye. Equal cortical representation from both eyes is evident. Picture **B**, an autoradiograph from a monkey whose right eye was closed during infancy, illustrates what happens after monocular deprivation. Note the marked expansion of the light areas, and the shrinkage of the dark bands. The light areas are the inputs from the eye that was open during the experiment. (Reprinted with permission from LeVay S, Wiesel TN, Hubel DH: The development of ocular dominance columns in normal and visually deprived monkeys. J Comp Neurol *191:*11, 1980.)

If kittens are deprived of visual input altogether, compensatory changes are seen in the visual areas; there are now neurons that respond to auditory and somatosensory stimulation. Within altered cortex there are alterations in the concentration of serotonin, dopamine, norepinephrine, glutamate, and acetylcholinesterase. This demonstrates that the morphological synaptic, and molecular plasticity of the critical period is crucial for normal cortical connectivity and functioning.

Strabismus has also been experimentally induced in cats and monkeys by unilateral ablation of one extraocular muscle. Although these animals are born with a normal CNS, the abnormal visual input and neural activity induced by strabismus causes structural CNS changes. The morphology of retinogeniculate axons is altered, with smaller arbors and fewer boutons compared to normal. The lateral geniculate nucleus contains smaller neuronal cell bodies. The anatomical organization of the visual cortex is also altered with a reduction in the proportion of cells that respond to binocular input and a loss of the normal orientation selectivity.

Early environmental manipulations may also impact higher cognitive functioning. This has been elegantly explored in a series of experiments investigating monkey visual recognition memory. Visual recognition memory is the ability to see an object and to consciously remember having seen it before. This capacity requires the interaction of visual pathways and the limbic system. In adult monkeys, area TE is critical for this interaction. Area TE is a cortical region on the lateral temporal lobe that receives projections from multiple visual areas in prestriate cortex, and sends direct and indirect projections to the amygdala, perirhinal cortex, and hippocampus. Adult lesions in area TE significantly impair visual recognition memory.

In contrast, infant lesions in area TE leave visual recognition memory intact. This sparing of function is explained by the enhanced plasticity of the immature brain that results from the redundancy of connections. In infants, normally transient projections distribute memory functions throughout several visual association areas. During normal maturation, visual memory becomes more localized to area TE as projections to other areas retract. In animals with TE lesions during infancy, these immature projections are maintained. Moreover, visual areas not normally involved in recognition memory take over that function after early TE lesions. These findings offer evidence for substantial remodeling of cognitive neural networks in response to early environmental manipulations. Additionally, the observation that a specific set of neural connections involved in memory processing normally regresses after infancy has potentially fascinating implications for understanding phenomena such as infantile amnesia.

Critical Periods for Cognition and Emotion The importance of critical periods does not apply solely to visual and language cortices. It has stunning implications for how early childhood experiences can leave brain traces that affect brain function and behavior throughout adult life. Just as visual cortex is shaped by experience, neural systems subserving cognition and affect may be equally impacted. For example, animals reared in complex environments have a greater width of the cortical mantle with increased dendritic arborizations, increased numbers of synapses per neuron, and longer postsynaptic densities compared to animals reared in standard cages. Early postnatal environmental manipulations result in long-lasting changes in hippocampal and prefrontal cortical glucocorticoid receptors, which may permanently alter an animal's stress response.

Early brain manipulations can also have delayed effects on the regulation of neurochemical systems implicated in adult-onset psychiatric illness. For example, scientists have recently shown that neonatal rat pups who undergo a hippocampal lesion during the first week of life appear relatively normal during their equivalent of childhood. However, during early adulthood they manifest dramatically abnormal behavioral responses to environmental and pharmacological stresses. Antipsychotic medications ameliorate some of these abnormal responses. The abnormalities appear to be modiated by rewiring of the connections involved in the regulation of mesolimbic dopaminergic function. Rats with this developmental lesion have been studied as a potential animal model of a number of phenomena associated with schizophrenia.

Behavioral studies in monkeys have shown that early childhood experience can have a profound impact on adult adaptation, especially in the context of social stress. When infant monkeys are removed from their mothers, even for relatively brief periods, their tolerance for stress during adulthood may be reduced. Moreover, the genetic tendency of an animal to be stress sensitive interacts with maternal separations. If a monkey is innately hyperresponsive to environmental stress, childhood maternal separation leads to exaggerated stress responses as an adult. Recently, the molecular consequences of early stress are being identified. In rats, variations in maternal behavior predict alterations in the expression of synaptic markers in the brain of adult animals. Thus, animal studies suggest that early environmental influences have a permanent impact on underlying cerebral structure and function.

In humans, there is evidence that early environmental stimulation, even before preschool, improves learning with an effect that lasts for years. Preliminary work suggests that children who have survived global environmental neglect may have underdevelopment of cerebral structures. Similarly, children exposed to chronic trauma have behavioral impulsivity, cognitive distortions, and difficulties with cognitive organization. These children also evidence an array of physiological abnormalities, including hyperarousal, an increased startle response, sleep difficulties, and affect-regulation problems. The plasticity of postnatal cerebral systems provides a neurobiological explanation for the major impact that childhood experiences have on adult functioning. It also offers a substantial opportunity for early childhood therapeutic interventions in vulnerable populations.

NEURONAL PLASTICITY

Synaptic plasticity is a property of adult as well as developing or young cortex, and reflects how synaptic strength changes with experience. Its relevance to psychiatry is seen in the course of the illnesses psychiatrists treat. Clinical research supports the notion that psychiatric illnesses progress and become more refractory to treatment over time. This has been demonstrated most clearly in bipolar disorders and schizophrenia. The expression or severity of an illness changing over time implies an underlying change in the neurobiology of the illness. Neuroscience studies of learning and memory have helped to illuminate the plasticity of adult cortex, which can be used as a blueprint for brain changes associated with psychiatric illnesses. What evidence is there for structural brain changes with learning?

Cortical Remodeling Human functional neuroimaging studies demonstrate changes in neural activity patterns as a behavior or a response is learned. In nonhuman primates, this can be investigated by recording the firing pattern of cortical neurons. When an adult monkey learns a task, its behavior reflects alterations of neuronal firing patterns distributed in the cortical regions involved in the task. An altered neuronal firing pattern can lead to cortical remodeling; for example, if an adult monkey attends to a tactile stimulus to its finger, the cortical representations from that digit increase.

How can neuronal firing patterns lead to a remodeled cortex? Short-term changes, or memory, result from the strengthening of existing synapses. This occurs via the covalent modification of existing proteins after the activation of second-messenger systems. Long-term memory requires neuronal gene expression and protein synthesis, resulting in the growth of new synaptic connections (Fig. 1.3-5).

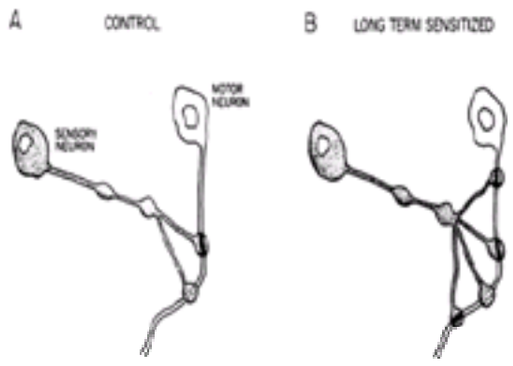

FIGURE 1.3-5 Neurons show plasticity associated with learning and experience. This drawing is of identified neurons from the sea slug *Aplysia*. The sensory neuron and motor neuron are responsible for a behavior that can be observed. The control panel **(A)** represents the synaptic connections in an untrained animal. After learning trials the number of synaptic connections increases, as demonstrated in **B**. (Reprinted with permission from Kandel ER: Genes, nerve cells, and the remembrance of things past. J Neuropsychiatry Clin Neurosci *1:*118, 1989.)

Long-Term Potentiation (LTP) Learning is being actively explored in mammals, using a model called long-term potentiation in which a prolonged excitatory stimulus delivered to presynaptic hippocampal neurons leads to a long-lasting increased response in postsynaptic neurons. Somehow, the postsynaptic neuron senses the coincidence between its own and presynaptic activity and sends a signal back to concurrently active presynaptic inputs to selectively increase their strength.

Neurotransmitters modulate the changes associated with learning and synaptic strengthening. Dopamine is a good candidate as a neuromodulator in the hippocampus, because late LTP can be blocked by dopamine type 1 receptor (D_1) antagonists. Acetylcholine and norepinephrine probably play major roles in facilitating cortical plasticity, and serotonin plays a role in invertebrate systems.

LTP involves several phases. Initially, presynaptic stimulation leads to a transient increase in postsynaptic calcium. The increase in intracellular calcium leads to a brief presynaptic increase in neurotransmitter release. However, calcium returns to resting levels within minutes; therefore long-lasting changes in synaptic strength involve additional processes in the presynaptic and postsynaptic neurons.

The signal that goes from the postsynaptic to the presynaptic neuron is still being explored, although it may involve nitric oxide. The signal activates second messengers presynaptically, which induce autonomous protein kinase activation. Protein kinases are enzymes that phosphorylate multiple substrates, altering their functioning, altering neuronal physiology, and increasing synaptic strength. When protein kinases become autonomously activated, they are independent of the second messenger. This explains how a short-lived increase in second messengers results in longer-lasting changes in synaptic strength.

Protein kinases involved in LTP include protein kinase C (PKC), calcium/calmodulin-dependent kinase II (CaMKII), the cyclic adenosine monophosphate (cAMP) dependent protein kinase (PKA), and protein tyrosine kinase (PTK). Substrates for phosphorylation implicated in long-term potentiation include GAP-43 for PKC, the glutamate receptor by CaMKII, and synaptophysin, the nicotinic acetylcholine receptor, and the glutamate receptor by PTKs. Phosphorylating GAP-43 may increase presynaptic neurotransmitter release; it also is associated with inducing a neuronal state of growth and synaptic sprouting.

Following activation of protein kinases, LTP depends on RNA transcription and protein synthesis and cAMP plays a central role in this process. cAMP concentrations increase in LTP due to calcium and calmodulin stimulation of adenylyl cyclase, the enzyme that produces cAMP. Additionally, D_1 and D_5 receptors are coupled to a G protein that increases cAMP concentration when activated.

cAMP concentration is crucial to LTP because of its effect on gene transcription. There is a cAMP response element (CRE), which when phosphorylated activates gene transcription. The mRNAs of several CRE-linked genes, including the immediate early gene c-*fos,* increase during long-term potentiation. The synaptic remodeling underlying learning depends on gene expression.

Learning and Gene Expression Immediate early genes (IEG) encode nuclear regulatory proteins that cause stable alterations in the transcription of late genes. Triggering IEG expression can lead to a cascade of gene transcription and synaptic remodeling. In addition to LTP IEGs are implicated in more behaviorally relevant learning paradigms. One-day-old chicks learn to avoid a bitter-tasting bead after a single training exposure. Training induces the IEGs c-*fos* and c-*jun* in certain brain regions. After c-*fos* and c-*jun* induction, there is enhanced synthesis of a variety of proteins, and increased fucosylation of membrane glycoproteins, including NCAM. Structurally, training results in a 60 percent increase in the density of dendritic spines, increases in synaptic number, and a 60 percent increase in the numbers of synaptic vesicles per synapse. The net result is synaptic remodeling, with active synapses showing increased numbers of boutons.

GAP-43 is another molecule important in adult cortical plasticity. In the neocortex of adult humans and nonhuman primates, GAP-43 remains present in limbic and associative areas, suggesting that these areas continue to undergo structural changes associated with learning and memory. Even when networks are formed, the precise connections within them remain responsive to environmental input. The guiding principle, both in final synaptic selections in development and in adult cortical plasticity is summed up in the adage “neurons that fire together wire together.”

Implications for Psychiatry Because psychiatric illnesses are thought to be associated with a pattern of neuronal activity, this activity may result in a type of learning that strengthens activity patterns representing the ill state. If the principle “neurons that fire together wire together” operates in psychiatric illnesses, this predicts that, if untreated, psychiatric illnesses would somehow become more entrenched neurobiologically and perhaps become more refractory to treatment. Alternatively, episodes of illness could become more frequent or more severe.

Progression of Illness In schizophrenia, the longer a person goes without seeking treatment, the more refractory the illness becomes, requiring more time on and higher doses of medication before symptoms remit. Similar observations are true of mood disorders. Most patients who have one episode of a mood disorder will have repeat episodes, and, especially in bipolar disorder, the intervals between episodes may become shorter. Although the initial episodes of mood disorders are often associated with stressors, later episodes can arise spontaneously. These observations support the hypothesis that the neurobiological underpinnings of these disorders are dynamic, changing with time and as a result of cortical remodeling.

Two experimental models have been used to explain the progression of bipolar disorder. One is kindling, in which electrical current in the amygdala induces seizures in rats. After a number of current-induced seizures, spontaneous epilepsy develops in the absence of stimulation. The second is stimulant-induced sensitization, where an animal shows greater behavioral changes to a consistent amount of stimulant after repeated exposures. In both these models, the environmental manipulations rapidly activate neurotransmitter pathways, and over the long term, also activate gene expression, including of *c-fos*. The abnormal neural activity induced by seizures results in axonal growth and synaptic reorganization in limbic structures, analogous to the changes seen in memory.

Treatment Implications The clinical implications of these models are critical. Neuroscience predicts that preventing subsequent episodes of a major psychiatric illness will positively alter the course of the disorder. This argues that pharmacological prophylaxis is essential. There is supporting evidence in this regard for schizophrenia, major depression, and bipolar disorder. However, there is ample room to speculate about parallel neurobiological processes in posttraumatic stress disorder, obsessive-compulsive disorder, panic disorder, and substance-related disorders.

Additionally, if abnormal cellular processes contribute to the etiology of major psychiatric disorders, how do pharmacological interventions normalize these processes? Are medications effective only because of their neurotransmitter receptor profiles? Or do they influence second-messenger systems, gene transcription, and protein translation, as in learning? The time course of pharmacological efficacy suggests that medications do not merely affect neurotransmitters, but also alter underlying cellular functioning. Dopamine, norepinephrine, acetylcholine, glutamate, and opiates have all been associated with changing gene expression.

Not surprisingly, antipsychotic medications induce the expression of c-*fos* and c-*jun*. In rats, the short-term administration of clinical doses of antipsychotic agents, such as haloperidol (Haldol), clozapine (Clozaril), and olanzapine (Zyprexa) induce c-*fos* in the nucleus accumbens. Antipsychotic agents that clinically cause extrapyramidal symptoms (e.g., haloperidol) also induce c-*fos* in the dorsal striatum. Clozapine, which clinically does not cause extrapyramidal adverse effects, does

not induce c-*fos* in this region. This suggests that extrapyramidal and antipsychotic effects can be dissociated in terms of their respective molecular neuroanatomies. Antidepressant treatments increase intracellular phosphorylation of cAMP-responsive proteins (e.g., CRE) that lead to transcription of specific genes. One of these genes, brain-derived neurotrophic factor, has also been implicated in neuronal plasticity and may play a role in the potential restitutive effects of treatment with antidepressant medications.

These recent observations on the intracellular effects of psychiatric medications have potentially far-reaching implications for the understanding of mental illness and approaches to their treatments. The traditional view that psychiatric medications can be characterized by their actions at synapses where they bind to cell surface proteins (e.g., receptors) is yielding to a more enlightened vision that the synapse is only the tip of the iceberg of cellular function and plasticity that is of relevance to psychiatry.

1.4 MONOAMINE NEUROTRANSMITTERS

LAURENCE H. TECOTT M.D., PH.D.

Historically the monoamine neurotransmitters and acetylcholine have been strongly implicated in the etiology and treatment of a wide variety of neuropsychiatric disorders. The monoamines serotonin, norepinephrine, dopamine, and histamine are widely distributed throughout the central nervous system (CNS). The activity of each monoamine neurotransmitter system modulates multiple neuronal pathways that mediate diverse behavioral and physiological processes. Conversely, each CNS function is regulated by multiple interactive neurotransmitter systems. In light of this complexity, determining the mechanisms through which monoamine systems impact the etiology and treatment of psychiatric disorders poses a major challenge. Advances in molecular neurobiology provide powerful new tools to aid in this endeavor. Molecular cloning studies have led to the identification and functional characterization of gene products that contribute to monoaminergic transmission, such as monoamine receptors, transporters, and synthetic and degradative enzymes. More recently, these genes have provided targets for powerful techniques that enable the precise introduction of mutations into the mouse genome. Thus, the functional consequences of perturbing gene function may be examined in the context of the intact, behaving organism. The molecular cloning of genes involved in monoaminergic transmission has also led to the identification of allelic variants of human genes, which raises the intriguing prospect that the inheritance of particular variants may contribute to disease susceptibility and to the efficacy of therapeutic agents.

ANATOMY OF MONOAMINE SYSTEMS

The anatomical organization of monoaminergic systems shares a number of common features. Monoaminergic systems are strikingly divergent: monoaminergic cell bodies are generally found in aggregates located in a few restricted subcortical brain regions. Individual monoaminergic neurons typically possess long and extensively branched axonal processes, innervating a large number of postsynaptic cells. This organization may permit monoaminergic systems to exert control in a coordinated manner over diverse brain regions. The actions of monoamines in particular brain areas are determined not only by the extent of monoamine innervation, but also by the receptor subtypes expressed in these regions. Monoaminergic receptors are diverse with regard to their regional and synaptic localization within the brain, and to the intracellular signaling systems to which they couple. This receptor diversity provides a means through which a single signaling molecule may produce effects that vary in different postsynaptic neurons.

Serotonin Although approximately one in a million brain neurons are serotonergic, serotonin systems influence CNS activity at all levels of the neuraxis. Serotonergic neurons are clustered in midline raphe nuclei of the midbrain, pons, and medulla. These neurons project extensively throughout the brain and descend to the spinal cord (Fig. 1.4-1). The majority of the serotonergic innervation of the forebrain arises from the dorsal and median raphe nuclei of the midbrain. Ascending projections from these nuclei course through the medial forebrain bundle before diverging to many target regions. Whereas the median raphe nucleus provides the majority of the serotonergic innervation of the limbic system, the dorsal raphe nucleus provides the primary innervation of the striatum and thalamus. In addition to the differences in target areas innervated by the median raphe and dorsal raphe, structural differences in the axonal projections from these nuclei have been observed. Whereas fibers from the dorsal raphe are fine, with small vesicle-containing swellings called *varicosities,* median raphe axons are beaded, with large spherical varicosities. These axons show differential sensitivity to the neurotoxic effects of the amphetamine analog 3,4-methylene-dioxymethamphetamine (MDMA, “ecstasy”). This agent produces a selective loss of fine axons while sparing the larger beaded projections derived from the median raphe. The significance of the morphological differences in these projection fibers remains to be determined. Both types of fibers are found in the neocortex, which receives a rich serotonergic innervation derived from both nuclei. The divergent nature of serotonergic projections is illustrated by this innervation; it has been estimated that each serotonergic neuron may influence 500,000 target neurons. Furthermore, each cortical neuron may be associated with over 200 serotonergic varicosities, which provides a means through which serotonin could affect widespread and coordinated modulation of cortical function. The caudal raphe serotonergic neurons project to the medulla, cerebellum, and spinal cord.

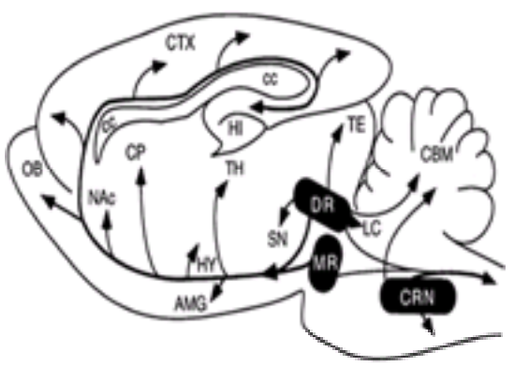

FIGURE 1.4-1 Brain serotonergic pathways (in rats). Serotonergic neurons are located in brainstem midline raphe nuclei and project throughout the neuraxis. (There is an approximate similarity between monoamine pathways in rats and in humans.) Abbreviations: AMG, amygdala; BFC, basal forebrain complex; CBM, cerebellum; cc, corpus callosum; CP, caudate putamen; CRN, caudal raphe nuclei; CTX, neocortex; DR, dorsal raphe nucleus; HI, hippocampus; HY, hypothalamus; LC, locus ceruleus; LTN, lateral tegmental noradrenergic nuclei; MPC, mesopontine complex; MR, median raphe nucleus; NAc, nucleus accumbens; OB, olfactory bulb; PFC, prefrontal cortex; PI, pituitary; SNC, substantial nigra pars compacta; TE, tectum; TH, thalamus; TM, tuberomammillary nucleus of hypothalamus; VTA, ventral tegmental area.

Dopamine Dopamine neurons are more widely distributed than those of other monoamines, residing in the midbrain substantia nigra and ventral tegmental area, and in the periaqueductal gray, hypothalamus, olfactory bulb, and retina. Of particular relevance are three dopamine containing systems: (1) the nigrostriatal, (2) mesocorticolimbic, and (3) tuberohypophyseal system (Fig. 1.4-2). The nigrostriatal dopamine system has been the most extensively studied of the dopaminergic pathways. Dopamine cell bodies located in the pars compacta division of the substantia nigra send ascending projections to the dorsal striatum, particularly the caudate and putamen. This projection modulates motor function, as highlighted by the motor disturbances of Parkinson's disease, a disorder characterized by degeneration of the nigrostriatal system. In addition, the extrapyramidal adverse effects of antipsychotic drugs are believed to result from the blockade of striatal dopamine receptors.

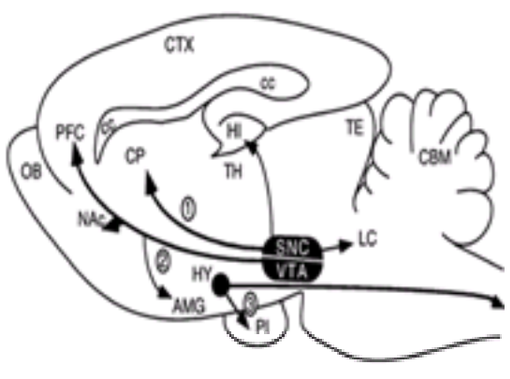

FIGURE 1.4-2 Brain dopaminergic pathways (in rats). The three principal dopaminergic pathways: (1) nigrostriatal pathway, (2) mesocorticolimbic pathway, and (3) tuberohypophyseal pathway.

The midbrain ventral tegmental area lies medial to the substantia nigra and contains dopaminergic neurons that give rise to the mesocorticolimbic dopamine system. These neurons send ascending projections that innervate limbic structures, such as the nucleus accumbens and amygdala, as well as associated cortical structures, particularly the prefrontal cortex. The mesoaccumbens projection is believed to regulate the rewarding properties of a wide variety of stimuli, including drugs of abuse. The mesocortical projection is believed to be a major target for the antipsychotic properties of dopamine receptor antagonist drugs. In this regard, the decreased predisposition of clozapine (Clozaril) to produce extrapyramidal adverse effects has been attributed to relatively selective actions on the mesocortical system. The tuberohypophyseal system consists of dopaminergic neurons in the hypothalamic arcuate and periventricular nuclei, and their projections to the pituitary gland. These projections provide inhibitory regulation of prolactin release. The administration of dopamine receptor antagonist antipsychotic drugs may lead to a disinhibition of release, resulting in galactorrhea.

Norepinephrine and Epinephrine Norepinephrine-producing neurons are found in the pons and medulla, in two major clusterings: the locus ceruleus and the lateral tegmental noradrenergic nuclei (Fig. 1.4-3). Noradrenergic projections from both these regions ramify extensively as they project throughout the neuraxis. In humans the locus ceruleus is found in the dorsal portion of the caudal pons, and contains approximately 12,000 tightly packed neurons on each side of the brain. These cells provide the major noradrenergic projections to the neocortex, hippocampus, thalamus, and midbrain tectum. The activity of locus ceruleus neurons varies with the sleep/wake cycle and is responsive to sensory stimuli, indicating a role for this structure in arousal state and vigilance. The projections from lateral tegmental noradrenergic nuclei neurons, which are loosely scattered throughout the ventral pons and medulla, partially overlap with those of the locus ceruleus. Fibers from both cell groups innervate the amygdala, septum, and spinal cord. Other regions, such as the hypothalamus and lower brainstem, receive adrenergic inputs predominantly from the lateral tegmental noradrenergic nuclei. The relatively few neurons that utilize epinephrine as a neurotransmitter are located in the caudal pons and medulla, intermingled with noradrenergic neurons. Projections from these groups ascend to innervate the hypothalamus, locus ceruleus, and visceral efferent and afferent nuclei of the midbrain.

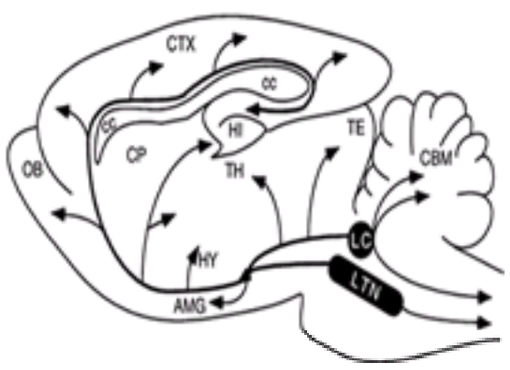

FIGURE 1.4-3 Brain noradrenergic pathways (in rats). Projections of noradrenergic neurons located in the locus ceruleus and lateral tegmental noradrenergic nuclei.

Histamine Central histaminergic neural pathways have only recently been characterized by immunocytochemistry using antibodies to the synthetic enzyme histidine decarboxylase and to histamine. Histaminergic cell bodies are located within the tuberomammillary nucleus of the posterior hypothalamus. As with other monoaminergic systems, histaminergic fibers project diffusely throughout the brain and spinal cord (Fig. 1.4-4). Ascending projections course with other monoaminergic fibers in the medial forebrain bundle, and descending projections travel through the midbrain central gray to the dorsal hindbrain and spinal cord. The fibers have varicosities that are seldom associated with classical synapses. The hypothalamus receives the densest histaminergic innervation, consistent with a role for this transmitter in the regulation of autonomic and neuroendocrine processes.

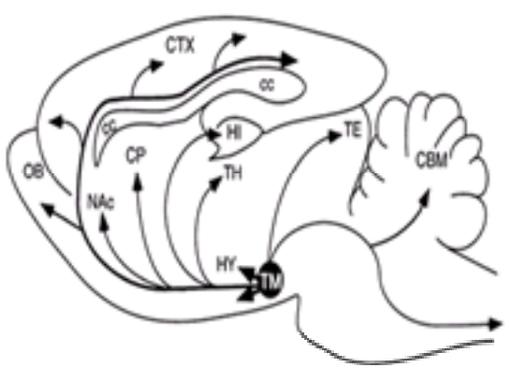

FIGURE 1.4-4 Brain histaminergic pathways (in rats). Histaminergic neurons are located in the tuberomammillary nucleus of the caudal hypothalamus and project to the hypothalamus and more distant brain regions.

Acetylcholine The axonal processes of cholinergic neurons may either project to distant brain regions (projection neurons) or contact local cells within the same structure (interneurons). Two large clusters of cholinergic projection neurons are found within the brain: the basal forebrain complex and the mesopontine complex (Fig. 1.4-5). The basal forebrain complex provides the vast majority of the cholinergic innervation to the nonstriatal telencephalon. It consists of cholinergic neurons within the medial septal nucleus, the nucleus of the diagonal band, the substantia innominata, the preoptic field, and the nucleus basalis of Meynert. In Alzheimer's disease the majority of nucleus basalis neurons are lost, leading to substantial impairments in the cortical cholinergic innervation. These impairments are believed to contribute to the symptoms of the disease and to correlate with the severity of dementia. The mesopontine complex consists of cholinergic neurons within the pedunculopontine and laterodorsal tegmental nuclei of the midbrain and pons. Regions innervated by these projections include the lateral hypothalamus, thalamus, tectum, substantia nigra, raphe nuclei, locus ceruleus, and cranial nerve nuclei. Acetylcholine is also found within interneurons of several brain regions, including the striatum. The modulation of striatal cholinergic transmission has been implicated in the antiparkinsonian actions of anticholinergic agents. Within the periphery, acetylcholine is a prominent neurotransmitter, located in preganglionic autonomic neurons, postganglionic parasympathetic neurons, and motoneurons innervating skeletal muscle.

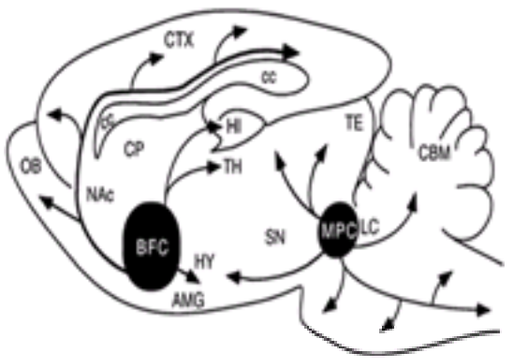

FIGURE 1.4-5 Brain cholinergic projection pathways (in rats). The majority of cholinergic projection neurons are located in the basal forebrain complex and the mesopontine complex.

MONOAMINE SYNTHESIS, STORAGE, AND DEGRADATION

In addition to similarities in neuronal organization, monoaminergic systems are similar with regard to their synthesis, storage, and degradation (Fig. 1.4-6). Monoamines are synthesized within neurons from common amino acid precursors (Fig. 1.4-6, Step 1) and taken up into synaptic vesicles via a vesicular monoamine transporter (Fig. 1.4-6, Step 2). Upon stimulation, vesicles within nerve terminals release neurotransmitter into the synaptic cleft (Fig. 1.4-6, Step 3). Once released, the monoamines interact with postsynaptic receptors to alter the excitability of postsynaptic cells (Fig. 1.4-6, Step 4). Monoamines may also interact with presynaptic autoreceptors located on the nerve terminal to suppress further release (Fig. 1.4-6, Step 5). In addition, released monoamines may be taken back up from the synaptic cleft into the nerve terminal by plasma membrane transporter proteins (Fig. 1.4-6, Step 6). Reuptake plays an important role in limiting the magnitude and duration of action of synaptically released monoamines. Once monoamines are taken up, they may be subject to enzymatic degradation (Fig. 1.4-6, Step 7) or they may be protected from degradation by uptake into vesicles. The processing of acetylcholine differs from this scheme, and is described below.

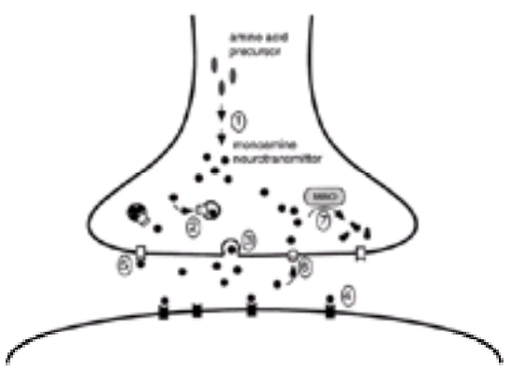

FIGURE 1.4-6 Schematic diagram of monoaminergic synapse. Steps involved in synaptic transmission are described in the text.

Serotonin The CNS contains less than 2 percent of the serotonin in the body; peripheral serotonin is located in platelets, mast cells, and enterochromaffin cells of the gastrointestinal system. Despite the abundance of peripheral serotonin, its inability to cross the blood-brain barrier necessitates the synthesis of serotonin within the brain. Serotonin is synthesized from the amino acid tryptophan, which is derived from the diet. The rate-limiting step in serotonin synthesis is the hydroxylation of tryptophan by the enzyme tryptophan hydroxylase to form 5-hydroxytryptophan (Fig. 1.4-7). Under normal circumstances this enzyme is not saturated by substrate, so tryptophan concentration can impact the rate of serotonin synthesis; therefore much attention has focused on the factors that determine tryptophan availability. Unlike serotonin, tryptophan is taken up into the brain via a saturable active carrier mechanism. Because tryptophan competes with other large neutral amino acids for transport, brain uptake of this amino acid is determined both by the amount of circulating tryptophan and by the ratio of tryptophan to other large neutral amino acids. This ratio may be elevated by carbohydrate intake, which induces insulin release and the uptake of many large neutral amino acids into peripheral tissues. Conversely, high-protein foods tend to be relatively low in tryptophan, thus lowering this ratio. The administration of specialized low-tryptophan diets has been found to produce significant declines in brain serotonin levels. Following tryptophan hydroxylation, 5-hydroxytryptophan is rapidly decarboxylated by aromatic amino acid decarboxylase to form serotonin.

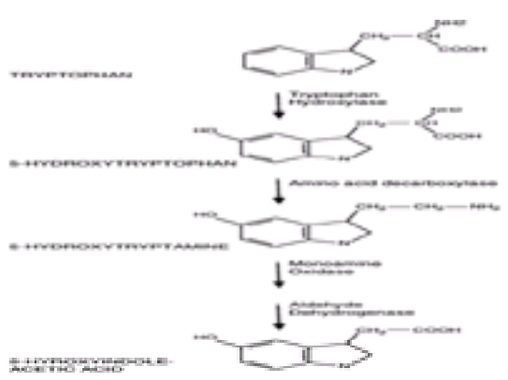

FIGURE 1.4-7 Synthesis and catabolism of serotonin.

The first step in the degradation of serotonin is mediated by monoamine oxidase (MAO) type A. A (MAO_A), which oxidizes the amino group to form an aldehyde. MAO_A is located in mitochondrial membranes and is nonspecific in its substrate specificity; in addition to serotonin, it oxidizes norepinephrine. The elevation of serotonin levels by MAO inhibitors (MAOIs) is believed to underlie the antidepressant efficacy of these drugs. Following oxidation by MAO_A, the resulting aldehyde is further oxidized to 5-hydroxyindoleacetic acid (5-HIAA).

Catecholamines The catecholamines are synthesized from the amino acid tyrosine, which is taken up into the brain via an active transport mechanism (Fig. 1.4-8). Within catecholaminergic neurons, tyrosine hydroxylase catalyzes the addition of a hydroxyl group to the meta position of tyrosine, yielding dopa. This rate-limiting step in catecholamine synthesis is subject to inhibition by high levels of catecholamines (end-product inhibition). Because tyrosine hydroxylase is normally saturated with substrate, manipulation of tyrosine levels does not readily impact the rate of catecholamine synthesis. Once formed, dopa is rapidly converted to dopamine by dopa decarboxylase, which is located in the cytoplasm. It is now recognized that this enzyme acts not only on dopa, but on all naturally occurring aromatic l-amino acids, including tryptophan. Thus, this enzyme is more accurately termed *aromatic amino acid decarboxylase*. In noradrenergic and adrenergic neurons, dopamine is oxidized in catecholaminergic vesicles by dopamine b-hydroxylase to form norepinephrine. This promiscuous enzyme will oxidize most phenylethylamines, producing metabolites that may replace norepinephrine at nerve terminals. These metabolites may act as false neurotransmitter, producing minimal postsynaptic effects. In adrenergic neurons, norepinephrine is converted to epinephrine by phenylethanolamine *N*-methyltransferase (PNMT), which is located within the cytoplasmic compartment.

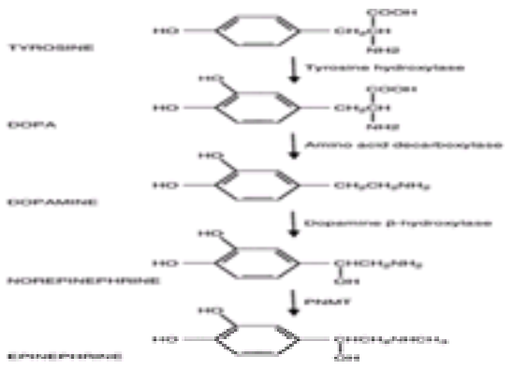

FIGURE 1.4-8 Synthesis of catecholamines.

Two enzymes that play major roles in the degradation of catecholamines are monoamine oxidase and catechol *O*-methyltransferase (COMT). Monoamine oxidase is located on the outer membrane of mitochondria and oxidatively deaminates catecholamines to their corresponding aldehydes. Two MAO isozymes with differing substrate specificities have been identified: MAO_A, which preferentially deaminates serotonin and norepinephrine, and MAO type B (MAO_B), which deaminates dopamine, histamine, and a broad spectrum of phenylethylamines. The blockade of monoamine catabolism by MAOIs produces elevations in brain monoamine levels. MAO is also found in peripheral tissues such as the gastrointestinal tract and liver, where it prevents the accumulation of toxic amines. MAO inhibitors may produce adverse effects by elevating the levels of these peripheral amines. For example, peripheral MAO degrades dietary tyramine, an amine that can displace norepinephrine from sympathetic postganglionic nerve endings, producing hypertension. Thus, patients treated with MAOIs are cautioned to avoid pickled and fermented foods that typically have high levels of this amine. COMT is widely distributed throughout the brain and peripheral tissues. It has a wide substrate specificity, catalyzing the transfer of methyl groups from *S*-adenosyl methionine to the *m*-hydroxyl group of most catechol compounds. The catecholamine metabolites produced by these and other degradative enzymes are frequently measured as indicators of the activity of catecholaminergic systems. In humans the predominant metabolites of dopamine and norepinephrine are homovanillic acid (HVA) and 3-methoxy-4-hydroxyphenylglycol (MHPG), respectively.

Histamine As is the case for serotonin, the brain contains only a small portion of the histamine found in the body. Histamine is distributed throughout most tissues of the body, predominantly in mast cells. Because it does not readily cross the blood-brain barrier, histamine is believed to be synthesized within the brain where it is formed by the decarboxylation of the amino acid histidine by a specific histidine decarboxylase. As this enzyme is not normally saturated with substrate, histamine synthesis is sensitive to histidine levels, which is consistent with the observation that the peripheral administration of histidine elevates brain histamine levels. Histamine is metabolized in the brain by histamine methyltransferase, producing methylhistamine; in turn, methylhistamine undergoes oxidative deamination by MAO_B.

Acetylcholine Acetylcholine is synthesized by the transfer of a methyl group from acetyl coenzyme A to choline in a reaction mediated by choline acetyltransferase (CAT). Choline availability is the rate-limiting factor in acetylcholine synthesis. The majority of choline within the brain is transported from the blood, and a high-affinity transport mechanism exists within cholinergic nerve terminals, where CAT is also found. The rate of choline transport is regulated such that increased cholinergic neural activity is associated with enhanced choline uptake. Following synthesis, acetylcholine is stored in synaptic vesicles through the action of a vesicular acetylcholine transporter. Following vesicular release into the synaptic cleft, acetylcholine is rapidly hydrolyzed to choline by acetylcholinesterase located in the synaptic cleft. Choline is then taken back into the presynaptic terminal via the choline transporter. One strategy in the treatment of dementia due to Alzheimer's disease is the augmentation of cholinergic transmission using cholinesterase inhibitors, such as tacrine (Cognex).

Plasma Membrane Transporters A great deal of progress has been made in the molecular characterization of the monoamine plasma membrane transporter proteins. These membrane proteins mediate the reuptake of synaptically released monoamines into the presynaptic terminal. The reuptake of monoamines across the presynaptic membrane into the nerve terminal is an energy-requiring process dependent upon the activity of a Na^+, K^+-activated adenosine triphosophatase (ATPase). Monoamine reuptake is an important mechanism for limiting the extent and duration of activation of monoaminergic receptors; also, transporters serve as molecular targets for a number of antidepressant drugs, psychostimulants, and monoaminergic neurotoxins. Whereas transporter molecules for serotonin, dopamine, and norepinephrine have been well characterized, transporters selective for histamine and epinephrine have not been demonstrated.

The molecular cloning of serotonin, dopamine, and norepinephrine transporter molecules has confirmed that all belong to a common gene family of transporter molecules that also includes those for g-aminobutyric acid (GABA), glycine, and choline. These proteins share strong sequence homologies and are believed to be integral membrane proteins that span the plasma membrane twelve times. In contrast to monoaminergic receptors, there is evidence for only a single type of transporter molecule for serotonin, dopamine, and norepinephrine. The expression of these proteins appears to be restricted to the corresponding class of monoaminergic neurons. For example, the messenger ribonucleic acid (mRNA) encoding the serotonin transporter molecule is restricted to serotonergic neurons, the one coding the dopamine transporter molecule is restricted to dopaminergic neurons, and the one coding the norepinephrine transporter molecule is restricted to noradrenergic neurons.

Monoaminergic transporters are molecular targets for psychotherapeutic drugs as well as substances of abuse. The therapeutic effects of tricyclic drugs, such as amitriptyline and imipramine, have been associated with their blockade of the serotonin transporter molecule and the norepinephrine transporter molecule although these drugs also interact directly with several monoaminergic receptor subtypes. More blockers of serotonin transporter molecules, such as the selective serotonin receptor inhibitors (SSRIs) (e.g., citalopram [Celexa], fluoxetine [Prozac], fluvoxamine [Luvox], paroxetine [Paxil], and sertraline [Zoloft]), are used in the treatment of depressive, anxiety, and a variety of other disorders. Conversely, compounds with relative selectivity for the norepinephrine transporter molecules, such as nortriptyline (Pamelor) and desipramine (Norpramin), also have antidepressant efficacy. Among drugs of abuse, cocaine binds with high affinity to all three known monoamine transporters, although the rewarding and stimulant properties of the drug have been attributed primarily to its blockade of the dopamine transporter molecule. This view has been recently supported by the absence of cocaine-induced locomotor stimulation in a strain of mutant mice engineered to lack this molecule. In fact, psychostimulants produce a paradoxical locomotor suppression in these animals that has been attributed to the serotonin molecule transporter-blocking properties of these compounds. Transporters may also provide routes that allow neurotoxins to enter and damage monoaminergic neurons; examples include the dopaminergic neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) and the serotonergic neurotoxin MDMA.

Vesicular Monoamine Transporter In addition to the reuptake of monoamines into the presynaptic nerve terminal, a second transport process serves to concentrate and store monoamines within synaptic vesicles. The transport and storage of monoamines in vesicles may serve several purposes: (1) to enable the regulated release of transmitter under appropriate physiological stimulation, (2) to protect monoamines from degradation by MAO, and (3) to protect neurons from the toxic effects of free radicals produced by the oxidation of cytoplasmic monoamines. In contrast with the plasma membrane transporters, a single type of vesicular monoamine transporter is believed to mediate the uptake of monoamines into synaptic vesicles within the brain. Consistent with this, blockade of this vesicular monoamine transporter by the antihypertensive drug reserpine (Serpasil) has been found to deplete brain levels of serotonin, norepinephrine, and dopamine. The molecular cloning of this transporter has revealed it to have 12 putative membrane-spanning domains; however, it does not display sequence homology to the plasma membrane transporters. Moreover, it utilizes a H^+ gradient rather than Na^+/Cl^- gradients. Vesicular transport requires a H^+ pumping ATPase, which establishes a concentration gradient of H^+ across the vesicle membrane. In the presence of this gradient, the vesicular monoamine transmitter takes up neurotransmitter in a manner that is coupled to the release of luminal protons; the activity of the transporter is altered by amphetamine-like agents. These compounds are taken up via plasma membrane transporters into monoaminergic terminals, where they act as weak bases to disrupt pH gradients. This produces a reversal of vesicular monoamine transmitter activity, leading to monoamine release from vesicles and reversal of plasma membrane transporter activity. The resulting release of monoamines from presynaptic terminals contributes to the stimulant properties of these compounds. The anorectic agent fenfluramine is believed to stimulate serotonin release in an analogous manner. Recently a separate vesicular transporter for acetylcholine has been molecularly cloned; its structure is homologous to that of the vesicular monoamine transmitter, and both are believed to have a common bioenergetic mechanism.

RECEPTORS

Ultimately the effects of monoamines on CNS function and behavior depend upon their interactions with receptor molecules. The binding of monoamines to these plasma membrane proteins initiates a series of intracellular events that modulate neuronal excitability. Unlike the transporters, multiple receptor subtypes exist for each monoamine transmitter (Table 1.4-1). The initial classification of many receptor subtypes was based on radioligand binding studies. Receptor binding sites were identified on the basis of the rank order of binding affinities for a number of agonist and antagonist compounds. More recently, the molecular cloning of monoamine

receptors has confirmed that many of the sites initially defined by these binding studies did indeed correspond to distinct receptor proteins encoded by unique genes. Molecular cloning has also led to the identification of previously unknown receptors, and to the introduction of powerful tools to characterize receptor structure and function.

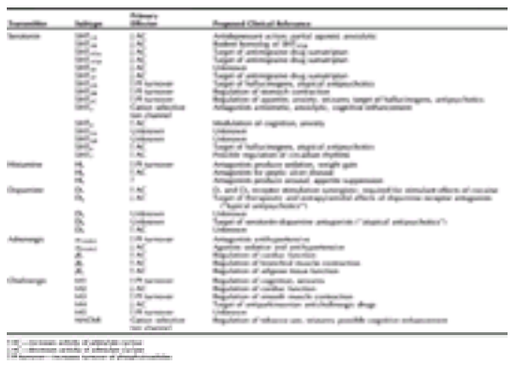

Table 1.4-1 Monoamine Receptors: Overview

Neurotransmitter receptors produce intracellular effects by one of two basic mechanisms: (1) via interactions with G proteins that couple receptors to intracellular effector systems, and (2) by providing channels through which ions flow when transmitters bind (ligand-gated ion channels). With the exception of the serotonin type 3 (5-HT_3) receptor subtype (a ligand-gated ion channel), all known monoaminergic receptors belong to the superfamily of G-protein–coupled receptors. However, within each monoaminergic receptor family, the subtypes are heterogeneous with regard to the G proteins with which they interact, and to the second-messenger effects that they produce. Monoaminergic receptors are also diverse in their regional patterns of expression within the brain, their neurotransmitter binding affinities, and in their synaptic localization. Whereas many receptor subtypes are located exclusively in postsynaptic membranes, others are located presynaptically in axon terminal membranes. Some receptors on the presynaptic terminal respond to monoamines that are released by that neuron and these presynaptic autoreceptors often act to inhibit neurotransmitter release. Several monoaminergic receptor subtypes are located presynaptically in some brain regions and postsynaptically in others.

In the wake of the recent proliferation of known receptors subtypes, much work needs to be done to determine the functional roles of individual receptors. In many instances this effort is hampered by the paucity of selective agonist and antagonist drugs. Recently, a molecular genetic approach to examining receptor function has been applied to complement pharmacological studies. Gene targeting procedures have enabled the generation of mouse strains with disruptions in genes that encode individual receptor subtypes; the resulting mutant mice have a complete and specific absence of the targeted receptor. Studies in these animals are providing clues to receptor function and to the contributions of the targeted receptors to the actions of nonspecific drugs. Molecular and pharmacological approaches will guide the generation of subtype-selective compounds and facilitate the development of therapeutic agents that will alter monoaminergic transmission in a more refined manner.

Serotonin Receptors Brain serotonin receptors were initially characterized on the basis of radioligand binding studies into two classes: serotonin type 1 (5-HT_1) receptors, to which [$_3$H]5-HT bound with high affinity, and 5-HT_2 which were labeled with high affinity by [^{3}H]spiperone. Subsequent binding studies revealed that each of these classes consisted of multiple subtypes. The application of molecular cloning techniques has produced a proliferation in the number of known subtypes. The great diversity of serotonin receptors provides a means whereby a single neurotransmitter may produce a wide variety of cellular effects in multiple neuronal systems. At present, at least 14 distinct serotonin receptor subtypes have been identified and molecularly cloned, which has led to rapid advances in determining the structure, pharmacology, brain distribution, and effector mechanisms of these receptors and to a more precise classification of serotonin receptor subfamilies on the basis of their structural homologies and primary effector mechanisms.

The 5-HT_1 receptors comprise the largest serotonin receptor subfamily, with human subtypes designated: 5-HT_{1A}, 5-HT_{1Da}, 5HT_{1Db}, 5-HT_{1E}, and 5-HT_{1F}. All five 5-HT_1 receptor subtypes display intronless gene structures and high affinities for serotonin and adenylate cyclase inhibition. The most intensively studied of these has been the 5-HT_{1A} receptor, a subtype that is found on postsynaptic membranes and serotonergic neurons, where it functions as a somatodendritic autoreceptor. The stimulation of these autoreceptors suppresses the activity of serotonergic neurons. The desensitization of 5-HT_{1A} autoreceptors by the chronic administration of SSRIs has been implicated in their antidepressant effects. An additional role for this receptor subtype in the regulation of anxiety is suggested by the anxiolytic properties of partial 5-HT_{1A} receptor agonists such as buspirone (Buspar) and by the enhancement of anxiety-related behaviors in a strain of mutant mice lacking 5-HT_{1A} receptors. The 5-HT_{1Da} and 5-HT_{1Db} receptors resemble each other in structure and brain localization. 5-HT_{1D} receptors are found on axon terminals of serotonergic and nonserotonergic neurons, where they act to reduce neurotransmitter release. The study of these receptors has been hindered by a lack of selective pharmacological tools. This is also true for the 5-HT_{1E} and 5-HT_{1F} receptor subtypes. The highest levels of 5-HT_{1E} receptor expression are found in the striatum and entorhinal cortex whereas 5-HT_{1F} receptor expression is highest in the dorsal raphe nucleus, hippocampus, cortex, and striatum. In addition, 5-HT_{1D} and 5-HT_{1F} receptors are expressed in cerebral vessels, and are stimulated by the antimigraine drug sumatriptan (Imitrex). The relative importance of these receptors in the therapeutic efficacy of this drug remains to be determined.

At least three receptor subtypes mediate the effects previously attributed to a single 5HT_2 receptor subtype. The classic 5-HT_2 receptor has thus been renamed 5-HT_{2A} to indicate that it is a member of a serotonin receptor subfamily. A second receptor initially termed 5-HT_{1C} has been renamed 5-HT_{2C} to indicate that it belongs within this subfamily. The third known 5HT_2 receptor, termed 5-HT_{2B}, contributes to the contractile effects of serotonin in the stomach fundus. All three subtypes exhibit high sequence homology, similar pharmacological binding profiles, and stimulation of phosphoinositide turnover. High levels of 5-HT_{2A} receptors are found in the neocortex and in peripheral locations such as platelets and smooth muscle. Much recent attention has focused on the contributions of 5-HT_{2A} and 5-HT_{2C} receptors to the actions of serotonin-dopamine antagonists, such as clozapine (Clozaril), risperidone (Risperdal), and olanzapine (Zyprexa). Analysis of the receptor-binding properties of these drugs has led to the hypothesis that 5-HT_{2A} receptor blockade correlates with the therapeutic effectiveness of these antipsychotic agents. The relative importance of related serotonin receptors to the efficacy of these agents remains to be determined. The 5-HT_{2C} receptor is expressed at high levels in many CNS regions including the hippocampal formation, prefrontal cortex, amygdala, striatum, hypothalamus, and choroid plexus. Stimulation of 5-HT_{2C} receptors has been proposed to produce anxiogenic and anorectic effects. Accordingly, a transgenic mouse strain lacking this receptor subtype exhibits an obesity syndrome associated with overeating; these animals also display an enhanced susceptibility to seizures, implicating this receptor in the regulation of neuronal network excitability. A variety of antidepressant and antipsychotic drugs antagonize 5-HT_{2C} receptors with high affinity. Conversely, hallucinogens such as lysergic acid diethylamide (LSD) display agonist activity at 5-HT_2 serotonin receptor subtypes, among others.

The 5-HT_3 receptor is unique among monoaminergic receptors in its membership within the ligand-gated ion channel superfamily. Rather than activating G proteins, the binding of serotonin to this receptor permits passage of Na^+ and K^+ ions through an ion channel located within the 5-HT_3 receptor complex. This produces rapid excitatory effects in postsynaptic neurons. The receptor is expressed within the hippocampus, neocortex, amygdala, hypothalamus, and brainstem motor nuclei. Outside the brain, it is found in the pituitary gland, enteric nervous system sympathetic ganglia, and in sensory ganglia. 5-HT_3 receptor antagonists such as ondansetron (Zofran) have been used as antiemetic agents and are under evaluation as potential antianxiety and cognitive-enhancing agents.

Investigations into the functions of recently identified 5-HT_4; 5-HT_5, including subtypes 5-HT_{5A} and 5-HT_{5B}; 5-HT_6 and 5-HT_7 receptors are hindered by a lack of selective agonist and antagonists. Studies of the cloned receptors reveal that all but the 5-HT_5 receptor are linked to the stimulation of adenylate cyclase. The primary effector mechanisms of the 5-HT_5 receptors remain to be determined. The 5-HT_4 receptors are expressed in the hippocampus, striatum, substantia nigra, and superior colliculus, and have been implicated in the serotonergic regulation of cognition and anxiety. The two 5-HT_5 receptor subtypes are highly homologous, and are expressed in the neocortex, hippocampus, raphe nuclei, and cerebellum. 5-HT_6 receptors may contribute to the actions of the several antidepressant, antipsychotic, and hallucinogenic drugs that bind with high affinity. These receptors are expressed in the neocortex, hippocampus, striatum, and amygdala; highest concentrations of 5-HT_7 receptor expression are found in the hypothalamus and thalamus. These receptors have been proposed to contribute to the serotonergic modulation of circadian rhythms. Although it is premature to assign functional roles to these new receptor subtypes with confidence, it is likely that these receptors will ultimately provide targets for the development of useful therapeutic compounds.

Dopamine Receptors In 1979 it was clearly recognized that the actions of dopamine are mediated by more than one receptor subtype. Two dopamine receptors, termed type 1 (D_1) and type 2 (D_2) were distinguished on the basis of differential binding affinities of a series of agonists and antagonists, distinct effector mechanisms, and distinct distribution patterns within the CNS. It was subsequently found that the therapeutic efficacy of antipsychotic drugs correlated strongly with their affinities for the D_2 receptor, implicating this subtype as an important site for the action of antipsychotic drugs. Until recently, these were the only two identified dopamine receptors; however, molecular cloning studies have revealed additional receptor heterogeneity. Three additional dopamine receptor genes have been identified, encoding the D_3, D_4, and D_5 dopamine receptors. Based on their regional brain distributions and primary effector mechanisms, the D_3 and D_4 receptors are considered to be D_2-like, and the D_5 receptor is considered to be D_1-like. The functional roles of these subtypes remain to be determined, although several intriguing possibilities are under investigation.

The D_1 receptor was initially distinguished from the D_2 subtype by its high affinity for the antagonist SCH 23390 and its relatively low affinity for butyrophenones such as haloperidol (Haldol). Whereas D_1 receptor activation stimulates cAMP formation, D_2 receptor stimulation produces the opposite effect on cAMP formation. In addition to the stimulation of adenylate cyclase, D_1 receptors may also stimulate phosphoinositide turnover. D_1 receptor mRNA is expressed in the terminal fields of the nigrostriatal and mesocorticolimbic pathways, with high levels in the dorsal striatum, nucleus accumbens, and amygdala. In contrast, little D_1 mRNA expression is found in dopamine cell body regions such as the substantia nigra pars compacta and the ventral tegmental area. This finding, and the persistence of D_1 receptor binding following lesions of dopaminergic neurons, suggests that this receptor subtype is not found on dopaminergic neurons and is therefore not an autoreceptor. Electrophysiological studies have indicated that D_1 receptor activation is required for striatal D_2 receptor activation to produce its maximal effect. The proposed synergistic effects of striatal D_1 and D_2 receptor activation have recently received support from studies in a mouse strain with a targeted elimination of D_1 receptors. The effects of both D_1 and D_2 receptor activation were attenuated in these animals; moreover, these mice were resistant to the hyperlocomotor effects of cocaine, indicating that D_1 receptors contribute significantly to the effects of cocaine on the CNS.

The D_5 receptor was molecularly cloned on the basis of its sequence homology with the D_1 receptor. The two receptors have a higher degree of homology with each other than with the D_2 and D_4 subtypes. This structural similarity is reflected in the similar affinities of a wide variety of dopaminergic drugs for these two receptors. The main distinguishing feature of their binding profiles is that the binding affinity of dopamine is higher for D_5 than for D_1 receptors. Not surprisingly, these two receptors are also similar in that they both stimulate adenylate cyclase activity. However, these receptors differ in their regional distributions within the CNS: the expression of D_5 receptors appears to be highly restricted to limbic system structures such as the hippocampus and hypothalamus. The lack of selective drugs hinders attempts to distinguish the functional roles of D_1 and D_5 receptors.

The dopamine D_2 receptor was initially distinguished from the D_1 receptor on the basis of its high affinity for butyrophenones. Moreover, D_2 receptor stimulation was observed to inhibit rather than to stimulate adenylate cyclase activity. Subsequently, the D_2 receptor subtype was found to display interactions with a variety of G proteins, leading to diverse second-messenger effects such as modulation of Ca^{++} and K^+ channel function and the alteration of phosphoinositide production. The intracellular consequences of D_2 receptor activation appear to depend upon the cell type in which the receptor is expressed. In addition to D_2 receptor mRNA expression in brain regions that receive dopaminergic innervation, D_2 transcripts are found in dopaminergic neurons of the ventral tegmental area and substantia nigra. The D_2 receptor may have either a postsynaptic function or an autoreceptor function. D_2 autoreceptors may be found on dopaminergic terminals or on the cell bodies and dendrites of dopaminergic neurons. D_2 receptors are also expressed in the anterior pituitary and mediate the dopaminergic inhibition of prolactin and melanocyte-stimulating hormone release. Molecular cloning has revealed a long and short form of the D_2 receptor that differ in length by 29 amino acids, products of alternative splicing of a single gene; differences in the functional roles of the long and short forms remain to be determined.

A great deal of attention has focused on the clinical correlates of D_2 receptor function. It has been proposed that the brains of untreated schizophrenia patients have elevations in D_2 receptor density. Furthermore, radioligand binding studies have revealed a correlation between the clinical efficacy of antipsychotic drugs and their antagonist affinities for this receptor subtype. This finding has contributed significantly to the “dopamine hypothesis” of schizophrenia. The extrapyramidal adverse effects of antipsychotic drugs, such as dystonia and parkinson-like symptoms, have been attributed to the blockade of striatal D_2 receptors. A significant contribution of D_2 receptors to the dopaminergic regulation of motor function is further highlighted by a parkinson-like movement disorder observed in a mutant mouse strain that lacks this receptor subtype.

The D_3 and D_4 receptors are considered to be D_2-like on the basis of similarities in their gene structures, sequence homologies, and pharmacology. These receptors are expressed in lower abundance than the D_2 receptor and their regional distributions are distinct. Whereas D_3 receptor expression is high in the nucleus accumbens, highest levels of D_4 receptors are expressed in the frontal cortex, midbrain, amygdala, and medulla. Whereas little D_3 receptor expression has been detected outside the nervous system, D_4 receptors are more abundant in the heart than in the brain. The primary effector mechanisms associated with the stimulation of brain D_3 and D_4 receptors remain to be determined. Particular attention has been paid to a potential role of D_4 receptors in schizophrenia. On postmortem, elevated D_4 receptor levels have been found in the brains of patients with schizophrenia. Moreover, the atypical antipsychotic drug clozapine (Clozaril) has a high affinity for the D_4 receptor; this receptor is highly polymorphic in humans and at least 25 distinct alleles have been identified. Studies are therefore under way to determine whether particular D_4 alleles are associated with psychotic disorders or with responsiveness to antipsychotic drugs.

Adrenergic Receptors Adrenergic receptor heterogeneity was first discovered in the 1940s, when a and b subtypes were identified in pharmacological studies of isolated peripheral tissues. Subsequently, radioligand binding and molecular cloning studies have identified three main adrenergic receptor subfamilies; a_1, a_2, and b. Each subfamily consists of at least three distinct receptor subtypes. Receptors within each subfamily share similar sequence homologies, pharmacological binding profiles, and effector mechanisms. The activation of a_1 receptors (subtypes designated a_{1A}, a_{1B}, and a_{1C}) stimulates phosphoinositide turnover. These receptors are believed to play a significant role in regulating smooth muscle contraction and have been implicated in the control of blood pressure, nasal congestion, and prostate function. Although all three subtypes are expressed in the brain, their contributions to the central actions of norepinephrine remain to be determined.

The a_2 receptors (designated including subtypes a_{2A}, a_{2B}, and a_{2C}) have been implicated in the regulation of cardiovascular function, autonomic nervous system activity, and arousal. The functions of a_2 receptor subtypes have been difficult to determine because of a lack of selective agonists and antagonists; a_2 receptors display both presynaptic autoreceptor and postsynaptic actions, and all appear to inhibit cAMP formation. The stimulation of a_2 autoreceptors inhibits firing of the noradrenergic neurons of the locus ceruleus, which have been implicated in arousal states. This mechanism has been proposed to underlie the sedative effects of the a_2 receptor agonist clonidine (Catapres). In addition, the stimulation of brainstem a_2 receptors has been proposed to reduce sympathetic nervous system activity and to augment parasympathetic nervous system activity, which may relate to the utility of clonidine in lowering blood pressure and in suppressing the sympathetic hyperactivity associated with opiate withdrawal. The a_2 receptor antagonist yohimbine (Yocon) is used in the treatment of erectile disorder (impotence); the neural mechanisms that underlie this effect remain to be determined.

Like the a-adrenergic receptors described, b-adrenergic receptors (designated including subtypes b_1, b_2, and b_3) are found both in the brain and in many peripheral tissues. The functional roles of the peripheral b-adrenergic receptors are better understood than are its central functions. Cardiac b_1 receptors play a major role in the regulation of heart function, and b_2 receptors regulate bronchial muscle contraction. b_3 receptors are found in adipose tissue, where they stimulate fat catabolism. Although b_1 and b_2 receptors are widely distributed in the CNS, their contributions to catecholamine function are not well understood. Propranolol (Inderal) is a widely used nonspecific antagonist of both b_1 and b_2 receptors. In addition to its utility for the treatment of hypertension and arrhythmias, its effectiveness in blunting autonomic symptoms underlies its utility in the management of social phobia; also, through mechanisms that are currently unknown, it is also effective in the treatment of akathisia.

Histamine Receptors Histaminergic systems have been proposed to modulate arousal, wakefulness, feeding behavior, and neuroendocrine responsiveness. Three histaminergic receptor subtypes have been identified. Histamine type 1 (H_1) receptors are expressed throughout the body, particularly in smooth muscle of the gastrointestinal tract and blood vessel walls. H_1 receptors are widely distributed throughout the CNS, with particularly high levels in the forebrain and cerebellum. H_1 receptor activation stimulates phosphoinositide turnover, and tends to increase excitatory neuronal responses. These receptors are the targets of antihistaminergic agents used in the treatment of allergic rhinitis and conjunctivitis. The well-known sedative effects of these compounds have been attributed to their actions in the CNS. In addition, the sedation and weight gain produced by a number of antipsychotic and antidepressant drugs have been attributed to H_1 receptor antagonism;

conversely, H_1 receptor agonists stimulate arousal and suppress food intake in animal models.

H_2 receptors are also widely distributed throughout the body, and are found in gastric mucosa, smooth muscle, cardiac muscle, and cells of the immune system. Within the CNS, H_2 receptors are abundantly expressed in the neocortex, hippocampus, amygdala, and striatum. Activation of these receptors stimulates adenylate cyclase and produces excitatory effects in neurons of the hippocampal formation and thalamus. H_2 receptor antagonists are widely used in the treatment of peptic ulcer disease. The functional significance of central H_2 receptors is unclear, although several studies indicate that stimulation of these receptors produces antinociceptive effects.

Unlike H_1 and H_2 histamine receptors, H_3 receptors are located presynaptically on axon terminals. Those located on histaminergic terminals act as autoreceptors to inhibit histamine release. H_3 receptors are also located on nonhistaminergic nerve terminals, where they inhibit the release of a variety of neurotransmitters. Particularly high levels of H_3 receptor binding are found in the frontal cortex, striatum, amygdaloid complex, and substantia nigra. Lower levels are found in peripheral tissues such as the gastrointestinal tract, pancreas, and lung. Antagonists of H_3 receptors have been proposed to have appetite suppressant, arousing, and cognitive-enhancing properties.

Cholinergic Receptors Two major classes of cholinergic receptors exist: G protein–coupled muscarinic receptors and nicotinic ligand-gated ion channels. Muscarinic receptors have been implicated in learning and memory, sleep regulation, pain perception, and the regulation of seizure susceptibility. The five known subtypes of muscarinic receptors are heterogeneous with regard to regional brain distribution and primary effector mechanisms. The muscarinic type 1 (M_1), M_3, and M_5 receptors stimulate phosphatidylinositol (PI) turnover, and the M_2 and M_4 receptors inhibit adenylate cyclase. The functional roles of the individual subtypes within the CNS are not well understood because highly subtype-selective agonists and antagonists have been unavailable. Based on brain distribution and the actions of nonspecific drugs, M_1 receptors have been implicated in learning and memory processes. Striatal M_4 receptors have been implicated as putative targets for anticholinergics used as antiparkinson agents. Recently, a line of mice lacking functional M_1 receptors has been generated and found to be resistant to the convulsant effects of muscarinic agonists. In the periphery, M_2 receptors regulate heart rate and contractility and M_3 receptors mediate smooth muscle contraction and glandular secretion.

Nicotinic acetylcholine receptors, like 5-HT_3 receptors, are members of the ligand-gated ion channel superfamily. They are composed of a pentameric complex of membrane protein subunits radially arranged around a central ion pore. The binding of acetylcholine to this receptor permits passage of Na^+ and K^+ ions through the ion channel, depolarizing the postsynaptic cell. Nicotinic acetylcholine subunits are heterogeneous and associate in varied combinations. Thus, the properties of an individual complex will depend upon its particular subunit composition. The relative frequencies of various subunit combinations in discrete brain regions and their functional significance remain to be fully clarified.

Within the human brain, nicotinic acetylcholine receptors are found at highest densities within the hippocampal formation, neocortex, substantia nigra, ventral tegmental area, dorsal raphe nucleus, periaqueductal gray, and the basal forebrain cholinergic complex. Consistent with this distribution, these receptors have been implicated in cognitive function. Cortical acetylcholine receptors are diminished in Alzheimer's disease, and nicotine administration improves attention defects in some patients. In some schizophrenia patients nicotine administration improves measures of sensory gating. This and other data have led to the proposal that the high incidence of cigarette smoking in this population represents a form of self-medication. Recently, some rare familial epilepsy syndromes have been associated with mutations of nicotinic acetylcholine receptors. Finally, the reinforcing properties of tobacco use are proposed to involve the stimulation of nicotinic acetylcholine receptors located in mesolimbic reward pathways.

SUGGESTED CROSS-REFERENCES

The intracellular consequences of receptor activation are discussed in Section 1.8. The electrophysiological effects of brain monoamines are described in Section 1.9. The basic concepts of molecular biology that are relevant to current monoamine research are presented in Section 1.18. Alzheimer's disease and seizure disorders are covered in Chapter 10. Section 31.5 presents b-adrenergic receptor antagonists, Section 31.6 presents anticholinergics, Section 31.7 presents antihistamines, Section 31.15 presents cholinesterase inhibitors, Section 31.17 presents dopamine receptor antagonists, 31.26 presents serotonin-dopamine antagonists, and Section 31.25 presents selective serotonin reuptake inhibitors.

1.5 AMINO ACID NEUROTRANSMITTERS

RICHARD P. SHANK, PH.D., VIRGINIA L. SMITH-SWINTOSKY, PH.D. AND ROY E. TWYMAN, M.D.

Throughout the first half of the twentieth century there was a prevailing view that neurons within the vertebrate central nervous system (CNS) are electrically coupled at their synapses and that synaptic transmission therefore could only be mediated electrically. About 1950 John Eccles and his colleagues realized that this could not be not true, and they were forced to conclude that synaptic transmission must be primarily a chemically mediated process. This realization stimulated research to identify the chemical messengers (neurotransmitters or transmitters). Electrophysiological experiments revealed that several amino acids either increased or decreased the excitability of neurons when applied to the extracellular surface. The amino acids that increased neuronal excitability include glutamate, aspartate, cysteate, and homocysteate, which are all similar structurally. Those that decreased neuronal excitability include g-aminobutyric acid (GABA), glycine, b-alanine and taurine, which also exhibit structural similarity.

After the neuronal effects of these amino acids were reported, a debate arose as to whether these amino acids were really neurotransmitters or served some other undefined function in regulating or modulating the excitability of neurons. This debate is still not fully resolved, in part because there is not yet a precise understanding of all the chemical events that regulate neuronal excitability and their physiological significance. Nevertheless, rigorous criteria have been developed that can be used to determine whether an amino acid is actually a neurotransmitter. Currently, three amino acids (glutamate, GABA, and glycine) meet the criteria sufficiently to allow a consensus conclusion that they are true neurotransmitters. Furthermore, there is now little doubt that glutamate is the major excitatory neurotransmitter and that GABA and glycine are the major inhibitory neurotransmitters in the brain and spinal cord, respectively. Two more, aspartate and taurine, are likely to serve a significant, but as yet undefined, role in modulating the excitability of neurons. A role for cysteate, homocysteate, and b-alanine is less certain.

NEUROPHYSIOLOGICAL SIGNIFICANCE OF EXCITATORY AMINO ACIDS

Nontransmitter Functions of Glutamate and Aspartate Glutamate and aspartate serve several functions in neural tissues unrelated to their role as neurotransmitters. Both are major constituents in proteins and several peptides, including *N*-acetylaspartylglutamate, a putative transmitter or cotransmitter. Aspartate is a precursor of *N*-acetylaspartate, a primary organic anion in the CNS. Glutamate and aspartate also have a role in energy metabolism; they are intermediates in the malate-aspartate shuttle, a metabolic pathway that reoxidizes cytosolic nicotine adenine dinucleotide (NADH) formed by aerobic glycolysis and captures the energy within mitochondria for adenosine triphosphate (ATP) formation (Fig. 1.5-1). Because glucose is rapidly consumed via aerobic metabolism in neural tissues, this pathway is quite active.

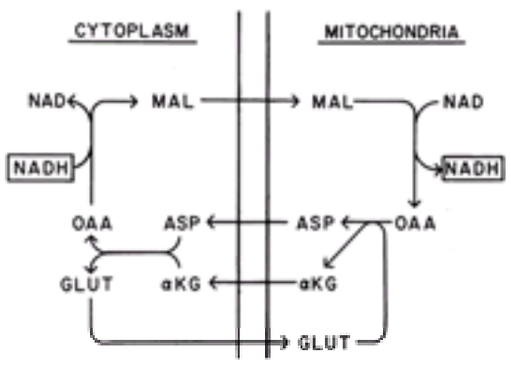

FIGURE 1.5-1 The metabolic components of the malate-aspartate shuttle. Although it is not evident from the diagram, the flux of aspartate (ASP) across the mitochondrial membrane is coupled to the flux of glutamate (GLUT) in the reverse direction. The fluxes of malate (MAL) and a-ketoglutarate (a-KG) may be similarly coupled. OAA, oxaloacetate.

Glutamate is also the immediate metabolic precursor of nearly all GABA synthesized in neural tissues, which presumably occurs only in neurons that use GABA as a neurotransmitter (i.e., GABAergic neurons). Glutamate also can serve as an intermediate in the detoxification of ammonia.

Glutamate as a Neurotransmitter Glutamate is the principal excitatory neurotransmitter in the mammalian central nervous system (CNS). Most neurons that use glutamate as a neurotransmitter (termed either *glutamatergic* or *glutaminergic*) are projection neurons—exemplified by the pyramidal neurons that arise in the cerebral cortex and project to various subcortical regions or other cortical areas—somatic primary afferent sensory neurons, and ganglion neurons that arise in the retina and project to the lateral geniculate (Table 1.5-1). Glutamatergic interneurons include cerebellar granule cells, bipolar cells in the retina, and granule cells in the hippocampus. Glutamatergic neurons are particularly prevalent in the hippocampus, where they appear to have a significant role in memory formation.

Anatomical Pathway	Type of Neuron	Behavioral Role
Corticoamygdala	Pyramidal	Emotion
Corticocortical	Pyramidal	Association, perception
Corticonucleus tractus solitarius	Pyramidal	Regulation of breathing, heart rate, taste, olfaction
Corticospinal	Betz	Movement, pain sensation
Corticostriate	Pyramidal	Motor
Corticothalamic	Pyramidal	Relay, integration
Primary sensory afferents	Aδ, C fibers	Sensory input
Intercerebellar	Granule cells	Motor
Entorhinal-hippocampal	Perforant path	Learning, memory, emotion
Intrahippocampal	CA3 pyramidal cells	Learning, memory (Schaffer collaterals)
Dentate-hippocampal	Granule cells (mossy fibers)	Learning, memory, association
Hippocampal-tuberculoseptal-mammillary	CA1 pyramidal	Learning, memory, emotion
Interstitia	Photoreceptors, bipolar	Primary visual input
Retinotectal	Ganglion cells	Vision—sensory
Visual geniculocortico	Optic radiation	Vision—integration
Olfactory bulb-olfactory cortex	Mitral cells, tufted cells	Olfaction—integration
Cochlea	Hair cells, spiral cells	Primary auditory ganglion

*Pathways and behavioral roles are more complex than indicated.

Table 1.5-1 Principal Glutamatergic Pathways, Neuron Types and Behavioral Roles*

Aspartate as a Neurotransmitter Although aspartate has been shown to be a potent stimulatory factor in the CNS, its role in the brain is unclear. No specific receptors for aspartate have been identified, but it may be a physiologically relevant agonist (ligand) at some types of glutamate receptors. Compelling evidence indicates that some interneurons within the hippocampus and spinal cord concentrate aspartate within their synaptic terminals and release this amino acid during

membrane depolarization. However, it has not been established that aspartate is concentrated in specific types of synaptic vesicles released via exocytosis.

NEUROPHYSIOLOGICAL SIGNIFICANCE OF INHIBITORY AMINO ACIDS

GABA as a Neurotransmitter GABA is prevalent throughout the CNS but at comparatively low concentrations brainstem and spinal cord, where glycine concentration is high. GABA is generally not found in peripheral neurons, but it is detected in some endocrine tissues, including b islets in the pancreas and in ovaries. GABA is not an essential amino acid and is not used as a building block for protein, but it is a constituent of some peptides, such as homocarnosine, a dipeptide of GABA and histidine. GABA is now recognized as the major inhibitory neurotransmitter within the CNS, but actual proof of this awaited identification of specific receptors for GABA in the postsynaptic membranes adjacent to presynaptic terminals and a demonstration that vesicles within the synaptic terminals of neurons that synthesize GABA (GABAergic neurons) selectively accumulate and concentrate GABA. The latter criterion was essential because the release of neurotransmitter molecules from synaptic terminals is quantal, which implies that transmitter molecules are released from synaptic vesicles into the synaptic cleft by an exocytotic process.

Within the CNS GABA is synthesized only in select types of neurons, which are likely to GABAergic neurons. These are usually small interneurons with short axons, but some projection neurons, such as the Purkinje cells in the cerebellum and the striatonigral and pallidonigral neurons in the basal ganglia are GABAergic (Table 1.5-2). Physiologically, the most common function of inhibitory GABAergic neurons appears to be to focus and refine the firing pattern (nerve-impulse generation) of the projection neurons that transfer neural information from one functional unit to another. An example of this is surround inhibition, which occurs when excitatory projection neurons activate inhibitory interneurons via collateral axons; which in turn inhibit surrounding projection neurons via synaptic contacts on the cell soma near the axon hillock. GABAergic neurons can also facilitate the output of excitatory projection neurons by a process of disinhibition, which occurs when two GABAergic neurons are linked synaptically in series. The first inhibits the ability of the second to depress the activity of an excitatory neuron, thereby increasing the excitatory output. GABA also mediates presynaptic inhibition, which occurs when a small presynaptic terminal impinges on a larger one and inhibits the release of transmitter molecules from it.

Anatomical Location	Type of Neuron	Neural Systems Influenced
Cerebral cortex	Inhibitory interneurons	Cortical efferents
Basal ganglia	Neostriatal interneurons	Striatal efferents
	Striatonigral neurons	Extrapyramidal output
	Pallidonigral neurons	Extrapyramidal output
Cerebellum	Purkinje	Cerebellar output
	Basket cells	Cerebellar efferents
	Golgi cells	Cerebellar efferents
	Stellate cells	Cerebellar efferents
Hippocampus	Basket cells	Hippocampal efferents
Retina	Amacrine cells	Retina efferents
Olfactory bulb	Inhibitory interneurons	Olfactory bulb efferents
Brainstem, spinal cord	Inhibitory interneurons	Central integration of sensory efferents; motorneuron output

Table 1.5-2 Principal GABAergic Neuron Anatomical Locations, Neuron Types, and Neural Pathway Influenced

Glycine as a Neurotransmitter Glycine is present throughout the CNS but is more prevalent in the brainstem and spinal cord, which are the primary areas where it appears to serve a transmitter function. In all tissues, glycine is a major constituent of protein and several peptides such as glutathione. Virtually all criteria required to establish glycine as a neurotransmitter have been met. These include the identification of specific receptors in the postsynaptic membrane adjacent to presynaptic terminals and a demonstration that vesicles within the synaptic terminals of presumptive glycinergic neurons selectively accumulate and concentrate glycine. Anatomically, glycinergic neurons are usually small interneurons, predominantly located in the brainstem and spinal cord, and often functionally associated with a-motoneurons.

Taurine Taurine, a sulfonated amino acid, is prevalent throughout the CNS and many other tissues. Taurine is highly concentrated (10 to 20 mmol/L) in the immature brain and declines during synaptogenesis. It is also abundant in white matter and therefore does not have a tissue distribution expected of a neurotransmitter. There is no compelling evidence that taurine activates specific receptors localized to synaptic terminals or that it accumulates into synaptic vesicles. Therefore, although the inhibitory effects of taurine on neuronal excitability suggest that this amino acid does function to depress neuronal excitability, it is not likely to be involved in synaptic signaling.

AMINO ACIDS AS COTRANSMITTERS

Some glutamatergic and GABAergic neurons also use another agent, usually a peptide, as a neurotransmitter. For example, glutamatergic primary afferent neurons also release substance P. In addition, enkephalin and cholecystokinin have been colocalized with glutamate in the perforant path fibers of the hippocampus. Some glutamatergic neurons may also use aspartate or *N*-acetylaspartylglutamate as a cotransmitter. Cholecystokinin-8 (CCK-8), neuropeptide Y, and galanin are each colocalized with GABA in some cortical, limbic, and spinal neurons, respectively. Enkephalin and thyrotropin-releasing hormone (TRH) are also localized in some spinal GABAergic neurons. Some studies suggest that the peptide neurotransmitters are released from synaptic terminals primarily during periods of high-frequency neuronal firing.

BIOCHEMICAL PROCESSES THAT MEDIATE TRANSMITTER FUNCTION

Synthesis and Regulation of the Neurotransmitter Pool of Glutamate Glutamate is rapidly synthesized from glucose in neural tissues, including synaptic terminals, but this reflects the role of glutamate in energy metabolism. The biochemical process used to replenish the neurotransmitter pool appears to involve a net synthesis of glutamate precursors in astrocytes, which are released and subsequently taken up into glutamatergic synaptic terminals and converted to glutamate. Glutamine is the most firmly established precursor serving this function, but a-ketoglutarate and malate may also be used in this capacity (Fig. 1.5-2).

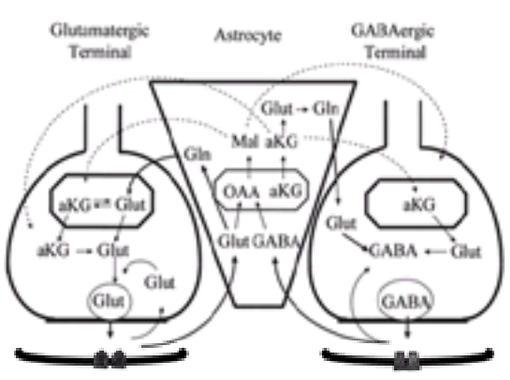

FIGURE 1.5-2 Some biochemical events associated with the neurotransmitter functions of glutamate and GABA. Many of the molecules of glutamate and GABA released from presynaptic terminals are transported into astrocytes and therein converted to glutamine and possible an intermediate of the tricarboxylic acid cycle, which are released and transported into the nerve terminals for subsequent conversion back into glutamate or GABA. MAL, malate, aKG, a-ketoglutarate.

The transmitter pool of glutamate may be defined as the molecules stored within synaptic vesicles. Glutamate is concentrated within vesicles by an ATP-dependent transporter specific for glutamate and present only in the membrane of vesicles in glutamatergic terminals. The vesicle transporter can concentrate glutamate approximately tenfold above the cytosolic level (~10 mmol/L). By comparison, the concentration of glutamate in the synaptic cleft when the synaptic terminal is inactive (resting state) is approximately 1 μmol/L. Sodium ion (Na^+)-Dependent transporters with high affinity for both glutamate and aspartate present in the

cytoplasmic membrane also contribute to the regulation of the transmitter function of glutamate and aspartate. Specific types of transporters are expressed in neurons and astrocytes. Transporters in astrocytes and in neuronal synaptic membranes contribute to neurotransmitter inactivation by maintaining low extracellular concentrations around synapses, whereas neuronal transporters in nonsynaptic regions may contribute to regulating the excitability of neurons by controlling the ratio of the intracellular to extracellular concentration within neurons. In this regard, although the transporters generally function as uptake systems (sometimes termed *reuptake*), they can also serve an export function during membrane depolarization.

Regulation of the neurotransmitter pool of aspartate is presumed to be similar to that for glutamate. A major difference is that relatively few neurons appear to contain synaptic vesicles with ATP-dependent transporters specific for aspartate. Therefore aspartate may function as a neurotransmitter in comparatively few neurons.

Synthesis and Regulation of the Neurotransmitter Pool of GABA Glutamate is the major metabolic precursor of GABA, although a small amount of GABA is derived from polyamines. Glutamate decarboxylase (GAD) catalyses the reaction, and two distinct forms of this enzyme exist—GAD I and GAD II. The enzyme requires pyridoxal phosphate (vitamin B_6) as a coenzyme, which also serves a regulatory function. GABA is synthesized from a pool of glutamate that is rapidly formed from a-ketoglutarate, a tricarboxylic acid cycle intermediate. Much of the GABA synthesized via this pathway is probably not in synaptic terminals and therefore is not within the transmitter pool. Although some of the GABA molecules formed via this pathway may be released into extracellular fluid via a transport process, most is likely converted immediately to succinate by the enzyme GABA transaminase. The primary metabolic pathway by which the transmitter pool of GABA is replenished appears to be one in which glutamine and possibly a-ketoglutarate are supplied by astrocytes to GABAergic synaptic terminals. These are transported into the synaptic terminals and metabolized to glutamate, which is then converted to GABA, and transported into the synaptic vesicles (Fig. 1.5-2).

Release of Transmitter Molecules From Synaptic Terminals Amino acid neurotransmitters are released from synaptic terminals by a process similar to that for acetylcholine and the monoamine neurotransmitters. Glutamate, GABA, glycine, and aspartate are each accumulated in their own specific type of synaptic vesicle via a Na^+-independent vesicular ATP-dependent transporter (pump). Neurotransmitters are concentrated within synaptic vesicles at concentrations about tenfold that the cytoplasmic concentration, resulting in an intravesicular concentration of nearly 100 mmol/L. Because the diameter of synaptic vesicles is about 10^{-7} meter, one vesicle can contain approximately 5000 molecules.

Transmitter release is triggered by depolarization of the presynaptic membrane by an action potential. This results in the opening of voltage-dependent calcium ion (Ca^{2+}) channels, allowing calcium to flow into the presynaptic terminal. The rise in intracellular Ca^{2+} concentration initiates a cascade of events involving at least eight proteins (mostly protein kinases) that enable the vesicles to dock at specific sites within the presynaptic membrane, whereupon the vesicles fuse with the membrane and release their contents into the synaptic cleft. Although the presynaptic terminal of neurons within the CNS may contain numerous vesicles, a single action potential typically induces transmitter release from only a few (1 to 3). This suffices to raise the concentration of neurotransmitter molecules within the synaptic cleft to nearly 1 millimeter for a few milliseconds, which will effectively saturates adjacent postsynaptic receptors.

Removal of Transmitter Molecules From the Synaptic Cleft (Transmitter Inactivation) Transmitter molecules within the cleft can readily diffuse into extracellular fluid adjacent to the synapse, where the concentration of transmitter molecules is at least 1000-fold lower. As long as the 1000-fold gradient is maintained, diffusion can restore the resting concentration within the cleft to micromolar concentrations within a few milliseconds. Uptake of transmitter molecules back into the presynaptic terminal or into the postsynaptic neuron also contributes to the inactivation process. A key element in the inactivation of the transmitter function of glutamate, GABA, and aspartate is the vigorous uptake of the amino acids by transporters in the cytoplasmic membrane of astrocytes. This is primarily how a low (£ μmol/L) extracellular concentration (£μmol/L) of these amino acids is maintained, thereby allowing diffusion to remove molecules from the synaptic cleft rapidly. The molecules of glutamate, GABA, and aspartate taken up by astrocytes are metabolized to glutamine and intermediates of the tricarboxylic acid cycle (Fig. 1.5-2).

AMINO ACID NEUROTRANSMITTER RECEPTORS

Glutamate Receptors Glutamate receptors are found throughout the brain and are expressed on both neurons and glia, although not all glutamate receptor subtypes are found on both cell types. Glutamate receptors, sometimes referred to as *excitatory amino acid receptors*, were initially classified into *N*-methyl-D-aspartate (NMDA), quisqualate, and kainate receptors on the basis of their preferential activation by these exogenous agonists. More recently, five categories of glutamate receptors (NMDA, kainate, a-amino-3-hydroxy-5-methylisoxazole-4-propionic acid [AMPA], L-2-amino-4-phosphonobutyrate (L-AP4), and trans-1-aminocyclopentane-1,3-dicarboxylic acid [ACPD] receptors) have been established on the basis of pharmacological, electrophysiological, and molecular biological criteria. The L-AP4 receptor type is defined by its agonist and acts as an inhibitory autoreceptor, while the quisqualate receptors of the previous classification have been subdivided by means of more-specific agonists into AMPA and ACPD receptors. AMPA and Kainate receptors are sometimes collectively referred to as non-NMDA receptors. NMDA, kainate and AMPA receptors are ionotropic glutamate receptors; the L-AP4 and ACPD receptors are grouped as metabotropic receptors. Ionotropic receptors are ligand-gated cation-specific channels that are activated rapidly (milliseconds), whereas metabotropic receptors coupled to G proteins and second-messenger systems function more slowly on a scale of several hundred milliseconds to seconds. Representative agonists and antagonists for each of these glutamate receptor classes are shown in Table 1.5-3.

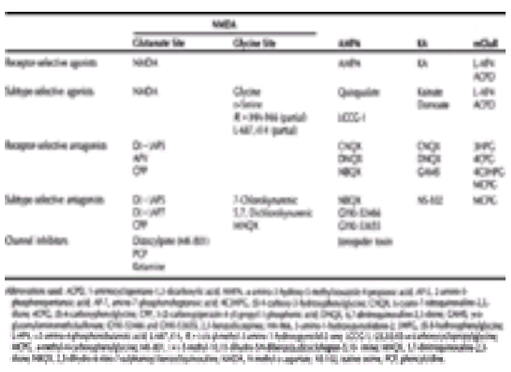

Table 1.5-3 Common Glutamate Receptor Agonists and Antagonists

AMPA Receptors Recent cloning efforts have clearly demonstrated that AMPA and kainate receptors are distinct receptor complexes, although they can be activated by the same agonists. Four genes encode the AMPA receptor (*GluR*1 through *GluR*4 [*GluR*-A through *GluR*-D]) and five genes encode the kainate receptor (*GluR*5 through *GluR*7 and *KA*1 and *KA*2). The four AMPA receptor subunits are similar in size and amino acid sequence. Each subunit exists in two different forms, “flip” and “flop,” created by alternative splicing. AMPA receptor subunits are expressed predominantly in the flip form in embryonic brains and gradually change over to the flop form, which dominates in the adult brain. The AMPA receptor channels are permeable to Na^+ and potassium (K^+) predominantly but will allow permeability to Ca^{+2} in the absence of the *GluR*2 (*GluR*-B) subunit. This however is only known to occur in a small population of hippocampal and neocortical nonpyramidal neurons in the brain. The AMPA receptor has at least three binding sites at which agonists or antagonists can interact: glutamate binding, desensitization and intra-ion-channel binding sites. Recently, a family of drugs called ampakines have been shown to selectively increase AMPA receptor-gated currents and improve cognitive performance in a series of behavioral tasks.

Kainate Receptors Although kainate is an effective agonist of AMPA receptors, it also activates its own distinct class of ionotropic receptors, the kainate-preferring receptors. The five subunits are divided into two groups; *GluR*5 through *GluR*7 represent the low-affinity kainate-binding site (K_d = 50 nmol/L), whereas *KA*1 and *KA*2 correspond to the high-affinity kainate-binding site (K_d = 5 nmol/L). Each group is of similar size and amino acid sequence identity, with the *KA*1 and *KA*2 subunits being slightly larger than the *GluR*5 through *GluR*7 subunits. Despite their wide distribution throughout the CNS, the physiological significance of kainate receptors remains largely unknown, although they have been implicated in fast glutamatergic transmission in hippocampal neurons. In addition to postsynaptic functions, kainate receptors act presynaptically on mossy fiber terminals within the hippocampus to generate epileptiform activity.

NMDA Receptors NMDA receptors mediate excitatory neurotransmission in the CNS in different ways from AMPA and kainate receptors. They are characterized by voltage-dependent block by magnesium ions (Mg^{2+}), a high permeability to Ca^{2+}, and slow gating kinetics. The NMDA receptor is a ligand-gated ion channel composed of two different subunits: *NMDAR*1 and *NMDAR*2. *NMDAR*1 can exist in seven splice variants, and there are four different genes encoding variants of *NMDAR*2 (2A, B, C, D). At present it is not clear how many R1 and R2 subunits are present in each functional NMDA receptor or if additional subunits exist, although

the receptor is thought to be pentameric. However, it is known that *NMDAR*1 serves as the core subunit of a functional NMDA receptor, with the *NMDAR*2 subunits acting as modulatory components of the receptor. Both *NMDAR*1 and *NMDAR*2 are required for receptor function.

NMDA receptors have a number of distinct recognition sites for endogenous and exogenous ligands, each with discrete binding domains. At present there are at least seven pharmacologically distinct sites through which compounds can alter the activity of this receptor (Fig. 1.5-3). Drugs that affect NMDA receptor function are divided into four groups, those acting at (1) the glutamate and NMDA recognition site, which is highly conserved on the NMDA NR2 subunits; (2) the strychnine-insensitive glycine binding site, where glycine is required as a coagonist for channel opening; (3) the intraion-channel binding site, where Mg^{2+} sits blocking ionic currents through the receptor at resting potentials; and (4) modulatory sites such as the redox modulatory site, the proton sensitive site, the zinc (Zn^{2+}) site, and the polyamine site.

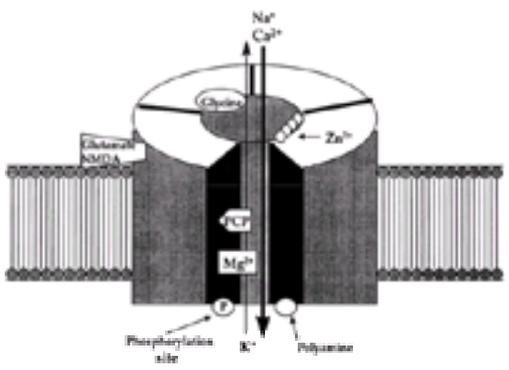

FIGURE 1.5-3 Diagrammatic illustration of the NMDA receptor–ion-channel complex and its modulatory sites. PCP, phencyclidine.

The NMDA receptor has three characteristic features: (1) at resting potentials it remains blocked by Mg^{2+}, and ionic currents flow through the receptor only if the neuronal membrane is partially depolarized; (2) significant amounts of extracellular Ca^{2+} enter the cell interior during activation of the receptor; and (3) NMDA receptor–mediated neurotransmission occurs slowly and lasts for a prolonged period. Because of these properties, it has been shown that the NMDA receptor serves a critical role in synapse development and plasticity, including the phenomena of long-term potentiation and long-term depression. Abnormal functioning of the NMDA receptor can lead to a variety of neurological disorders. Overactivation of the NMDA receptor has been indicated in ischemic insults, head trauma, and epileptic seizures, triggering a cascade of cellular events that culminate in neuronal cell death. On the other hand, hypofunction of the NMDA receptor elicits a psychomimetic state that closely resembles schizophrenia.

Metabotropic Receptors Not as much is known about the last group of glutamate receptors, the metabotropic receptors. The metabotropic receptor proteins belong to the superfamily of G-protein–coupled receptors, all of which contains seven-transmembrane domains. So far, the metabotropic receptor gene (*mGluR*) family has been shown to contain eight members, which are closely related in primary structure and can be divided into three groups on the basis of amino acid sequence homology, agonist sensitivity, and associated signal-transduction mechanisms. Group I receptors (mGlu1 and mGlu5) are coupled to the inositol (1,4,5) triphosphate-Ca^{2+} cascade, while group II (mGlu2 and mGlu3) and group III (mGlu4 and mGlu6 through mGlu8) lead to the inhibition of adenylate cyclase. Some members of the *mGluR* families exist in alternatively spliced variants. Several lines of evidence suggest that the N-terminal large extracellular domain of the receptors contains glutamate binding sites, while the C-terminal domain plays a role in determining the potency of agonists regulating the transduction mechanisms of the metabotropic receptors. Glutamate, quisqualate, and ibotenate activate both mGluRs and ionotropic receptors. Some glutamate analogues, such as ACPD and L-AP4, are specific for metabotropic receptors, while their potencies differ for each mGluR subtype (Table 1.5-3). Generally, metabotropic receptor agonists induce a slow membrane depolarization (a rise time of around 5 seconds and lasting up to 60 seconds, which is about 1000-fold slower than ionotropic receptors) accompanied by an increase in firing rate in many neurons. These effects are attributed to direct inhibitory effects on K^{+} channels. In addition to direct excitatory postsynaptic effects, metabotropic receptor activation suppresses both excitatory and inhibitor transmission at synapses by presynaptic mechanisms via an autoreceptor-type mechanism, thereby modulating presynaptic activity. Several metabotropic receptors have been implicated in synaptic plasticity that occurs in learning and memory.

GABA RECEPTORS

$GABA_A$ Receptor The $GABA_A$ receptor is a member of the superfamily of ligand-activated ion channels in the cell membrane. GABA type A ($GABA_A$) receptors are most closely related to strychnine-sensitive glycine receptors, more distantly related to acetylcholine nicotonic receptors and serotonin 5-hydroxytryptamine (5-HT) [5-HT] type receptors, and even more distantly related to glutamate ionotropic receptors (AMPA and kainate receptors and NMDA receptors). $GABA_A$ receptors are heteropentameric protein complexes, which when activated undergo a series of conformational changes that form an open channel (pore) selectively permeable to anions, specifically chlorine anion (Cl^-) and to a lesser degree (HCO^{-3}). Receptor activation normally results in an influx of Cl^- which rapidly and transiently hyperpolarizes the membrane, a process generally referred to as the generation of an inhibitory postsynaptic potential. The increase in Cl^- flux also decreases the resistance of the membrane, which acts as a shunt to impede the ability of depolarizing excitatory postsynaptic potentials to elicit action potentials (nerve impulses). For this reason, inhibitory synapses are most effective when located near the point at which action potentials are initiated, usually the axon hillock. Therefore, it is not surprising that GABAergic inhibitory synapses are often concentrated on neuronal cell bodies near the axon hillock.

$GABA_A$ receptors are heteromeric in that the receptor can comprise at least four types of subunit proteins, termed a, b, g, and d. It is pentameric in that each receptor has a total of five proteins; therefore all $GABA_A$ receptors have more than one copy of at least one type of subunit protein. There are multiple subtypes of three of the subunit proteins, at least six subtypes of a, three of b, and two of g. Although theoretically there could be many thousands of $GABA_A$ receptor subtypes, it is likely that fewer than 20 exist naturally. Most often the receptors contain two a, two b, and one g, or one a, two b, and two g subunits. The different subunits and the different subtypes of each subunit from which a particular type of receptor is formed can influence the physiological properties of the receptor (e.g., channel open time and rate of desensitization) as well as susceptibility to pharmacological agents as discussed below.

$GABA_A$ receptors are regulated by phosphorylation of some serine hydroxyl residues in the inner loop of the b subunits. Phosphorylation can be mediated by protein kinase A or protein kinase C. Depending on the type of b subunit, phosphorylation can affect the channel gating properties (e.g., channel open time and rate of receptor desensitization) either positively or negatively.

A variety of pharmacological agents can influence the activity of $GABA_A$ receptors. At least five separate drug binding sites have been identified (Fig. 1.5-4 and Fig. 1.5-5). Many clinically useful drugs are known to bind to benzodiazepine or barbiturate sites. These sites are allosteric to the GABA binding site. Drugs that bind to them influence the ability of GABA to activate the receptor by either altering the affinity between GABA and its binding sites ($GABA_A$ receptors probably possess two GABA binding sites) or by altering the channel open time and rate of receptor desensitization. It now seems unlikely that either of these sites serves a physiological purpose. An unusual characteristic of the benzodiazepine site is that drugs binding to it can exert either a positive modulatory (an agonist) or negative modulatory (an inverse agonist) effect, or no effect at all (an antagonist). The steroid site may have some yet-undetermined physiological relevance. Several of the pharmacological effects of ethanol are mediated through effects on $GABA_A$ receptors, but it may not act at a specific and unique site.

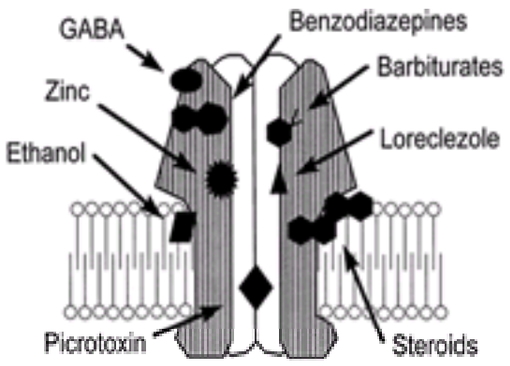

FIGURE 1.5-4 Diagrammatic illustration of the $GABA_A$, receptor–ion-channel complex and its modulatory sites.

FIGURE 1.5-5 Structure of the prototypical $GABA_A$ and benzodiazepine receptor agonists and antagonists. (Courtesy of Daniel C. Javitt, M.D., Ph.D., and Stephen R. Zukin, M.D.)

$GABA_B$ Receptors The metabotropic $GABA_B$ receptors are a member of the superfamily of G-protein-coupled receptors expressed in the cell membrane. These receptors generally exert an inhibitory effect on neuronal excitability by generating hyperpolarizing potentials that are much slower in onset and longer in duration than those mediated by $GABA_A$ receptors. Because $GABA_B$ receptors are G-protein coupled, receptor activation initiates guanosine triphosphate (GTP) hydrolysis and thereby causes dissociation of the G-protein subunits (a, b, g) from the receptor. $GABA_B$ receptors are coupled to a G_i subtype of G protein, and the dissociated a subunit activates a type of K^+ channel, thereby hyperpolarizing the membrane. $GABA_B$ receptors are often located on presynaptic terminals where they serve to inhibit transmitter release by reducing the efficacy of action potentials to activate Ca^{2+} influx.

CLINICAL CONSIDERATIONS

Glutamate and Aspartate Glutamate and aspartate function effectively as excitatory neurotransmitters because their extracellular and intracellular concentrations are tightly regulated by several biochemical processes, most of which require a constant source of energy (e.g., ATP). These include the vigorous transport systems in the membrane of astrocytes and neurons that rapidly remove glutamate from extracellular fluid (e.g., synaptic cleft) and transport systems within the synaptic vesicles from which the transmitter molecules are released into the synaptic cleft. Glutamate and aspartate can be rapidly metabolized, but only intracellularly. Therefore any condition that impairs the ability of the membrane transport systems to maintain these amino acids at very low extracellular levels can have a severe impact on the physiological activity of neurons.

Ischemia-Induced Neurodegeneration The events that cause neuronal cell death as a result of stroke, head trauma, or any condition involving a dramatic loss of oxygen or glucose supply to the brain are complex and not clearly elucidated. However, it is likely that a breakdown in the regulation of glutamate is a major factor. Early metabolic consequences of ischemia or hypoxia include accumulation of lactic acid, a concomitant decrease in pH, and a decrease in energy storage molecules (phosphocreatine and ATP). This has an immediate deleterious effect on the activity of the sodium-potassium ion pump, which accounts for more than 50 percent of ATP-supplied energy use in the CNS. This in turn results in a dissipation of transmembrane gradients for K^+ and Na^+ and a concomitant depolarization of the cell membrane. Dissipation of the Na^+ gradient inhibits the removal of glutamate from extracellular fluid, and membrane depolarization activates voltage-sensitive Ca^{2+} channels in synaptic terminals, thereby promoting excessive glutamate release. Consequently, high levels of glutamate accumulate in the synapse, causing excessive activation of NMDA and AMPA receptors. Because of the prevalence of these receptors, the intracellular accumulation of Ca^{2+} is greatly exacerbated. This pathological accumulation of Ca^{2+} promotes a cascade of events that can result in neuronal cell death. Neurological disorders in which this pathological cascade may be involved include global and focal ischemia (stroke) but also hypoglycemia, head trauma, spinal injury, status epilepticus, drug abuse, and certain food toxicities (e.g., monosodium glutamate, and mussel poisoning).

Chronic Neurodegenerative Disorders Dysregulation of glutamate and aspartate and overactivation of their receptors may contribute neuronal cell loss in chronic disorders such as acquired immune deficiency syndrome (AIDS) dementia, Parkinson's disease, motor neuron disease (including amyotrophic lateral sclerosis), Huntington's disease, and Alzheimer's disease. Tissue-specific defects in glial transporter genes resulting in impaired glutamate uptake have been identified in several cases of the sporadic form of amyotrophic lateral sclerosis. Lathyrism, which is clinically similar to amyotrophic lateral sclerosis, has been linked to the ingestion of cycad beans, which contain an excitotoxin b-*N*-methylamino-L-alanine. Abnormal activation of excitatory pathways within the basal ganglia appears to play a part in the symptom expression of parkinsonism in animal models. In primates, NMDA and non-NMDA antagonists increase the therapeutic efficacy of the dopaminergic drug, levodope (Larodopa).

Epilepsy Epilepsy is a group of neurological disorders characterized by spontaneous recurrent seizures. A seizure is an abnormal paroxysmal firing of cerebral neurons in synchronous fashion and is often associated with motor signs and sensory, autonomic, or psychic symptoms. Loss or impairment of consciousness often occurs. Epileptic syndromes are defined on the basis of clusters of signs and symptoms that generally occur together in a patient with recurrent seizures. They are classified on the basis of the seizures: localization related, generalized, undetermined, or a special syndrome (1989 International League Against Epilepsy classification). The epileptic syndromes are further divided by etiology: idiopathic, cryptogenic, or symptomatic. Epilepsy occurs in 1 to 2 percent of the population worldwide, and epileptic patients account for a major proportion of the return visits in neurological clinics. Although compounds that antagonize the action of glutamate at NMDA receptors or AMPA and kainate receptors are generally effective in blocking seizures, the only marketed antiepileptic drug in which glutamate antagonism is thought to be a prominent component of its antiseizure activity is topiramate (Topamax). Topiramate selectively antagonizes AMPA and kainate receptors.

Although many neurobiological factors may contribute to seizure formation, a prominent feature of most seizures is an abnormal and excessive firing of glutamatergic neural pathways. Therefore, abnormalities in the regulation of glutamate may be a factor in the initiation, spread and maintenance of seizure activity in some types of epilepsy. The involvement of glutamatergic receptors in seizures and epilepsy is widely accepted on the basis of evidence that injections or focal applications of glutamatergic agonists at NMDA receptor or AMPA and kainate receptors seem to produce seizures or epileptic-like activity in numerous in vitro and animal models of epilepsy. Furthermore, selective antagonists to these receptors reduce epileptic activity or are potent anticonvulsants in several models. Elevated plasma concentrations of glutamate have been observed in a epileptic-like mouse strain and in probands with generalized epilepsy. Some studies using in vitro or ex vivo techniques and studies in animal models indicate that glutamate or aspartate release increases during seizure activity. A study using chronically implanted microdialysis probes in bilateral hippocampi of epileptic humans showed marked increases in extracellular glutamate concentrations immediately prior to the onset of seizures on the side of seizure origin.

Many patients with temporal lobe or complex partial epilepsy have neuronal loss and sclerosis, particularly in mesial hippocampus. Mesial temporal sclerosis is a common finding in surgical specimens removed from patients suffering from chronic refractory complex partial seizures. Neuronal loss is prominent in CA1, CA3 and

dentate hilus. Interestingly, the pathology closely resembles the findings seen in model systems of prolonged seizure activity or in those induced by application of excitotoxins.

Kindling, which is a gradual induction of a hyperexcitable neuronal state, can occur by focal repetitive subconvulsive stimulation of the hippocampus, amygdala, or some other brain areas. Kindling results in increased susceptibility toward seizures and has been studied extensively in animals, particularly rodents. The basis for the persistent hyperexcitable state remains controversial, and the actual involvement of excitatory amino acid receptors in this hyperexcitable state remains unclear. However, there is good evidence that glutamatergic receptors, particularly NMDA types, play a role in the development and enhancement of the kindled or seizure-prone state. NMDA receptor antagonists can prevent the kindling phenomenon despite the expression of seizurelike discharges in in vitro models such as hippocampal slices. A variety of NMDA antagonists, including those that act as channel inhibitors or compete with the glutamate recognition or glycine recognition sites, appear to be highly effective in blocking the development of kindling. They do not appear to be as effective as anticonvulsants in fully expressed seizures unless they are used at dosages that produce significant toxic effects, such as neurological or behavioral impairment. In contrast, AMPA receptor antagonists are highly effective in blocking the expression of seizures, but they seem to have little effect on the induction of the kindled state. Further research is needed to define the role of excitatory amino acids in kindling and hippocampal injury. Much of the research has focused on ionotropic glutamate receptors. With the recent discovery of more-selective metabotropic glutamate receptor agonists and antagonists, along with the cloning of metabotropic receptor genes, the role of metabotropic receptors is now being explored.

Schizophrenia The cause of schizophrenia remains elusive, although several observations suggest that it may involve abnormalities in glutamatergic transmission. This hypothesis has been spurred on by the knowledge that phencyclidine (PCP, “angel dust”), a noncompetitive NMDA receptor antagonist, generates psychomimetic behaviors similar to those seen in schizophrenia. Clinical data supporting a role for glutamate in the etiology of schizophrenia are sparse but interesting. In the 1980s it was observed that glutamate concentration was lower in the cerebrospinal fluid (CSF) of schizophrenic patients than in that of control patients. These results have not been replicated successfully. Postmortem studies of schizophrenics have shown a consistent increased density of glutamate receptors (NMDA and non-NMDA) within the frontal and temporal cortex, together with some evidence for decreased production or release of glutamate, or both. Such results suggest that schizophrenia involves decreased glutamatergic transmission.

Neuropathic Pain Activation of afferent C fibers with nociceptive stimuli produces pain sensations that are enhanced during pathological conditions. Activity-dependent increases in excitability are induced in the spinal dorsal horn neurons by repetitive stimulation of C fibers. This is thought to contribute to the development and maintenance of chronic pain symptoms. NMDA antagonists, ketamine (Ketalar) and D-amino-propyl-valeric acid, have consistently reduced this activity in the rat dorsal horn nociceptive neurons, suggesting that the NMDA receptor contributes to this phenomenon. AMPA and kainate receptors may also play a role in modulating pain. In situ hybridization studies have revealed that expression of kainate receptor gene *GluR*5 is particularly prominent in dorsal root ganglion neurons. Animal studies have indicated that kainate receptor antagonists significantly reduce nociception, and early human trials with some of these agents show them to be promising for analgesia.

Substance Abuse Several lines of evidence indicate that one of the acute effects of ethanol is to inhibit glutamate receptor function, particularly NMDA and kainate receptors. Such inhibition leads to depressed synaptic transmission and may result in ethanol-induced cognitive deficits. Indeed, low concentrations of ethanol are known to inhibit long-term potentiation in the hippocampus.

GABA

Epilepsy Like the glutamatergic system, GABA and GABA receptor subtypes play a central role in the expression of seizures. GABA, as the major inhibitory neurotransmitter in the CNS, can be found in up to 30 percent of CNS synapses. In general, for the mature brain, loss or blockade of GABA inhibition can result in increased hyperexcitability and expression of seizures. Unlike with the glutamatergic system, several GABAergic drugs are widely used in the treatment of epilepsy. Clinically effective benzodiazepines and barbiturates likely act at $GABA_A$ receptors to enhance inhibition. Both have been shown to be effective in the control of partial, complex partial, and generalized tonic-clonic seizures. Benzodiazepines are also effective in the short-term treatment of generalized absence, but a functional tolerance tends to develop, thereby reducing their efficacy. Barbiturates may exacerbate generalized absence seizures. Benzodiazepines are also effective in the treatment of atypical absence and myoclonic seizures. Anticonvulsant benzodiazepines and barbiturates are highly sedating, which limits their use. Phenobarbital (Solfoton) an anticonvulsant barbiturate, has been used for the treatment of epilepsy since the early 1900s, and it is still the most widely used anticonvulsant in the world, primarily because of its low cost.

Other evidence that the GABAergic system is important in the expression of seizures is that manipulation of $GABA_A$ receptor function can cause, exacerbate, or reduce seizure activity. The mushroom poisons picrotoxin and bicucculine antagonize $GABA_A$ receptors noncompetitively and competitively, respectively, and can elicit seizures. Penicillin given at high doses (especially in renal failure patients or intrathecally) can result in partial or generalized seizures. Penicillin reduces GABA-induced chloride current flow by blocking the ion channel pore. The $GABA_A$ receptor has numerous modulatory sites that can allosterically increase or decrease the chloride ion channel current flow. For example, negative modulators that act at the benzodiazepine site (e.g., b-carbolines) or the steroid site (e.g., pregnenolone sulfate) can lower seizure thresholds.

In the mature or adult brain, enhancement of $GABA_A$ receptor function generally raises the seizure threshold. Certain naturally occurring and synthetic pregnane-derived steroids are potent positive modulators, now called neuroactive steroids, or neurosteroids. Some data support the role of the endogenous neurosteroids in cyclical changes in behavior and in catamenial or menstrually related epilepsy. A pregnane-derived synthetic neurosteroid is in clinical trials for treatment of epilepsy.

Not only does positive modulation of these allosteric sites result in anticonvulsant activity, increases in GABA availability also seem to be of clinical benefit. Reduction of GABA clearance by inhibition of GABA uptake or reduction of GABA degradation by poisoning GABA transaminase are both effective. A GABA uptake inhibitor has been recently approved for treatment of partial seizures, but it may exacerbate generalized absence seizures. An irreversible inhibitor of GABA transaminase also effective in the treatment of partial seizures is in the late stages of development. Finally, some evidence in animal models suggests that modulation of $GABA_B$ receptors may play a role in the treatment of generalized absence seizures.

Anesthesia Pentobarbital (Nembutal) has been a popular drug for induction of anesthesia. Like phenobarbital, pentobarbital allosterically enhances $GABA_A$ receptor function, but over a narrow concentration range it also can directly activate $GABA_A$ receptors. Pentobarbital also has activity in blocking glutamate receptors and voltage-gated calcium channels. The potent benzodiazepines midazolam (Versed) and lorazepam (Ativan) have replaced diazepam (Valium) as a drug of choice for induction of anesthesia.

In the 1990s pentobarbital was replaced by propofol (Diprivan), which is more easily titrated and is especially useful in the neurosurgical setting. Propofol, which has a short duration of action, allosterically enhances $GABA_A$ function and directly activates these receptors. Several neurosteroids also can directly activate $GABA_A$ receptors, and it has been proposed that this direct effect is in part responsible for the anesthetic qualities of these agents.

In the 1940s, parenteral administration of cholesterol was shown to induce sedation in animals, and this subsequently led to the development of synthetically derived steroids for sedation. Although its mechanism of action was unknown at the time, one derivative, alfaxalone (Alfathesin) was a popular agent during the early 1970s for the induction of anesthesia. It has been subsequently discovered that alfaxalone's pregnane-based structure is similar to that for the neurosteroids and that it is a potent enhancer of $GABA_A$ receptor function.

Anxiety- and Sleep-Related Disorders Benzodiazepines and barbiturates have a long history in the treatment of anxiety and insomnia. Diazepam was once the most prescribed medication in the United States. With the cloning of GABA receptor genes, it is now recognized that the hints of subtypes of $GABA_A$ receptors from previous pharmacological experiments are true. This is especially true for subclasses of benzodiazepine-sensitive receptors. Benzodiazepines with greater anxiolytic than sedative-hypnotic properties are in use clinically, and their efficacy may be related to preferential binding to particular subtypes of $GABA_A$ receptors.

Spasticity Loss of spinal and supraspinal inhibition may result in spasticity or hyperreflexic states. One particular disorder, stiff person syndrome, is associated with increased reflexivity and muscle spasms and occasionally with seizures, diabetes or both in some patients. The disorder is frequently associated with circulating antibodies to GAD, the GABA synthesis enzyme. Interestingly, antibodies to GAD are associated with type I diabetes (autoimmune-associated juvenile form). Benzodiazepines, especially diazepam, and baclofen are mainstays in the treatment of spasticity. However, these agents are often only moderately effective,

especially in supraspinal forms of spasticity.

Substance Abuse Ethanol enhances GABA receptor function in some in vitro preparations potentially via a protein-binding site. Although studies have been controversial, many accept that ethanol may selectively alter function of some subtypes of GABA receptors. $GABA_A$-active benzodiazepines and barbiturates are known for their development of tolerance and potential addictive activity during long-term administration.

Glycine Glycinergic neurotransmission is important in the circuits for local inhibitory control in the spinal cord. Genetic defects in glycine subunit genes have been identified as causes of hypersensitive reflexes and spasticity in both humans and animals. Opportunities for pharmacotherapeutic modulation of glycine receptors have been rather limited by the lack of readily identifiable allosteric regulatory sites. Strychnine, a potent antagonist, has long been used as a poison for rodents and in humans, where it has been used as an instrument of malicious intent. Clinically relevant positive modulators of the glycine receptor include ethanol and the anesthetic propofol.

SUGGESTED CROSS-REFERENCES

Further information about the neuroanatomy of specific excitatory and inhibitory projections can be found in Section 1.2 on neuroanatomy. Further information on the receptor transduction mechanisms can be found in Section 1.9 on electrophysiology. Information regarding the contributions of specific cortical regions and pathways in schizophrenia can be found in Section 12.3 on brain structure and function and Section 12.4 on neurochemical, vital, and immunological studies in schizophrenia. The role of GABA benzodiazepine receptors in mood disorders is discussed in Chapter 14, and their role in anxiety disorders is discussed in Chapter 15. The clinical use of benzodiazepines is discussed in Section 31.10. Epilepsy is covered in Section 2.4.

1.6 NEUROPEPTIDES: BIOLOGY AND REGULATION

MICHAEL J. OWENS, PH.D., CHARLES B. NEMEROFF, M.D., FH.D. AND GARTH BISSETTE, PH.D.

The past several decades have witnessed a veritable explosion of knowledge about the central nervous system (CNS), and in no area has this been as impressive as in peptide neurobiology. Numerous peptide neurotransmitter candidates have been identified and characterized, their CNS distributions mapped, and their genes cloned. The tenet “one neuron-one transmitter” erroneously attributed to Dale has been convincingly refuted with numerous demonstrations of neurons containing multiple peptides or combinations of peptide and nonpeptide neurotransmitters. Additionally, since the early 1980s there has been an embarrassment of riches in the form of knowledge about neurotransmitter receptor diversity, diversity of receptor-effector coupling, and neurotransmitter transporters. These discoveries have not yet been fully integrated into what is known about normal or aberrant CNS function, although dysfunction at virtually any level could conceivably lead to neuropsychiatric deficits. This chapter summarizes, with several examples, the general principles governing neuropeptide biology and includes a review of several neuropeptides that have been unequivocably demonstrated to be involved in the pathophysiology of one or another neuropsychiatric disorders.

By definition, a neuropeptide is a chain of two or more amino acids linked by peptide bonds, and differs from other proteins only in the length of the amino acid chain. Over 100 unique biologically active peptide sequences have been purified from biological sources; their sizes range from two (carnosine and anserine) to over 40 amino acids (corticotropin-releasing factor [CRF] and growth hormone-releasing factor [GRF]) (Table 1.6-1). Most of the other known active peptides fall within these size limits. By convention, peptides greater than 90 amino acids in length (about 10,000 molecular weight) are considered proteins. The five examples discussed here are somatostatin (somatotropin release-inhibiting factor [SRIF]), thyrotropin-releasing hormone (TRH), neurotensin neuromedin N, and CRF. Their structures are illustrated Table 1.6-2, and are written by convention from the amino terminus (NH_2–) beginning on the left to the carboxyl terminus (–COOH) on the right.
Somatostatin, CRF, and TRH are hypothalamic hypophysiotropic hormones and, like neurotensin and neuromedin N, function in the CNS as neurotransmitters in ways that are often quite distinct from their effects on the endocrine axes. Neuropeptides have been implicated as chemical mediators in pathways subserving a variety of behavioral and physiological effects, including such diverse behaviors as thermoregulation, food and water consumption, sex, sleep, locomotion, memory, learning, responses to stress and pain, and emotion. Those actions have stimulated interest in the contribution of the peptidergic neuronal systems to the symptoms and behaviors exhibited in such major psychiatric illnesses as psychotic disorders, mood disorders, and dementia. In addition to their endocrine and neurotransmitter roles, many peptides and their receptors apparently play active roles in development and often appear transiently in various anatomical regions or in such abundance that a trophic effect is postulated, an effect that does not necessarily persist beyond early development. An example of this ontogenetic shift is found in the distribution of messenger ribonucleic acid (mRNA) for SRIF in developing rats. The mRNA exhibits more regional heterogeneity in developing rats than it does in adult animals, with the hypothalamic mRNA concentrations being much higher than the cerebrocortical expression.

Adrenocorticotropin hormone (ACTH)
Angiotensin
Atrial natriuretic peptide
Bombesin
Calcitonin
Calcitonin gene-related peptide (CGRP)
Cholecystokinin (CCK)
Corticotropin-releasing factor (CRF)
Dynorphin
β-endorphin
Leu-enkephalin
Met-enkephalin
Galanin
Gastrin
Gonadotropin-releasing hormone (GnRH)
Growth hormone
Growth hormone-releasing hormone (GHRH)
Insulin
Motilin
Neuropeptide Y
Neurotensin
Orphanin FQ/Nociceptin
Oxytocin
Pancreatic polypeptide
Prolactin
Secretin
Somatostatin (SRIF)
Substance K
Substance P
Thyrotropin-releasing hormone (TRH)
Vasoactive intestinal polypeptide (VIP)
Vasopressin

Table 1.6-1 Selected Neuropeptide Transmitters

Name	Amino Acid Sequence
Thyrotropin-releasing hormone (TRH)	pGlu-His-Pro-NH_2
Somatostatin (SRIF-28)	NH^2-Ser-Ala-Asn-Ser-Asn-Pro-Ala-Met-Ala-Pro-Arg-Glu-Arg-Lys-Ala-Gly-Cys-Lys-Asn-Phe-Phe-Trp-Lys-Thr-Phe-Thr-Ser-Cys-OH
Neurotensin	pGlu-Leu-Tyr-Glu-Asn-Lys-Pro-Arg-Arg-Pro-Tyr-Ile-Leu-OH
Neuromedin N	NH_2-Lys-Ile-Pro-Tyr-Ile-Leu-OH
Corticotropin-releasing factor (CRF)	Ser-Glu-Glu-Pro-Pro-Ile-Ser-Leu-Asp-Leu-Thr-Phe-His-Leu-Leu-Arg-Glu-Val-Leu-Glu-Met-Ala-Arg-Ala-Glu-Gln-Leu-Ala-Gln-Gln-Ala-His-Ser-Asn-Arg-Lys-Leu-Met-Glu-Ile-Ile-NH_2

Subscript numbers refer to points of known peptidase cleavage
1. Pyroglutamate aminopeptidase (E.C. 3.4.19.3)
2. Prolyl endopeptidase (E.C. 3.4.21.26)
3. Carboxypeptidase (E.C. 3.4.17.10)
4. Metalloendopeptidase (E.C. 3.4.24.15)
5. Neutral endopeptidase (E.C. 3.4.24.11)
6. Metalloendopeptidase (E.C. 3.4.24.16)

Table 1.6-2 Selected Neuropeptide Structures

Many of the known behavioral effects of neuropeptides are observed only after their direct injection into the CNS because most peptides do not penetrate the blood-brain barrier in amounts sufficient to produce effects before being inactivated by serum and tissue enzymes that degrade them. The degradation is usually the result of the cleavage of specific amino acid sequences targeted by a specific peptidase designed for that purpose. Peptide fragments often possess full or partial biological activity at peptide receptors, and the relatively lengthy period of peptide-induced effects may be attributable to this delayed cessation of activity. How much neuropeptide must be injected to elicit a physiological or behavioral effect is debatable because endogenous neuropeptides exist in picomolar to femtomolar concentrations whereas nanomolar concentrations are often required to produce such effects. Such differences should be expected, however, when it is realized that the anatomical substrate mediating the behavior or effect may be quite far from the site of injection, that the preexisting endogenous peptide signal and its regulatory and feedback systems must be overwhelmed, that a gauntlet of peptidases must be negotiated, and that synaptic concentrations may indeed reach high nanomolar concentrations. Another disconcerting fact about neuropeptides is the propensity for a property or effect to be elicited by one or more apparently unrelated peptides. Although often frustrating and potentially confounding to researchers, that property can be explained by the ability of more than one sequence of amino acids to assume similar three-dimensional shapes and charge distributions, all of which may be recognized by the receptor, by the presence of multiple receptor types contained on neurons initiating the behavior, and by possible similarities between second-messenger transduction mechanisms activated by discrete and distinct peptide receptor types. The tertiary structure for recognition is also used by the immune system for the production of specific antibodies, as well as by biological receptors. Because both descriptive (immunohistochemical) and quantitative (radioimmunoassay) methods for detecting the small concentrations of endogenous peptides rely on immunological techniques, it is always possible that a similarly shaped structure could confound the interpretation of immunoassay results. Thus, descriptions of antisera specificity and amount of cross-reactivity with other potential ligands are crucial to the proper evaluation of results. The dichotomy in methodology for detecting neuronal localization of peptide versus regional peptide concentration is also seen in the tools for peptide receptor identification by

autoradiography (localization) and regional membrane preparations for receptor quantification (“grind and bind”). The analogous procedures for detecting peptide mRNA are in situ hybridization (localization), Northern blot analysis, ribonuclease protection assay, and the polymerase chain reaction for regional mRNA quantification. Measurements of neuropeptide concentration changes do not indicate which of several mechanisms may be mediating the observed changes. Increases in concentration may represent increased synthesis and release, decreased release with continued synthesis, or decreased degradation. Attempts to verify peptide turnover may be made if the mRNA concentration, peptide concentration, receptor up-regulation or down-regulation, and degradative activity are known. Although methods to achieve each of these goals are now available, they have not generally been applied in combination to the same tissue sample.

Whereas the differences between neuropeptides and the classic monoamine and amino-acid neurotransmitters are often striking, their CNS effects are similar in that they primarily excite or inhibit discrete neurons upon direct application. Because both these effects may be observed among neurons from the same region, effects observed in one location cannot be generalized to either immediate or distal neurons. However, the onset of activity is often delayed for neuropeptides (seconds) as compared with the classic transmitters (milliseconds), whereas the duration of activity can be relatively delayed for neuropeptides (minutes) as compared with most of the classic transmitters (seconds).

DISTRIBUTION

Neuropeptides are found throughout the CNS, as well as in various peripheral organs, such as the gastrointestinal tract, pancreas, and adrenal glands. Many CNS peptides, such as neurotensin and SRIF, play dual roles in the brain and gut. The full extent of any communication between the CNS and gut systems employing the same peptide is not known with certainty, but may be considerable. Although CNS neuropeptides are found predominantly in neurons, peptide receptors have been reported in glia.

Neuropeptides were originally purified from hypothalamic extracts and thus it is not surprising that some of the highest concentrations of certain neuropeptides are found in the hypothalamus. This is true for all four of the example peptides: TRH, CRF, SRIF, and neurotensin. These many other neuropeptides are also widely distributed in extrahypothalamic brain areas and may occur in either intrinsic interneurons or in longer projection neurons. Immunohistochemical and retrograde tracing studies have focused on the locations and morphological types of neurons containing SRIF. In the hypothalamus most of the SRIF-containing neurons that project to the median eminence have been shown to emanate from cell bodies mainly in the rostral periventricular nucleus, with some in the paraventricular nucleus and none in the arcuate nucleus. Thus, the other hypothalamic regions (arcuate, suprachiasmatic, ventromedial) containing SRIF neurons probably do not project to the median eminence and may perform a regulatory or feedback function on neurons containing other hypothalamic releasing factors, such as GRF, CRF, TRH, or their afferents. In the cortex of rats SRIF is found in some of the large stellate-shaped neurons and in abundance among the fusiform-shaped, nonpyramidal neurons of layers II to V, and particularly in layer V of the sensory cortex. In monkeys, however, layer III is where SRIF is predominantly located in visual, auditory, or association cortex, and cortical neurons containing SRIF are usually oriented vertically in layers II to V and horizontally in layer VI. In human entorhinal cortex, SRIF neurons are abundant in the white matter underlying the cortex and are relatively uniformly distributed throughout the cortical layers, being absent only in the outer molecular layer. A recent comparison of human and monkey distribution of the prosomatostatin-derived peptides SRIF-28, SRIF-14, and SRIF-28 $_{1\text{-}12}$ in the prefrontal cortex found reduced staining of SRIF-28 in unperfused monkeys and human brain obtained 5 hours after death, indicating that the processing of peptides may continue after death. In the rat striatum SRIF is extensively colocalized in neuropeptide-Y–containing neurons, and although not influenced by lesions of the dopamine neurons innervating the striatum, SRIF concentrations are increased by the destruction of cortical inputs. In the human hippocampus, SRIF neurons are arranged in a manner similar to that in rats and nonhuman primates, with cell bodies in the deep layers of the dentate gyrus projecting fibers to the outer two thirds of the molecular layer. In the basal forebrain region of nonhuman primates, SRIF is contained within small neurons of the nucleus basalis of Maynert, which apparently communicate with the cholinergic neurons there. Those data indicate that the neuronal cell types and afferent and efferent connections of SRIF-containing neurons vary widely among different brain regions and that species differences occur with enough frequency to render direct extrapolations between species difficult.

Many neuropeptides have now been shown to be colocalized in neurons that also contain classic transmitters, other neuropeptides, or both. Neurotensin is found in neurons containing the dopamine synthetic enzyme tyrosine hydroxylase in the ventral tegmental area and arcuate nucleus of the hypothalamus of rats. Neurotensin is found in dense-core vesicles only in tyrosine hydroxylase-positive staining cell bodies in ventral tegmental area. Other nerve terminals that were stained for neurotensin did not contain tyrosine hydroxylase. These findings are discordant with other evidence showing decreases in both dopamine and neurotensin concentrations after reserpine and the dual release of frontal cortex dopamine and neurotensin after electrical stimulation of the median forebrain bundle. Another subset of ventral tegmental area neurons projecting to the frontal cortex has been shown to contain neurotensin, cholecystokinin (CCK), and tyrosine hydroxylase. Many other examples of colocalization have been cited, including reports of three to six peptides in a single neuron. TRH colocalization with another peptide, substance P, and a classic transmitter, serotonin, has been described in a population of neurons on the median raphe nucleus and spinal cord. Corticotropin-releasing factor has been reported to be colocalized with three other neuropeptides (vasopressin, oxytocin, and neurotensin) in some neurons of the hypothalamic paraventricular nucleus in both rats and humans. Somatostatin has been found in g-aminobutyric acid (GABA) neurons of the thalamus of cats and the cortex of rats, and with neuropeptide Y in the striatum, hippocampus, and cortex. Colocalization reports may be more species specific than is generally realized, as the neurotensin-dopamine colocalization in the ventral tegmental area and frontal cortex was clearly demonstrated to be absent in humans and nonhuman primates.

The two main methods for mapping peptides, immunohistochemistry and radioimmunoassay, are complementary in their determination of neuropeptide locations and concentrations, respectively, but they do not indicate which immunoreactive neuronal cell bodies are connected to the various immunoreactive terminal fields. Through the use of retrograde tracing methods and dual staining techniques, several pathways for certain peptides have now been delineated. They include projections of amygdala neurons containing neurotensin, SRIF, or CRF to the parabrachial nucleus of the mesencephalon, and a neurotensin-containing projection from the lateral parabrachial nucleus back to the central amygdala has also been described. Two other neurotensin projections that have been observed in rats are those from the ventral tegmental area to the nucleus accumbens and from the endopiriform nucleus and prepiriform cortex to the diagonal band area. This methodology has also led to the identification of TRH neurons in the paraventricular nucleus and bed nucleus of the stria terminalis as the origin of projections to the median eminence and septum, respectively. Lesion studies with excitotoxic amino acids or electrocoagulation have also demonstrated putative connections between discrete anatomical loci, such as the increased TRH immunoreactive concentrations in the nucleus of the solitary tract after bilateral electrolytic lesions of the TRH-containing paraventricular nucleus in rats. Although such work is beginning to elucidate neuropeptide wiring diagrams in mammalian brain, the association between discrete anatomical pathways containing a neuropeptide and the behaviors or effects observed after neuropeptide administration remains nascent. One of the best examples of this kind of association is seen in the response of CRF neuronal systems to stressful stimuli. The distribution of CRF neurons in the rat CNS is illustrated in Figure 1.6-1. Radioimmunoassay studies have documented increased CRF content in the locus ceruleus and decreased CRF concentrations in the median eminence after a regimen of acute or chronic stress in rats. Other studies have shown that CRF-containing nerve terminals impinge upon noradrenergic neurons of the locus ceruleus and that exogenous CRF applied to those neurons alters their firing rate. Some of the noradrenergic locus ceruleus neurons, in turn, project to the hypothalamic paraventricular nucleus where their input increases CRF synthesis and release. Because CRF injection into the locus ceruleus elicits fearful or anxious behavior, one could postulate that stress activates the CRF neurons terminating in the locus ceruleus noradrenergic neurons and that the increased CRF content in the locus represents an increased release of the CRF in this region onto the noradrenergic cell bodies. One can further postulate that the resulting increased noradrenergic signal, and perhaps other inputs to the paraventricular nucleus of the hypothalamus, mediates the stress-induced increased release of CRF from the median eminence, which is detected as decreased CRF concentrations. Thus, both an observed increase and decrease in regional CRF content can be hypothesized as resulting from an increased release of CRF with or without concomitant new synthesis of CRF to replace the released peptide. An alternative explanation for the apparent decrease in median eminence CRF concentrations after stress versus increased concentrations in the locus ceruleus is that they are both released, but the CRF released from the median eminence is removed by the pituitary portal system whereas that in the locus ceruleus remains in the tissue that is dissected. Similar studies utilizing mRNA measures are ongoing under the hypothesis that changes in mRNA production might more accurately reflect biosynthetic rates of neuropeptide production.

Neuroendocrinology *36:*165, 1983.)

BIOSYNTHESIS

The biosynthesis of neuropeptides involves the transcription of mRNA sequences from deoxyribonucleic acid (DNA) templates contained on the appropriate genes. Since the 1980s the application of molecular biological techniques has allowed the genes of many of the various peptides to be cloned and the complementary DNA probes constructed that allow mapping of the regions where the mRNA's coding for the peptide prohormone is located. A good example of the exploitation of such techniques is provided by TRH. Although TRH was the first of the hypothalamic releasing factors to be chemically identified in 1969, the TRH precursor was the last of the releasing-factor prohormones to be described. The gene for TRH in humans resides on chromosome 3; in the rat it consists of three exons (coding regions) separated by two introns (noncoded sequences). The first exon contains the 5' untranslated end of the mRNA encoding the TRH preprohormone, the second exon contains the signal sequence and much of the remaining amino terminal end of the precursor peptide, and the third contains the remainder of the sequence, including five copies of the TRH precursor sequence, the carboxy terminal region, and the 3' untranslated region. Regions in the 5' flanking sequence correspond to promoter regions and have sequence homologies with a glucocorticoid receptor binding site and the thyrotropin b subunit gene that may regulate the expression of the TRH gene. Although some disagreement about the precise sizes of the TRH precursors exists, the TRH prohormone has been mapped immunohistochemically to regions previously shown to exhibit TRH-containing cell bodies, including the paraventricular nucleus of the hypothalamus and the raphe nuclei, whereas the axons and terminals that have been identified as containing TRH do not stain as intensely for the precursor.

The neurotensin-neuromedin N gene was originally cloned from canine ileal mucosa, and complementary deoxyribonucleic acid (cDNA) probes constructed against this form were used to clone the rat gene. The rat gene contains four exon sequences separated by three introns and spans approximately 10.2 kilobases. In the rat the neurotensin-neuromedin N sequence is contained in the fourth exon and the single copies of each peptide sequence are separated by a pair of dibasic residues. The human neurotensin gene has been localized to chromosome 12 (12q21). In pheochromocytoma (PC-12) neurons in culture, the neurotensin-neuromedin N gene is regulated by lithium, nerve growth factor, cyclic adenosine monophosphate (AMP) activators, and dexamethasone through their effects on a 5' cis-regulating region. The distribution of the neurotensin-neuromedin N mRNA is generally the same as described for neurotensin-containing neuronal cell bodies, except in the hippocampus and subiculum, where few neurons stain immunohistochemically for neurotensin and yet an abundance of the neurotensin-neuromedin N mRNA is found.

The role of 5' regulatory sequences on peptide genes has been well described for the SRIF gene. The human SRIF gene is located on chromosome 3. The regulatory region in the SRIF gene is upstream from the sequence coding the SRIF mRNA and contains the palindrome sequence of eight base pairs that is found in other genes regulated by cyclic AMP. The promoter region acts on the downstream sequence as an enhancer for transcription and exhibits both distance and orientation sensitivity for the sequence being enhanced. This cyclic AMP response element demonstrates recognition sites for protein kinases A and C and casein kinase II, which may in turn regulate that activity.

PEPTIDE PROCESSING

Because neuropeptides are first synthesized as larger precursor molecules, a wide variety of processes can come into play in the cleavage of the active peptide forms from the precursor (Fig. 1.6-2). For example, SRIF is first produced as a 116 amino acid prohormone called preprosomatostatin, and it contains a 24 amino acid signal sequence that is removed in the formation of the 92 amino acid prosomatostatin. It is further processed to either SRIF-28 or SRIF-14, and a major site of the processing step has been identified as the Golgi apparatus. The last processing step shows significant species differences, which should be considered when extrapolating between human and animal studies. For example, the 12 amino acid sequence of SRIF-28 that is cleaved in the formation of SRIF-14 is much more abundant in rodent than in human brain. The joint actions of a basophilic aminoprotease and an endoprotease contained in secretory granules cleaves SRIF-14 from SRIF-28. Most active peptide sequences are flanked by dibasic amino acids (Arg and Lys), which act as cleavage sites for the carboxypeptidase-B types of enzymes. However, SRIF-28 is cleaved at a single arginine from its prosomatostatin precursor. Related peptides are often contained in the same prohormone sequence, as is the case for neurotensin and neuromedin N. Those peptides are separated by a single pair of dibasic residues on their common mRNA and yet have distinctly different distribution patterns in the brain. Other tissues may also exhibit processing that is different from that of the brain, as is seen for neuromedin N in the mouse ileum. Multiple active peptide copies can also be contained in the prohormone structure as is noted with TRH, which has five complete copies in the mammalian 285 amino acid prohormone. Studies using antisera that recognize the intervening sequences between the five copies of TRH within the prohormone indicate that all five copies are liberated during processing. Regional differences of prohormone processing have been demonstrated within the brain, as is clearly seen for TRH. In the hypothalamus, the main storage forms of TRH are TRH, pre-pro TRH (160-169), pre-pro TRH (178-199), and two additional forms that are found in the olfactory bulb region. The differences in the ratio of TRH to its prohormone precursor in various extraneuronal tissues also indicates widely varying regional differences in processing of the TRH precursors. Processing also differs across the life cycle, as has been reported for TRH. Hypothalamic TRH prohormone processing in mice was observed to accelerate during development based on the ratio of TRH to its precursors, and immunohistochemical staining or in situ hybridization autoradiography indicated that a significant amount of processing occurred during post-Golgi transport and storage.

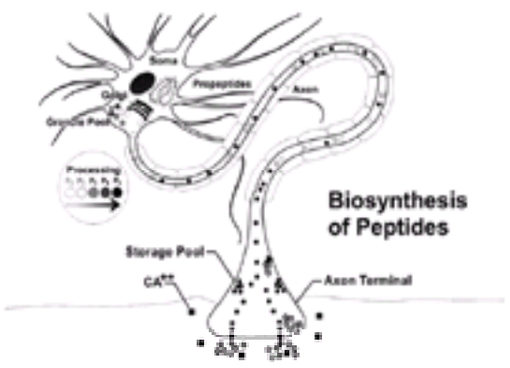

FIGURE 1.6-2 The peptide neuron. The figure shows the main steps in the chain of events from the information stored in the DNA molecule to the peripherally detected peptide fragments. The DNA sequence in the nucleus is transcribed to the mRNA molecule for further transport to the endoplasmic reticulum, where a translation takes place to form a large precursor protein (preproprotein). That protein is prepared for axonal transport by packaging into neurosecretory vesicles within the Golgi complex. During transport, the precursor protein is processed by specific cleavage enzymes into active and inactive peptide fragments. After release, the peptides are further degraded into smaller peptide fragments or constituent amino acids. (Courtesy of Thomas Davis, Ph.D.)

Although many known peptides are complete and biologically active when cleaved from the prohormone, many others are subjected to posttranslational processing. Certain peptides have a metabolically blocked carboxy terminus that is often amidated. A glycine residue in the prohormone sequence often acts as the amide donor, and in the case of TRH is attacked by a monoxygenase that is contained in secretory granules. TRH is further processed on the N-terminus where glutamine is cyclized by a glutamylcyclase. These alterations are usually effective in reducing susceptibility to degradation, and are often required for biological activity, as is the case for TRH, which is rendered inactive when the C-terminal amide is removed by proline endopeptidase to generate the free-acid structure. Other posttranslational processing events for active peptides include glycosylation and cyclization, which are often required for either biological activity or transport.

RECEPTORS AND SECOND MESSENGERS

Neuropeptide receptors have undergone the same process of discovery and characterization that receptors for other neurotransmitters have enjoyed. The process begins with the pharmacological characterization of the receptor's physicochemical binding properties by assessing the affinity of various metabolically derived and synthetic peptide fragments, and the native molecule, for the receptor binding site found in membrane preparations. Peptide receptor locations are mapped with radioactive or fluorescent tags that are inserted into peptide molecules, which often contain substituted amino acids at the most vulnerable peptidase cleavage sites. Previously, once the peptide receptor was characterized pharmacologically, it was usually purified from some relatively enriched biological tissue source or brain region by affinity column chromatography. After it had been purified, binding parameters and activity were recharacterized for the reconstituted purified receptor protein and structural information obtained by X-ray crystallography. This process was closely followed in the purification of the neurotensin-neuromedin N receptor. Because neurotensin and neuromedin N share significant sequence homology, the latter is active in displacing ligands from the neurotensin receptor, but with approximately 20 times less potency. The neurotensin receptor was first characterized by photoaffinity labeling and cross-linking of radioiodinated ligands, which resulted in two labeled subunits of about 49 Kd and 51 Kd from rat brain synaptosomes. The receptor was next solubilized and characterized for ligand affinity and binding capacity in mouse brain, which was followed by affinity column chromatographic purification and confirmation of an aggregate molecular weight of approximately 100,000. However, similar work with bovine cerebral cortex yielded a purified neurotensin receptor of approximately 72,000, indicating that significant species differences may exist. The neurotensin receptor mRNA has been cloned, and regional in situ hybridization mapping studies indicate that its distribution is generally the same as was shown for the receptor using radioactive ligands and autoradiography. The location is particularly rich in dopamine cell body regions and some dopamine terminal regions, and thus it is not surprising that dopamine neuronal activity seems to regulate neurotensin receptor expression. Neurotensin receptors have been shown to be colocalized with enzymes that degrade both neurotensin and neuromedin N in primary cultures of neurons from the forebrains of 14-day-old mouse embryos.

The much more powerful tools of molecular biology have been utilized more recently. Utilizing expression cloning techniques or a variety of low-stringency hybridization screening methods, numerous receptors and peptides have been cloned. Transfection studies allow for the production of highly enriched cell preparations expressing a variety of peptides or peptide receptors. Moreover, now that it is possible to purify mRNAs for peptide receptors, the induction of mutations allows for the identification of the regions controlling ligand binding. The distribution of receptors mapped with autoradiographic techniques has been largely verified by in situ hybridization using receptor mRNA probes. That information will make it possible to design drugs specifically to fit those binding sites on the receptor, leading to the ability to manipulate peptide systems in ways that are currently enjoyed by the more classic neurotransmitters. Finally, transgenic techniques such as targeted gene overexpression and gene knockouts or knockdowns will contribute to our understanding of the physiological roles of these peptides and their receptors.

Receptor populations for peptides exhibit changes in the numbers of binding sites on the basis of the magnitude of transmitter signal received and the input from second messenger feedback regulation. The up-regulation and down-regulation of peptide receptors has been most often demonstrated in the anterior pituitary, but has also been described in the cerebral cortex and other brain regions. Peptide receptor affinity for ligands usually remains stable in the face of this regulation of receptor number. Receptor expression fluctuates in various brain regions during development as well. Autoradiography has demonstrated high concentrations of SRIF receptors in rat somatosensory cortex at day 16 of the embryo in the intermediate zone and a transient decrease in cortical plate SRIF receptors at birth. Decreases to adult levels of SRIF receptors in somatosensory cortex are achieved by postnatal day 21. Somatostatin receptors in the cerebellum of 13-day-old rats have been shown to be pharmacologically similar to those of adults in binding parameters. Several research groups have described different classes of SRIF receptors on the basis of selective binding by various pharmacological ligands. Regional differences in the binding of SRIF-28 and SRIF-14 and their inability to desensitize each other's binding site has indicated that separate receptor populations may exist for these two forms. Further evidence for distinct populations of SRIF-28 and SRIF-14 receptors is provided by their production of different second messenger effects, and their opposite effects on potassium conductance in rat cortex. Five different SRIF receptor subtypes have been identified with molecular techniques.

Neuropeptide receptors have been associated with just about every type of second messenger signal transduction system that has been identified. Mechanisms using cyclic AMP; cyclic guanosine monophosphate (cGMP); protein kinases A and C; sodium, potassium, and calcium channels; and inositol phosphate and diacylglycerol have all been identified as neuropeptide receptor signal transduction mechanisms. Such mechanisms offer a myriad of possible modulatory effects, from the amplification to the attenuation of postsynaptic signals, and contribute greatly to the integrative power of neural networks. Both the neurotensin and the TRH receptors are internalized within the postsynaptic cell upon binding of their endogenous ligand or the appropriate agonist, where portions of the complex may eventually be transported to the receptive cell's nucleus with subsequent regulatory effects. Specific peptide receptor antagonists have been difficult to develop, with opioid antagonists being the most successful. Altered molecular forms of native peptides, such as a-helical CRF $_{9\text{-}41}$, have been used but are not ideal owing to size constraints on diffusion and lack of ability to penetrate the blood-brain barrier.

The inability to block specific neuropeptide signals pharmacologically has severely hindered research into the roles of the endogenous peptides in various behaviors and physiological effects. The disadvantages of trying to decipher a substance's role in neurotransmission by examining only the effects of excess concentrations should be obvious to even casual observers. As noted previously, this is an area in which the use of transgenic laboratory animals can be of great service, although the results are potentially confounded by differing roles for neuropeptides and receptors in early development and adulthood. More recently, several pharmaceutical companies have synthesized nonpeptidergic, lipophilic compounds that act as neuropeptide agonists or antagonists.

PEPTIDASES

Peptides are degraded to smaller fragments, and eventually to single amino acids, by specific enzymes termed *peptidases*. As yet, peptides or their fragments have not been shown to be actively taken up by presynaptic nerve terminals, as is the case for the monoamines. The enzymes may be found bound to post- or presynaptic neural membranes or in solution in the cytoplasm and extracellular fluid, and they are distributed widely in peripheral organs and serum as well as in the CNS. They often have a metal ion among their subunit components; those components form the active site for cleavage of the target peptide sequence, and that active site often forms a three-dimensional cleft where the specific peptide bond cleavage occurs. There are several general classes of peptidases, with several distinct enzymes in each class. Those classes include the serine endopeptidases containing such enzymes as trypsin and chymotrypsin; the thiol peptidases, such as pyroglutamate amino peptidase and cathepsin B and C; the acid proteases, such as pepsin and renin; the metalloendopeptidases, such as neural endopeptidase and angiotensin-converting enzymes; and the metalloexopeptidases, such as the aminopeptidases and the carboxypeptidases such as enkephalin-convertase and carboxypeptidase A and B. These degradative enzymes are often the same as those used in processing but have different subcellular locations. An example is carboxypeptidase B, which cleaves the dibasic amino acid residues flanking the active peptide sequence in the prohormone during processing, or reduces activity at the receptor if the peptide contains dibasic amino acids in the active sequence, such as neurotensin. Peptidases have pH and temperature optimums for activity and can be inhibited by various chemicals or chelators or by amino acid substitution at vulnerable points in the peptide chain. Alterations in peptidase activity or concentration can contribute to alterations in the synaptic availability of a peptide, and the regulation of peptidase levels may be as exquisitely controlled as receptor number and peptide synthesis and release. Table 1.6-2 shows the potential cleavage points for neuromedin N, neurotensin, SRIF, and TRH. Cleavage of the actively released form of the peptide usually ends or significantly reduces biological activity, but examples abound of partial or complete receptor activation by partially metabolized peptides or their fragments.

The metabolism of TRH has been investigated fairly completely, principally because of the limited number of fragments that can be generated from a tripeptide. The principal cleavage enzymes are pyroglutamyl amino peptidase, which cleaves the cyclized glutamyl residue from the C-terminus and generates a histidine-proline (His-Pro) fragment. That fragment spontaneously cyclizes into a diketopiperazine, the so-called cyclo His-Pro, after the N-terminal amide has been removed by the action of the proline endopeptidase. The active site of the pyroglutamyl amino peptidase enzyme has been shown to contain tyrosine; histidine, arginine, and possibly lysine residues, but does not contain serine, cysteine, aspartate, or glutamate. Regional differences in TRH degradation have been described, with spinal cord metabolism of TRH generating more deamidated TRH than cerebral cortex degradation. The half-life of TRH in serum is estimated at only 2 to 3 minutes, and CSF is now known to contain pyroglutamyl amino peptidase activity. Neonatal CSF has less of activity of this enzyme when compared to the CSF of adults, and differences in subcellular localization of the enzyme in the adult hypothalamus (soluble fraction) and cerebral cortex (membrane bound) has been reported as well, with the brain activity of both forms decreasing during development. Both of those TRH peptidases have been detected in the cytosol of brain homogenates, but are found only in trace amounts in the soluble fraction of synaptosomes; most of their activity is associated with synaptosomal membranes. Thyroid hormones have been shown to regulate pyroglutamyl amino peptidase in the membrane-bound fraction but not in the soluble form, although in serum the peptidase does not appear to be influenced by thyroid hormones. Thus peptidases offer yet another opportunity for the integration and regulation of neuropeptide transmitter actions and synaptic availability. Because the present peptidase inhibitors are relatively nonspecific in their ability to inhibit various peptidases, there have been few attempts to influence peptide concentrations by pharmacological blockade of their associated peptidases; however, the angiotensin-converting enzyme (ACE) inhibitors such as captopril are one exception. It is expected that second- and third-generation peptidase inhibitors, with discrete peptidase and possibly regional specificity, will be developed that eventually may allow the truly elegant manipulation of endogenous neuropeptide concentrations. In addition, the genes coding for the peptidases are being cloned, and knockout experiments will provide novel and valuable information.

NEUROENDOCRINE SECRETION

With the exception of neuromedin N, each of the example peptides are known to play major roles in pituitary-target endocrine organ regulation, including CRF-induced release of proopiomelanocortin products, such as adrenocorticotropic hormone (ACTH) and b-endorphin; TRH release of thyrotropin (thyroid-stimulating hormone [TSH]) and prolactin; and SRIF-induced inhibition of the release of growth hormone, thyrotropin, gonadotropins, and ACTH. Neurotensin, which is abundant in the hypothalamus and median eminence, may mediate the preovulatory release of luteinizing hormone and receive feedback for the induction of mRNA synthesis by estrogen, but it is not a hypothalamic hypophysiotropic hormone in the classic sense. A sexually dimorphic distribution of the neurotensin-neuromedin N mRNA in the preoptic hypothalamus also supports such a role for neurotensin in rodents.

The peptides involved in neuroendocrine regulation have cell bodies residing in the hypothalamus that receive feedback from all levels of the endocrine axes. The complexity of those interactions has been well demonstrated for the hypothalamic-pituitary-thyroid axis and the hypothalamic-pituitary-adrenal axis and have now been extended to the molecular level. The regulatory feedback of thyroid hormones onto the TRH-synthesizing neurons of the paraventricular nucleus was first demonstrated with evidence of TRH concentration changes, reported to be reduced in the median eminence after thyroidectomy, but not in the rest of the hypothalamus, and which could be prevented by thyroid hormone replacement. The treatment of normal rats with exogenous thyroid hormone decreases TRH concentration in the paraventricular nucleus and the posterior nucleus of the hypothalamus. That effect was corroborated for the TRH prohormone as well, with median eminence levels of TRH prohormone being reduced by thyroidectomy and the precursor levels increasing toward normal concentrations after thyroxine treatment. The TRH mRNA also exhibits such regulation by thyroid hormone as expected, with increased mRNA concentration in the paraventricular nucleus 14 days after thyroidectomy. Unilateral tri-iodothyronine implants prevent the increase in TRH mRNA that is seen on the contralateral untreated side in propylthioruracil-induced hypothyroidism. The effects of thyroid hormones on TRH expression in the paraventricular nucleus of developing rats are not observed until between embryo day 20 and 7 days after birth, although TRH mRNA is evident as early as embryo day 16. The ability of thyroid hormones to regulate TRH mRNA can be superseded by other stimuli that activate the hypothalamic-pituitary-thyroid axis. In that regard repeated exposure to cold (which releases TRH from the median eminence) induces increases in the levels of TRH mRNA in the paraventricular nucleus despite concomitantly elevated concentrations of thyroid hormones. Further evidence of the different levels of communication of the hypothalamic pituitary-thyroid axis are seen in the ability of TRH to regulate the production of mRNA for the pituitary TRH receptor and for TRH concentrations to regulate the mRNA coding for both the a and b subunits of the TSH molecule. The latter effect has been shown to be dependent on intracellular calcium and protein kinase C. The regulatory interplay also extends to the accessible pools of second messenger phosphoinositides, whose pool size is regulated by TRH receptor number. TRH-containing synaptic boutons have been observed in contact with TRH-containing cell bodies in the medial and periventricular subdivisions of the paraventricular nucleus, thus providing anatomical evidence for ultrashort feedback regulation of TRH concentrations there.

Regional differences in CRF receptor regulation by corticosterone have also been reported, which have been shown to partly result from differential glycosylation of the CRF receptor. The regulation of neuropeptide mRNA concentrations may be influenced by other neuropeptides, as well as by components of the particular endocrine axis normally associated with the particular peptide, as demonstrated by the ability of neuropeptide Y to increase hypothalamic CRF mRNA.

Because many endocrine systems are cyclic in their regulatory functions, it is not surprising that neuropeptides often exhibit rhythms in concentrations that are based on diurnal, lunar, and circannual periodicities. Hypothalamic and certain extrahypothalamic regional concentrations of CRF exhibit increased concentrations in the afternoon as compared to morning concentrations, and this increase can be attenuated by corticosterone only in certain brain regions such as the hypothalamus. Somatostatin, CRF, and TRH concentrations in the CSF of nonhuman primates exhibit daily fluctuations, and the monthly cycles in gonadotropins of mammals exhibiting estrus are well recognized. Circannual rhythms of neurotensin and SRIF concentrations that are 180 degrees out of phase in rodent hypothalamus have been noted. Changes in mRNA expression during development have been seen in CRF mRNA, which is present at gestational day 17, but decreases from day 19 to day 21, when concentrations again rise to attain adult levels by 4 days after birth. Other peptide mRNAs, such as SRIF, do not exhibit such fluctuations during development, but do show differential distribution during ontogeny. Daily fluctuations in rat paraventricular nucleus CRF mRNA expression are lowest during the period of highest plasma corticosterone levels during the 24-hour cycle.

NEUROPEPTIDES IN PSYCHIATRIC DISORDERS

Humans are less than ideal subjects for neuropeptide research for several reasons. The peripheral sources of many peptides, the relatively high concentration of serum peptidases, and the blood-brain barrier all conspire to render serum concentrations of CNS neuropeptides difficult to interpret at best. The use of biopsy to assess tissue concentrations directly is not routinely repeatable, is limited to superficial structures, suffers from potential morbidity, and would provide only limited information. However, CSF has been shown to reflect extracellular fluid concentrations of transmitter substances, is in direct contact with the CNS, is screened from peripheral serum sources by the blood-brain barrier, and may be sampled across time. The limitations of CSF studies include a lack of information about the regional CNS source of any concentration changes detected, the use of lumbar CSF, which is somewhat removed from higher CNS sources of peptides and subject to spinal cord peptide contributions, and the potentially confounding effects of previous drug treatments or disease episodes. Postmortem tissue studies of neuropeptide concentration changes in psychiatric disease are affected by agonal state, postmortem delay, previous drug treatment, and coexisting illnesses. Most of the data on CSF concentration changes or tissue concentration changes of neurotransmitters have been derived from comparisons between diagnostically defined psychiatric groups and control groups. However, the controls may be so-called neurologically or psychiatric controls, not healthy volunteers, and the accuracy and consistency of the diagnoses may be less than optimal. In addition, the etiology of a diagnostic class of disease may differ among subjects in the same diagnostic group. Even after matching for age, gender, or other demographic variables, heterogeneity among human research populations results in individual variations of absolute peptide values that are often quite wide. Such variations severely reduce the power of group comparisons to detect alterations in peptide concentrations. The use of pretreatment and posttreatment CSF samples, or of samples taken during the active disease state versus when the patient is in remission, has begun to address the serious limitations in study design. For such progressive diseases as schizophrenia or Alzheimer's disease, serial CSF samples may be a valuable indicator of disease progression or response to treatment. Even with these constraints, significant progress has been made in describing the effects of various psychiatric disease states on neuropeptide systems in the CNS.

Alzheimer's Disease Dementia of the Alzheimer's Type represents up to two thirds of the demented population encountered in clinical practice, and over half of the nursing home beds in the United States are currently occupied by such patients. The disease is characterized by a progressive, gradually worsening dementia that cannot be ascribed to metabolic disorders, pharmacological treatment, or infectious agents and is neuropathologically associated with the pathological presence of senile plaques and neurofibrillary tangles within the CNS. The first described specific neurochemical deficit to be associated with Alzheimer's disease was reduced amounts of choline acetyltransferase-containing nerve terminals in cortical regions as a result of degeneration of cholinergic neuronal perikarya in the nucleus basalis of Meynert in the substantia innominata region of the basal forebrain. Within a few years of that finding, SRIF was found to be markedly reduced in concentration in the cerebral cortex of Alzheimer's disease patients. Subcortical regions containing SRIF, such as the substantia innominata, hypothalamus, and bed nucleus of the stria terminalis, were spared whereas SRIF receptors in the cortex were decreased in number. In regions such as the hippocampus, findings of SRIF depletions were less consistent than in the cortex, but when depleted in the hippocampus, the SRIF neurons colocalized with neuropeptide Y were spared. Somatostatin concentration in the CSF of Alzheimer's disease patients has also been consistently found to be decreased, and this decrease has been correlated with the magnitude of cognitive impairment. Therapies that slow or partially reverse the dementia associated with Alzheimer's disease have been reported to also partially reverse the decrease in CSF SRIF. However, CSF SRIF concentrations are also decreased in delirium, major depressive disorder, schizophrenia, multiple sclerosis, and dementia associated with Parkinson's disease. Increased activity of an SRIF cleaving peptidase have been described in certain cortical regions of the brain tissue of persons with Alzheimer's disease, raising the possibility that increased SRIF degradation may contribute to the decreases in SRIF concentration observed. Treatment of Alzheimer's disease patients with SRIF infusion systemically, however, has not been successful in reversing the dementia, probably because of poor penetration across the blood-brain barrier. In experimental animals cysteamine depletion of hippocampal SRIF leads to deficits in performance on tasks requiring retention of information. It is unclear whether the neuropeptide deficits precede, succeed, or occur in tandem with the cholinergic deficits seen in Alzheimer's disease, and whether the neurochemical systems and regions first exhibiting deficits are the site of the onset of pathology.

The CRF-containing interneurons of the cortex are also consistently depleted in Alzheimer's disease (Fig. 1.6-3). As with SRIF, subcortical areas containing CRF neurons may be spared, but unlike SRIF, CRF receptors are increased in number (up-regulated) with no change in affinity. Various research groups have reported the CRF concentrations in the CSF of patients with Alzheimer's disease to be increased, decreased, or unchanged; these inconsistencies are likely due to when the CSF sample was obtained. Other peptides have been shown to be altered less consistently in Alzheimer's disease, such as substance P or neurotensin, whereas most peptides are reported to be unchanged, including TRH, vasoactive intestinal peptide, CCK, and the enkephalins. Only one peptide, galanin, is reported to be reliably increased in concentration in Alzheimer's disease. Novel agonists at peptide receptors such as CRF or SRIF may allow for the development of new treatments; currently, compounds that increase the availability of CRF by competing for the binding site on the CRF-binding protein are being planned for clinical trial in Alzheimer's disease patients.

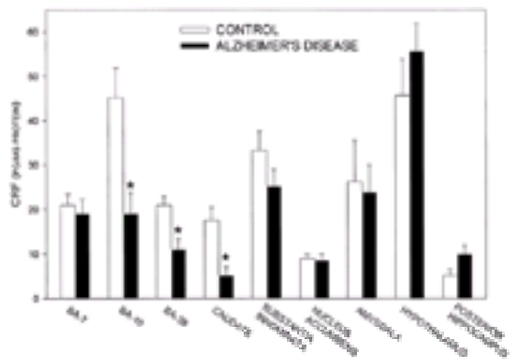

FIGURE 1.6-3 Regional brain concentrations of CRF in patients with dementia of the Alzheimer's type and in controls. *N* = 7-13 per group. Data presented as mean ± SE 7 * P < 0.01 by Student's *t*-test. (Data derived from Bissette G, Reynolds GP, Kilts CD, Widerlov E, Nemeroff CB: Corticotropin-releasing factor like immunoreactivity in senile dementia of the Alzheimer type. JAMA *254:*3067, 1985.)

Mood Disorders

Corticotropin-Releasing Factor After a search spanning nearly three decades, CRF was isolated and characterized in 1981 as a 41-amino acid peptide. CRF is the primary hypothalamic ACTH-secretagogue in most species; it also functions as an extrahypothalamic neurotransmitter in a CNS network that apparently coordinates global responses to stressors. CRF and its homologs represent an ancient family of peptides subserving numerous functions. In higher organisms, including mammals, convincing evidence supports the hypothesis that CRF plays a complex role in integrating the endocrine, autonomic, immunological, and behavioral responses of an organism to stress.

Hyperactivity of the hypothalamic-pituitary-adrenal axis in major depressive disorder remains one of the most consistent findings in biological psychiatry. The reported hypothalamic-pituitary-adrenal axis alterations in major depression include hypercortisolemia, resistance to dexamethasone suppression of cortisol secretion, blunted ACTH responses to intravenous CRF challenge, and elevated concentrations of CRF in CSF. The exact pathological mechanisms underlying hypothalamic-pituitary-adrenal axis dysregulation in major depressive disorder and other mood disorders remains to be elucidated. Defects have been postulated to exist at corticolimbic loci, hypothalamic loci, or both.

Once the phenomenon of hypothalamic-pituitary-adrenal axis hyperactivity in patients with major depression was established, many clinical research groups utilized various provocative neuroendocrine challenge tests as a “window into the brain” in attempts to elucidate pathophysiological mechanisms. In normal subjects the CRF stimulation test, using either rat or human CRF or ovine CRF, yields robust ACTH, b-endorphin, b-lipotropin, and cortisol responses following intravenous or subcutaneous administration. However, in patients with major depressive disorder, blunting of ACTH or b-endorphin secretion with a normal cortisol response has been repeatedly reported. Patients with posttraumatic stress disorder, 50 percent of whom also fulfill the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) criteria for major depressive disorder also show blunted ACTH secretion in response to a CRF challenge. Importantly, researchers have reported normalization of the ACTH response to CRF following clinical recovery from depression, suggesting that the blunted ACTH response, like dexamethasone nonsuppression, may be a state marker for depressive disorders.

Mechanistically, two hypotheses have been advanced to account for the ACTH blunting following exogenous CRF administration. The first hypothesis suggests that pituitary CRF receptor down-regulation occurs as a result of hypothalamic CRF hypersecretion. The second hypothesis postulates altered sensitivity of the pituitary to glucocorticoid negative feedback. Substantial support has accumulated favoring the first hypothesis. It should be kept in mind that neuroendocrine studies represent a secondary measure of CNS activity; the pituitary ACTH responses principally reflect the activity of hypothalamic CRF rather than that of the corticolimbic CRF circuits, which are most likely to be involved in the pathophysiology of depression.

A potentially more direct method for evaluation of extrahypothalamic CRF tone may be obtained from measurements of CRF concentrations in CSF. A marked dissociation between CSF and plasma neuropeptide concentrations has been described, thus indicating that neuropeptides are secreted directly into CSF from brain tissue as opposed to being derived from plasma-to-CSF transfer. Evidence that CRF concentrations in CSF originate from nonhypophysiotropic CRF has been obtained from studies in which CRF concentrations in CSF were repeatedly measured over the course of the day. Two independent research groups reported that CRF concentrations in the CSF of in rhesus monkeys are not entrained with pituitary-adrenal activity. The proximity of corticolimbic, brainstem, and spinal CRF neurons to the ventricular system suggests that these areas make substantial contributions to the CRF pool in CSF.

A series of studies have demonstrated significant elevations of CRF concentrations in the CSF of drug-free patients with major depression or following suicide (Fig. 1.6-4). Additionally, severity of depression appears to correlate significantly with CRF concentrations in the CSF of patients with anorexia nervosa, multiple sclerosis, and Huntington's disease. The elevation of CRF concentrations in the CSF of patients with anorexia nervosa reverts to the normal range as these patients approach normal body weight. No alterations of the concentrations of CRF in CSF have been reported in other psychiatric disorders including mania, panic disorder, and somatization disorders as compared to controls.

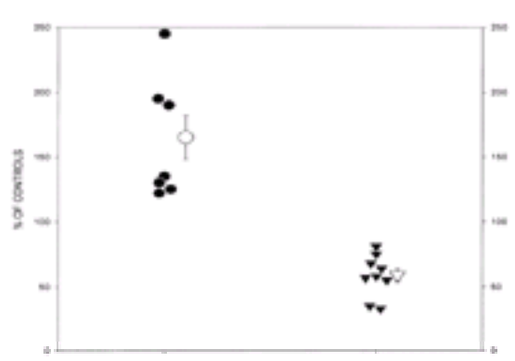

FIGURE 1.6-4 Scatterplot showing the mean cerebrospinal fluid neuropeptide values in patients with major depression. Each individual point represents an individual study. Mean % Control ± SEM for all studies shown by hollow symbols. (Adapted from Owens MJ, Plotsky PM, Nemeroff CB: Peptides and affective disorders. In *Biology of Schizophrenia and Affective Disorders,* SJ Watson, editor. American Psychiatric Press, Washington, DC, 1996.)

Of particular interest is our demonstration that the elevated concentrations of CRF in CSF in drug-free depressed patients are significantly decreased 24 hours after their final ECT treatment, indicating that CSF CRF concentrations, like hypercortisolemia, represent a state rather than a trait marker; other recent studies have confirmed the normalization of CRF concentrations in CSF following successful treatment with fluoxetine. One group demonstrated significant reduction of elevated CRF concentrations in the CSF of 15 female patients with major depression who remained depression free for at least 6 months following antidepressant treatment as compared to little significant treatment effect on the CRF concentrations in the CSF of 9 patients who relapsed in this 6-month period. This suggests that elevated or increasing CRF concentrations in CSF during antidepressant drug treatment may be the harbinger of a poor response in major depressive disorder despite early symptomatic improvement. Interestingly, treatment of normal subjects with desipramine fluoxetine-containing antidepressants is associated with a reduction in the concentration of CRF in CSF.

In preclinical studies, CRF hypersecretion is associated with CRE-receptor down-regulation. Depression is a major determinant of suicide more than 50 percent of completed suicides are accomplished by patients with major depressive disorder. If CRF hypersecretion is a characteristic of depression, evidence of related CRF-receptor down-regulation should be evident in the CNS of depressed suicide victims. Indeed, it has been reported that there is a marked (23 percent) decrease

in the density of CRF receptors in the frontal cortex of suicide victims as compared to matched control samples; these findings have been confirmed in a second study.

Somatostatin Like a number of other neuropeptides, somatostatin was serendipitously discovered during attempts to purify growth hormone-releasing factor (GRF). As the name implies, SRIF inhibits the release of growth hormone from the anterior pituitary. Since its structural identification 20 years ago, SRIF has been unequivocally shown to be the major inhibitory influence on growth hormone secretion. Also, SRIF fulfills a number of criteria for neurotransmitter status within the CNS. The acceptance of a role for SRIF as a neurotransmitter has led to its investigation in a number of psychiatric and neurological diseases. Nonhyphysiotropic SRIF-containing neurons may play a role in a number of disorders including but not limited to depressive disorders, dementia, and epilepsy.

Like many other neuropeptide transmitters, central administration of SRIF produces a variety of behavioral and physiological effects. Briefly, the peptide produces a non–opioid-mediated analgesia in animals and man. Sleep patterns, food consumption, locomotor activity, and memory processes are also altered by central SRIF administration. Of particular interest is the fact that the sleep, eating, psychomotor activity, and anterior pituitary hormone secretion are all altered in depressed patients. Investigation of a role for this peptide in mood disorders was therefore of interest. The clearest evidence for involvement of SRIF in psychiatric illness has come from studies of major depression. A consistent decrease has been reported in SRIF concentrations in the CSF of drug-free depressed patients (Fig. 1.6-4). Research has revealed that a number of neuropeptides in CSF are almost exclusively of central origin, though the actual sites of production remain obscure. Decreases in SRIF concentrations in CSF are proposed to be the result of decreased neuronal synthesis and release. Whether this is a primary or secondary effect of the illness is unknown. Moreover, although SRIF levels in CSF did not correlate with severity of depression, clinically improved patients exhibited a rise in SRIF towards normal concentrations. In nine patients with bipolar I disorder followed longitudinally, SRIF concentrations in CSF were significantly decreased during the major depressive episode state versus mood-improved manic episodes.

Although the data is still relatively limited, overview of the extant literature suggests that decreases in concentrations of SRIF in CSF are a consistent state-dependent finding in depression. Indeed, secondary to the hypercortisolemia associated with depression, this is one of the more consistent findings in biological psychiatry. However, the finding has little apparent diagnostic usefulness because similar changes are observed in a number of neurological disorders without psychiatric comorbidity. However, reductions in SRIF concentrations in CSF do appear to be associated with impairment in cognitive function. Some investigators have suggested that the decrease in SRIF concentrations in CSF may be related to the hypothalamic-pituitary-thyroid axis overactivity commonly found in patients with depression. Whether one is responsible for the other, or whether both are responses to dysregulation of other neurotransmitter systems associated with depression is unknown. Rational design of peptide or nonpeptide-based drugs selectively active at different SRIF receptor subtypes will certainly aid in understanding its role in behavior, and may ultimately lead to novel therapeutic agents.

Thyrotropin-Releasing Hormone The early availability of adequate tools such as assays and synthetic peptides to assess hypothalamic-pituitary-thyroid axis function, coupled with observations that primary hypothyroidism is associated with depressive symptomatology, ensured extensive investigation of the involvement of this axis in mood disorders. Indeed, TRH, a pyroglutamylhistidylprolinamide tripeptide, was the first of the hypothalamic-releasing hormones to be isolated and characterized.

Early studies established the hypothalamic and extrahypothalamic distribution of TRH. The extrahypothalamic presence of TRH quickly led to speculation that TRH might function as a neurotransmitter or neuromodulator; indeed, a large body of evidence supports such a role for TRH.

Interest in putative CNS actions of TRH were stimulated by studies of the hypothalamic-pituitary-thyroid axis and depression by Prange and colleagues. In the 1970s it was hypothesized that thyroid function was integral to the pathogenesis of, and recovery from, mood disorders because of the copious interactions among thyroid hormones, catecholamines, and adrenergic receptors in the CNS. Overall, these studies suggest a role for thyroid dysfunction in refractory depression and are consonant with clinical studies that suggest the existence of an increased rate of hypothyroidism among patients with refractory depression.

The use of TRH as a provocative agent for assessment of hypothalamic-pituitary-thyroid axis function evolved rapidly after its isolation and synthesis. Clinical use of a standardized TRH stimulation test revealed blunting of the TSH response in approximately 25 percent of euthyroid patients with major depression; these data have been widely confirmed.

The observed TSH blunting in depressed patients does not appear to be the result of either excessive negative feedback resulting from hyperthyroidism or to SRIF hypersecretion. In fact, depressed patients exhibit reduced CSF concentrations of SRIF. It is possible that TSH blunting is a reflection of pituitary TRH receptor down-regulation as a result of median eminence hypersecretion of endogenous TRH. Indeed, the observation that concentrations of TRH in CSF are elevated in depressed patients as compared to controls supports the hypothesis of TRH hypersecretion but does not elucidate the regional CNS origin of this tripeptide. These elevations may be relatively specific to depression because no such alteration has been reported in patients with Alzheimer's disease, anxiety disorders, or alcoholism. Some investigators have suggested that the development of autoimmune thyroiditis gives rise to hypersecretion of hypothalamic TRH as a compensatory mechanism to maintain normal plasma triiodothyronine (T_3) and thyroxine (T_4) concentrations. Clearly, further studies in which CSF TRH concentrations in CSF are measured are needed.

Schizophrenia Both clinical and postmortem investigations of schizophrenia patients, as well as animal studies, have sought to elucidate the role of neuropeptides in the pathological manifestations of schizophrenia. Although constrained by diagnostic uncertainties and drug treatment effects, the research to date on the postmortem brain tissue of schizophrenia patients has not revealed major alterations of neuropeptide systems. A number of peptides (endogenous opioids, substance P, cholecystokinin [CCK], SRIF) have been reported to be altered in the CSF of schizophrenia patients, but many of these findings either have not been independently reproduced or describe a marginally statistically significant difference in CSF peptide concentrations among groups of patients and controls with variance of over 100 percent around the mean. Further confounds are the effects of treatment with antipsychotic drugs on peptide systems; such drugs have been described for regional neurotensin, CCK, substance P, and SRIF concentrations in laboratory animals. How much time is necessary to abolish those drug-induced alterations of neuropeptide system concentration changes is not known for humans, but may significantly exceed the 2 to 3 weeks of drug holiday used in most clinical studies.

The most likely candidate neuropeptide with evidence of selective alteration in schizophrenia is neurotensin. It was first shown to have pharmacological interactions with dopamine while undergoing characterization of its potent hypothermic and sedative potentiating activity. Subsequent work indicated that neurotensin possessed many properties that were also shared by antipsychotic drugs, including the ability to inhibit avoidance responding, but not escape, in a conditioned active avoidance task; the ability to block the effects of indirect dopamine agonists or endogenous dopamine in the production of locomotor behavior; and the ability to elicit increases in dopamine release and turnover. Unlike antipsychotic drugs, neurotensin is not able to displace dopamine from its receptor; neurotensin is colocalized in certain subsets of dopamine neurons and is coreleased with dopamine in the mesolimbic and medial prefrontal cortex dopamine terminal regions that are implicated as the site of dopamine dysregulation in schizophrenia. Antipsychotic drugs that act at dopamine type 2 (D_2) and D_4 receptors increase the synthesis and concentration of neurotensin in those dopamine terminal regions but not in others. That effect of antipsychotic drugs in increasing neurotensin concentrations persists after months of treatment and is accompanied by the expected increase in neurotensin mRNA concentrations, as well as expression of the “immediate early gene” c- *fos* and the transcription factor Fos within hours of initial drug treatment. The altered regulation of neurotensin expression by antipsychotic drugs apparently extends to the peptidases that degrade the peptide; recent reports have revealed decrease neurotensin metabolism in rat brain slices 24 hours after the administration of haloperidol.

Decreased neurotensin concentrations in CSF have been reported in several populations of patients with schizophrenia when compared to controls or patients with other psychiatric disorders. Although treatment with antipsychotic drugs has been observed to increase neurotensin concentrations in the CSF, it is not known whether this increase is causal or merely accompanies the decrease in psychotic symptoms seen with successful treatment. Postmortem studies have shown an increase in neurotensin concentrations in the dopamine-rich Brodmann's area 32 of the frontal cortex, but that result may have been confounded by premortem antipsychotic treatment. Other researchers have found no postmortem alterations in neurotensin concentrations of a wide sampling of subcortical regions. A comparison of the genomic sequence of the neurotensin neuromedin N gene in schizophrenia patients compared with age- and sex-matched controls found no differences in the gene sequence in the coding region. A critical test of the hypothesis that neurotensin may act as an endogenous antipsychotic-like substance awaits the development of a neurotensin receptor agonist that can penetrate the blood-brain barrier.

1.7 NEUROTROPHIC FACTORS

ERIC STEPHEN LEVINE, PH.D. AND IRA B. BLACK, M.D.

Trophic factors are survival molecules that are essential for the development of the nervous system. These factors regulate a wide range of developmental events that transcend their survival-promoting effects, including modulation of neurite outgrowth, phenotypic differentiation, and synaptogenesis. In addition to their roles during development, trophic factors regulate neuronal function and response to injury throughout life. The neurotrophin gene family is a widely distributed group of factors that subserves multiple functions in the nervous system. Neurotrophic factors have been implicated in pathophysiological mechanisms underlying neuropsychiatric disease, including schizophrenia and depression. These factors may also be important in neurodegenerative disorders such as Alzheimer's disease, Huntington's disease, and Parkinson's disease; each involves the selective loss of a neurotrophin-sensitive neuronal population.

NEUROTROPHINS AND THEIR RECEPTORS

The prototypical trophic factor is nerve growth factor (NGF), discovered by Rita Levi-Montalcini and Viktor Hamburger in the 1950s. NGF was originally isolated based on its ability to dramatically promote neurite outgrowth from sympathetic and sensory ganglia. It was later discovered to be essential for the survival and development of peripheral sympathetic and certain sensory neuronal populations. In the absence of NGF or when its action is blocked, there is a virtually complete loss of these responsive neuronal populations. Importantly, specific neuronal systems in the brain also respond to NGF and related trophic factors, greatly expanding their functional roles.

NGF is one member of a gene family of closely related trophic factors known as *neurotrophins*. This family includes brain-derived neurotrophic factor (BDNF), neurotrophin-3 (NT-3) and NT-4/5, each of which shares high-sequence homology with NGF. These factors are expressed in neurons and glial cells throughout the nervous system. BDNF, NT-3, and NT-4/5 are found in virtually all areas of the brain, with highest levels of expression in the cerebral cortex and hippocampus. The distribution of NGF is much more restricted, with expression in cortex and hippocampus, but low levels in most other areas. Neurotrophin expression reaches its peak during development, but persists throughout life. Neurotrophin expression is also increased following specific neuronal insults, suggesting roles in responses to injury.

The biological effects of neurotrophins are mediated via binding to specific transmembrane receptors that trigger changes in intracellular second messengers. Neurotrophins bind to two distinct classes of receptor. Members of the trk tyrosine kinase receptor family appear to mediate most of the biological actions of these factors. The trk family consists of three related receptors, trkA, trkB, and trkC. TrkA is the primary receptor for NGF, trkB for BDNF and NT-4/5 and trkC for NT-3, although NT-3 also interacts at lower affinity with trkA and trkB as well (Fig. 1.7-1). These receptors have intrinsic tyrosine kinase activity and become autophosphorylated upon binding of the appropriate ligand. Phosphorylated tyrosine residues, in turn, provide binding sites for several downstream second messenger signals that attach to recognition sites (e.g., *src* homology 2 [SH-2] domains) on the intracellular domain of the trk receptor. The diverse second messengers include various protein kinases and transcription factors. These multiple, parallel signaling pathways evoke distinct biological effects on neurons, such as neurite outgrowth or survival itself.

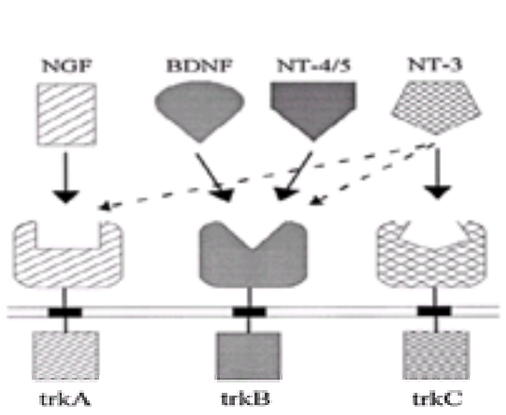

FIGURE 1.7-1 Schematic representation of the ligand-receptor relationship between neurotrophins and the trk family of tyrosine kinase receptors. Primary ligand-receptor interactions are indicated by thick arrows; secondary interactions are indicated by thin, dashed arrows. Only full-length receptor isoforms are depicted in this diagram. (Adapted from Barbacid M: J Neurobiol *25:*1386, 1994.)

The distribution of trk receptors is widespread in the nervous system; trkB and trkC, in particular, are expressed in virtually all regions of the brain, with highest levels in cortex and hippocampus. They are also found in thalamus, hypothalamus, cerebellum, basal ganglia, and brainstem, implying functional roles within neuronal populations subserving diverse functions, such as sensory perception, motor activity, endocrine regulation, cognition, motivation, and emotion. Distribution of the trkA receptor is more restricted, with high levels of expression only in the striatum and basal forebrain, suggesting that NGF acts on a limited population of central neurons.

Several different isoforms of the trk receptors are expressed in the nervous system. These splice variants are encoded by alternate messenger ribonucleic acid (mRNA) derived from the *trk* genes. In addition to the full-length, signaling receptors, *trk*B and *trk*C receptors are expressed in truncated forms. These truncated receptors contain the extracellular, ligand-binding domain, but lack the intracellular tyrosine kinase signaling domain. Functional roles of these receptors are unclear, but they may act as dominant-negative inhibitors of trk signaling or they may play a role in ligand clearance or presentation. The truncated receptors are the major variant expressed by glial cells. Expression of truncated forms is also higher during maturity than during development. These alternate receptor forms may provide added flexibility in neurotrophin signaling.

In addition to high-affinity binding to respective trk receptors, all the neurotrophins bind with relatively equal (and lower) affinity to the common neurotrophin receptor, known as *p75*. The functional role of this receptor is unclear. It is a member of the tumor necrosis factor family and may play roles in cell death. Signaling mechanisms mediated by p75 have not been readily identified but are thought to include activation of the sphingomyelin pathway. In some cellular populations, (e.g., oligodendrocytes), activation of p75 can trigger death, in contrast to the survival-promoting effects associated with neurotrophin signaling via trk receptors. Thus, differential expression of these two receptor systems may provide a mechanism for balancing opposing neurotrophin effects.

REGULATION OF GENE EXPRESSION

To appreciate the physiological significance of neurotrophin action in the brain, it is essential to understand the regulation of availability. In peripheral target organs, neurotrophins are synthesized and released constitutively by nonneuronal cells, independent of the influence of innervating neurons. In the brain, however, neuronal expression of neurotrophin genes is modulated by impulse activity itself. For example, trophin expression in vivo in the hippocampus and neocortex is increased by limbic seizures. Dramatic increases in NGF and BDNF mRNA concentrations are produced by different methods of seizure induction, including dentate gyrus lesions, kainic acid injections, and electrical stimulation. Increased neurotrophin expression may facilitate further seizure activity, suggesting potential roles in mechanisms

underlying epilepsy and kindling.

Specific mechanisms governing activity-dependent regulation of trophin gene expression have been characterized in vitro. Direct pharmacological depolarization markedly increases hippocampal neuron NGF and BDNF mRNAs, potentially leading to increased protein concentrations. BDNF expression increases almost fourfold within 3 hours and attains a maximal increase within 6 hours whereas NGF mRNA exhibits a smaller and more sluggish response. Activation of specific neurotransmitter receptors mimics these effects. In particular, excitatory glutamatergic and cholinergic inputs increase neurotrophin mRNAs and inhibitory g-aminobutyric acid (GABA)-ergic inputs decrease message levels. The persistent activation of neurotrophin genes by transient electrical activity may be critical in triggering changes in downstream gene expression. In turn, these sequelae may result in long-term changes in neuronal function.

Neurotrophins and Long-Term Potentiation Direct stimulation of intrinsic anatomical pathways also regulates neurotrophin gene expression, providing a critical physiological context. In vivo, pharmacological activation of hippocampal afferent pathways increases BDNF and NT-3 mRNAs. Electrical stimulation evokes similar effects in vitro. Of particular interest is the relationship between neurotrophin gene expression and long-term potentiation, which is a form of activity-dependent synaptic plasticity most commonly studied in the hippocampus; it has been invoked as a cellular substrate for learning and memory. Stimulation patterns that induce long-term potentiation increase both BDNF and neurotrophin-3 messages in the hippocampus. Moreover, gene knockout animals with null mutations (i.e., inactivation) of the BDNF gene exhibit impaired long-term potentiation, which supports the contention that neurotrophins play critical roles in synaptic plasticity and perhaps in memory.

Neurotrophins and Stress Neurotrophin gene expression in the brain is modulated by stressful stimuli, with potential relevance to neuropsychiatric disease. Physiological responses to stress resemble symptoms of depression, and chronic stress exacerbates clinical depression. Chronic stress also increases neuronal vulnerability to a wide variety of insults (e.g., metabolic toxins, seizure activity), mediated at least in part by increased circulating glucocorticoids. BDNF expression is decreased in response to short-term or long-term stressors (e.g., forced immobilization), which may contribute to resulting hippocampal damage. NT-3 mRNA levels increase in response to stress whereas treatment with antidepressant agents produces a decrease. It is not yet clear whether these changes in neurotrophin availability play a role in adaptive changes. These complex interactions between environmental stimuli and neurotrophins may mediate cognitive changes that occur in response to stress and in the course of psychiatric or degenerative disease, an area that is being actively studied.

Although the regulation of neurotrophin gene expression has been intensely studied, much less is known about the mechanisms underlying neurotrophin release. This is crucial, however, because it is only after release and subsequent receptor binding that neurotrophins exert biological effects. Recent studies have begun to identify the mechanisms that control neuronal neurotrophin release. In the hippocampus, both NGF and BDNF are released from neuronal axon terminals and dendritic processes in an activity-dependent manner. Atypically, release is dependent on sodium, but independent of extracellular calcium, although intracellular calcium stores are involved. Much remains to be elucidated concerning the spatial localization and kinetics of trophin release. Nevertheless, activity-dependent regulation of neurotrophin gene expression and release provides a set of mechanisms through which the external or internal environment may regulate availability.

ROLES OF NEUROTROPHINS DURING DEVELOPMENT

Neurotrophins play an essential role in coordinating diverse developmental processes. The most dramatic effects of NGF are on the survival of peripheral sensory and sympathetic neurons. During development, there is widespread, naturally occurring cell death, and the survival of many neuronal populations appears to be dependent on access to target-derived trophic factors. In many targets, neuronal innervation density is proportional to NGF synthesis. Thus, the neurotrophic hypothesis states that competition for limiting amounts of neurotrophins provides a mechanism to match the number of afferent neurons to target size. Lack of NGF results in the loss of most sympathetic and some sensory neurons. Exogenous NGF, on the other hand, rescues a larger number of neurons than normally survive during the period of developmental cell death.

The effects of neurotrophins on survival are complex and appear to be critically dependent on the specific cellular context. Neuronal cell death arises from two distinct processes: apoptosis or necrosis. Apoptotic or programmed cell death is an active process requiring new protein synthesis, and can be induced in vitro by serum deprivation or calcium channel blockers. This type of cell death is commonly associated with development as well as with neurodegenerative disease. Apoptosis can be markedly reduced or prevented by treatment with neurotrophic factors, consistent with their role as survival-promoting agents. Neurotrophins also prevent cell death after axotomy, an apoptotic type of cell death caused by trophic factor deprivation. However, necrotic cell death often occurs after an acute insult or injury, such as oxygen-glucose deprivation; this type of cell death can be enhanced by neurotrophins under some conditions. The situation is complicated by the fact that both necrotic and apoptotic cell death occur under most complex conditions, such as stroke and brain trauma. Thus, the therapeutic potential of trophic factors after neuronal injury may be critically related to the specific nature of the insult, the temporal profile of the derangement, and its physiological context.

Trophic factors exert widespread actions throughout the nervous system and are not limited to the foregoing examples. Other neurotrophin family members act on specific neuronal populations during development. For example, BDNF, NT-3, and NT-4/5 promote the survival of developing motor neurons. BDNF and NT-4/5 acting through the trkB receptor, promote the survival of nodose ganglion neurons. BDNF also increases expression of substance P in neural–crest-derived sensory neurons. Many other neurotransmitter and neuropeptide systems are also targets for neurotrophin modulation.

NEUROTROPHINS IN THE CENTRAL NERVOUS SYSTEM

Neurotrophins and their receptors are widely distributed in the central nervous system, with distinct differences in modes of action from the peripheral model. Trophic support in the central nervous system can be derived from target neurons as well as afferent neurons and local support cells, including astrocytes, oligodendrocytes, and microglia. In addition, brain neurons are not critically dependent on a single factor for survival, but instead have overlapping trophic dependence. This has been most clearly shown in animals with targeted inactivation of specific neurotrophin genes or their receptors. Although specific peripheral neuronal populations are severely depleted in these animals, there is little dramatic neuronal loss in the brain.

One of the best-characterized NGF-responsive cell populations in the brain are the cholinergic neurons of the basal forebrain. These neurons provide a dense modulatory input to the hippocampus. Taken together, the basal forebrain-hippocampal system plays a central role in attention, learning, and memory, with a particular emphasis on spatial learning and declarative memory. The prominent degeneration of basal forebrain cholinergic neurons in dementia of the Alzheimer's type is thought to be responsible for many of the ensuing cognitive deficits of the disorder. NGF enhances the survival of these neurons after axotomy or injury in animal models, and modulates neuronal function by increasing activity of choline acetyltransferase, an essential enzyme in acetylcholine biosynthesis. Thus, NGF may be clinically efficacious in rescuing this degenerating neuronal population and enhancing function of surviving neurons in disease states, with potential therapeutic implications.

NGF also has actions in the spinal cord that play a role in nociception. NGF promotes the survival of pain fibers and induces expression of voltage-gated ionic conductances in spinal nociceptive neurons, including induction of the peripheral nerve-type PN-1 sodium channel, which may play a role in the regulation of nociception. Animals with a targeted deletion of the NGF gene or chronic exposure to NGF blocking antisera exhibit decreased responsiveness to pain and temperature and a selective loss of small-diameter dorsal root ganglion neurons. Trophic factor interventions may therefore be useful in alleviating chronic pain syndromes.

BDNF and NT-4/5 acting via the trkB receptor, have a range of effects on multiple neuronal populations implicated in neuropsychiatric and neurodegenerative disease. These include the basal forebrain cholinergic neurons as well as dopaminergic neurons of the substantia nigra. Degeneration of nigral dopamine neurons results in the motor deficits observed in Parkinson's disease. BDNF enhances expression of dopamine synthetic enzymes, and protects these cells from exogenous neurotoxins. Trophic factors also increase axonal sprouting, resulting in increased connectivity with target neurons that may compensate for neuronal loss. This range of actions provides potential therapeutic opportunities for treating degenerative disease.

BDNF has also been implicated in the pathophysiology of mood disorders, including depression. Current treatment for clinical depression centers on enhancement of serotonergic neurotransmission, through the use of serotonin-specific reuptake inhibitors. Administration of BDNF also evokes antidepressant-like effects in some animal models, which may result from changes in the activity of serotonergic systems. BDNF promotes sprouting of serotonergic axons, increases serotonin synthesis, and dramatically enhances the survival of these neurons after exposure to neurotoxins. Because the typical therapeutic effects of antidepressant medications take several weeks to achieve clinical efficacy, it is possible that growth–factor-induced changes in neuronal morphology or connectivity might play a role in these processes. Thus, BDNF may ameliorate neuropsychiatric conditions that involve dysfunction of monoaminergic (e.g., serotonergic, noradrenergic) systems.

Neurotrophins and Synaptic Transmission Synapses are the main communicative junctions between neurons, and modulation of synaptic transmission is thought

to be central to learning and memory, cognition, and plasticity of circuits underlying motivation and emotion. In addition to well-established effects on neuronal survival, growth, and differentiation, recent work indicates that neurotrophins also acutely regulate synaptic efficacy, greatly expanding their functional relevance. Neurotrophins affect synaptic transmission through multiple mechanisms of action, including induction of ion channel expression, enhancement of presynaptic neurotransmitter release, and modulation of postsynaptic receptor responsiveness. These newly discovered effects have been identified both in the developing and mature nervous systems, indicating that mechanisms responsible for the formation of neural circuits during development also play roles in the dynamic regulation of activity within established circuits.

Direct presynaptic effects on neurotransmitter release have been best characterized at the neuromuscular junction, one of the more accessible and easily studied synapses in the nervous system. At developing neuromuscular synapses in culture, BDNF and NT-3 potentiate evoked synaptic currents within minutes of exposure by enhancing acetylcholine release from presynaptic nerve terminals. Increased transmitter release results from local effects at the terminal and does not require cell body signaling. In addition to this short-term effect, long-term exposure to BDNF or NT-3 for several days enhances synaptic maturation through effects on presynaptic processes. Similar effects are observed in mammalian systems in vitro, where NGF and BDNF directly potentiate the release of acetylcholine and glutamate in the hippocampus and cortex. Moreover, this enhanced transmitter release augments synaptic transmission in a subpopulation of neurons.

Neurotrophins also modulate synaptic activity via postsynaptic mechanisms. In the hippocampus, BDNF elicits sustained enhancement of action–potential-driven synaptic activity within minutes of exposure. This increase results from modulation of postsynaptic responsiveness to excitatory input via phosphorylation-dependent mechanisms (Fig. 1.7-2). TrkB receptor activation is critical for this response because neurotrophin-4, another trkB ligand, elicits similar effects. In contrast, the related neurotrophins NGF and neurotrophin-3, as well as the unrelated growth factors epidermal growth factor and basic fibroblast growth factor, do not share this effect. A postsynaptic locus of action is substantiated by the finding that the full-length trkB receptor is an intrinsic component of the postsynaptic density, a specialization of the postsynaptic membrane that anchors neurotransmitter receptors and second messenger signaling molecules. Furthermore, BDNF acutely enhances phosphorylation of the *N*-methyl-D-aspartate (NMDA) subtype of glutamate receptor in the isolated postsynaptic density, leading to altered receptor function. BDNF-induced modulation of NMDA receptor activity appears to play a critical role in the modulatory effects of BDNF on synaptic transmission.

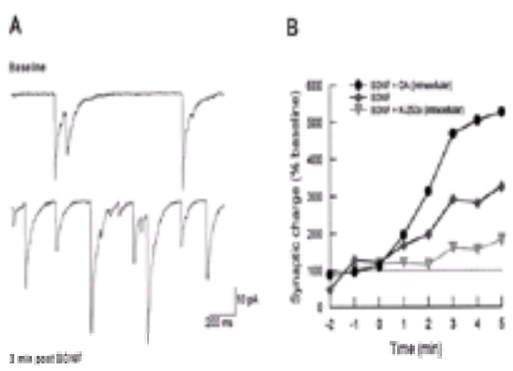

FIGURE 1.7-2 A. BDNF-induced potentiation of synaptic transmission. Whole-cell voltage clamp recordings from a hippocampal neuron before and 3 minutes after exposure to BDNF. Downward deflections represent excitatory postsynaptic currents. **B**. The postsynaptic component of BDNF modulation. Time course of a recording from an individual neuron shows the effect of bath-applied BDNF (50 ng/ml; diamonds). The effect of BDNF is decreased by postsynaptic injection of the trk tyrosine kinase inhibitor K-252a (200 nM; triangles), and enhanced by injection of the phosphatase inhibitor okadaic acid (OA; 0.5 μM; circles). Each point represents the average synaptic activity for a 1-minute period. (Reprinted with permission from Levine ES, Dreyfus LF, Black IB, Plummer MR: Proc Natl Acad Sci USA *92:*8074, 1995.)

Thus, neurotrophins potentiate synaptic transmission via both presynaptic and postsynaptic effects, increasing the efficacy of synaptic transmission and the probability of triggering postsynaptic action potentials. The effects of neurotrophins on synaptic activity may have specific consequences for activity-dependent plasticity in the hippocampus, including long-term potentiation, a potential cellular substrate of learning and memory. Animals with a targeted deletion of the BDNF gene have deficits in long-term potentiation that can be restored by reintroduction of BDNF. Endogenous BDNF enhances long-term potentiation, although specific mechanisms are controversial. Modulation of postsynaptic glutamate receptors by neurotrophins may contribute to changes in long-term potentiation. Similar mechanisms are thought to occur in widespread areas of the brain, subserving multiple adaptive processes. Taken together, these data point to an important role for neurotrophins in the regulation of synaptic plasticity and potentially for the learning and memory processes that are dependent on this type of plasticity. Increasing neurotrophin availability may represent a novel approach towards reversing cognitive deficits resulting from injury, disease, or aging.

In addition to direct effects on synaptic efficacy, neurotrophins also regulate expression of voltage-gated ion channels that regulate neuronal excitability. This has been most closely examined in a pheochromocytoma cell line (PC-12) that differentiates into a sympathetic neuron-like phenotype in response to NGF. In these cells NGF induces the expression of multiple types of sodium, potassium, and calcium channels. The increase in sodium channel expression is mediated at least in part by cyclic adenosine-monophosphate–dependent protein kinase (PKA). NGF also increases expression of voltage-gated sodium, calcium, and potassium currents in a neuroblastoma cell line. Whereas continuous exposure to NGF causes the induction of a family of sodium channels, brief exposure selectively induces expression of the peripheral nerve-type sodium channel gene *PN-1*. Although these effects have been typically characterized in clonal cell lines, similar mechanisms occur in primary neurons. For example, functional expression of N-type calcium (Ca^{2+}) channels is greatly enhanced by NGF in sympathetic neurons; in dorsal root ganglia, NGF accelerates the acquisition and diversity of sodium currents. Thus, modulation of ionic currents represents another important facet of neurotrophin modulation.

These mechanisms also occur in the brain, with functional implications for psychiatric and neurodegenerative disease resulting from basal forebrain-hippocampal dysfunction. In basal forebrain cholinergic neurons, NGF increases both L-type and N-type components of voltage-gated calcium currents. This effect is specific to NGF because BDNF does not have a similar effect. Calcium entry via these voltage-dependent channels regulates neurotransmitter release and neuronal firing patterns and also modulates neuronal gene expression. Thus, calcium influx via these channels may mediate some of the well-known trophic actions of NGF. Since these neurons provide a dense cholinergic input to the hippocampus, this effect of NGF may also play a role in modulation of hippocampal synaptic transmission. Regulation of these ionic currents could therefore have long-lasting consequences for neuronal responsiveness to synaptic inputs. Importantly, the memory loss and cognitive impairment that accompanies dementia of the Alzheimer's type is thought to result from deficits in the basal forebrain-hippocampal system. Neurotrophins therefore are potential candidates for underlying pathophysiology and as a potential treatment opportunity.

Regulation of Neuronal Connectivity In addition to dynamic changes in electrical activity, modulation of neuronal function can result from changes in neural architecture and circuit formation. Along these lines, neurotrophins may influence synaptic transmission in the brain via direct effects on axonal outgrowth, dendritic morphology, and synaptic connectivity. In addition to promoting survival (neurotrophism), these factors also have neurotrophic effects, guiding the direction of neurite growth. For example, growth cones of sensory neurons in vitro grow towards a source of NGF. It is not known whether NGF acts in vivo to guide axons to their proper targets, but once they reach their targets, NGF can regulate the shape and arborization of terminal contacts. NGF promotes neurite elaboration in developing cerebellar Purkinje neurons, and these effects are dependent on neuronal activity, requiring simultaneous exposure to NGF and depolarizing agents. NT-3 also enhances neurite outgrowth and branching in cultures of embryonic rat hippocampus. In developing cortex, endogenous neurotrophins regulate the development of characteristic dendritic branching patterns and laminar organization. Specific neurotrophins increase the length and complexity of dendrites of cortical neurons. Basal dendrites of neurons in each cortical layer respond most strongly to a single neurotrophin, whereas apical dendrites respond to several neurotrophins. These effects are also dependent on interactions with ongoing neuronal activity.

The physiological relevance of these effects may relate to activity-dependent formation of neuronal circuitry during development and its reorganization after injury. For example, during the development of the visual system, axons from the thalamus carrying visual information become segregated into eye-specific patches (ocular dominance columns) within their target in the primary visual cortex. This reorganization results from activity-dependent synaptic competition between axons representing the two eyes. Infusion of BDNF or NT-4/5 into cat primary visual cortex blocks column formation. Neurotrophin-receptor antagonists, which block the actions of endogenous neurotrophins, also inhibit the formation of these columns. These data suggest that neurotrophins, normally present in limiting amounts within visual cortex, are necessary for the selective growth and segregation of thalamic axons into ocular dominance columns.

OTHER NEUROTROPHIC FACTOR FAMILIES

Many other growth and trophic factor families are expressed in the CNS, with specific neuronal targets that overlap and are distinct from neurotrophin targets. Examples include glial-derived neurotrophic factor (GDNF), a recently discovered trophic molecule isolated from an astrocyte cell line, that is a distant member of the transforming growth factor-b (TGF-b) family. GDNF is the most potent survival factor yet identified for dopamine neurons, which degenerate in Parkinson's disease, and motor neurons, which degenerate in amyotrophic lateral sclerosis. Thus, trophic factors may represent a promising therapeutic approach to rescuing these vulnerable neuronal populations. Dopamine neurons are also implicated in the pathophysiology of schizophrenia, and most antipsychotic medications target specific dopamine receptor subtypes. Dopaminergic neurotransmission may also be acutely modulated by trophic factors, providing therapeutic alternatives for clinical intervention. Other important growth factors include ciliary neurotrophic factor, which in addition to promoting survival of cultured ciliary neurons also acts on a wide range of neurons, including motor neurons and basal forebrain cholinergic neurons. The fibroblast growth factor family promotes cellular proliferation (mitogenesis) in a variety of cell types. In addition, basic fibroblast growth factor and acidic fibroblast growth factor, members of a gene family that now numbers seven related factors, also promote the survival and differentiation of numerous cellular types. Thus, disorders involving various transmitter systems may be potential targets for intervention using different trophic factors.

Many questions regarding the functional roles of trophic factors remain unanswered. Are there discrete families of factors that preferentially act on specific neuronal systems? What is the function of the overlapping responsiveness to different neurotrophins? Are there distinct signaling pathways mediating different downstream trophic effects? The recently discovered neuromodulatory effects of trophic factors suggest that targeting these molecules may represent a novel strategy for subtly fine-tuning nervous system function. The growing knowledge of neurotrophin roles in the adult nervous system will have important consequences for understanding brain function and dysfunction as it relates to neuropsychiatric and neurodegenerative disease.

SUGGESTED CROSS-REFERENCES

Neuroanatomy is discussed in Section 1.2 and Section 1.3. Excitatory amino acid neurotransmitters are presented in Section 1.5. Section 1.8 discusses intraneuronal signaling pathways, and Section 1.9 covers basic electrophysiology.

1.8 INTRANEURONAL SIGNALING PATHWAYS

JAY M. BARABAN, M.D., FH.D.

Prior to delineating the organization of specific intraneuronal signaling pathways, it is important to consider, in general terms, their role in helping neurons interpret and respond to the barrage of afferent stimulation impinging on them continuously. From an evolutionary perspective, second messenger systems predate neurotransmitters and neurotrophins, examples of first messengers detected by cell surface receptors. Before the advent of neurotransmitters, prokaryotic organisms relied on cyclic adenosine monophosphate (cAMP) and other intracellular signaling pathways to coordinate diverse responses located in disparate parts of these unicellular organisms to changes in ambient nutrients or conditions. Neurotransmitters and neurotrophins have evolved subsequently to take advantage of these internal signaling pathways that have undergone a parallel growth process.

Intraneuronal signaling pathways do more than merely enlarge the sphere of influence of afferent stimuli beyond the local environment of the cell surface receptor. With the aid of these internal signaling pathways, the postsynaptic neuron partakes actively in amplifying or muting the initial signal conveyed by a particular receptor and is not relegated to the subservient status of a totally passive partner in responding to these external cues. Although each neurotransmitter receptor is dedicated to recognizing a specific molecular structure, the flexibility inherent in the organization of intraneuronal signaling pathways allows that recognition event to have entirely different meanings depending on the current context of the signal as well as the neuron's past experience. In other words, these internal signaling pathways empower neurons to shape their responses to incoming stimuli; collectively, these changes in ensembles of neurons are of paramount importance in enabling the nervous system to adapt to its environment and learn from experience.

The concept that neurons or networks of neurons have the ability to modify their responses to a given stimulus is also directly relevant to understanding the actions of psychotropic drugs. In the absence of second messenger systems, drugs would be expected to exert consistent effects with repeated administration. Thus, all of the complex time-dependent changes in psychotropic drug action, such as tolerance to opiates or benzodiazepines, or the delayed therapeutic response to antidepressant or antipsychotic drugs, ultimately result from the ability of neurons, through their internal signaling pathways, to mount a compensatory response to this form of stimulation. In some instances, this adaptation may run counter to the desired clinical effect, such as tolerance to the analgesic effects of opioids or substance dependence. Alternatively, this active adaptation can be highly desirable because it presumably underlies the therapeutic action of antidepressant or antipsychotic agents, which develop after a lag of days to weeks following the onset of treatment. These examples underscore the direct relevance of intraneuronal signaling pathways to the most challenging problems facing psychiatry.

Although the overwhelming majority of psychiatric drugs target extracellular receptors or uptake sites, the explosion of information on intraneuronal signaling pathways suggests that these may represent suitable drug targets. In particular, the availability of transgenic approaches to examine the phenotype caused by deleting a specific component of a signaling pathway will be invaluable in developing a new generation of psychiatric drugs aimed at signaling pathways that function beneath the neuronal surface. Furthermore, insights gleaned from the ongoing search for genes involved in inherited psychiatric syndromes may help to focus attention on specific pathways as therapeutic avenues that are capable of compensating for these pathological defects.

Psychiatrists have long been taught that a true understanding of normal and abnormal behavior requires an appreciation of the interplay of forces lurking beneath the surface. Advances in defining the signaling pathways mediating neurotransmitter and neurotrophin action indicate that this notion rings true at the cellular level. Accordingly, deciphering the logic of intraneuronal signaling pathways is of paramount importance in understanding how neurons behave and represents a new frontier in dissecting the molecular and cellular basis of behavior and of the action of psychiatric drugs.

MAJOR SIGNALING PATHWAYS

Cyclic AMP System The classic cross-perfusion experiments conducted by Otto Loewi at the turn of the century led to the identification of acetylcholine as a neurotransmitter and revolutionized the conception of synaptic transmission. In a similar manner, the discovery of cAMP by Sutherland and Rall nearly half a century later using an analogous approach established the principle that intracellular transmitters or second messengers are instrumental in conveying information from cell surface receptors to their targets within the cell. The accumulation of decades of research on this system has revealed its operating principles in great detail and has served as a blueprint for deciphering other signaling pathways as well.

For this signaling pathway, generation of cAMP is controlled by the balance between the activity of its synthetic enzyme, adenylyl cyclase, which converts adenosine triphosphate (ATP) to cAMP, and phosphodiesterase, which cleaves cAMP to an inactive breakdown product, AMP. Adenylyl cyclase is regulated by cell surface receptors, via a family of adapter proteins referred to as *G proteins* because they bind guanosine 5'-triphosphate (GTP) when the receptor is activated. In this activated configuration, the a subunit of the G protein complex dissociates from the bg subunits, enabling it to regulate cyclic AMP formation. The a subunit possesses an intrinsic GTPase activity that converts GTP to guanosine diphosphate (GDP), which allows the subunits to reassemble into an inactive configuration.

Neurotransmitter receptors may couple to adenylate cyclase via different classes of G proteins, referred to as G_s or G_i, depending on whether they stimulate or inhibit cyclic AMP formation (Fig. 1.8-1). In this way, the net effect of the transmitter on a given neuron is determined by the specific receptor subtypes expressed on its surface. For example, norepinephrine stimulates adenylate cyclase via its interaction with b-adrenergic receptors, the type that speed heart rate, and it inhibits adenylate cyclase via the muscarinic cholinergic receptor subtype.

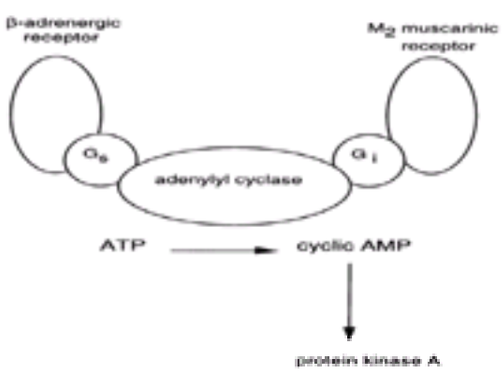

FIGURE 1.8-1 Organization of the cyclic AMP system. Generation of cyclic AMP from ATP by adenylyl cyclase can be stimulated or inhibited by receptor-G protein linkages. In the example shown, the b-adrenergic receptor coupled to G_s stimulates cyclic AMP synthesis whereas an M_2 muscarinic receptor inhibits this process via its linkage to G_i. Cyclic AMP exerts many of its cellular actions via its ability to activate protein kinase A.

Cyclic AMP exerts a wide variety of actions on neuronal function via its stimulatory effect on cyclic AMP-dependent kinase, which has a broad range of substrate proteins involved in regulating virtually every aspect of neuronal function from ion channel gating to axonal transport, much as the autonomic nervous system influences the activity of diverse organ systems to achieve a cohesive response. One target of the cAMP system that has been the focus of attention in recent years is a transcription regulatory factor that enables elevations in cyclic AMP to regulate gene expression. This factor, referred to as cAMP response element binding (CREB)

protein, binds to a short sequence of deoxyribonucleic acid (DNA) in the regulatory regions of its target genes. Phosphorylation of CREB on a specific serine residue is required for it to promote transcription of target genes. Thus, alterations in cyclic AMP levels can affect neuronal function over a broad range of time scales. Rapid effects can be induced by targeting ion channel gating or transmitter release machinery. On a more sluggish time scale, cyclic AMP can influence neurotransmitter synthesis or energy metabolism. Furthermore, longer-lasting changes in neuronal function can be achieved by this messenger as a result of its ability to control the expression of specific target genes.

Cyclic GMP Besides cyclic AMP, another cyclic nucleotide, cyclic guanosine monophosphate (GMP) has been identified as a second messenger regulated by neurotransmitter receptor stimulation. The discovery of cyclic GMP-dependent protein kinases suggested that both cyclic nucleotide systems followed similar blueprints. However, subsequent studies have revealed startling contrasts between these systems. The link between neurotransmitter receptor activation and stimulation of guanylate cyclase does not appear to rely primarily on G protein coupling. Instead, the available evidence indicates that elevations in intracellular calcium trigger increases in nitric oxide production, which in turn activate guanylyl cyclase (Fig. 1.8-2). This complex cascade introduces a novel element, (i.e., a gaseous second messenger that is capable of diffusing both within cells as well as across membranes to neighboring cells, blurring the semantic distinction between first and second messengers). Nitric oxide has the ability to coordinate responses in clusters of cells within its sphere of diffusion, ensuring that neighboring neurons can be made aware of the status of postsynaptic neurons in their vicinity, as well as the activity of afferents emanating from distant parts of the nervous system. Furthermore, nitric oxide has the ability to influence afferent terminals, a retrograde feedback function that may be important in regulating the activity of incoming stimuli. Thus, the discovery of nitric oxide as a neuronal messenger breaches the classical notion that synapses convey information in only one direction. Recent studies have also suggested that another diffusible gas, carbon monoxide, which is also capable of activating guanylate cyclase, may also function in an analogous fashion to nitric oxide.

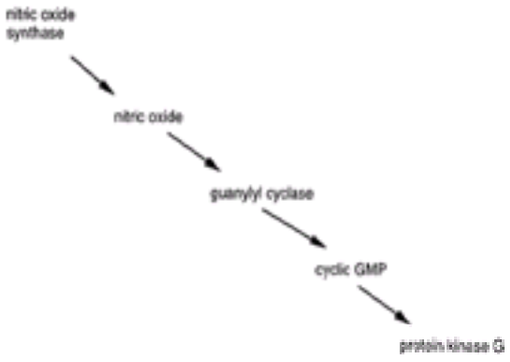

FIGURE 1.8-2 Organization of the cyclic GMP system. In contrast to cyclic AMP, cyclic GMP synthesis is regulated by stimulation of guanylyl cyclase by nitric oxide. Beyond this point in the pathway, cyclic GMP mimics cyclic AMP as it acts by stimulating its cognate kinase, protein kinase G.

Phosphoinositide (PI) Characterization of the neurotransmitter receptors coupled to the cAMP system revealed that there were many receptors that did not act via this second messenger pathway. This discrepancy generated interest in the possible existence of other second messenger systems operating in parallel with the cAMP system. This line of research came to fruition in the early 1980s with the emergence of a coherent view of the phosphoinositide second messenger system. This second messenger system parallels many aspects of the cAMP system (Fig. 1.8-3). Neurotransmitter receptor stimulation is coupled, via G proteins, to activation of a second messenger generating enzyme, phospholipase C. This enzyme cleaves inositol-containing phospholipids located in the plasma membrane into two second messengers, diacylglycerol and inositol trisphosphate (IP_3). Thus, activation of neurotransmitter receptors linked to the phosphoinositide system generates a pair of second messenger signals that can affect cellular responses via distinct pathways.

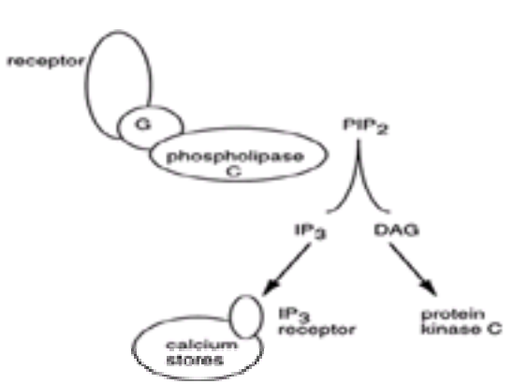

FIGURE 1.8-3 Organization of the PI system. In this system neurotransmitter receptor stimulation leads via G protein coupling to activation of phospholipase C. This enzyme cleaves the membrane phospholipid, PIP_2, into the second messengers, IP_3 and diacylglycerol (DAG). IP_3 releases calcium from intracellular stores; DAG stimulates protein kinase C.

Because the effects of cAMP are mediated to a large extent via activation of a kinase, it was generally assumed that each of these second messengers acted in a similar fashion. This turned out to be true of diacylglycerol, which activates protein kinase C, a kinase that is highly enriched in the brain. In contrast, IP_3 acts much like an intracellular transmitter that has its own receptor present on the cytoplasmic face of intracellular organelles that store calcium. Binding of IP_3 to its receptor triggers release of calcium from these intracellular stores. Calcium, in turn, is a second messenger in its own right that is capable of regulating many intracellular processes, ranging from regulation of ion channel activity to gene expression. Previous studies had led to an appreciation of the vital role calcium plays as a mediator of transmitter release following action potential invasion of nerve terminals. In that situation, calcium enters the nerve terminal via opening of voltage-dependent calcium channels. Thus, it had been assumed that neurotransmitter regulation of intracellular calcium levels was mediated by their ability to elicit depolarization and subsequent activation of voltage-dependent calcium channels. In contrast, the IP_3 system provides an alternative route by which neurotransmitters can regulate intracellular levels of calcium, an important determinant of cellular function.

It is noteworthy that lithium (Eskalith) played an important role in the studies that led to the current understanding of the phosphoinositide second messenger system. It had been noted in studies aimed at defining the effects of lithium on the central nervous system that lithium caused a modest decrease in concentrations of inositol, a sugar closely related to glucose. In pursuing the basis for this effect, investigators noted that lithium was an effective inhibitor of a phosphatase that converted inositol phosphate into inositol. Lithium could then be used to force accumulation of inositol phosphates, providing a convenient means of measuring activation of the phosphoinositide system. As a result of lithium treatment, researchers were able to detect the presence of inositol trisphosphate and realized that it was generated by phospholipase C acting on PI biphosphate (PIP_2), producing both diacylglycerol and IP_3 in one reaction.

The discovery that lithium acts as an inhibitor of a key enzyme that generates free inositol needed to replenish inositol phospholipids has prompted the hypothesis that depletion of inositol and subsequent rundown of the PI cycle may underlie lithium's therapeutic action. However, this view has been challenged recently in light of animal studies demonstrating that inositol levels in brain are unaffected by lithium concentrations within its therapeutic range.

Direct Coupling Between G Proteins and Ion Channels The elucidation of the cAMP, cyclic GMP, and PI second messenger systems focused attention on the importance of diffusible small molecules, which acted much like intracellular neurotransmitters. Instead of being released from a presynaptic site and diffusing across the synaptic cleft to act at receptor sites on the postsynaptic side, they diffused from their site of formation on the cytoplasmic side of the plasma membrane to act on their receptors within the cell whether they be kinases, as in the case of cAMP, calcium, or diacylglycerol, or receptors, as found for IP_3. However, diffusible second messengers are not universal components of the signaling pathways that mediate the actions of G–protein–coupled neurotransmitter receptors. In many important situations, the G proteins themselves link neurotransmitter receptor activation to ion channels shortcircuiting the rest of the cascade. Prominent examples of this type

of arrangement are provided by opioid receptors and muscarinic receptors involved in vagal slowing of the heart. As these receptors had been shown to be linked to G_i and cause inhibition of adenylate cyclase, it had been taken for granted their important effects on ion channel regulation, in particular opening of potassium channels causing hyperpolarization, was a result of lowering cAMP concentrations. However, this theory was shattered by experiments in which restoration of cAMP concentrations was ineffective in reversing this effect. Analysis of this paradox revealed that even though G_i was involved in mediating this response, it was due to a direct effect of G_i on the potassium channels (Fig. 1.8-4). Subsequently, this direct coupling has been found to be a common type of linkage between neurotransmitter receptors and ion channels.

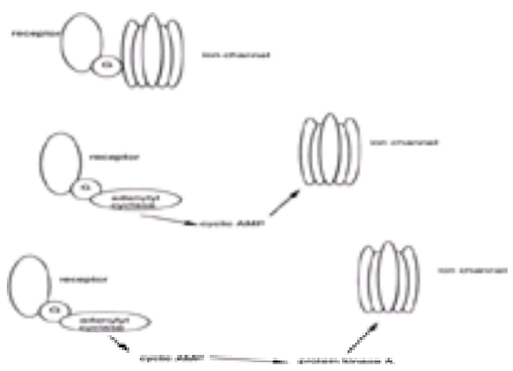

FIGURE 1.8-4 Regulation of ion channels by G-protein–coupled receptors. Not all the effects of cyclic nucleotides are mediated by protein kinases. As shown in upper panel, G proteins can directly link neurotransmitter receptors to ion channels. This configuration underlies regulation of potassium channels that slow the heart in response to vagal stimulation of muscarinic cholinergic receptors. Alternatively, cyclic nucleotides can directly affect ion channels in a kinase-independent fashion, as illustrated in the middle panel. Cyclicnucleotide–gated channels play a key role in photoreceptor responses to light. The conventional kinase-dependent pathway is shown in the bottom panel. This type of arrangement mediates the well-known ability of sympathetic stimulation to speed the heart rate via activation of b-adrenergic receptors.

In this regard, it is interesting to note that the generalization that cyclic nucleotides always act via kinases has also been debunked by studies in sensory neurons demonstrating that these signaling molecules interact directly with ion channels, without kinases acting as intermediaries. These alternate arrangements emphasize the notion that intracellular signaling cascades have evolved in ways that heighten their versatility, with each of the components having multiple signaling capacities.

Tyrosine Phosphorylation The landmark discovery that viral oncogenes were mutant versions of cellular genes that had been hijacked by tumor viruses has had a major impact on the entire field of tumor biology. In addition, characterization of the mode of action of several of these proto-oncogenes yielded another surprise—they represent a novel class of kinases that phosphorylate tyrosine residues, rather than serine or threonine residues that are targeted by all previously described mammalian kinases.

Since the late 1970s intense exploration of this novel form of phosphorylation has provided compelling evidence that it can exert powerful influences on neuronal function. Initially it was assumed that because tyrosine kinases were proto-oncogenes involved in regulating cellular proliferation, this type of phosphorylation would have little relevance to the nervous system, which has extremely low levels of cellular proliferation. Contrary to this presumption, surveys of the level of tyrosine phosphorylation present in various tissues revealed that the brain has one of the highest concentrations of phosphotyrosine-containing proteins as well as of tyrosine kinases.

Studies of tyrosine kinase signaling cascades have provided important new sights into the mode of action of nerve growth factor and other neurotrophins. Binding of growth factors to the extracellular portion of these receptors leads to activation of a tyrosine kinase domain located in the cytoplasmic tail of the receptor protein. It is thought that growth factor binding brings together two receptor molecules that then phosphorylate each other on tyrosine residues. This simple modification of the cytoplasmic tail converts it into a magnet for an array of signaling proteins that are brought together at the inner surface of the membrane. This arrangement triggers multiple divergent signaling cascades from this nidus. One of these branches can lead to activation of the PI system, as one of the isoforms of phospholipase C contains a domain that is attracted to the activated growth factor receptor. Another branch leads to activation of *ras*, a proto-oncogene that has G-protein–like properties.

Another family of tyrosine kinases has been identified that differs from the receptor tyrosine kinases in that it contains only the cytoplasmic domain. The absence of an extracellular ligand binding domain has prompted questions about how members of this family are regulated; these questions are still largely unresolved. Nevertheless, evidence is accumulating that these non-receptor tyrosine kinases, such as *fyn, src,* and *yes* play a critical role in multiple neuronal responses, including ion channel regulation.

The organization of the tyrosine kinase pathways provides an interesting contrast to the classical, second–messenger-based pathways outlined previously. First, the tyrosine kinase pathways do not utilize small, diffusible second messengers. In theoretical terms, this may have the advantage of maintaining a restricted spatial domain of signal propagation, as opposed to the classical second messenger systems, which have a larger sphere of influence. Second, the ability of multiple adapter proteins to interact with the activated cytoplasmic tail of tyrosine kinase receptors confers a remarkable degree of divergence as multiple signaling pathways can be engaged simultaneously. Thus, the importance of tyrosine phosphorylation signaling does not reside simply in the availability of another residue that is amenable to modification by phosphorylation; rather, it represents an intracellular signaling system built on an alternative set of architectural principles.

Identification of the signaling pathway downstream of Ras has opened up a new avenue to understanding the mechanism of action of growth factors and neurotransmitters. Members of the Ras family are referred to as *small G proteins* because of their lower molecular weight compared to their large G protein relatives linked to the cyclic AMP and PI systems. Like their cousins, Ras and other small G proteins bind GTP following activation of growth factor receptors and slowly hydrolyze it to GDP with the help of accessory proteins called *GTPase-activating proteins* (*GAP*). In contrast to the large G proteins that are involved in regulating the synthesis of small second messenger molecules or in regulating ion channel activity, activated *ras* has the ability to stimulate a cascade of kinases arranged in series, that lead to activation of mitogen-activated protein (MAP) kinase (Fig. 1.8-5). Unlike protein kinase A (PKA) or protein kinase C (PKC), each of these kinases is regulated by phosphorylation by an upstream activator kinase, instead of by small second messengers. However, like PKA or PKC, this kinase cascade has numerous targets within the cell ranging from influencing the organization of the cytoskeleton in the cytoplasm to control of gene expression in the nucleus. The pervasive influence of this signaling pathway helps to explain many of the remarkable effects of neurotrophins on neuronal growth and differentiation.

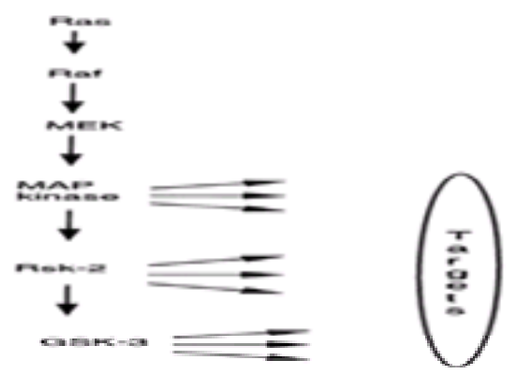

FIGURE 1.8-5 Kinase cascade activated by Ras. Ras, a member of the small G protein family, has been identified as an important mediator of growth factor responses. Activation of Ras stimulates a kinase, Raf, which regulates a series of downstream kinases. In contrast to the “classical” second messenger systems described above, these kinases are directly regulated by upstream kinases rather than by second messengers.

MAP kinase is particularly interesting from the perspective of neuronal signal transduction because it was initially identified using *MAP-2*, a neuron-specific cytoskeletal protein, as a preferred substrate. Once investigators realized that the kinase was widely distributed and also activated by mitogens and other extracellular agonists, its name was changed from *MAP-2 kinase* to *mitogen activated protein kinase* (MAP kinase) or *extracellular agonist regulated kinase* (ERK). Recent studies have demonstrated that MAP kinase in neuronal dendrites is associated with microtubules and indicate that MAP-2 is a physiological substrate of this kinase in vivo. Other substrates that have been identified include tyrosine hydroxylase and transcription regulatory factors, as well as another downstream kinase referred to as *Rsk-2*, which is capable of phosphorylating and activating CREB. The length of the kinase cascade distal to MAP kinase has also been stretched to add yet another kinase called (glycogen synthase kinase-3), which is downstream of Rsk-2. GSK-3 has received attention recently as the target of lithium, accounting for its teratogenic effects in several model systems of development. Further studies are needed to help elucidate whether this kinase may also play a role in mediating lithium's therapeutic action in mood disorders.

Cross-Talk Among Signaling Pathways The organization of intraneuronal signaling pathways allows for a high degree of interaction or cross-talk among pathways. For example, growth factor receptor activation can also engage the PI system initially identified as a target of neurotransmitter receptors. Conversely, activation of neurotransmitter receptors can also stimulate MAP kinase initially linked to growth factor receptor activation. Thus, neurotransmitters have the ability to influence the response to neurotrophins and vice versa. In this context it is noteworthy that neurotransmitters can also regulate the MAP kinase pathway. This interplay among signaling pathways increases their versatility by providing alternative routes for regulating many of the same effector proteins.

Although kinase regulation has been focused on, it is important to emphasize that there are analogous regulatory cascades involved in controlling dephosphorylation. In this way, the longevity of phosphorylation on a specific residue can vary dramatically depending on the substrate protein involved and the context it which it occurs. For example, PKA phosphorylation of dopamine regulated phosphoprotein-32 (DARPP-32), a protein phosphatase inhibitor that is highly enriched in neurons that receive dopaminergic innervation, is required for it to be functional. Thus, if a neuron receives simultaneous stimulation of both a calcium-dependent kinase and PKA, activation of DARPP-32 may greatly prolong the duration of phosphorylation of residues normally removed by the phosphatase inhibited by DARPP-32. An analogous cascade involves another phosphatase inhibitor, referred to as *I-2*, which is inhibited by GSK-3. Thus, in this case, activation of the MAP kinase/GSK-3 pathway would also affect the longevity of phosphorylation on residues regulated by the I-2–sensitive phosphatase. As a result of cross-talk between systems, coordinate activation of multiple pathways can have important synergistic effects.

Another level of cross-talk has been observed at the level of specific target proteins (Fig. 1.8-6). Rather than being substrates for specific kinases, the more common situation is that a given target is phosphorylated by multiple kinases. This overlapping of substrate specificity allows for complex patterns of regulation. For example, phosphorylation of a specific substrate by both protein kinase A and protein kinase C may have qualitatively different effects than modification by either alone. In addition, there are intriguing examples of conditional phosphorylation in which a protein only becomes a substrate for a protein kinase when it is first phosphorylated on a nearby residue by a distinct kinase. This sequential form of interaction confers a conditional switching mechanism that will only allow a substrate protein to be modified when a specific pre-condition is met. Furthermore, there are situations that represent the equivalent of “or” operations, when multiple kinases can substitute for each other in phosphorylating a specific residue. Therefore, if any one of the corresponding pathways is activated, the response will be triggered. A specific example of the “or” situation is presented by CREB. Phosphorylation on serine 133 by PKA converts this transcription factor into its active form. In addition, this same residue can be phosphorylated by calcium on calmodulin-dependent kinases, as well as Rsk-2, a kinase downstream of MAP kinase. Thus, activation of any one of these signaling pathways is sufficient to trigger CREB activation, allowing these distinct pathways to converge on CREB to induce changes in gene expression. In summary, multiple levels of cross-talk between signaling pathways transforms them from isolated pathways into a highly integrated network that possesses a high degree of sophistication and versatility in detecting and responding to incoming stimuli.

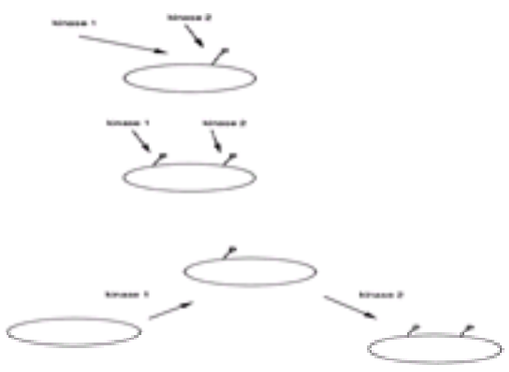

FIGURE 1.8-6 Cross-talk between kinases. As multiple kinases target individual protein substrates, multiple types of interaction can occur at this level. As shown in the top panel, there are instances where multiple kinases are capable of targeting the same residue. This arrangement is analogous to an “or” circuit, since activation of either kinase 1 or kinase 2 is sufficient to influence the target protein. In contrast, phosphorylation of a substrate by two different kinases on distinct residues may be needed to elicit a functional change in activity of the substrate (middle panel). As both kinases are necessary, this configuration is analogous to an “and” circuit. As illustrated in the bottom panel, the sequence of phosphorylation can also be crucial. In the example shown, both kinases are necessary, but they must be activated in the correct order because kinase 2 cannot act on the target unless it has already been phosphorylated by kinase 1.

SYNAPTIC PLASTICITY

In its simplest form, the postsynaptic response to neurotransmitter release can be mediated by a single protein complex. For example, nicotinic acetylcholine receptors are self-contained stimulus-response modules that both detect a stimulus, acetylcholine, and generate a response, passage of ion currents. In a similar vein, other members of this superfamily of ionotropic receptors, including g-aminobutyric acid (GABA) and glutamate receptors, have the ability to function in a manner that is independent of the intracellular signaling pathways discussed. Thus, in contrast to growth factor or G-protein–coupled receptors, which often recruit elaborate cascades to elicit a response, the simplicity of self-sufficient ionotropic receptor complexes represents an optimal design for achieving reliability, precision, and speed. However, this view of ionotropic receptors as insulated from their social environment has had to be abandoned in the face of overwhelming evidence that this class of receptors is dynamically regulated by intraneuronal signaling pathways. Although these receptors do not rely on intraneuronal signaling pathways to operate ion channels, because these channels are an intrinsic feature of the receptor complex the linkage between ligand binding and ion channel gating is nevertheless subject to regulation by the network of intraneuronal signaling pathways just described. For example, phosphorylation of the GABA or glutamate receptors modulates their response to ligand exposure.

Long-Term Depression The principle that ion channels are regulated by second messenger pathways is of central importance in considering how neuronal responses are altered by experience. Perhaps, one of the best examples for which the intracellular pathways involved have been worked out is the paradigm of long-term depression induced in Purkinje cells of the cerebellum. In this model of synaptic plasticity, the responses of Purkinje neurons to activation of ionotropic glutamate receptors is reduced for extended periods of time, by coincident activation of multiple signaling pathways. Even though the direct response to glutamate receptor activation does not rely on second messenger systems, its amplitude is indirectly modulated by a network of intraneuronal signaling pathways. This arrangement appears to be a general feature of synaptic transmission in which slower, second-messenger–based signaling pathways have a major impact on the fast modes of synaptic transmission.

In the specific example of long-term depression in cerebellar Purkinje cells, the plasticity observed is triggered by coordinate activation of two distinct classes of afferents to these neurons. Purkinje cells receive a major input from both climbing fibers arising from the inferior olive and parallel fibers that emanate from granule cells of the cerebellum. The parallel-fiber response in an individual Purkinje cell is decreased if that cell is coincidentally activated by a climbing fiber input. Analysis of this phenomenon has revealed that it is dependent on coincident activation of two distinct types of glutamate receptors: an a-amino-3-hydroxyl 5-methyl-4-isoxazole propionic acid (AMPA) type of ionotropic glutamate receptors and a G-protein–coupled (metabotropic) glutamate receptor that linked to the PI system. In addition, the climbing fiber input produces a massive depolarization of the Purkinje cell that opens voltage gated calcium channels. The coordinated presentation of these three signals: (1) depolarization with subsequent calcium entry, (2) activation of the PI/PKC system, and (3) AMPA receptor stimulation conspire to produce a prolonged decrease in responses elicited by AMPA receptor stimulation. Any combination of only two of these signals is insufficient to trigger this form of synaptic plasticity. The exact mechanism by which these signals are integrated or detected simultaneously has not yet been worked out. However, the requirement for simultaneous

activation of multiple pathways provides a compelling example of how these pathways can act synergistically to modulate neuronal responses. This example also underscores the importance of intraneuronal signaling pathways in regulating the responsiveness of ionotropic receptor channels.

Long-Term Potentiation The notion that coactivation of multiple second messenger pathways can have a qualitatively different impact than any one individually is also borne out in another well-known model of synaptic plasticity, *long-term potentiation*. In this paradigm, which has received intense attention because it provides a model of associative learning, modification of the synaptic responses to glutamate are also dependent on co-activation of multiple second messenger pathways. This requirement for coordinate activation of multiple pathways presumably represents a form of safeguard against changing synaptic weight inadvertently, which could have devastating effects on the nervous system. Accordingly, the requirements for synapse modification that underlie learning appear to have evolved in a way that entails the approval of multiple branches of the signaling network as a means of checking that the pattern of synaptic activity is of sufficient importance to warrant a long-term change in the synapses to be modified.

Role of NMDA Receptor Activation Prior to outlining the intracellular signaling pathways involved in long-term potentiation, it is first important to understand the key synaptic events that trigger plasticity in this paradigm. Studies of long-term potentiation of inputs to CA1 hippocampal neurons have highlighted the role of *N*-methyl-D-aspartate (NMDA) receptors as coincidence detectors. In this system basal levels of synaptic activity are mediated by activation of AMPA receptors. Even though the same synapses also express NMDA receptors, under quiescent conditions these do not open in response to glutamate because NMDA receptors have an additional requirement that must be met before they open. Unlike AMPA receptors, NMDA receptors will only pass current if they detect glutamate and membrane depolarization simultaneously. Thus, NMDA receptors represent an unusual hybrid between ligand-gated ion channels and voltage-gated ion channels. In contrast to AMPA glutamate receptors or nicotinic acetylcholine receptors, which open automatically whenever they detect glutamate or acetylcholine, NMDA receptors are indifferent to the presence of glutamate unless they simultaneously detect that the neuronal membrane is depolarized. Only when both these conditions are met does the NMDA receptor open its channel, allowing influx of depolarizing current.

This unusual property of NMDA receptors provides a molecular mechanism for conferring associative properties on long-term potentiation. When a glutamatergic input is of sufficient strength to meet both requirements of NMDA receptor activation, (i.e., glutamate and depolarization), then it will trigger a persistent potentiation of the response to that input. In contrast, an input that is too weak to elicit sufficient depolarization for NMDA receptor activation on its own will not undergo potentiation, unless it is presented simultaneously with other inputs that induce depolarization. Thus, the special requirements of the NMDA receptor allow weak inputs to be strengthened as long as they are presented simultaneously (i.e., associated) with strong stimulation of other inputs. This associative property of long-term potentiation has many of the same formal features as classical associative conditioning. For example, the conditioned stimulus, a bell in Pavlov's famous experiment, when presented by itself is insufficient to trigger a response, salivation. However, when the bell is sounded together with an unconditioned stimulus, such as food, then the temporal pairing of the two is capable of altering the response to the weak bell stimulus.

Role of Phosphorylation The associative property of this model of synaptic plasticity has focused attention on deciphering the intraneuronal signaling pathways that mediate the long-term change in synaptic transmission triggered by NMDA receptor stimulation. NMDA receptor activation leads to transient rises in intracellular levels of calcium making this second messenger an attractive candidate. Experiments demonstrating that intracellular calcium chelators block this form of long-term potentiation corroborated the critical role of calcium in this process. Subsequent studies investigated whether either of the calcium-sensitive kinases that are highly enriched in neuronal dendrites, calcium/calmodulin-dependent kinase II and protein kinase C, were critical for this process. Unexpectedly, inhibition of either kinase blocked long-term potentiation, indicating that activation of both is necessary to trigger this persistent change in synaptic responsiveness. Thus, in both long-term potentiation and long-term depression simultaneous activation of multiple signaling pathways is used to detect unusual forms of stimulation that warrant an adjustment of synaptic responses.

To underscore this general point, subsequent studies have also demonstrated that activation of the cyclic AMP system is also necessary for long-term potentiation to occur. The role of cyclic AMP in this paradigm may be related to its ability to suppress phosphatase activity. A key effect of PKA is to phosphorylate and thereby inactivate phosphatase inhibitors, such as DARPP-32. In this way, PKA on the one hand phosphorylates effector substrates and at the same time inactivates the phosphatase that erases its effects or the effects of other kinases.

Given the data linking phosphorylaton or dephosphorylation to synaptic plasticity, there is intense interest in defining the substrates involved. Evidence suggesting that the potentiation of synaptic responses reflects an increase in responsiveness of AMPA receptors located in the postsynaptic membrane has focused attention on these receptors themselves as candidate substrates. In this regard, it is interesting that the AMPA receptor is a substrate for PKA, PKC, and calcium/calmodulin-dependent kinase. On the other hand, there are those who subscribe to the alternate view that long-term potentiation may reflect a presynaptic alteration in transmitter release that is produced by a retrograde messenger, such as nitric oxide, generated postsynaptically.

Although the formal similarities between the associative properties of long-term potentiation and classical conditioning have provided compelling support for the hypothesis that this form of synaptic plasticity underlies associative learning, it has been difficult to gain experimental support linking this electrophysiological response to the behavioral phenomena. An important breakthrough in this area has been the utilization of transgenic animals with targeted mutations in genes encoding signaling molecules involved in long-term potentiation. The ability to examine the effect of these genetic alterations on behavior in the intact animal as well as on long-term potentiation in vitro has provided a means of bridging the gap between intraneuronal signaling pathways and behavior. Ongoing experiments in this area have validated the hypothesis that long-term potentiation and long-term depression represent the synaptic counterparts of learning. Application of this powerful genetic strategy to analysis of behavior provides an unprecedented means of dissecting the signaling pathways involved in modifying behavior in response to naturally occuring stimuli as well as to psychiatric drugs. As the technology employed by this approach is still developing rapidly, its application can be expected to become more widespread in the near future and provide a wealth of insights into the molecular substrates of a wide variety of behavioral responses.

Actions of Psychotropic Drugs In addition to providing insight into the molecular mechanism underlying synaptic plasticity, studies of intraneuronal signaling pathways are also directly relevant to deciphering the mode of action of psychotropic drugs. Modern psychopharmacology has made tremendous advances in defining the primary site of action of the major classes of psychiatric drugs. For example, benzodiazepines act via GABA receptors, cocaine blocks the reuptake of monoamines, and opioids act via an array of opiate receptor subtypes. However, these important advances have not always provided an adequate explanation of the delayed effects elicited by these agents. For example, the primary site of action of the most widely used class of antidepressant drugs is the serotonin uptake site. However, it is clear that blockade of this uptake pump is not sufficient to elicit an antidepressant effect because this blockade occurs rapidly whereas the therapeutic response is delayed. This paradox has focused attention on the neuronal adaptation to serotonin uptake blockade to look for clues to the basis for the antidepressant response. A leading hypothesis to account for the delay in antidepressant response hinges on the observation that prolonged uptake blockade leads to downregulation of inhibitory presynaptic receptors on serotonin nerve terminals. This adaptation may then allow for increased release of serotonin, with each action potential invading the serotonin nerve terminals. According to this theory, the intracellular signaling pathway regulating the responsiveness of presynaptic receptors is the critical determinant of the antidepressant response.

Another example is provided by recent studies implicating the cAMP system in mediating responses elicited by long-term opiate administration. Many of the acute effects of opiate receptor activation on ion channel function are mediated directly by G_i proteins, independent of cAMP. However, in parallel with these electrophysiological effects, opioid receptor activation also suppresses cAMP concentrations. With long-term administration of opioids, neurons adapt to this persistent suppression of cAMP concentrations by altering the expression of several components of the cAMP system, yielding a net increase in cAMP tone to compensate for the chronic negative influence of opioids. This adaptive shift in the cAMP system brings the system back into balance as long as opioid stimulation persists. However, if opioids are withdrawn, the neuron is left with an overly active cAMP system that may underlie many of the behavioral phenomena of withdrawal. Although it is unclear how long-term suppression of cAMP concentrations leads to a compensatory upregulation of this system, available evidence suggests that CREB, a transcription factor sensitive to cyclic AMP, mediates this response. Evidence supporting this theory has been provided by recent studies demonstrating that opiate withdrawal is attenuated in transgenic animals that are deficient in CREB. These landmark results provide important confirmation that intraneuronal signaling pathways play a central role in this important aspect of opiate action. In addition, these findings exemplify how application of molecular biological approaches to deciphering intraneuronal signaling pathways will provide important insights into the mode of action of currently used psychiatric drugs and pave the way for a new generation of improved treatment approaches.

1.9 BASIC ELECTROPHYSIOLOGY

CHARLES F. ZORUMSKI, M.D., AND KEITH E. ISENBERG, M.D.

Neurons use electrical signals to send and receive information. These electrical signals determine local and network properties of the central nervous system (CNS) and result from the flow of ions across cell membranes through macromolecular pores called *ion channels*. Neurons possess two classes of ion channels, *gated* and *nongated*. Nongated ion channels open spontaneously and contribute to the cellular resting membrane potential. The opening and closing of most ion channels is regulated (gated) by changes in transmembrane voltage or neurochemicals. Certain voltage-gated sodium channels allow very rapid movement of ions and provide the basis for communication within and between neurons. These rapid signals *(action potentials)* are generated at or near the neuronal cell body and are transmitted to nerve terminals with little decrement in amplitude. The high-fidelity propagation of action potentials results from *saltatory conduction*, which is the ability of electrical signals to "jump" rapidly between axonal nodes of Ranvier.

At a nerve terminal an action potential causes a depolarization that opens voltage-gated calcium channels. The influx of calcium promotes the release of a chemical neurotransmitter into the extracellular space where the transmitter is able to influence a receiving cell. Neurotransmitters bind to specific protein receptors and alter neuronal excitability via actions on ion channels. There are two broad classes of neurotransmitter receptors: *ligand-gated ion channels* are directly opened by the binding of a transmitter whereas G-*protein–coupled receptors* influence the function of ion channels indirectly via guanine nucleotide binding proteins (G proteins) or chemical second messengers.

PRINCIPLES OF CELLULAR ELECTROPHYSIOLOGY

Resting Membrane Potential In nerve cells, potassium ions (K^+) are at higher concentration inside the membrane than outside whereas the opposite is true for sodium (Na^+), calcium (Ca^{2+}), and chloride (Cl^-) ions (Fig. 1.9-1). The bulk solutions on either side of the membrane are electrically neutral, with most of the intracellular negative charge being contributed by large organic anions (acids and proteins). The differential distribution of ions across neuronal membranes results in part from the action of membrane pumps that use energy from adenosine triphosphate (ATP) to drive ions against a concentration gradient into or out of the cell. The best characterized pump is the Na^+-K^+ adenosine triphosphatase (ATPase) that transports 3 Na^+ out of and 2 K^+ into the cell during each cycle. Because an unequal amount of charge is moved during each cycle, the pump is electrogenic and produces an electrochemical potential across the membrane that makes the inside of the membrane negative with respect to the outside. Na^+-K^+ ATPase activity is a major contributor to brain energy utilization, with as much as 40 percent of brain oxygen consumption resulting from pump activity required to reestablish ionic homeostasis following action potential firing and synaptic transmission. The cardiac glycosides digoxin (Lanoxin) and ouabain are effective inhibitors of Na^+-K^+ ATPase in the heart and improve myocardial contractility by depolarizing cardiac myocytes and increasing intracellular Ca^{2+}.

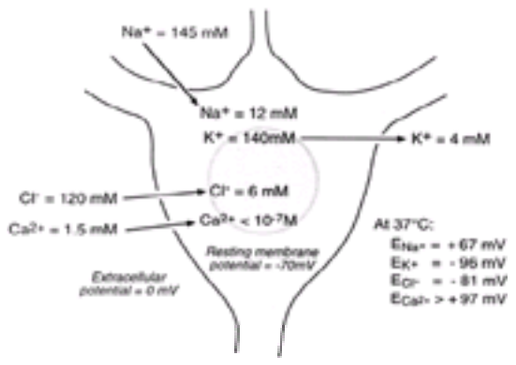

FIGURE 1.9-1 The distribution of Na^+, K^+, Ca^{2+}, and Cl^- across the membrane of a typical neuron. Using these ion concentrations, the equilibrium (Nernst) potentials for these ions at 37°C are shown at the lower right.

At rest, neuronal membranes are permeable to K^+ and Cl^- and to a lesser extent to Na^+, partly because of the flow of ions through nongated leakage channels. K^+ and Cl^- flow down their concentration gradients making the inside of the neuronal membrane negative with respect to the outside. The separation of charge establishes a voltage, called a *(potential difference)* across the membrane. The presence of a transmembrane potential difference creates an electrical gradient for the movement of ions in addition to the concentration gradient established by the differences in ion concentrations inside and outside the cell. By convention, the bulk extracellular solution is at 0 mV, making the resting membrane potential about –70 mV inside the neuron. The bulk extracellular and intracellular solutions are electrically neutral and the charge separation that produces the membrane potential occurs in the immediate vicinity of the membrane. The number of ions needed to change the membrane potential is very small relative to concentrations in the bulk solutions. For example, a potential change of 100 mV across a 1 cm^2 area of membrane requires the movement of only about 10^{-12} moles of a monovalent ion. By comparison, Na^+ and K^+ are present at about 10^{-1} M in the extracellular and intracellular fluids, respectively.

For each ion in solution there is a specific membrane potential at which the opposing forces of the electrical gradient and concentration gradient are balanced. This potential (known as the *Nernst potential* or *equilibrium potential*) can be calculated based on the ion concentrations on either side of the membrane. For K^+, the Nernst potential (designated E_K) is expressed as: $E_K = (RT/zF) \cdot \ln([K]_o/[K]_i)$, where R is the ideal gas constant (8.31 joules/degree/mole), T is the temperature in degrees Kelvin, z is the valence of the ion, F is Faraday's constant (96,500 coulombs/mole, the charge on a mole of monovalent ions), and $[K]_o$ and $[K]_i$ are the concentrations of K^+ outside and inside the cell. At 37° C, the Nernst potential for K^+ is –96 mV, while E_{Na} is +67 mV, E_{Cl} is –81 mV and E_{Ca} is greater than +97 mV. The importance of these equilibrium potentials comes from the fact that when an ion channel that is permeable to a specific ion opens, it drives the membrane potential towards the equilibrium potential for that ion. For example, when K^+-selective ion channels open, the neuronal membrane potential moves toward –96 mV. This makes the inside of the cell more negative, an effect that is termed *hyperpolarization*. Na^+ and Ca^{2+} channel opening has the opposite effect, making the inside of the cell less negative *(depolarization)*. At any time, the membrane potential is a weighted average of the equilibrium potentials of the ions to which the membrane is permeable.

Passive Membrane Properties To understand how ion concentration gradients, electrical gradients, ion channels, and the distribution of charges across the membrane are related, it is helpful to describe the cell membrane as an electrical circuit consisting of resistors (conductors), batteries, and capacitors. Because ions do not directly penetrate the lipid membrane but rather flow through ion channels, the ion channels can be thought of as variable resistors. Physiologists describe ion channels in terms of their ion selectivity (which ions flow through the channel) and their conductance (relative ease of passing ions). Conductance (g) is the inverse of resistance (R) in an electrical circuit (g = 1/R). The presence of a voltage across the membrane provides an electrical driving force for the flow of ions through ion channels resulting in a transmembrane current. The relationship among voltage (V), ionic current (I), and resistance (conductance) is given by the physiologists version of Ohm's law: $I_{ionic} = g \cdot (V_m – E_{rev})$ where V_m is the membrane potential, E_{rev} is the Nernst potential for the ions flowing through the channel, and $(V_m – E_{rev})$ represents the driving force for ion flow.

Another important passive electrical property is capacitance. A capacitor is an electrical device consisting of two conductors separated by an insulating material that is

capable of storing charges of opposite sign on the two conductors. In the case of neurons, the conductors are the extracellular and intracellular fluids while the lipid membrane is the insulator. Whenever current flows through the membrane, some current must flow to charge the membrane capacitance (C_m). The expression describing this capacitive current is: $I_{cap} = C_m \cdot (dV/dt)$. Note that capacitive current flows only when the membrane potential is changing (i.e., there is some change in voltage [dV] as a function of time [dt]. The total current flowing across a membrane at any given time is a sum of I_{cap} and I_{ionic}. One of the major tools used by physiologists to study ionic currents is a *voltage clamp* (or more recently a patch clamp). These techniques employ electrical devices to keep the membrane potential constant and eliminate the contribution of capacitive currents during physiological studies, thus making it possible to measure ionic currents directly.

One way to view the operation of an ion channel is as a battery (voltage source) in series with a conductor (resistor). The different types of ion channels can be viewed as being in parallel with each other and with the membrane capacitance. The net result is that the neuronal membrane can be represented by an equivalent electrical circuit (Fig. 1.9-2), which can be used to describe how current flows when ions enter and exit the cell in response to various stimuli.

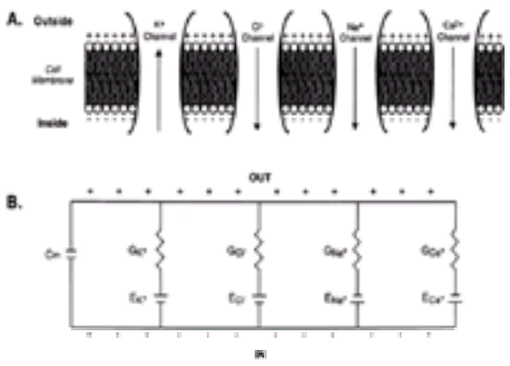

FIGURE 1.9-2 Ion channels form proteinaceous pores that traverse the lipid bilayer of the cell membrane. Because of the action of membrane pumps, the extracellular surface of the membrane has a net positive charge with respect to the intracellular surface. As a result of the transmembrane potential and the presence of ion channels, the neuronal membrane can be depicted as an equivalent electrical circuit in which each ion channel is a resistor (conductor, G_x) in series with a battery (E_x). Different ion channels are shown parallel with each other and parallel with the membrane capacitance (C_m).

Active Membrane Properties: Action Potentials Changes in membrane potential have important effects on excitability because certain ion channels are activated (gated) by voltage changes. When neurons are depolarized with respect to the resting potential, specific Na^+ channels open rapidly and drive the membrane potential towards the Na^+ equilibrium potential (+66 mV). Because of the leakage channels that are open at rest, there is initially a balance between the leakage currents and the currents flowing through Na^+ channels that are opened by depolarization. However, at a certain membrane potential the current flowing through Na^+ channels exceeds the current through the leakage channels. The membrane potential at which Na^+ currents exceed the leakage currents is called the *threshold potential*. Importantly, at potentials that are depolarized with respect to threshold the entry of more Na^+ into the neuron produces further depolarization, which in turn opens more Na^+ channels in a regenerative fashion. During this process the neuronal membrane potential depolarizes to potentials >0 mV but never reaches the Na^+ equilibrium potential for two reasons. First, during the depolarization, Na^+ channels not only activate but they also rapidly inactivate. *Inactivation* refers to a process by which voltage-gated ion channels enter a nonconducting state despite the continued presence of the activating stimulus (depolarization). Second, the depolarization produced by Na^+ entry also opens voltage-gated K^+ channels, which drive the membrane potential towards the K^+ equilibrium potential (–96 mV). The net effect of the activation and inactivation of Na^+ channels and the delayed opening of K^+ channels is that the neuronal membrane potential rapidly changes to values >0 mV and then returns rapidly to the resting membrane potential. This rapid sequence occurs over several milliseconds and is referred to as an *action potential* (or *spike*) (Fig. 1.9-3). The fact that the membrane potential transiently exceeds 0 mV is called an *overshoot*. Action potentials represent all-or-none increases in electrical excitability and are important contributors to information transfer within and between neurons, allowing the neuronal cell body to communicate rapidly with its terminals, and in the terminals providing the depolarization that promotes the Ca^{2+}-dependent release of neurotransmitters.

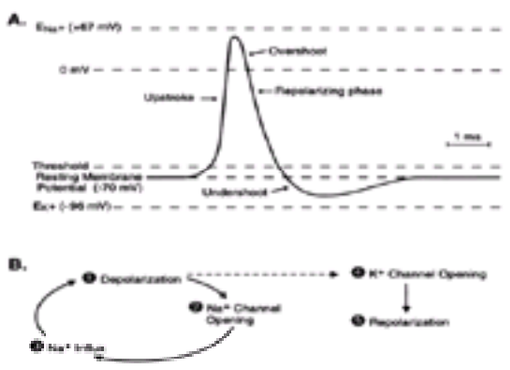

FIGURE 1.9-3 A. A neuronal action potential as recorded by an intracellular microelectrode. The portions of the action potential are described in the text. **B**. The sequence of events underlying the action potential.

In most neurons the K^+ equilibrium potential is negative with respect to the resting membrane potential. Thus, the action potential is often followed by a transient afterhyperpolarization (or undershoot) that decays back to the resting potential as the voltage-sensitive K^+ channels responsible for action potential repolarization close (Fig. 1.9-3). Following an action potential, there is a time during which stimulation either cannot elicit an action potential or during which it takes a very strong stimulus to evoke an action potential. These are called the absolute and relative refractory periods, respectively. The *absolute refractory period* results from the increased K^+ conductance that repolarizes the action potential and produces the undershoot; the *relative refractory period* reflects the time it takes for Na^+ channels to recover from inactivation.

Action Potential Conduction in Axons Action potentials are typically generated in the neuronal cell body or in the initial segment of the axon (also called the *axon hillock*) where Na^+ channels are densely collected. Because action potentials are generated at a distance from the nerve terminals where neurotransmitters are released, an important question concerns how action potentials are transmitted to the synaptic terminals. In a strictly passive nerve fiber, leakage of current across the membrane results in *decremental conduction* with the signal fading over a distance that is determined by the longitudinal (axial) resistance of the fiber, the membrane capacitance, and the transmembrane resistance. Decremental conduction is more typical of the spread of electrical signals along dendrites back to the neuronal cell body, although recent studies have shown that dendrites also have voltage-gated ion channels that play important roles in modifying electrical synaptic inputs to the dendrites.

Many axons are encased in myelin sheaths that allow them to send action potentials over longer distances. As a result of myelination, axons are electrically insulated except at Ranvier's nodes where there are collections of voltage-gated Na^+ channels involved in action potential generation (Fig. 1.9-4). The myelin sheath greatly increases the transmembrane resistance and diminishes current leakage from the axon, making it easier for current to flow down the length of the axon. Once generated, action potentials propagate rapidly and the wave of depolarization jumps from node to node in a form that transmits the signal faithfully to the nerve terminals. This process of action potential spread through axons is referred to as *saltatory conduction* (derived from the Latin word *saltare* meaning “to jump”) and is important because of the speed and fidelity with which electrical information is passed from a nerve cell body to its terminals. The importance of saltatory conduction can be readily appreciated when considering the distances over which impulses must travel from the CNS to cause movement in the toes. In several human illnesses, including multiple sclerosis and Guillain-Barré syndrome, demyelination of axons produces changes in axon conduction and specific neurological defects.

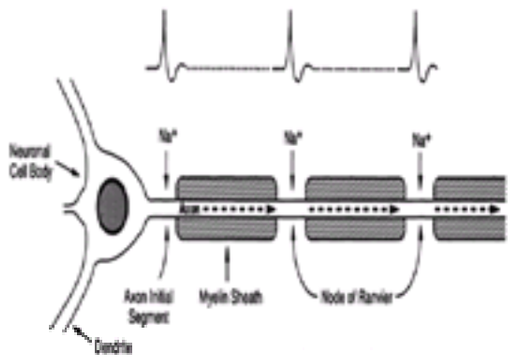

FIGURE 1.9-4 An example of saltatory conduction of an action potential in a neuron with a myelinated axon. The action potential is generated in the initial segment of the axon. As the signal moves along the axon, current tends to leak from the cell diminishing the amplitude. However, myelin insulates the axon and markedly diminishes current leakage out of the axon, thus enhancing flow down the axon to the first node of Ranvier. At the node of Ranvier, Na^+ channels of the type involved in action potentials open in response to the wave of depolarization and reproduce the all-or-none action potential. The sequence is repeated at subsequent nodes of Ranvier until the action potential reaches the nerve terminal.

ION CHANNELS

Structure and Function of Voltage-Gated Ion Channels Voltage-gated ion channels allow the flow of ions in response to changes in membrane voltage and are key elements in neuronal excitation and inhibition. Although ion channels can usually pass more than a single type of ion, voltage-gated channels are named according to the predominant ion that flows when the channel is open. Ion channels that are selective for Na^+, K^+, Ca^{2+}, or Cl^- have been described in neuronal membranes. Certain ion channels that are gated directly by chemical neurotransmitters such as glutamate and acetylcholine are selective for Na^+, K^+, and Ca^{2+} but exclude Cl^- and are called *nonselective cationic channels*.

Sodium (Na^+) Channels Na^+ channels are primarily responsible for the fast upstroke of action potentials, although in some neurons Na^+ channels also contribute to lower-level depolarizations and pacemaker firing. Pacemaker activity refers to the ability of certain neurons to depolarize spontaneously and to drive activity in a system of connected cells. Na^+ channels *activate* (open) rapidly in response to depolarization and also *inactivate* rapidly and nearly completely in response to prolonged depolarizations.

Cloning studies have provided important information about the structure of Na^+ channels. Na^+ channels cloned from rat brain contain three protein subunits—a main (or a) subunit with a molecular weight of 240 to 280 kd and two minor subunits with molecular weights of 30 to 40 kd (termed b *1* and b*2*) that appear to assemble in a 1:1:1 ratio. The a-subunit is a glycoprotein consisting of four structurally similar (*homologous*) domains that each have six proposed membrane spanning regions, referred to as S1 through S6 (Fig. 1.9-5). The properties of voltage dependence, ion permeation, activation, and inactivation are conferred by specific regions of the Na^+ channel protein. However, the exact manner in which the proteins assemble in the lipid membrane remains a matter of active study.

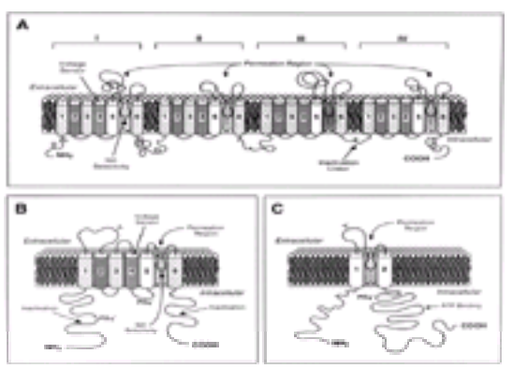

FIGURE 1.9-5 A. The diagram shows the proposed secondary structure of voltage-gated Na^+, Ca^{2+}, and K^+ channels based on analysis of the primary amino acid sequences. Na^+ and Ca^{2+} channels consist of four homologous domains (I,II,III, and IV), each of which has six membrane spanning regions (S1-S6). Both the amino (NH_2) and carboxy (COOH) terminals are located intracellularly. A stretch of amino acids between S5 and S6, called the p-loop, is believed to form two antiparallel b-sheets that line the channel pore. Positive charges in the S4 region are believed to comprise the voltage sensor. **B**. Some K^+ channels also have 6 transmembrane regions but lack the four homologous repeats seen in Na^+ and Ca^{2+} channels. **C**. Inwardly rectifying K^+ channels, including K-ATP channels, have a structure that differs from the scheme described above. These channels have two membrane spanning regions and a pore-lining p-loop. In contrast to channels gated by extracellular ATP (Fig. 1.9-7C), the bulk of the protein is located intracellularly.

Relations between primary protein structure and ion channel function in Na^+ channels have been examined using mutations of specific amino acid residues. It appears that both the amino- and carboxy-terminals of the a-subunits are located intracellularly. The fourth membrane spanning region (S4) plays a key role in sensing the transmembrane voltage changes that allow channel gating. Between the S5 and S6 membrane spanning regions there is a segment of hydrophobic amino acids that does not completely cross the lipid membrane bilayer. This reentrant loop of amino acids (called a *p loop*) is a feature shared by other voltage-gated ion channels and appears to form the lining of the ion channel pore.

Na^+ channels contain several sites at which neurotoxins and drugs act to influence excitability. Most but not all Na^+ channels contain an extracellular site at which tetrodotoxin (TTX) and saxitoxin (STX) act to block ion flow. TTX is a neurotoxin isolated from puffer fish that is used experimentally to block Na^+ channel function. At a site on Na^+ channels that is distinct from the TTX site, certain scorpion and sea anemone toxins act to modify gating properties. The a-scorpion toxin slows inactivation of Na^+ channels while b-scorpion toxins shift the voltage of activation and allow channels to open at voltages closer to the resting membrane potential. The net effect of the scorpion toxins is to enhance excitation, contributing to the increased firing in pain fibers and paralysis (tetany) that are associated with a scorpion sting. Mutations in the a-subunit of skeletal muscle Na^+ channels cause the human disorder hyperkalemic periodic paralysis. Like the anemone and a-scorpion toxins, these mutations slow channel inactivation.

Other toxins isolated from the buttercup family (aconitine), the lily family (veratridine), and frogs that are used for arrow poisons in South America (batrachotoxin) promote the direct opening of Na^+ channels and prolong the duration that the channels stay open. The net effect is similar to the scorpion toxins. Finally, certain local anesthetic drugs, including lidocaine and procaine, block Na^+ channels by binding reversibly to sites within the hydrophobic regions of the ion channel. The blockade of Na^+ channels is likely to contribute to local anesthetic effects as well as to the antiarrhythmic effects of these drugs in the heart. The rich pharmacology of voltage-gated Na^+ channels provides a means for understanding how certain neurotoxins act as well as a means by which Na^+ channel function can be manipulated therapeutically. It is important to emphasize that not all Na^+ channels in neurons are sensitive to all these agents. It is clear that TTX-insensitive Na^+ channels exist in a variety of excitable cells, although their function is not well understood at present.

Potassium (K^+) Channels K^+ channels represent the most diverse family of voltage-gated ion channels in excitable cells and are important participants in determining the firing properties of neurons. For example, the fast repolarization of neurons produced by certain K^+ channels allows an increased rate of action potential firing, which can then be used in frequency-dependent information coding. Most neurons express multiple types of K^+ channels that differ in their activation and inactivation kinetics, voltage dependence, and pharmacology. Because the equilibrium potential for K^+ is about –90 mV in most neurons, the opening of K^+ channels allows K^+ to flow out of the cell, resulting in membrane hyperpolarization and a decrease in excitability. The first K^+ channel to be identified was called a

delayed rectifier. These channels derive their name from the experiments of Hodgkin and Huxley on squid giant axons and are so named because the currents gated by these channels activate more slowly than the Na^+ channels that produce the upstroke of the action potential (i.e., the K^+ channel opening is delayed). A rectifier (or diode) is an electrical device that passes current better in one direction than another. The K^+ current is described as a rectifier because the channel is more effective in allowing K^+ ions to exit than to enter the cell.

Delayed-rectifier channels open slowly and show little inactivation during prolonged depolarizations. It appears that these channels help to determine the frequency with which neurons fire action potentials. Early experiments in squid giant axons indicated that delayed rectifier currents were the primary K^+ currents involved in action potential repolarization. However, in neurons the situation is more complex, with several more rapidly activating K^+ channels contributing significantly. These include two classes of calcium-activated K^+ channels that are opened by increases in intracellular Ca^{2+} and are called SK *small conductance Ca^{2+}-activated K^+* (*SK*) *channels* and *big conductance* (*BK*) *channels*, based on the relative ease (conductance) with which they pass K^+ when open. SK channels activate with relatively small intracellular Ca^{2+} increases to levels on the order of 100 nM whereas BK channels require Ca^{2+} levels to rise to 1 to 10 µM. In neurons, intracellular Ca^{2+} buffering mechanisms usually keep free Ca^{2+} concentrations <100 nM at rest. SK and BK channels are also distinguished by distinctive voltage-dependence and pharmacology. The bee toxin apamin blocks SK channels and the scorpion toxin charybdotoxin blocks BK channels. BK channels contribute to action potential repolarization in neurons, whereas SK channels produce a slow afterhyperpolarization responsible for the process of *accommodation* (adaptation) that diminishes repetitive action potential firing during prolonged depolarizations (Fig. 1.9-6).

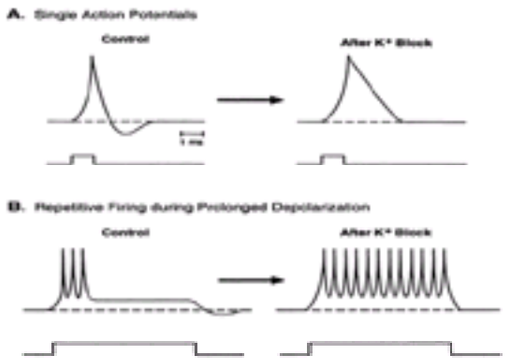

FIGURE 1.9-6 A. The traces show the effect of inhibiting K^+ channels involved in action potential repolarization. Following K^+ channel block, action potentials are broadened and show a diminished undershoot. **B**. During prolonged depolarizations, Ca^{2+}-activated K^+ conductances diminish repetitive firing by the process of accommodation (or spike adaptation). When these K^+ conductances are inhibited, prolonged depolarization results in repetitive action potential firing for the duration of the depolarizing stimulus.

A-type K^+ channels rapidly activate with depolarizations to potentials greater that –60 mV and rapidly inactivate at depolarized potentials; hence A channels are also referred to as transient (inactivating) K^+ channels. A channels are involved in setting the interspike frequency with which neurons can fire and contribute to action potential repolarization. D-type K^+ channels are inhibited by a-dendrotoxin and also appear to help action potential repolarization in neurons. These channels show slower activation and less inactivation than A-type channels.

M channels represent a class of K^+ channels that are activated in a time- and voltage-dependent fashion but are blocked by the neurotransmitter, acetylcholine, acting at muscarinic receptors. These channels contribute to action potential repolarization and help to slow repetitive firing. In the sea snail, *Aplysia californica*, S channels are K^+ channels that contribute to action potential repolarization are inhibited by the neurotransmitter serotonin. Importantly, the activity of these S channels is diminished during acute behavioral sensitization of the gill-withdrawal reflex in *Aplysia*, and studies of the role of these channels in synaptic function have provided important insights into the cellular basis of certain forms of learning and memory.

Some ion channels are opened by hyperpolarization instead of depolarization. These include anomalous (inward) rectifier and H channels that allow K^+ to enter rather than exit the cell. The name “anomalous rectifier” (also called “inward rectifier”) indicates that, in contrast to the delayer rectifier, this channel passes K^+ much better in an inward than in an outward direction. The anomalous rectifier and H channels (hyperpolarization activated channels) are believed to contribute to the neuronal resting membrane potential and to pacemaker firing in certain neurons. H channels are permeable to both K^+ and Na^+ and show little inactivation. Thus, H channels gate a persisting current at membrane potentials near rest. The Na^+ current contribution from H channels may contribute to the fact that the resting membrane potential in most neurons is depolarized with respect to the K^+ equilibrium potential.

In peripheral tissues and in some neurons a class of K^+ channels is regulated by intracellular ATP (K_{ATP}). In the pancreas these K_{ATP} channels are important because they are involved in controlling the release of insulin and are a site of action of the hypoglycemic sulfonylurea drugs, such as tolbutamide (Tolbutamide), that are used to treat patients with diabetes mellitus. The hypoglycemic drugs promote the release of insulin by blocking the ATP-sensitive K^+ channels, which in turn leads to membrane depolarization, calcium influx, and release of the hormone. Diazoxide (Hyperstat), an antihypertensive drug that has the adverse effect of increasing blood glucose concentrations and has the opposite effect on pancreatic (K_{ATP}) channels, opening the channels and diminishing the release of insulin.

K_{ATP} channels exist in the CNS and appear to be involved in regulating the release of certain neurotransmitters and perhaps in determining the response of some neurons to changes in intracellular energy levels. Although the role of K_{ATP} channels in regulating transmitter release in neurons is not well understood, the effects of the hypoglycemic drugs and diazoxide on the release of insulin from pancreatic islet cells raise instructive points concerning how K^+ channels help to control the release of transmitters and hormones. During action potentials, voltage-gated Ca^{2+} channels open and the resulting increases in intracellular Ca^{2+} promote transmitter release. When K^+ channels that normally contribute to the repolarization of action potentials are blocked, either by neurochemicals or drugs, the action potential duration is prolonged and more Ca^{2+} enters the cell, leading to enhanced transmitter release.

In the late 1980s several groups used the *Shaker* behavioral mutants in the fruit fly, *Drosophila melanogaster*, to clone specific K^+ channels. *Shaker* is a mutant fly that develops hyperexcitability (shaking) following exposure to specific anesthetics. The enhanced excitability results from abnormal function of A-type K^+ channels. Cloning studies of K^+ channels from *Shaker* indicate that some K^+ channels, like Na^+ channels, are proteins that have six putative membrane spanning regions (S1 through S6), a reentrant p loop between S5 and S6 that lines the ion channel pore, and a voltage sensor in the S4 region (Fig. 1.9-5). These K^+ channel proteins are only about one fourth the size of the Na^+ channel a-subunit and have only one of the homologous internal repeats seen in Na^+ channels. It also appears that there are multiple distinct subfamilies of K^+ channels based on genetic studies in *Drosophila*, where the most detailed analysis has been done. Presently, four subfamilies of K^+ channels have been identified (Kv1 through Kv4), each of which has multiple subtypes. Different K^+ channels within a subfamily and perhaps across subfamilies may combine to produce channels with diverse functions, but it is presently unclear how subunits assemble to produce functional K^+ channels. Best estimates suggest a structure with four pore-forming (a) subunits that are analogous to the four homologous repeats of Na^+ channels. K^+ channels also contain cytoplasmic (b) subunits that appear to be important in channel inactivation and in controlling cell surface expression of the a-subunits.

An important principle in K^+ channel physiology is that certain neurotransmitters alter the function of these channels. Acetylcholine, acting at muscarinic receptors, blocks several K^+ currents leading to enhanced neuronal excitability. In the hippocampus and other CNS regions, the neurotransmitters g-aminobutyric acid (GABA), serotonin, and adenosine open the same class of inwardly rectifying K^+ channels by activating a G protein. Similarly, acetylcholine activates inwardly rectifying K^+ channels in a variety of tissues including the heart and CNS. These G–protein–regulated, inwardly rectifying K^+ channels (GIRKs) allow divergent synaptic inputs to a single neuron to exert regulatory influences over neuronal firing through a single class of ion channels. The inwardly rectifying K^+ channels, including K_{ATP} channels, differ structurally from the Kv (*Shaker*) family described previously in that they have only two membrane spanning regions and a pore-forming loop (see Fig. 1.9-5); GIRKs also lack the voltage sensor found in the Kv family. K_{ATP} channels appear to be heteromultimers that contain an inwardly rectifying K^+ channel and a large subunit that binds ATP and sulfonylurens.

Calcium (Ca^{2+}) Channels Because Ca^{2+} is involved in numerous cellular events including enzyme activation, gene expression, and neurotransmitter release, the

regulation of intracellular Ca^{2+} levels is of major importance to neurons. Furthermore, excessive and prolonged increases in intracellular Ca^{2+} concentrations contribute to neuronal death in acute and chronic human neurodegenerative conditions. Voltage-activated Ca^{2+} channels provide a major source of the Ca^{2+} signal that is used to activate cellular processes, and neurons possess multiple classes of voltage-gated Ca^{2+} channels.

There are several ways to classify voltage-gated Ca^{2+} channels based on biophysical and pharmacological properties. Some Ca^{2+} channels are activated by relatively small depolarizations over the range of –80 to –50 mV and are called *low voltage-activated* (*LVA*) *Ca^{2+} channels*. These LVA channels inactivate rapidly and are relatively insensitive to dihydropyridine calcium channel inhibitors, such as nifedipine (Adalat) and nimodipine (Nimotop). LVA channels are also called *T-type Ca^{2+} channels* because of their transient (inactivating) currents. LVA Ca^{2+} channels contribute to burst firing and oscillatory activity in neurons because they are activated at membrane potentials near rest. Oscillatory neuronal firing may be important in driving coordinated movements and in maintaining wakefulness. LVA channels also appear to be present in neuronal dendrites and may contribute to synaptic integration and synaptic plasticity. These channels do not appear to participate in transmitter release.

A second group of Ca^{2+} channels is activated by larger depolarizations to membrane potentials above –50 mV and are called *high voltage-activated* (*HVA*) *Ca^{2+} channels*. In many neurons, even when Na^{+} channels that are typically involved in the upstroke of action potentials are blocked, HVA Ca^{2+} channels can produce regenerative spikes. These Ca^{2+} spikes are typically slower in onset and longer in duration than Na^{+} spikes, reflecting the kinetics of HVA channels. HVA Ca^{2+} channels are heterogeneous and several classes contribute to HVA Ca^{2+} currents. *L-type Ca^{2+} channels* (named for their "*long*-lasting" responses) show slow inactivation during sustained depolarizations and are sensitive to blockade by dihydropyridines. L-type Ca^{2+} channels provide sufficient Ca^{2+} influx during action potentials to activate Ca^{2+}-dependent second-messenger systems. *N-type Ca^{2+} channels* (named historically because they were neither L nor T type) are also HVA channels that appear to be involved in providing the Ca^{2+} signal necessary for the release of neurotransmitters from presynaptic terminals. N-type channels are blocked by w-conotoxin GVIA, a poison derived from the snail, *Conus geographicus. P-type Ca^{2+} channels* represent a third class of HVA channels and are so named because of their presence in Purkinje cells of the cerebellum. P-type channels are also found in pyramidal neurons of the hippocampus and cortex, and are insensitive to dihydropyridines and w-conotoxin GVIA but are blocked by a toxin from the funnel web spider, *Agelenopsis aperta*, that is designated w-*Aga-IVA*. P-type channels, like N-type channels, participate in the release of neurotransmitters at specific sites in the CNS. Recent evidence indicates that there are other classes of HVA Ca^{2+} channels that contribute to CNS function (designated *Q-type* and *R-type*), but their functions are not well understood at present. Q-type channels are potently blocked by w-conotoxin-MVIIC isolated from *Conus magus* and appear to participate in transmitter release. R-type channels are *r*esistant to the Ca^{2+} channels antagonists described above.

Most structural information about Ca^{2+} channels comes from skeletal muscle HVA Ca^{2+} channels. These channels consist of five distinct subunits that are termed a1 (165–195 kDa), a2/d (~170 kDa), b (50–60 kDa), and g (25–35 kDa). The a1-subunits show considerable sequence homology (~30 percent) to voltage-gated Na^{+} channels and form the ion channel pore. A recurring theme in the a1-subunits is the existence of four homologous internal repeats that each contain six putative membrane spanning regions and a p-loop. HVA a1 Ca^{2+} channel subunits contain the dihydropyridine binding site and show structural heterogeneity, with current evidence suggesting the existence of several different a1 subunits (designated $a1_{A-E}$). Additionally, an a, subunit for LVA Ca^{2+} channels has been cloned from rat brain (designated a1G). Point mutations in the a1-subunit of skeletal muscle T tubule Ca^{2+} channels appear to cause the human disorder hypokalemic periodic paralysis. The causative mutations occur in the S4 region of the channel involved in voltage sensing.

In some regions of the CNS, particularly retinal photoreceptors and olfactory epithelial cells, intracellular cyclic nucleotides (e.g., cyclic AMP and cyclic GMP) gate specific classes of ion channels. These cyclic-nucleotide gated (CNG) channels have structural features that are reminiscent of voltage-gated calcium channels, including the presence of six membrane spanning regions and a p-loop that lines the ion channel. CNG channels are nonselectively permeable to cations, but like voltage-gated calcium channels, the flow of monovalent cations through CNG channels is blocked by calcium.

Chloride (Cl^{-}) Channels In most neurons, Cl^{-} is present at higher concentrations extracellularly than intracellularly and the equilibrium potential fo r Cl^{-} is near the cell resting membrane potential. Thus, the opening of Cl^{-} channels tends to keep the neuronal membrane potential near rest, and in conjunction with K^{+} channels, serves as a mechanism to dampen neuronal excitability. Cl^{-} channels contribute significantly to the resting membrane potential in certain neurons and muscle cells. These channels are spontaneously open at resting membrane potentials and exhibit weak voltage and time-dependence. In certain muscle fibers the background Cl^{-} conductance is the largest resting conductance and the distribution of Cl^{-} is near equilibrium. In the human illness myotonia congenita, an abnormality of muscle Cl^{-} channels leads to increased muscular excitability and symptoms of fatigue and cramping during exercise. The rat muscle Cl^{-} channel involved in myotonia is a single polypeptide with 12 putative membrane spanning regions.

Some Cl^{-} channels are activated by increases in intracellular Ca^{2+} and others are activated by membrane depolarization. The Ca^{2+}-activated Cl^{-} channels may help to determine the interspike frequency with which neurons can fire. In addition to their roles in neuron excitability, Cl^{-} channels serve important functions in secretory cells providing the major source of Cl^{-} in tears, sweat, and digestive juices. A defect in secretory Cl^{-} channels that renders the channels insensitive to normal activating stimuli appears to be a major factor in the pathophysiology of cystic fibrosis. The cystic fibrosis transmembrane conductance regulator (CFTR) has a structure that is distinctly different from the muscle Cl^{-} channels involved in myotonia but is similar to ATPase-linked transporters with 12 transmembrane regions.

NEUROTRANSMITTERS AND ION CHANNELS

Classes of Neurotransmitters Much of the information transfer between neurons in the CNS occurs via chemical synapses. These synapses use a variety of messengers (neurotransmitters) that are released in a Ca^{2+}-dependent fashion from presynaptic terminals and act on specific protein receptors to produce biochemical and excitability changes in the receiving cell. There are two primary groups of neurotransmitters—low–molecular-weight amines and neuroactive peptides. These agents act on two classes of receptors, ligand-gated ion channels, at which the binding of the transmitter directly opens ion channels in the membrane, and G protein coupled receptors. The activated G protein then acts on ion channels or alters biochemical second-messenger systems. Physiologists classify synaptic transmission according to the speed of transmission (fast or slow) and according to the nature of the response (excitatory or inhibitory). Fast synaptic transmission occurs on a time scale of up to several hundred milliseconds and is mediated primarily by amine neurotransmitters acting at ligand-gated ion channels. Slow synaptic communication occurs on the scale of seconds to minutes or longer through the actions of either amines or peptides acting on G protein coupled receptors. Different ion channels determine whether transmitter effects are *excitatory* (depolarizing) or *inhibitory* (hyperpolarizing). Moreover, an excitatory synaptic input can exert an inhibitory influence on the firing characteristics of a region. For example, the release of an excitatory neurotransmitter onto an inhibitory interneuron can result in the inhibitory neuron diminishing the activity of a population of cells. Conversely, inhibition of inhibitory interneurons can enhance regional excitability. This provides a great deal of flexibility in controlling and fine-tuning the inputs and outputs of a region.

Currently, there are nine low–molecular-weight amines that serve as neurotransmitters. These include glutamate, the major fast excitatory transmitter in the mammalian CNS, acetylcholine, the excitatory transmitter at the vertebrate neuromuscular junction, g-aminobutyric acid (GABA), and glycine, the major fast inhibitory transmitters in the brain and spinal cord, respectively, and the biogenic amines, dopamine, norepinephrine, epinephrine, serotonin, and histamine. It also appears that the purines, adenosine and adenosine triphosphate (ATP), act as transmitters in some regions. A large number of neuroactive peptides alter neuronal excitability. However, it is uncertain whether all of these substances function as neurotransmitters. Many of these peptides, including vasopressin and cholecystokinin, were first identified as hormones in the vasculature and gut. ATP and certain neuroactive peptides coexist with amine neurotransmitters in some nerve terminals, and there is evidence for co-release of these agents at particular synapses. These observations suggest that interactions between classes of neurotransmitters may be important in determining the ultimate effects of a presynaptic neuron on its postsynaptic target.

Conductance Mechanisms Underlying Neurotransmitter Actions Neurotransmitter actions are often described in terms of effects on membrane conductances. The transmitters that act at ligand-gated ion channels increase the conductance of the cell membrane to specific ions. Excitatory transmitters, such as acetylcholine and glutamate, directly activate nonselective cationic channels, increasing the conductance to Na^{+}, K^{+}, and in some cases Ca^{2+}, while the inhibitory transmitters, GABA and glycine, increase the conductance to $C1^{-}$. A second group of transmitters increases membrane conductance, but does so indirectly through a G protein. For example, GABA, serotonin, and adenosine promote G-protein–mediated opening of inwardly rectifying K^{+} channels in a variety of neurons. A third set of transmitter actions results from indirect effects on voltage-gated or leakage ion channels. These transmitters typically decrease membrane conductance by activating chemical second messenger systems via G-protein coupled receptors. Certain voltage-gated K^{+} and Ca^{2+} channels are specific targets of this inhibition, resulting in excitation or inhibition, respectively. Most transmitters that act on G protein coupled receptors exert at least some of their effects by these decreased conductance mechanisms. The electrical principles underlying synaptic excitation or inhibition are identical to those described for voltage-gated ion channels and are based on the relative permeabilities of the ion channels and the Nernst potentials of the ions involved.

Several transmitters (e.g., GABA, glutamate, acetylcholine, serotonin) act at both ligand-gated ion channels and G-protein coupled receptors. This raises the point that receptors for almost all neurotransmitters, and consequently the effects of these transmitters, are heterogeneous, with the nature of the transmitter effect depending on the specific receptor to which the transmitter binds. Molecular cloning studies have demonstrated that receptors for most neurotransmitters are structurally complex, with multiple receptor subtypes being the rule rather than the exception. At the receptor level there is tremendous flexibility in determining the effects of a given neurotransmitter on a single neuron or on a set of neurons in a CNS region.

Structure of Neurotransmitter Receptors Considerable information now exists about the primary structure of neurotransmitter receptors. Most transmitter-gated ion channels are multimeric proteins consisting of several (usually 5) subunits that each have multiple (2 to 5) membrane spanning regions (Fig. 1.9-7). The functional receptor typically has a large amino-terminal region that extends into the aqueous extracellular environment. In this extracellular region are sites at which neurotransmitters bind and at which sugar molecules are attached to the receptor (glycosylation sites). The function of receptor glycosylation is poorly understood, but presumably plays a role in determining optimal conformations for channel gating. The intracellular regions of the receptor often contain sites at which a phosphate group can be attached. Phosphorylation represents an important mechanism by which second messenger systems modulate the function of receptors and ion channels and is likely to be involved in certain forms of short-term learning and memory.

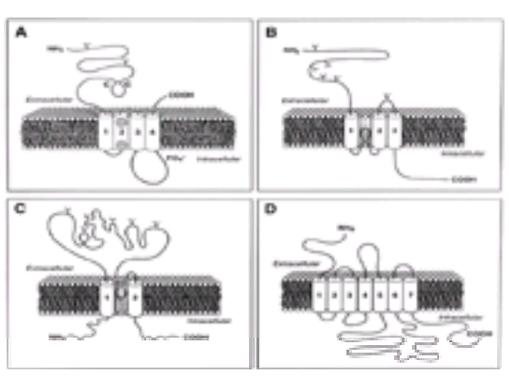

FIGURE 1.9-7 The diagrams show the proposed secondary structure of receptors for several neurotransmitters, including a GABA, receptor **(A)**, an ion-channel-linked glutamate receptor **(B)**, a channel gated by extracellular ATP **(C)**, and a G-protein coupled receptor **(D)**.

The first transmitter-gated channel to be cloned was the muscle-type nicotinic acetylcholine receptor. To date, five neuromuscular nicotinic receptor subunits have been identified (a, b, g, s, and e). Each of these subunits has four membrane spanning regions and a pair of cysteine residues located 15 amino acids apart in the extracellular region of the protein (Fig. 1.9-7). These cysteine residues form a disulfide bridged loop that may contribute to transmitter binding. The nicotinic ion channel is a nonselective cation channel that is permeable to Na^+, K^+, and Ca^{2+}. The membrane spanning regions of the subunits form the ion channel with the second transmembrane region forming the lining of the channel pore. The nicotinic receptor subunits assemble to form a pentamer with the stoichiometry of a $_2$bg and d or e depending on the age of the animal. Subsequent studies found that muscle-type nicotinic receptors are part of a superfamily that includes neuronal nicotinic, GABA type A ($GABA_A$), glycine, and serotonin (5-hydroxytintamine [5-HT]) type 3 ($5\text{-}HT_3$) receptors. Interestingly, $GABA_A$, and glycine receptors are anion selective, passing primarily Cl^- in physiological solutions, whereas nicotinic and $5\text{-}HT_3$ receptors are cation selective. Differences in charges on amino acids at the entrance to the ion channel pore determine whether the channel passes cations or anions. The presence of the paired cysteine residues in the extracellular domain and four membrane spanning regions is characteristic of this class of receptors, which is sometimes referred to as the *cysteine-loop superfamily of receptors*.

The ligand-gated ion channels gated by extracellular ATP (called *P2X receptors*) are exceptions to the scheme described above and have structures more typical of the inwardly rectifying K^+ channels (Fig. 1.9-7). ATP receptors have two membrane spanning regions and a pore forming region (p loop) that are connected by a large loop of extracellularly located amino acids. A major difference between the P2X receptors and the inwardly rectifying K^+ channel is that the bulk of the P2X receptor is extracellular whereas the majority of the K^+ channel is intracellular. P2X channels are cation selective and have a relatively large permeability to calcium. These receptors appear to play a role in fast excitatory synaptic transmission in certain regions of the CNS, including the thalamus. Native ATP receptors may consist of combinations of P2X subunits.

Ion channel-linked glutamate receptors also appear to be exceptions to the structural scheme proposed for $GABA_A$, and nicotinic receptors. The glutamate receptor subunits have three membrane spanning regions and a reentrant p loop that does not completely span the membrane (Fig. 1.9-7). The p loops in the glutamate-gated and ATP-gated channels are similar to those found in voltage-gated ion channels.

G-protein coupled receptors have a distinctly different structure from the ligand-gated ion channels. These receptors are typically single subunit proteins with seven membrane spanning regions (Fig. 1.9-7). Transmitter binding is believed to occur in a pocket formed by the intramembranous portions of the receptor. The coupling of the receptor to a G protein occurs at intracellular loops of the receptor. G-protein coupled receptors also have sites for glycosylation and phosphorylation.

PSYCHIATRIC ASPECTS OF ION CHANNELS

The successful application of electrophysiological methods to problems of interest in psychiatry makes it likely that principles of cellular physiology will be increasingly important to the understanding and treatment of psychiatric disorders. The ability to describe the effect of drugs on specific ion channels has had a major impact on psychopharmacology. Illuminating the mechanisms of action of commonly used psychotherapeutic agents by exploring the molecular and cellular effects of these drugs is likely to have further effects on the clinical use of the compounds. The interaction of anxiolytics, such as the benzodiazepines, with the $GABA_A$ receptor is an example. A molecular understanding of the effects of current psychotherapeutic agents offers the hope for the design of new agents with superior therapeutic properties. The ability to study the electrophysiological properties of individual neurons shows that the function of the cells partially reflects the selective expression of ion channels. Cells expressing the *N*-methyl-D-aspartate (NMDA) type of glutamate receptor develop enhanced responsivity when given high-frequency stimulation, a phenomenon called *long-term potentiation* (LTP). This process is a model for the synaptic plasticity that might be responsible for memory and learning. Other nerve cells exhibit intrinsic repetitive firing that drives certain neural networks. The sustained activity of some neural systems may be responsible for behavioral states such as sleep and wakefulness. These examples and others illustrate the importance of electrophysiological principles and will be presented briefly below. Ion channel defects also have been linked directly to several human disorders; examples are described to illustrate the pathological impact of channel defects.

GABA Receptors and Anxiolytic Drugs $GABA_A$ receptors are a type of ligand-gated ion channel that pass chloride ions selectively and are inhibitory in most CNS regions. Additionally, $GABA_A$ receptors are a site of action of many CNS depressants including barbiturates, neurosteroids, loreclezole, benzodiazepines, and probably ethanol. These agents appear to act at distinct sites within the $GABA_A$ receptor complex. Benzodiazepines, in particular, have complex effects on $GABA_A$ receptors. Agonists at benzodiazepine sites (e.g., diazepam [Valium], chlordiazepoxide [Limbrium], and alprazolam [Xanax]) increase the apparent affinity of $GABA_A$ receptors for GABA, enhancing responses to low GABA concentrations but not altering the peak responses to maximal GABA concentrations. The net effect of benzodiazepine agonists on $GABA_A$ ion channels is to increase the frequency of channel openings in the absence of changes in intrinsic channel kinetics (e.g., open channel durations). These effects differ from the effects of barbiturates and neurosteroids, which prolong channel open times and are capable of directly opening $GABA_A$ channels in the absence of GABA. A second class of drugs, called *benzodiazepine inverse agonists*, bind to benzodiazepine sites but inhibit Cl^- flux. Certain b-carbolines are examples of inverse agonists at benzodiazepine receptors. The inverse agonists have clinical effects that are the opposite of the effects of the benzodiazepine agonists (e.g., anxiogenic and convulsant activity in contrast to sedation). Flumazenil (Romazicon) binds to benzodiazepine sites but does not alter the flow of Cl^-. Rather, flumazenil blocks the effects of benzodiazepine agonists and inverse agonists, and is referred to as a *benzodiazepine receptor antagonist*. Flumazenil is clinically useful in reversing the effects of benzodiazepine receptor agonists in anesthetic or overdose situations.

The effects of benzodiazepine agonists are heterogeneous and depend on the region of the CNS and the subunit composition of the $GABA_A$ receptors. Certain sites have a high affinity for the hypnotic drug, zolpidem (Ambien) and are referred to as benzodiazepine *type 1 receptors* (BZ_1). Other sites have a lower affinity for this drug and are called *type 2 receptors* (BZ_2). BZ_1 receptors are the predominant $GABA_A$-benzodiazepine receptors in the CNS whereas BZ_2 sites are found primarily in

the hippocampus, neocortex, striatum, and spinal cord.

Studies using recombinant $GABA_A$ receptors have demonstrated that the distinction of the two benzodiazepine receptors results from differences in the subunit composition of $GABA_A$ receptors. So far 15 different $GABA_A$ receptor subunits have been cloned (termed a1-6, b1-4, g1-3, d, and e). Functional GABA-gated ion channels appear to be pentamers composed of various combinations of these subunits. GABA most likely binds to b-subunits, while the presence of a g-subunit is critical for benzodiazepine sensitivity. The distinction between BZ_1 and BZ_2 pharmacology depends on which a-subunit is expressed with b-and g-subunits; a1-containing $GABA_A$ receptors exhibit BZ_1 pharmacology whereas a2-, a3- and a5-containing receptors have BZ_2 responses. Receptors containing a6-subunits (and perhaps a4-subunits) are insensitive to benzodiazepine agonists. The prevalence of sleep and anxiety disorders, coupled with the important clinical effects of benzodiazepines as hypnotics, anxiolytics, anticonvulsants, and muscle relaxants has made $GABA_A$-benzodiazepine receptors a major target for drug development. Current efforts in this direction include the development of receptor-subtype selective agents (such as zolpidem [Ambien]) and partial agonists that have diminished intrinsic efficacy at $GABA_A$ receptors, fewer adverse effects, and perhaps less abuse potential than traditional benzodiazepine agonists.

NMDA Receptors and PCP The effects of neurotransmitters on ion channels is of considerable importance in understanding the mechanisms of actions of a variety of psychoactive drugs. An intriguing observation is that the NMDA class of glutamate receptors may be an important site of action for the street drug, phencyclidine (PCP, “angel dust”). PCP is abused for its hallucinogenic and dissociative (feelings of unreality) properties. PCP and its structural analogs, dizocilpine (MK-801) and ketamine (Ketalar), bind to a site within the NMDA channel and block ion flow. The block of NMDA channels by PCP-like drugs is long-lived, with the ion channel closing around the PCP molecule. Relief of PCP block requires that NMDA channels open at depolarized potentials. It is presently uncertain how the NMDA-channel–blocking effects contribute to the psychotomimetic effects of PCP, although understanding this interaction remains an area of intense investigation. The finding that PCP-like drugs produce pathomorphological changes in posterior cingulate cortical neurons suggests the involvement of specific limbic circuits. NMDA receptors also appear to be an important site of action of alcohol in the CNS; ethanol inhibits NMDA receptors through an unknown mechanism.

An important aspect of NMDA receptors is the role that these ligand-gated channels play in synaptic plasticity. Although the cellular mechanisms underlying learning and memory in the human brain are unknown, the changes are believed to be responsible for certain forms of memory reside in longer-term alterations in synaptic transmission. When glutamate synapses are used at high frequency, they undergo a persistent enhancement of responsivity, a process referred to as *long-term potentiation* (LTP). LTP induction depends critically upon activation of NMDA receptors and requires the coincident detection of changes in presynaptic function (glutamate release) and postsynaptic membrane depolarization. NMDA receptors have several unique properties that make them potential molecular switches for altering synaptic function. First, NMDA ion channels are highly permeable to calcium ions and when these channels open they provide a large calcium signal to neurons. Calcium, in turn, is an important messenger that drives a host of cellular biochemical changes that include activation of specific protein kinases, phospholipases, and other cellular synthetic enzymes. Thus, calcium influx mediated by NMDA channels serves as an important trigger for producing changes in synaptic function. Second, NMDA ion channels are effectively inhibited at membrane potentials near the neuronal resting membrane potential because of a voltage-dependent block by physiological concentrations of extracellular magnesium ions. The magnesium-dependent block of NMDA channels is relieved when the neuronal membrane potential is depolarized. In effect, NMDA receptors serve as coincidence detectors requiring for activation both the binding of glutamate and postsynaptic membrane depolarization. When these conditions are met, NMDA receptors participate in synaptic transmission and play key roles in the induction of LTP. Interestingly, NMDA receptors also participate in some forms of long-term synaptic depression as well, but in the case of “long-term synaptic depression” it appears that the degree of postsynaptic membrane depolarization is less than that which accompanies long-term potentiation possibly resulting in a smaller calcium signal and the preferential activation of protein phosphatases in postsynaptic cells. Presently, LTP and long-term depression are the leading candidates for cellular mechanisms underlying certain forms of learning in the mammalian nervous system. Given that PCP and ethanol inhibit NMDA receptors, it is tempting to speculate that the amnestic effects of these drugs (called “blackouts” in the case of alcohol) result from blockade of NMDA receptors.

Depolarization Block and Antipsychotic Drugs Although the mechanisms involved in the actions of antipsychotic drugs remain a matter of debate, it is clear that these agents alter dopamine function in the CNS, blocking dopamine receptors and increasing dopamine turnover. An interesting finding that may have relevance to the mechanism of action is that antipsychotic drugs alter the firing of dopaminergic neurons. During initial short-term administration, the antipsychotics increase firing of dopamine neurons. However, long-term administration over several weeks leads to a progressive decrease in firing frequency that is accompanied by persistent depolarization of dopamine neurons. The mechanisms responsible for this depolarization block are not well understood, but could involve depolarization-induced inactivation of voltage-gated sodium and calcium channels. The induction and maintenance of the block are known to depend upon afferent inputs to the dopamine neurons from striatum and nucleus accumbens. Recent evidence suggests that depolarization block may involve activation of glutamate-mediated excitatory feedback as a result of chronic blockade of postsynaptic dopamine receptors.

Both dopamine receptor antagonists and serotonin-dopamine antagonists depolarize neurons in the ventral tegmental area neurons that project to cortical and limbic sites whereas only the dopamine receptor antagonists depolarize neurons in the substantia nigra that project to the striatum. This suggests that the lack of effect of the serotonin-dopamine antagonists antipsychotics on substantia nigra dopamine neurons may account for the diminished frequency of extrapyramidal adverse effects associated with these agents. Furthermore, there is a correlation between the ability of antipsychotic drugs to produce depolarization block of mesolimbic dopamine cells and their therapeutic benefits.

Interpretation of the depolarization block hypothesis has been complicated by the fact that only 50 to 80 percent of dopamine cells exhibit depolarization block; the remaining cells show altered firing. Thus, despite the net decrease in firing rate, extracellular dopamine levels do not change. Thus, it may be possible that the mechanisms that compensate for depolarization block are keys to understanding the clinical effects of these drugs.

Oscillatory Neuronal Firing and Behavioral States Certain behavioral states, including wakefulness, attention, mood, and sleep appear to require sustained activity in specific neuronal circuits. Activity in these circuits sets a background tone against which phasic inputs can be evaluated for information content. How this background tone arises is not certain but is believed to involve an interplay of the intrinsic electrophysiological properties of specific neurons and sustained effects of more diffusely acting neurotransmitter systems such as the muscarinic and monoaminergic systems. Certain neurons have voltage-gated ionic conductances that allow them to fire rhythmically and spontaneously, thus having the behavior expected of a pacemaker or oscillator. For example, neurons in the inferior olivary nucleus fire action potentials spontaneously and sustain this firing for relatively long periods in the absence of outside inputs. These inferior olivary neurons fire conventional fast Na^+ spikes that provide the depolarization needed to open high-voltage–activated (HVA) Ca^{2+} channels. In turn, Ca^{2+} influx activates a Ca^{2+}-dependent K^+ conductance that rapidly and effectively hyperpolarizes the membrane. When hyperpolarized, low-voltage–activated (LVA) Ca^{2+} channels open and bring the membrane potential back to the threshold for firing Na^+ spikes, which then activate another cycle. In the case of the inferior olivary neurons, it is the properties of the LVA Ca^{2+} channels that allow oscillatory firing. LVA channels are inactivated at the neuronal resting membrane potential but can be activated only when the membrane is hyperpolarized with respect to rest. In effect, hyperpolarization becomes an activating stimulus that allows the LVA channels to open. The oscillatory firing of inferior olivary neurons then drives Purkinje neurons in the cerebellum at the inferior olivary neurons' preferred firing frequency. The Purkinje neurons thus resonate in response to the inferior olivary input. This resonating circuit is believed to contribute to the physiological resting tremor, which oscillates at about 10 cycles per second; in this circuit the inferior olivary neurons are considered pacemakers.

Pacemaker activity is found in other CNS cells, including thalamic neurons, where similar but not necessarily identical mechanisms are used to drive oscillatory firing. In the thalamocortical system, changes in neuronal activity are associated with the state of arousal and network activity in thalamic and cortical neurons, mediated by both intrinsic neuronal conductances and synaptic connections, drive specific changes in the electroencephalogram (EEG) during different stages of sleep and wakefulness. It is now clear that thalamocortical neurons exhibit two distinct activity states. During sleep, the cells exhibit synchronized rhythms that resemble delta, spindle, and other slow waves on the EEG; during awake states and REM sleep, these neurons show tonic activity. LVA calcium channels are important participants in thalamocortical network activity. The transition from sleep to wakefulness is mediated by the depolarization of thalamic reticular neurons and inactivation of LVA calcium channels. It also appears that specific abnormalities in thalamocortical neurons may be critical in the generation of the 3-Hz spike-and-wave activity seen during absence seizures.

In some regions of the CNS the immediate outputs of the pacemaker cells are mediated by fast excitatory or inhibitory transmitters. However, certain oscillatory cells are capable of firing in bursts of action potentials. Bursts are periods of frequent spike firing, followed by relatively long quiescent periods. This type of firing can be used to drive activity in a local or distributed neural network. Additionally, burst-like firing can provide the increased intracellular Ca^{2+} signal that stimulates release of peptide transmitters from certain cells. In turn, the slow synaptic actions of the peptides in combination with or independent of other G-protein coupled receptor systems can alter the frequency of oscillatory firing and bursting. A clear example of this is the repeated firing that occurs when spike-frequency adaptation is inhibited by blocking Ca^{2+}-activated K^+ conductances. In this fashion, the intrinsic electrical properties of neurons and the effect of modulatory transmitters conspire to determine a background level of activity (or tone) in specific neuronal systems.

Ion Channels and Disease It is now clear that certain clinical disorders result from heritable defects in ion channels. Although most of these illness would not be

considered psychiatric, the ion-channel disorders provide important models for understanding how defects in cellular excitability and ion transport produce pathological effects. One of the best examples of a disorder involving an ion channel is cystic fibrosis, an illness that results from a defect in a specific type of chloride channel protein. The cystic fibrosis transmembrane regulator (CFTR) is a chloride channel that is activated by ATP and phosphorylation. Numerous mutations in the CFTR protein have been described and these typically result in a failure of chloride ions to cross cell membranes. In more than 70 percent of cystic fibrosis cases, the defect is a deletion of a phenylalanine residue at position 508 that results in a failure of chloride channel insertion into cell membranes. The loss of these chloride channels results in marked abnormalities in various bodily secretions.

A second human disorder caused by defective ion channels is the long QT syndrome that is characterized by the presence of prolonged QT intervals on an electrocardiogram (ECG). Individuals with long QT intervals are predisposed to develop malignant cardiac arrhythmias (e.g., torsade des pointes) either spontaneously or during treatment with certain drugs, including tricyclic antidepressants. Several inherited mutations of cardiac ion channels have been implicated in the long QT syndrome. These include mutations in a protein (Kv1QT1) that contributes to the main delayed rectifier potassium current responsible for repolarization in the heart. A second mutation associated with long QT syndrome is in the *human ether-a-go-go-related gene (HERG)* that encodes a rapid potassium channel involved in cardiac repolarization. Interestingly, terfenadine (Seldane) and ketoconazole (Nizoral) block the *HERG* potassium channel, presumably accounting for the development of long QT intervals in patients treated with these drugs. A third ion channel defect associated with long QT syndrome involves a cardiac sodium channel (SCN5A) that participates in the fast upstroke of action potentials. The identified mutations alter sodium channel inactivation and cause prolonged cardiac action potentials.

In addition to disorders that involve ion channels, a number of therapeutic drugs, including psychotherapeutic agents, may alter voltage-gated ion channel function. Several examples have been cited earlier in this chapter, but it is important to emphasize that some anticonvulsants, including carbamazepine (Tegretol) and valproic acid (Depakene) inhibit the function of sodium channels. A dampening of excitability is likely to participate in the anticonvulsant actions, but may also be important in the mood-stabilizing effects of these drugs. Other agents [e.g., verapanil (Calan)] that dampen excitability by blocking voltage-activated calcium channels may also be useful in certain psychiatric disorders.

In the future it is likely that the diversity of voltage-gated and ligand-gated ion channels will be better understood at structural, biophysical, and genetic levels. Although the electrical events underlying neuronal excitability are relatively stereotyped, the various ion channels contributing to neuronal firing offer a great deal of flexibility in the control of cellular activity. Furthermore, the diversity of ion channels involved in electrical signaling provides a complex and powerful means by which excitability can be modulated by neurotransmitters and therapeutic drugs. Determining how subtle alterations in ion channel function contribute to behavior and clinical syndromes will remain a major goal of work in this field.

SUGGESTED CROSS-REFERENCES

Applied electrophysiology is discussed in Section 1.14, monoamine neurotransmitters are discussed in Section 1.4, amino acid neurotransmitters are discussed in Section 1.5, neuropeptides are discussed in Section 1.6, and intraneuronal signaling pathways in Section 1.8. Section 1.15 and Section 1.16 discuss neuroimaging, and basic molecular neurobiology is discussed in Section 1.10. The biology of memory is discussed in Section 3.5.

1.10 BASIC MOLECULAR NEUROBIOLOGY

STEVEN E. HYMAN, M.D. AND ERIC J. NESTLER, M.D., PH.D.

Deoxyribonucleic acid (DNA) contains the genetic blueprint of nearly all living organisms, from the most primitive bacteria to humans. Only among some viruses is ribonucleic acid (RNA) used instead of DNA for the storage of genetic information. During development the information contained in DNA is read out in a series of steps regulated partly by extracellular signals and partly by hierarchies of information encoded in the DNA itself. In mature organisms, even in postmitotic cells, such as neurons, DNA remains a reservoir of information to be called upon for maintenance of cellular integrity as well as to respond to environmental challenges. The regulation of gene expression by environmental signals is a fundamental mechanism of homeostasis, adaptation, and in the nervous system, of learning and memory. Activation and suppression of the expression of specific genes is involved, for example, in such diverse processes as adaptations to a changing diet, muscle hypertrophy or atrophy in response to changing physical loads, expansion of lymphocyte clones in response to an infection, or the production of long-term memories in the brain in response to environmental stimuli.

Gene-environment interactions are also crucial to understanding the pathogenesis of mental disorders. The eventual discovery of genes that confer vulnerability to (or that protect against) mental disorders will not supersede research on environmental factors; indeed, studies of the inheritance of mental disorders, including studies of monozygotic twins (i.e., twins with identical genomes), have demonstrated that genes confer vulnerability to but not the certainty of developing a mental disorder. To produce illness, and even a particular pattern of illness, genes collaborate with nongenetic factors, some perhaps the result of random events occurring during development, others representing identifiable environmental “second hits.” Increasingly, however, research on the genetics of behavior has found that the environmental factors that interact with genes to produce patterns of behavior are unshared among siblings, that is, they are not the result of readily identified shared factors such as socioeconomic status or a generalized parenting style. This makes the identification of vulnerability genes even more important for the generation of hypotheses or as prospective markers of vulnerability. The contribution of genes and nongenetic factors to illness is well known from general medicine; for example, based on prior gene-environment interactions that govern vulnerability a cigarette smoker may or may not develop lung cancer. The rule for most human illness—including mental illness—is that both genes and environment are likely to play at least some role.

NUCLEIC ACIDS: DNA AND RNA

The human genome contain approximately 80,000 genes, which comprise about 3 percent of the total 3 billion base pairs of DNA that make up the human genome. DNA is a double helix in which each of the two strands is an extended linear polymer synthesized from building blocks called *nucleotide bases*. DNA is synthesized out of four types of nucleotide bases, the purines, adenine (A) and guanine (G), and the pyrimidines, cytosine (C) and thymine (T), each connected to a deoxyribose sugar group.

In order to express the information contained in DNA, the DNA must be transcribed to produce ribonucleic acid (RNA). RNA has some independent functions within cells (e.g., it is a key structural element in ribosomes, the organelles on which proteins are synthesized), but its most prominent function is to serve as an intermediate in the synthesis of proteins, which are the most important structural and functional molecules in cells. RNA differs by one nucleotide building block from DNA; in RNA the pyrimidine uracil (U) takes the place of thymine. In addition, the attached sugar group is ribose instead of deoxyribose. Individual nucleotides are joined into strands of DNA or RNA via phosphate groups that form a phosphodiester linkage with a sugar group. The alternating deoxyribose sugar and phosphate groups that connect the bases of each DNA strand form a sugar-phosphate backbone on the outside of the double helix with the bases arrayed on the inside. In DNA, the nucleotide base A is always paired with or is complementary to T on the opposite strand (A·T), and G is paired with C (G·C). In RNA, U, which is structurally similar to T, is also complementary to A (T·A) (Fig. 1.10-1). The rules of base pairing observed in DNA result from the fact that only complementary pairs of nucleotides form a maximum number of stabilizing hydrogen bonds. Any other arrangement of bases destabilizes the structure of the DNA. If there are too many mismatched bases the two strands will not anneal to form a double helix; areas that are not annealed are targets for DNA repair enzymes.

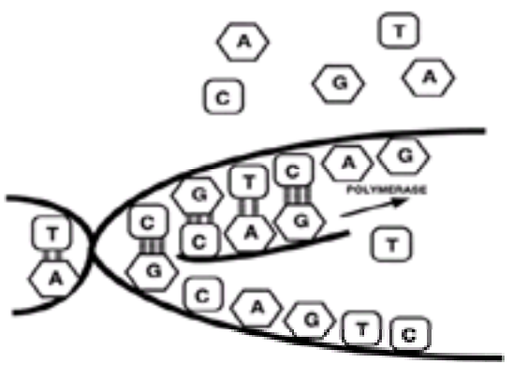

FIGURE 1.10-1 DNA replication. For replication or transcription into RNA, DNA is first unwound and after a variety of biochemical steps an appropriate polymerase adds nucleotides to a growing nucleic acid chain based on the principle of complementary base pairing with the existing strand used as a template. A new double helix is stabilized when hydrogen bonds form between complementary bases of the two strands. Two hydrogen bonds form when A is across from T; three hydrogen bonds form when G is across from C. Other appositions of bases are destabilizing and are repaired by other enzymes; for example, a noncomplementary nucleotide is replaced by a complementary one.

A critical property of such a linear polymer as DNA or RNA is that it can serve as a template for the processive synthesis of other macromolecules. The principle of complementary base pairing provides the mechanism by which information can be transferred. An enzyme, a DNA polymerase in the case of DNA replication, or RNA polymerase in the case of transcription of DNA into RNA, can move down a template strand of DNA adding sequential nucleotide bases complementary to the bases on the template strand (Fig. 1.10-1).

Although the actual enzymatic steps involved in the replication of DNA are complex, the overall principles are simple. Replication begins with separation of the two strands of the double helix in a local region. Each strand then serves as a template for a new DNA molecule by the sequential addition of nucleotides to a growing complementary strand (Fig. 1.10-1). Eventually the replication process generates two complete DNA double helices, each identical in sequence to the original. DNA replication is said to be semiconservative because each daughter DNA molecule contains one of the original parental strands plus one newly synthesized strand. Transcription of DNA into RNA is conceptually similar except that only one DNA strand, not both, serves as a template and when synthesis of the RNA is complete it is released and the DNA strands reanneal into a double helix.

INFORMATION FLOWS FROM DNA TO RNA TO PROTEIN

DNA carries information in its linear sequence of nucleotides. Although the linear polynucleotide structure of DNA is well suited for the stable storage of information and for self-replication, its chemical simplicity and its relatively rigid helical structure limit its biological functions. Thus, the information contained within DNA must be

read out to yield RNAs and proteins. Like DNA, RNA is chemically quite simple (i.e., composed of four nucleotides), but since it is a flexible single strand, free to fold into a variety of conformations, it is functionally more versatile than DNA.

Messenger RNA (mRNA) functions as an intermediate between the sequences of DNA that comprise the transcribed regions of gene, and the sequence of proteins (Fig. 1.10-2). Not all RNA serves as mRNA, however. Other RNAs serve distinct functional roles in cells. Ribosomes, the organelles on which proteins are synthesized, are constructed out of complexes of various ribosomal RNAs (rRNAs) together with proteins. Transfer RNAs (tRNAs) transport specific amino acids to the ribosomes for incorporation into proteins during the process in which mRNA is translated into protein.

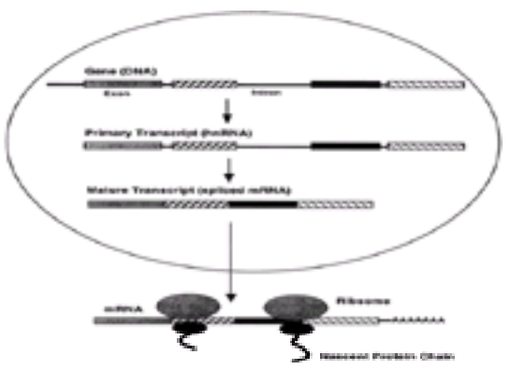

FIGURE 1.10-2 Processing of RNA. Gene transcription produces an RNA that is colinear with the transcribed region of the DNA. This complementary copy of the DNA contains sequences destined to be exported from the nucleus to be translated into protein (exons) and intervening sequences that will remain in the nucleus and be degraded (introns). The primary transcript is often described as heteronuclear RNA (hnRNA). Only after the introns are spliced out and other chemical modifications occur is the messenger RNA (mRNA) ready to exit the nucleus to be translated into protein within the cytoplasm. The most significant chemical modifications are aimed at increasing the stability of the mRNA. These include the addition of multiple A nucleotides at the end of the RNA (a so-called *poly-A tail*). Particular exons within some genes in some cells may be excluded from the mature mRNA. This process of alternative splicing permits the generation of more than one mRNA and therefore more than one protein from a single gene. Within the cytoplasm, multiple ribosomes can process down the mRNA at once.

As in the case of DNA, mRNA carries information encoded in its linear sequence of nucleotides. DNA and mRNA specify amino acid building blocks for proteins in linear stretches of three nucleotides. Proteins are comprised of unbranched chains of amino acid building blocks. An amino acid is a small molecule that contains an amino group (NH_2) and a carboxylic acid or carboxy group (COOH), plus a variable side chain. The side chains used by the 20 common amino acids differ markedly in size, shape, hydrophobicity, and charge. Amino acids are linked to each other by peptide bonds that join the amino group of one amino acid to the carboxy group of another amino acid.

Within the portion of an mRNA that is translatable into a protein, each successive group of three nucleotide bases specifies either one amino acid or termination of the protein chain and is called a *codon*. The rules specifying the correspondence between each trinucleotide combination (codon) and an amino acid is called the *genetic code*. Since RNA is a linear polymer of 4 nucleotides, there are 4^3 (i.e., 64) possible codons, but only 20 amino acids. As a result, although each codon specifies only a single amino acid, most amino acids are specified by more than one codon. The genetic code is therefore said to be degenerate. With only a few minor exceptions the code has been conserved across evolution. The codons in an mRNA molecule do not interact directly with the amino acids they specify; the translation of mRNA into protein depends on the presence of tRNAs, which serve as adapter molecules that recognize a specific codon in the mRNA as well as the corresponding amino acid (Fig. 1.10-3).

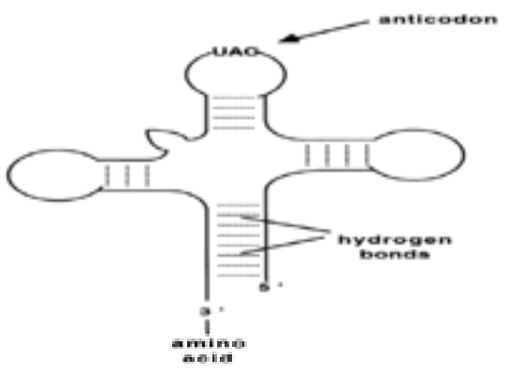

FIGURE 1.10-3 Transfer RNA. Transfer or tRNA is a single strand of RNA that folds on itself based on the formation of complementary base pairs. This hybridization provides hydrogen bonds—indicated by the dotted lines—that stabilize the secondary structure of the molecule. One of the loops that is formed contains the anticodon, the sequence of three nucleotides on the tRNA that binds to the complementary codon on a messenger RNA molecule. For the anticodon UAC shown in the figure, the corresponding codon on the mRNA would be AUG. The free end of the tRNA binds to a specific amino acid, in this case, methionine. Each tRNA with a given anticodon binds only one type of amino acid. (Adapted from Hyman SE, Nestler EJ: *Molecular Foundations of Psychiatry*. American Psychiatric Association, Washington, DC, 1993.)

The ribosome is a structure composed both of proteins and structural RNAs. These organelles provide a structure on which tRNAs can interact via their anticodons with the codons of an mRNA in sequential order. The ribosome finds a specific start site on the mRNA that sets the reading frame, and then moves along the mRNA molecule progressively, translating the nucleotide sequence one codon at a time, using tRNAs to add amino acids to the growing end of the polypeptide chain (Fig. 1.10-2 and Fig. 1.10-3).

Unlike nucleic acids, which are constructed of four bases that are chemically quite similar, proteins are constructed out of twenty quite different amino acids. By incorporating so many different types of amino acids, each with their chemically diverse side chains, proteins have extraordinary functional versatility, unlike DNA or RNA. The specific properties of proteins depend not only on the linear sequence of their amino acid building blocks (primary structure), but also on the tendency of certain combinations of amino acids to form intrinsic structural motifs (secondary structures, e.g., a helixes or b sheets), and by their folded three-dimensional characteristics (tertiary structure). In addition, proteins form stable interactions with other proteins (quaternary structure). In such cases the individual polypeptide chains are called *subunits*. The folding of proteins, and the interactions of proteins with each other and with other molecules such as nucleic acids, may also be regulated by chemical modification of the protein, most often of particular side chains. For example, one ubiquitous mechanism of regulation of protein function is by the covalent addition of a phosphate group (by specific enzymes called *protein kinases*) to the hydroxyl groups found in serine, threonine, or tyrosine side chains. Cells may contain tens of thousands of distinct proteins, each with unique structural and functional properties. Some examples include neurotransmitter receptors, neuropeptides, ion channels and pumps, cytoskeletal and contractile proteins, and many different types of enzymes.

GENES AND CHROMOSOMES

As a first approximation, genes can be defined as stretches of DNA that encode a single protein or a single functional RNA, such as an rRNA or tRNA. There are exceptions to this rule because there are mechanisms, such as alternative splicing of the primary RNA transcript into different mRNAs, that may intervene between a given gene and a finished protein. As a result, in some cases a single gene may actually encode multiple proteins.

Genes are arrayed on extremely long chains of DNA called *chromosomes*. Chromosomes of eukaryotic organisms also contain large amounts of intergenic DNA. Indeed, within the human genome the 80,000 genes take up perhaps only 3 percent of chromosomal DNA. Moreover, genes are not distributed equally along the

chromosomes, but are often found in clusters. Some chromosomal regions are gene rich and others relatively gene poor. Within intergenic regions there is a great deal of DNA with unique sequences of unknown function, but also long stretches of tandemly repeated sequences, known as *satellite DNA*. These tandem repeats, which show a great deal of variability in length from person to person, are the basis of commonly used genetic markers for research on the pattern of heritability of traits, such as in linkage analysis, as well as for the identification of individuals in forensic investigations.

The chromosomes of eukaryotic cells are so long that they would not fit in the nucleus in their extended form. Stretches of the DNA that are not being actively transcribed are tightly packed into a conformation described as a *coiled coil*, which permits the chromosomes to fit within the nucleus. To create packed conformations, lengths of DNA are coiled around structural and regulatory proteins of which the most important are the histones. Regions of DNA that are being actively transcribed into RNA may be greater than 1000-fold more extended than regions that are transcriptionally quiescent.

GENE EXPRESSION

Proteins are not synthesized directly from the DNA that encodes them, but in two sequential processes: transcription of DNA into mRNA, which occurs in the nucleus, and translation of the mRNA into protein according to the rules of the genetic code, which occurs in the cytoplasm. Transcription of protein-coding genes can be divided into three major steps. First, the enzyme primarily involved in RNA synthesis, RNA polymerase, must interact with the gene at an appropriate transcription start site and begin transcribing (*initiation*). Second, the RNA polymerase must successfully transcribe an appropriate length of RNA (*elongation*). Third, transcription of the RNA must terminate appropriately. The resulting RNA is then posttranscriptionally processed. It receives a stretch of adenine nucleotides, called a *poly-A tail*, which makes the RNA more stable in the cell (Fig. 1.10-2). The primary transcript, which is an exact complement to the DNA, is also called *heteronuclear RNA*.

In higher eukaryotes, not all transcribed sequences contribute to the formation of the mRNA, which will eventually be translated into protein. There are also intervening sequences of unknown function that interrupt the continuity of the gene. DNA sequences within a gene that code for a segment of mRNA are called *exons* because the information in those sequences will be exported from the nucleus; the intervening sequences, which remain in the nucleus are called *introns*. When a protein coding gene is first transcribed, a long RNA, the primary transcript, is produced that is colinear with the DNA and therefore contains both exons and introns (Fig. 1.10-2). Before the transcript exits the nucleus, the introns are removed and the exons are spliced together to form a mature mRNA. Precise RNA splicing depends on three types of DNA sequence. Two mark either side of the splice junction; the third is located within the intron itself and is called the *branch point*. This sequence plays a critical role in the chain of reactions that produce accurate splicing. The spliced mRNA leaves the nucleus and binds to a ribosome in the cytoplasm where it can direct the synthesis of a protein; however, the entire mature mRNA is not translated. All mRNAs contain untranslated flanking sequences at their ends.

Many genes contain multiple introns and exons that may not be spliced identically in every cell type or in a given cell type at every stage of development. This mechanism, alternative splicing, can produce functionally very different forms of a protein or even entirely different proteins from a single gene. One of the first examples of alternative splicing discovered was that of calcitonin and calcitonin gene-related peptide (CGRP), two different peptides derived from alternative splicing of the same primary transcript.

TRANSCRIPTIONAL CONTROL

It is at the step of transcription initiation that environmental signals most often exert powerful regulatory control on gene expression, both during development and in mature cells. In addition to containing information that ultimately directs the synthesis of proteins (i.e., the genetic code), genes also contain regulatory information. Every cell in our bodies contains in its nucleus all 80,000 or so of our genes, but not every gene is active in every cell. Our cells differ—indeed, their identity is defined by the fact that each type of cell in the body expresses only a subset of the entire complement of genes. In any given cell, some genes are “on,” being read out to make RNA and hence proteins, and the rest are silent. For example, in the red blood cell precursors of the bone marrow, the genes that encode globins, the proteins that form the critical building blocks of hemoglobin, are highly active making globin-encoding mRNA. In the midbrain a subset of cells make a protein called tyrosine hydroxylase, which is the rate-limiting enzyme for the synthesis of dopamine and other catecholamines. It would not be adaptive for midbrain neurons to be synthesizing large amounts of hemoglobin, just as red blood cell precursors might find it deleterious to express the enzyme activity conferred by the presence of tyrosine hydroxylase.

Regulatory sequences within DNA control the expression of genes by virtue of their ability to bind specific regulatory proteins. Certain regulatory sequences of DNA specify the beginnings and ends of DNA segments that can be transcribed into RNA. Other regulatory sequences determine in what cell types and under what circumstances the gene to which they are linked can be read out. DNA sequences that subserve control functions are often called *cis*-regulatory elements (Fig. 1.10-4). The term *cis* refers to the fact that the relevant regulatory sequences are physically linked on the DNA to the region being controlled. The proteins that bind to *cis* elements have been described as *trans*-acting factors because they may be encoded anywhere in the genome rather than on the same stretch of DNA that they regulate. Proteins that are involved in specifying whether and under what circumstances a gene will be transcribed are more generally known as *transcription factors*. Many transcription factors bind DNA directly; others interact only indirectly via protein-protein interactions with other factors that do bind DNA.

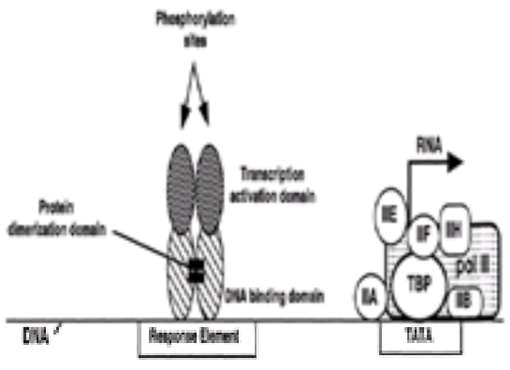

FIGURE 1.10-4 *Cis* and *trans* regulation. The figure shows two *cis*-regulatory elements (open rectangles) along the stretch of DNA (thin line). The element to the left represents a response element that serves as a binding site for a hypothetical transcription factor that binds as a homodimer. The other is the TATA element, shown binding the TATA binding protein TBP. Multiple general transcription factors and RNA polymerase II (pol II) associate with TBP. This basal transcription apparatus recruits RNA polymerase II into the complex and also forms the substrate for interactions with activator proteins, such as those binding to the activator elements shown. The transcription factor shown binding to the response element is a substrate for a protein kinase that phosphorylates its activation domain. This in turn would alter the ability of the transcription factor to interact with the basal transcription factor apparatus. (Adapted from Hyman SE: Regulation of gene expression by neural signals. Neuroscientist *2:*217, 1996.)

Those *cis*-regulatory elements that specify the site within a gene at which transcription starts, and upon which the complex of proteins that forms the basal transcription apparatus is assembled, are called the *basal* or *core promoter*. The core promoters for most protein-encoding genes are comprised of a sequence motif rich in the nucleotide bases A and T, and are thus commonly called the *TATA box*. The TATA box is generally located between 25 and 30 nucleotides upstream of the actual site at which transcription of DNA into RNA is initiated. In eukaryotes, transcription of protein-coding genes is carried out by the enzyme RNA polymerase II, which does not directly contact DNA but interacts with the complex of proteins that assembles at the TATA box (Fig. 1.10-4).

Transcription Factors The basal transcription complex, which is assembled at the TATA box, is sufficient to set the start site and direction of transcription, but it is not adequate to initiate more than low levels of transcription of DNA into RNA. To achieve significant levels of gene expression the basal transcription complex requires help from additional transcription factors that bind to *cis*-regulatory elements found elsewhere within the gene. *Cis*-elements that exert control near the core promoter itself have been called *promoter elements* and those that act at a distance—often several hundred to more than a thousand nucleotide base pairs away—have been called *enhancer elements*, but the commonly made distinction between promoter and enhancer elements is artificial. Both are composed of small “modular” sequences of DNA (generally 7 to 12 base pairs in length), each of which is a specific binding site for one or more transcription factors. Multiple *cis*-regulatory elements arrayed throughout the control regions of a gene, and the proteins they bind, act in a combinatorial fashion to give each gene its distinct patterns of expression and regulation.

Transcription factors that are tethered to DNA by binding *cis*-elements often have a modular structure comprised of physically separate domains: a domain that recognizes and binds a specific DNA sequence, an activation domain that interacts with the basal transcription complex or an adapter protein to form an active complex, and a oligomerization domain that permits the formation of homomeric complexes or heteromeric complexes with other transcription factors (Fig. 1.10-5A and Fig. 1.10-5B, and Fig. 1.10-6). Many transcription factors are active only as dimes or higher-order complexes. Within transcription factor dimers, whether homodimers or heterodimers, it is common for both partners to contribute jointly to both the DNA-binding domain and to the activation domain. Some transcription factors contact the basal transcription complex directly; others interact through the mediation of adapter proteins. In either case, transcription factors that bind *cis*-regulatory elements at a distance from the core promoter can interact with the basal transcription apparatus because the DNA forms loops that bring distant regions in contact with each other (Fig. 1.10-5B).

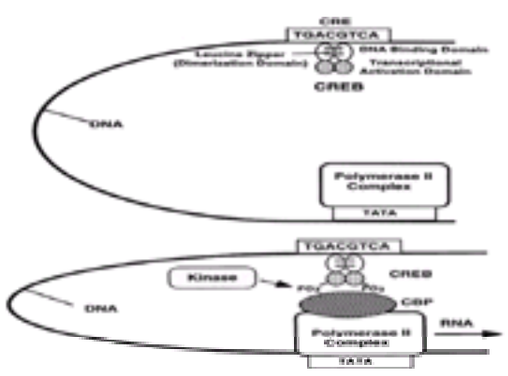

FIGURE 1.10-5 A and B. Looping of DNA permits activator (or repressor) proteins binding at a distance to interact with the basal transcription apparatus. The basal transcription apparatus is shown as a single box bound at the TATA element. The activator protein, CREB, is shown bound as a homodimer to its cognate *cis*-regulatory element, the CRE, at a distance from the TATA element (**A** and **B**). CREB dimerization occurs at a specialized domain called a leucine zipper, because several leucine residues on one CREB molecule bind (via hydrophobic interactions) with several leucine residues on the other CREB molecule. Upon phosphorylation many activators such as CREB are able to recruit adapter proteins that mediate between the activator and the basal transcription apparatus. An adapter protein that binds phosphorylated CREB is called CREB binding protein (CBP). With the recruitment of the adapter, a mature transcription complex forms that permits the synthesis of RNA by RNA polymerase II (**B**). (Adapted from Hyman SE: Regulation of gene expression by neural signals. Neuroscientist *2:*217, 1996.)

Regulation of Gene Expression by Extracellular Signals The nervous system responds to salient environmental stimuli, drugs, and changes in the internal milieu with long-term changes in neural function, which may result in alterations in behavior. A high degree of plasticity is characteristic of the mammalian brain, including its ability to form long-term memories within many different types of circuits. Plasticity is required for normal development and learning, but also contributes to the pathophysiology of psychiatric disorders and also to their treatment. Many neural mechanisms contribute to plasticity, but the formation of long-term memories and long-lived adaptations to changes in the environment depends on the regulation of gene expression.

Environmental stimuli are transduced by neurons into neurotransmitter signals. The binding of neurotransmitter to their receptors initiates cascades of intracellular signals, most notably second messengers and signal-regulated protein kinases. Along with neurotransmitters another important intracellular signaling mechanism are the steroid hormones, such as cortisol, which are released in response to stress. Both second messenger systems and steroid hormones regulate the expression of genes in the cell nucleus. Some second messengers may actually enter the cell nucleus. In most cases, however, they modify the function of another protein such as a protein kinase, which enters the nucleus and interacts with transcription factors that directly or indirectly bind to DNA. Steroid hormones are lipophilic molecules that cross the cell membrane and bind a receptor in the cytoplasm. The activated steroid-receptor complex then translocates to the nucleus where it binds to specific *cis*-regulatory elements. Many and possibly most genes contain *cis*-regulatory elements that confer responsiveness to such physiological signals. Such *cis*-elements are called *response elements*. Response elements work by binding transcription factors that are activated (or inhibited) in response to specific physiological signals, such as second messenger–dependent phosphorylation, steroid hormone binding, or drugs. Many examples of transcription factors activated by physiological and pharmacological signals are now known. A small number of these will be described because of their relevance to neural plasticity, including the action of psychotropic drugs.

Cyclic Adenosine Monophosphate (cAMP) Response Elements in the Regulation of Neural Genes One of the first types of response elements to be characterized in detail was an element that permits genes to respond to stimulation of receptors, such as b-adrenergic, dopamine (D_1), or type 1 serotonin (5-hydroxytryptamine [5-HT]) type 4 ($5\text{-}HT_4$), $5\text{-}HT_6$, and $5\text{-}HT_7$ receptors, that activate the cyclic AMP (cAMP) pathway (see Fig. 1.10-6). Such cAMP response elements were subsequently shown to confer responsiveness to calcium (Ca^{2+}) as well. Ca^{2+} is an important second messenger in the nervous system. Neurons express a variety of receptors, such as *N*-Methyl-D-aspartate glutamate receptors, that permit Ca^{2+} entry, and also express a large number of voltage-sensitive Ca^{2+} channels that are activated when a neuron is depolarized. Most recently, cAMP response elements have been shown to be responsive to several types of growth factors, which produce their effects on neurons via complex signal transduction pathways. Thus, there are many intercellular signals that could ultimately converge to produce activation of gene expression via cAMP response elements.

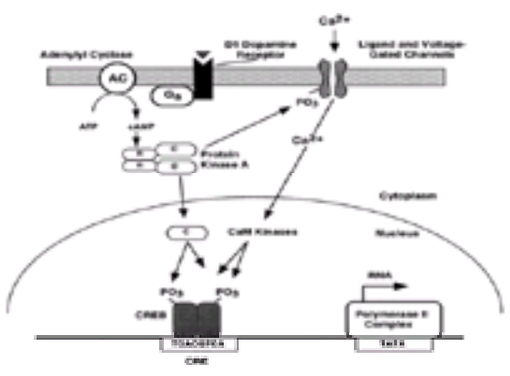

FIGURE 1.10-6 Summary of cyclic AMP-mediated signaling to the nucleus. Many neurotransmitters (shaded triangle) bind to receptors (black) that are linked via the G protein G_s to activation of adenylyl cyclase (AC). Adenylyl cyclase catalyzes the synthesis of the second messenger cAMP from adenosine triphosphate (ATP). While cAMP has several functions in cells, its major effect is to bind to the regulatory subunits, R, of the cyclic AMP-dependent protein kinase (also known as protein kinase A or PKA). Following cAMP binding to R, the catalytic subunits, C, are freed to phosphorylate substrate proteins. For example, they may phosphorylate L-type Ca^{2+} channels, increasing Ca^{2+} entry into cells. The C subunits can also directly enter the cell nucleus where they phosphorylate the cyclic AMP response element binding protein, which binds DNA at cyclic AMP response elements that contain the DNA sequence motif CGTCA. This converts CREB into a transcriptional activator, Ca^{2+} may also lead to CREB phosphorylation. The precise nuclear translocation step is unclear, but may involve the direct transport of Ca^{2+} into the nucleus where it can activate Ca^{2+}/calmodulin-dependent protein kinases (especially CaMK-IV) found in the nucleus. (Adapted from Hyman SE: Regulation of gene expression by neural signals. Neuroscientist *2:*217, 1996.)

Among the first genes in which cAMP response elements were identified were genes encoding the neuropeptides, somatostatin, proenkephalin, and vasoactive intestinal polypeptide. However, cAMP response elements have now been identified in a large number of genes expressed in the nervous system, ranging from enzymes such as tyrosine hydroxylase to transcription factors such as c-*fos*.

CRE binding protein (CREB) is the major protein that binds cAMP response element in most cell types that have been investigated. The cAMP response element is a palindromic DNA sequence that most often binds two molecules of CREB associated with each other as a homodimer (Fig. 1.10-6). However, CREB is a member of a

family of related proteins that can bind cAMP response elements. Many transcription factors are members of families, permitting subtle forms of positive and negative regulation. CREB is closely related to proteins called the *activating transcription factors* and the cAMP response element modulators (CREMs). Many of these proteins can dimerize with CREB and regulate its activity.

CREB is constitutively synthesized in most cells, and, under basal conditions, is already bound to cAMP response elements. Bound CREB becomes a transcriptional activator when it is phosphorylated on a critical amino acid (Ser_{133}) by any of several protein kinases, including cAMP-dependent or Ca^{2+}-dependent protein kinases or certain growth–factor-activated protein kinases. Such phosphorylation permits CREB to interact with adapter proteins, such as CREB binding protein *(CBP)* or a protein called p300 (Fig. 1.10-5A and Fig. 1.10-5B), which in turn contacts the basal transcription apparatus and permits transcriptional activation.

Because CREB is already located within the nucleus under basal conditions, CREB activation requires the translocation of protein kinases (or regulators of protein kinases) to the nucleus (Fig. 1.10-6). The stimulation of receptors, such as b-adrenergic or D_1 receptors, that are coupled to the stimulatory G protein G_s activates adenylyl cyclase, leading to generation of cAMP at the cell membrane. The cAMP-dependent protein kinase is activated by binding of cAMP to its regulatory subunits, which leads to release of active catalytic subunits that can translocate into the nucleus where they can phosphorylate CREB (Fig. 1.10-6). Phosphorylation of CREB by Ca^{2+}-dependent protein kinases involves a somewhat different mechanism or translocation. It appears that Ca^{2+} interacts with its binding protein, calmodulin in the cytoplasm. The calcium/calmodulin complex then translocate to the nucleus where it activates Ca^{2+}/calmodulin dependent protein kinase type IV. This kinase phosphorylates CREB.

The convergence of multiple signaling pathways (the cAMP and Ca^{2+} pathways) on a single transcription factor has important implications. Such convergence is particularly important in the nervous system because this is a candidate mechanism for the formation of associative memories. Associative memory depends on the temporally closely coordinated arrival of two different signals that must then be integrated within target cells and circuits. The attractiveness of hippocampal long-term potentiation as a mechanism of memory is based in part on the need for simultaneous activation of two different inputs for its initiation. There is strong evidence from a variety of model systems that the conversion of short-term to long-term memory requires new protein synthesis and therefore new gene expression. Indeed, there is good evidence that certain kinds of long-term plasticity are dependent on cAMP response elements and CREB. For example, experiments in *Drosophila* and mice in which CREB activity was altered gene targeting yield organisms with deficits in long-term memory.

CREB has also shown to be phosphorylated in the striatum, including the nucleus accumbens, in response to the administration of cocaine and amphetamine, and to be activated in the locus nucleus coeruleus during opiate withdrawal. CREB-deficient mice, and animals with more selective reductions in CREB levels in specific brain regions achieved by use of antisense oligonucleotide methods, exhibit attenuated behavioral withdrawal from opiates, further suggesting that CREB is involved in adaptation to long-term opioid administration. Understanding how CREB activation by extracellular stimuli leads to the altered expression of target genes that lead to the formation of memory in the hippocampus, or aspects of addiction in the nucleus accumbens and locus coeruleus, are currently areas of intense research. Overall, the mechanisms underlying the many forms of plasticity of which the nervous system is capable are likely to be quite complex, involving a multitude of different target genes and many different types of regulation. Nevertheless, CREB appears to be important, and also provides a good model to understand the role of gene expression in long-term changes in neural function.

AP-1 Family of Proteins In addition to the CREB family, another family of transcription factors that appears to play a crucial role in the regulation of neural gene expression is the *activator protein-1 (AP-1) protein* family that binds as heterodimers (and sometimes as homodimers) to the DNA sequence TGACTCA, the AP-1 sequence. The AP-1 sequence differs from the sequence of cAMP response elements by only a single base. Yet this one base difference strongly biases protein binding away from CREB (which requires an intact CGTCA motif) to the AP-1 proteins. Thus, under most circumstances this sequence will not confer cyclic AMP responsiveness on linked genes. Instead, AP-1 sequences confer responsiveness to certain growth–factor-stimulated signaling pathways as well as several other pathways. The first signaling pathway shown to activate transcription via AP-1 sequences was the protein kinase C pathway; the AP-1 DNA sequence is sometimes described as a 12-O-tetradecanoyl-phorbol-13-acetate (TPA), *response element* (TRE) because the phorbol ester TPA, which activates protein kinase C, can induce gene expression via the AP-1 site.

The AP-1 proteins generally bind DNA as heterodimers comprised of one member each of two different families of related proteins, the Fos family and the Jun family. The known members of the Fos family are c-Fos, Fra-1 (Fos-related antigen-1), Fra-2, and FosB; The known members of the Jun family are c-Jun, JunB, and JunD.

Unlike CREB, which is constitutively synthesized, members of the Fos family are generally induced from low basal levels upon neuronal stimulation, and rapidly return to basal levels shortly after stimulation. It has been shown, for example, that following a seizure c-Fos is induced from very low levels in the hippocampus, with the other Fras induced similarly with a slightly delayed time course. As another example, acute administration of cocaine or of haloperidol [Haldol] rapidly and transiently induces c-Fos and the various Fras from very low concentrations in different cells in the striatum and prefrontal cortex. A very different pattern is seen, however, after long-term stimulation. After repeated administration of cocaine, the ability of a subsequent acute stimulus to induce c-Fos and the various Fras shows desensitization. Instead, there is a gradual accumulation of truncated products of the *fos*B gene (also termed *chronic Fras*) that have a very long half-life. This change over time in the members of the Fos family that are expressed is likely to have important consequences for the regulation of target genes. Alterations in AP-1 complexes over time with long-term stimuli, such as long-term cocaine administration, might permit cells to activate specific programs of adaptation appropriate to the strength and time course of the stimulus.

Immediate Early Genes Genes that are transcriptionally activated by synaptic activity, drugs, and growth factors have often been classified into two main groups. Genes, such as the c-*fos* gene, that are activated rapidly (within minutes), transiently, and without requiring new protein synthesis are frequently referred to as *cellular immediate early genes* (IEGs). Genes that are induced or repressed more slowly (over hours), and are dependent on new protein synthesis, may be described as *late-response genes*. The term *IEG* was initially applied to describe viral genes that are activated immediately upon infection of eukaryotic cells by commandeering host cell transcription factors for their expression. Viral immediate early genes generally encode transcription factors needed to activate viral “late” gene expression. This terminology has been extended to cellular (i.e., nonviral) genes. The terminology is somewhat problematic because many cellular genes are induced independently of protein synthesis, but with a time course intermediate between classic IEGs and late-response genes. Some genes may be regulated with different time courses or requirements for protein synthesis in response to different extracellular signals. Moreover, many cellular genes regulated as IEGs encode proteins that are not transcription factors. Despite these caveats, the concept of IEG-encoded transcription factors in the nervous system has provided a useful heuristic for understanding cascades of gene regulation. The protein products of those cellular IEGs that function as transcription factors bind to *cis*-regulatory elements contained within a subset of late-response genes to activate or repress them. IEGs such as c- *fos* have therefore been termed “third messengers” in signal transduction cascades, with neurotransmitters designated as intercellular first messengers, and small intracellular molecules, such as cyclic AMP and Ca^{2+}, as second messengers. Overall, neural genes that are regulated by extracellular signals are activated or repressed with varying time courses by reversible phosphorylation of constitutively synthesized transcription factors and by newly synthesized transcription factors, some of which are regulated as IEGs.

Because of their rapid induction from low basal levels in response to neuronal activation (the critical signal being Ca^{2+} entry) and second messenger and growth factor pathways, several IEG products, including c-Fos, c-Jun, and Zif268 (Egr-1) have been used widely as cellular markers of neural activation. IEG mapping is now one of the fundamental tools of functional neuroanatomy. As long as a stimulus is excitatory or activates the appropriate second messengers, it is likely to activate several IEGs, such as c-*fos*, in cells that process the stimulus. Thus, IEG expression has been used to identify cells in the nervous system that respond to a wide variety of perturbations: for example, sensory stimuli (e.g., stress, nociceptive stimuli, conditioning), drugs (e.g., cocaine, antipsychotic drugs), and immunological challenges (e.g., bacterial endotoxin).

Steroid Hormones Another important family of physiologically regulated *cis*-regulatory elements are the glucocorticoid response elements (GREs). Glucocorticoid and other steroid hormones bind to and thereby activate specific receptors within the cytoplasm of cells. These receptors are held in the cytoplasm of cells by a variety of proteins (called *chaperone proteins*) until hormone binding occurs. Once activated by steroid hormone binding, the receptors are freed from their cytoplasmic anchoring proteins and translocate into the nucleus where they bind to GREs or other steroid hormone response elements contained within particular genes. Such binding then increases or decreases the rate at which these target genes are transcribed, depending on the precise nature and DNA sequence context of the element. Most of the known effects of glucocorticoids, gonadal steroids, thyroid hormone, retinoic acid, and vitamin D on cellular function are mediated via such actions on gene expression. Of great interest, steroid hormone receptors appear to be able to form protein-protein interactions with AP-1 proteins and with members of the CREB family, creating the possibility of very complex regulatory mechanisms.

FUTURE DIRECTIONS

Information encoded in the approximately 80,000 genes in the human genome is read out during development and in mature cells in response to information from the environment. An understanding of how variations in gene sequences lead to disease vulnerability or resistance, and an understanding of how disease, drugs, and

salient environmental stimuli lead to activation or suppression of the expression of genes are among the most important goals of current biology. Both aspects of molecular genetics will play a central role in the eventual understanding of mental illness and its treatment.

SUGGESTED CROSS-REFERENCES

Intraneuronal signaling pathways are discussed in Section 1.8, neurotransmitters in Section 1.4 and Section 1.5, and genetics in Section 1.17 and Section 1.18.

1.11 PSYCHONEUROENDOCRINOLOGY

VICTOR I. REUS, M.D. AND SYDNEY FREDERICK-OSBORNE, ꟻH.D.

The term “psychoneuroendocrinology” expresses an appreciation of inextricable structural and functional relationships between the hormonal system and the central nervous system (CNS) and the behaviors that modulate and are derived from both. Endocrine disorders are frequently associated with secondary psychiatric symptoms such as depressed mood and disturbances in thought, while a significant percentage of patients suffering from defined psychiatric syndromes display regular patterns of endocrine dysfunction. In the classic conception hormones were defined as products of endocrine glands that were transported by blood to exert their action at sites distant from their release. However, advances in neuroscience have shown that the brain not only serves as a site of regulatory control but also has secretory functions of its own, and that classic distinctions between the origin, structure, and function of nerve cells as opposed to endocrine cells are not valid.

Over the course of evolution, as organisms have increased in complexity, hormones that first appeared in unicellular organisms have been recruited to serve a multiplicity of functions, a quality referred to as *pleiotropy*. A single hormone may act at multiple sites, including binding to receptors on the membrane, cytoplasm, or nucleus, each with different effects, and subtle differences in molecular structure or metabolic processing can have profound physiological consequences. Hormones are thus ideally suited to regulate complex behavioral activities. This chapter emphasizes neuroendocrine systems that have been most directly linked to specific behavioral functions, particularly those involved in the organism's response to stress, and the principles underlying their regulation and interaction.

HORMONE SECRETION

Hormones are divided into two general classes: (1) proteins, polypeptides, and glycoproteins and (2) steroids and steroidlike compounds (Table 1.11-1) that are secreted by an endocrine gland into the bloodstream and are transported to their site(s) of action. When a hormone is colocalized and cosecreted with a neurotransmitter (e.g., norepinephrine), it may be referred to as a *neuromodulator*, although some hormones or neuromodulators have been shown to meet criteria for neurotransmitters themselves.

Structure	Examples	Storage	Lipid Soluble
Proteins, polypeptides, glycoproteins	ACTH, β-endorphin, TRH, LH, FSH	Vesicles	No
Steroids, steroid-like compounds	Cortisol, estrogen, thyroxine	Diffusion after synthesis	Yes
Functions			
Autocrine	Self-regulatory effects		
Paracrine	Local or adjacent cellular action		
Endocrine	Distant target site		

ACTH, adrenocorticotropin; TRH, thyrotropin–releasing hormone; LH, leutinizing hormone; FSH, follicle-stimulating hormone

Table 1.11-1 Classifications of Hormones

Hormone secretion is stimulated by the action of a neurohormone, a neuronal secretory product of neuroendocrine transducer cells of the hypothalamus. Neurohormones (Table 1.11-2) include corticotropin-releasing hormone (CRH), which stimulates adrenocorticotropin (adrenocorticotropic hormone [ACTH]), thyrotropin-releasing hormone (TRH), which stimulates release of thyroid-stimulating hormone (TSH), gonadotropin-releasing hormone (GnRH), which stimulates release of leutinizing hormone (LH) and follicle-stimulating hormone (FSH), and somatostatin (somatotropin release-inhibiting factor [SRIF] and growth–hormone-releasing hormone (GHRH) both of which stimulate growth hormone release. Chemical signals cause the release of these neurohormones from the median eminence of the hypothalamus into the portal hypophyseal bloodstream and their transport to the anterior pituitary to regulate the release of target hormones. Pituitary hormones in turn act directly on target cells (e.g., ACTH on the adrenal gland) or stimulate release of other hormones from peripheral endocrine organs. In addition, these hormones have feedback actions that regulate neurohormone secretion and effects in the brain itself, both directly and as modulators of neurotransmitter action (neuromodulation).

Neurohormone	Hormone Stimulated
Corticotropin-releasing hormone (CRH)	Adrenocorticotropic hormone (ACTH)
Thyrotropin-releasing hormone (TRH)	Thyroid-stimulating hormone (TSH)
	Luteinizing hormone (LH)
Gonadotropin-releasing hormone (GnRH)	Follicle-stimulating hormone (FSH)
Somatostatin (SRIF)	Growth hormone (GH)
Growth–hormone-releasing hormone (GHRH)	GH
Oxytocin	Prolactin
Arginine vasopressin (AVP)	ACTH

Table 1.11-2 Neurohormones

HORMONE SYNTHESIS AND STRUCTURE

Peptide hormones represent subsections of larger amino acid chains or polypeptides called *prohormones*. Production of a peptide hormone occurs by the cleavage of its prohormone chain at a given site on the chain by the appropriate enzyme. Proopiomelanocortin is a prohormone that contains the sequences for ACTH, b-endorphin, b-lipotropin, and a–melanocyte-stimulating hormone (MSH). Some hormones, called *dimers*, contain two or more peptide chains (e.g., FSH, LH, TSH). Further cleavage of these hormone peptide chains in the course of metabolism creates in some cases yet other biologically active peptides that may have different effects than those of the parent peptide. Even minor modifications of structure can drastically change the binding properties and metabolic processing of peptides.

CELLULAR MODE OF ACTION

Intracellular The primary mode of action of steroid hormones (glucocorticoids, estrogen, testosterone) and thyroid hormones (triiodothyronine or [T_3] and thyroxine or [T_4]) is by binding to intracellular receptors in the cytoplasm or nucleus. The hormone-receptor complex in turn binds to common response elements on chromosomal deoxyribonucleic acid (DNA) and alters transcription through a confirmational change that unmasks the binding site. The steroid hormone complex can also interact with transcription factors such as those produced by c-*fos*, c-*jun*, or activator protein-1 (AP-1) to either amplify or inhibit gene expression. By these mechanisms, hormones regulate the induction of such gene products as enzymes and other cell proteins that effect metabolic change. Based on their amino acid structure, steroid receptors are classified into two groups, with glucocorticoid, mineralocorticoid, progesterone, and androgen receptors in one class, and estrogen, thyroid, cholecalciferol (vitamin D_3), and retinoic acid receptors in the other.

Membrane Receptor Binding Alternatively, like peptides or other hormones steroids may exert a physiological effect within minutes, a time course precluding a genomic mechanism and deriving instead from binding to membrane-bound receptors and a resultant alteration in membrane permeability, ion flow, or neurotransmitter release.

CHARACTERISTICS OF ENDOCRINE ACTIVITY

In general, most hormonal compounds exert their effect in a tonic rather than phasic fashion, being diffused in a less precise manner than a neurotransmitter and over a longer time period. Theoretically, such a characterization would allow hormones to be more closely linked to integrated behavioral responses. Release of many hormones is pulsatile, and the pattern of these pulses (i.e., duration interpulse interval, slope of increase or decrease in rate, amplitude) is crucial to their effects. Other factors that can influence the effect of a hormone in a given individual include a history of exposure during critical developmental encoding periods, the frequency and chronicity of past exposure, the time since last exposure, and the status of other influences on the target system. A decrease in the amplitude of the stress response after repeated exposure is referred to as *habituation* and an enhancement is termed *sensitization*. Facilitation of a habituated response after exposure to a novel stimulus or more severe stressor is called *dishabituation*. In the case of the hypothalamic-pituitary-adrenal system, the release of cortisol by the adrenal gland is dependent on an integration of three separate control systems. These include an underlying circadian rhythm regulated by the suprachiasmatic nucleus; a stress-responsive circuit involving inputs to the hypothalamus from the brain stem, limbic system, and cerebral cortex; and a feedback control system exerted principally through two classes of corticosteroid receptor, mineralocorticoid (type I) and glucocorticoid (type II) located most importantly in the hippocampus, but also (for type II) in other brain regions as well. These receptors each have different functions: the mineralocorticoid is most densely concentrated in hippocampus and septum and regulates glucocorticoid levels at low concentration with a “high affinity-low capacity” system; the glucocorticoid is more widely distributed and binds glucocorticoids with lower affinity but higher capacity, such as would occur in stressful states.

DEVELOPMENTAL PSYCHONEUROENDOCRINOLOGY

Although a review of the effect of hormones on brain development is beyond the scope of this chapter, it is important to note that hormones can have organizational as well as activational effects. Exposure to gonadal hormones during critical stages of neural development directs changes in brain morphology and function (e.g., sex-specific behavior in adulthood). Similarly, thyroid hormones are essential for the normal development of the CNS, and thyroid deficiency during critical stages of postnatal life will severely impair growth and development of the brain, resulting in behavioral disturbances that may be permanent if replacement therapy is not instituted.

HYPOTHALAMIC-PITUITARY-ADRENAL AXIS

Since the earliest conceptions of the stress response by Hans Selye and others, investigation of hypothalamic-pituitary-adrenal function has occupied a central position in psychoendocrine research. CRH, ACTH, and cortisol are all elevated in response to a variety of physical and psychic stresses and serve as prime factors in the maintenance of homeostasis and the development of adaptive responses to novel or challenging stimuli. The hormonal response is dependent not only on the characteristics of the stressor itself, but also on how the individual assesses and is able to cope with it. Aside from generalized effects on arousal, distinct effects on sensory processing, stimulus habituation and sensitization, pain, sleep, and memory storage and retrieval have been documented. In primates, social status can influence adrenocortical profiles and in turn be affected by exogenously induced changes in hormone concentration.

Exposure to chronic stress produces increased concentrations of corticotropin-releasing factor (CRF) in the paraventricular nucleus of the hypothalamus as well as of colocalized arginine vasopressin (AVP), but to a reduction in CRF receptor number in the anterior pituitary because of downregulation over time. Release of CRF results in a simultaneous activation of the locus-ceruleus noradrenergic circuit, which functionally increases arousal and selective attention, and decreases vegetative functions such as appetite and sex drive. ACTH concentrations are increased in acute stress, but diminish over time in sustained stress, suggesting that corticosteroid receptor downregulation at the level of the hippocampus leads to an inhibition of negative feedback on CRF.

These systems are amplified, in turn, by serotonergic and cholinergic input and inhibited by g-aminobutyric acid (GABA) and opioids. Three types of inhibitory feedback of glucocorticoids on CRH and ACTH have been characterized. Fast, rate-sensitive feedback occurs while plasma concentrations of the glucocorticoid are rising, and regulates release rather than synthesis of CRH and ACTH. Intermediate, delayed feedback occurs from 1 to 12 hours following steroid administration, is dose-sensitive and duration-sensitive rather than rate-sensitive, and inhibits release of both CRH and ACTH as well as synthesis of CRH. Slow feedback is similar to intermediate and is distinguished by decreased synthesis of both CRH and ACTH (and other proopionielanocortin derivatives).

Similarities in the changes in neuroendocrine systems following chronic stress and in depressive disorders suggests that some psychiatric syndromes may not be distinct disease states per se, but rather exist on a continuum with normal functioning. In support of such a conception are a variety of studies showing that although immediate release of glucocorticoids serves homeostatic needs, more prolonged activation can result in structural neuropathology, glutamate toxicity, damage to CA1 and CA4 hippocampal neurons and speculatively, lasting behavioral change. Some of the neuropathological sequelae of normal human aging parallel such stress-induced adaptations in the hypothalamic-pituitary-adrenal system and may either produce or be secondary to changes in neuroendocrine function and stress responsivity.

Pathological alterations in hypothalamic-pituitary-adrenal function have been associated primarily with mood disorders, posttraumatic stress disorder, and dementia of the Alzheimer's type, although recent animal evidence also points toward a role of this system in substance use disorders as well. Disturbances of mood are found in more than 50 percent of patients with Cushing's syndrome (characterized by elevated cortisol concentrations), with psychosis or suicidal thought apparent in more than 10 percent of cases studied. Cognitive impairments similar to those seen in major depressive disorder principally in visual memory and higher cortical functions, are common and relate to the degree of hypercortisolemia present, and possible reduction in hippocampal size. In general, reductions in cortisol level result in a normalization of mood and mental status. Conversely, in Addison's disease (characterized by adrenal insufficiency), apathy, social withdrawal, impaired sleep, and decreased concentration frequently accompany prominent fatigue. Replacement of glucocorticoid but not of electrolyte results in resolution of behavioral symptomatology. In a similar fashion, hypothalamic-pituitary-adrenal abnormalities are reversed in individuals who are successfully treated with antidepressant medications, and these drugs have been found to stimulate corticosteroid receptor gene expression. A failure to normalize hypothalamic-pituitary-adrenal abnormalities is a poor prognostic sign. Alterations in hypothalamic-pituitary-adrenal function associated with depression include elevated cortisol concentrations, failure to suppress cortisol in response to dexamethasone, increased adrenal size and sensitivity to ACTH, a blunted ACTH response to CRH and, possibly, elevated CRH concentrations in brain. In addition to altered slow feedback, several groups have demonstrated decreased sensitivity to glucocorticoid fast-feedback as well. The pattern of these abnormalities has not thus far led to a definitive theory of mechanism. It may be that other elements such as AVP, which is synergistic with CRH, or MSH, which is synergistic with ACTH, are important to understanding the change in homeostasis in depression. For instance, it has recently been noted that individuals with depression have impaired secretion of pro-g MSH and b-endorphin, but not ACTH, following metyrapone inhibition of cortisol synthesis in individuals

with depression. The finding that corticosteroids have multiple regulatory effects on serotoninergic function, particularly on the serotonin (5-hydroxytryptamine [5-HT]) subtype 1A (5-HT_{1A}) receptor may also be relevant, as well as the state-dependent stimulant-like effects that glucocorticoids can exert on mesencephalic dopamine transmission.

ENDOGENOUS OPIOIDS

Since the discovery of endogenous opioid receptors and their endogenous ligands in the early 1970s, research into the possible behavioral roles of such compounds has grown at a rapid pace. The term “opioid” was initially introduced to differentiate endogenous opioid peptides from other exogenous opiate drugs but is now used to refer to all drugs with opioid activity. b-endorphin is the principal opioid peptide prototype and, like ACTH, MSH, and b-lipotropin, is derived from proopiomelanocortin. Methionine enkephalin (Met-entephalin) and leucine enkephalin (Leu-enkephalin) are two small pentapeptides that also possess direct opioid activity. Met-enkephalin is contained in both proopiomelanocortin and another precursor, proenkephalin, and Leu-enkephalin is contained in the prohormones proenkephalin and prodynorphin. At least three different receptor systems for these ligands have been identified (μ, d, and k), and it is likely that each of these has subtypes. The best-documented function of the endogenous opiates is in analgesia and alteration of pain perception, but effects on stress, appetite regulation, learning and memory, motor activity, and immune function have significantly expanded scientific consideration of the functional principles that govern opioid localization and release.

In animal models a number of stressors, including those that are purely psychological, induce opiate-mediated effects such as analgesia and hypomotility that are reversed by the opiate antagonist naloxone (Narcan). Several studies have found that concentrations of plasma b-endorphin in humans are correlated with measures of stress elicited by surgery, exercise, parachuting, or pain. Opioids also affect eating behavior. Most commonly, short-term administration of opioid agonists increases eating whereas antagonists reduce food intake by up to 30 percent, diminish intake of fats and highly palatable foods, and increase caloric expenditure. Thus far, however, their long-term use in obesity and eating disorders has not proven clinically useful. Some studies have found certain binge parameters (e.g., duration) to be reduced in bulimia, but no studies have demonstrated weight loss in obese subjects. Naltrexone (ReVia) has recently been demonstrated in double-blind trials to be an effective adjunct in the treatment of alcohol dependence, reducing drinking, craving, the high derived from drinking alcohol, and the likelihood that sampling alcohol would precipitate a relapse.

It is well known that exogenous opioids (e.g., heroin, morphine) can induce a euphoric mood state and that exercise increases release of endogenous opioids and is associated with mood enhancement; these observations, together with findings that exercise-induced mood enhancement is blocked by naloxone, suggest that endogenous opioids are also involved in the mediation of mood. Such conclusions must be moderated, however, by the recognition that additional specific and nonspecific effects on other neurochemical systems are possible contributors to exercise-related mood effects.

Early enthusiasm for the idea that a dysfunctional opiate system was etiologically related to mental illness, particularly schizophrenia, has waned in the face of contradictory findings. Increases in various endorphin compounds have been reported in plasma as well as in postmortem brain tissue of patients with schizophrenia but studies of short-term and long-term treatment with opioid antagonists show no consistent or reproducible effects on psychopathology. In rhesus monkeys, naloxone reduces maternal affect and social grooming.

NEUROPEPTIDE Y, GALANIN, AND INSULIN

Neuropeptide Y and the related peptide bind at three receptors, neuropeptide Y type 1 (Y_1) (postsynaptic), Y_2 (presynaptic and postsynaptic), and Y_3. Neuropeptide Y is synthesized in the arcuate nucleus of the hypothalamus, has a mutually inhibitory relation with insulin, and is stimulated by stress and corticosteroids. Neuropeptide Y has been studied for its potential anxiolytic, antinociceptive, antihypertensive, and memory-enhancing effects and for a possible role in schizophrenia and depression. Immunoreactive neuropeptide Y is found in the serotonin-containing raphe nucleus, and treatments for depression (antidepressants, lithium [Eskalith], electroconvulsive therapy [ECT]) increase neuropeptide Y concentrations in many brain areas in rats. Reduced concentrations of neuropeptide Y have been found in the brains of suicide victims and of depressed individuals who died of other causes. Significantly low levels of neuropeptide Y have also been reported in the temporal cortex of patients with schizophrenia. Neuropeptide Y has been found to increase feeding in a variety of animal studies, particularly with regard to carbohydrate ingestion; it also counteracts leptin effects on feeding. In a related function, neuropeptide Y suppresses the thermogenic activity of brown fat and increases the storage of white fat.

Galanin is an inhibitory peptide that is stimulated in a coordinated fashion with gonadal steroid release. Its documented actions include antinociception; increased release of growth hormone; memory impairment; and inhibition of insulin release, locus ceruleus noradrenergic firing, and acetylcholine release. Galanin can dramatically increase food consumption, partly because of an increased preference for fats over carbohydrates. Work on identifying receptor subtypes and developing specific antagonist ligands for them is in the early phase but holds promise for the treatment of obesity and eating disorders.

Insulin Increasing evidence indicates that insulin may be integrally involved in learning and memory. Insulin receptors occur in high density in the hippocampus and are thought to help neurons metabolize glucose. Patients with Alzheimer's disease have lower CSF insulin concentrations than controls, and both insulin and glucose dramatically improve verbal memory. Depression is frequent in patients with diabetes, as are indices of impaired hormonal response to stress. It is not known whether these findings represent direct effects of the disease or are secondary, nonspecific effects.

Hypothalamic-Pituitary-Gonadal Axis GnRH is a decapeptide that was sequenced and synthesized by Andrew Schally and colleagues in 1971. GnRH administration results in the rapid release of LH and FSH from the pituitary in healthy subjects and in some pathological states, such as acromegaly, an abnormal release of growth hormone or prolactin. The cell bodies of GnRH are located principally over the optic chiasm in the arcuate area with projections to the median eminence, and in the lamina terminalis. GnRH release is stimulated by norepinephrine and inhibited through negative feedback of gonadal steroids. Administration of GnRH can result in a depressive-like state, characterized by hot flashes, anxiety, insomnia, decreased libido, and fatigue in euthymic subjects, but it is not known whether this is a direct effect of the agent or is caused by the hypoestrogenic state that is produced when GnRH is given continuously. On this basis, a GnRH analogue has been found to have some efficacy in the treatment of paraphilia. In contrast to other neuroendocrine systems, there is relatively little evidence for a disturbance in the hypothalamic-pituitary-gonadal axis in depression; normal LH and FSH responses have been observed after even submaximal doses of GnRH.

The gonadal hormones (progesterone, androstenedione, testosterone, estradiol, and others) are steroids that are secreted principally by the ovary and testis, but significant amounts of androgens arise from the adrenal cortex as well. The prostate gland and adipose tissue are also involved in the synthesis and storage of dihydrotestosterone and contribute to individual variance in sexual function and behavior.

The timing and presence of gonadal hormones play a critical role in the development of sexual dimorphisms in the brain. Developmentally, these hormones direct the organization of many sexually dimorphic CNS structures and functions, such as the size of hypothalamic nuclei (INAH3), and corpus callosum, neuronal density in the temporal cortex, the organization of language ability, and responsivity in Broca's area. Women with congenital adrenal hyperplasia, a deficiency of the enzyme 21-hydroxylase, which leads to high exposure to adrenal androgens in prenatal and postnatal life, have in some studies been found to be more aggressive and assertive and less interested in traditional female roles than control female subjects. Sexual dimorphisms may also reflect acute and reversible actions of relative steroid concentrations (e.g., higher estrogen levels transiently increase CNS sensitivity to serotonin).

TESTOSTERONE

Testosterone is the primary androgenic steroid, having both androgenic (i.e., facilitating male gonadal development) and anabolic (i.e., facilitating linear body growth and somatic growth) functions. Testosterone is associated with increased violence and aggression in animals and in correlations studies in humans, but anecdotal reports of increased aggression with testosterone treatment have not been substantiated in human scientific investigations. Correlational reports may be confounded, however, by factors such as past history, and social factors, which are particularly important determinants of the effects of hormones in primates and in humans. For instance, in the cynomolgus monkey, administration of testosterone increases dominant behavior in dominant monkeys and submissive behavior in submissive monkeys; in hypogonadal men it improves mood and decreases irritability. Varying effects of anabolic-androgenic steroids on mood have been noted anecdotally. In the only prospective placebo-controlled study of anabolic-androgenic steroid administration in normal subjects, positive mood symptoms including euphoria, increased energy, and sexual arousal were reported, in addition to increases in negative mood symptoms of irritability, mood swings, violent feelings, anger, and hostility.

Testosterone is important for sexual desire in both men and women. In males, muscle mass and strength, sexual activity, desire, thoughts, and intensity of sexual feelings are dependent on normal testosterone levels, but these functions are not clearly augmented by supplementing testosterone in those with normal androgen levels. Addition of small amounts of testosterone to normal hormonal replacement in postmenopausal women has, however, proven to be as beneficial as its use in

hypogonadal men.

Dihydroepiandrosterone (DHEA) is an adrenal androgen and the most abundant circulating steroid. It has many physiological effects, but behavioral interest has centered on its steady decrement over the life span in humans, and its possible involvement in memory. Several controlled trials of DHEA administration point to an improvement in well-being and functional status in depressed as well as normal individuals. Its effects may result from its transformation into estrogen or testosterone or from its antiglucocorticoid activity.

ESTROGEN AND PROGESTERONE

The primary estrogens are estradiol (E_2), estrogen (E_1), and estriol (E_3), of which estradiol is the major secretory product of the ovaries. Two different estrogen receptors have been identified, each with different anatomical distribution and physiological effects. Estrogens can influence neural activity in the hypothalamus and limbic system directly through modulation of neuronal excitability and have complex multiphasic effects on nigrostriatal dopamine receptor sensitivity. Accordingly, there is evidence that the antipsychotic effect of psychiatric drugs may change over the menstrual cycle and that the risk of tardive dyskinesia is partly dependent on estrogen concentrations. Several studies have suggested that gonadal steroids modulate spatial cognition and verbal memory and are involved in impeding age-related neuronal degeneration. There is also increasing evidence that estrogen administration decreases the risk and severity of dementia of the Alzheimer's type in postmenopausal women. Estrogen has mood-enhancing properties and can also increase sensitivity to serotonin possibly by inhibiting monoamine oxidase. In animal studies long-term estrogen treatment results in a decrease in 5-HT_1 and an increase in 5-HT_2 receptors. In oophorectomized women, significant reductions in tritiated imipramine binding sites (which modulate presynaptic serotonin uptake) were restored with estrogen treatment.

Progesterone, the primary progestin, is produced by the corpus luteum of the ovary, and is a precursor for estrogens, androgens, and adrenocortical steroids. Although progesterone itself may be anxiogenic, metabolites of progesterone (allopregnanolone and pregnanolone) appear to have anxiolytic and hypnotic properties via (g-aminobutric acid [GABA] type A [$GABA_A$]) agonistic activity. Progesterone also modulates serotonin; it is colocalized with serotonin in cells of the median raphe in the macaque monkey; it causes increased serotonin uptake and turnover in several brain areas in rats.

The association of these hormones with serotonin is hypothetically relevant to mood change in premenstrual and postpartum mood disturbances. Premenstrual dysphoric disorder is a disorder in which a constellation of symptoms resembling major depressive disorder occurs in most menstrual cycles, appearing in the luteal phase and disappearing within a few days of the onset of menses. No definitive abnormalities in estrogen or progesterone levels have been demonstrated in women with premenstrual dysphoric disorder, but decreased serotonin uptake with premenstrual decreases in steroid levels have been correlated with severity of some symptoms. The rise and fall of these symptoms reflect progesterone levels, with a delay of 4 days, although evidence does not support the idea that progesterone per se is responsible for the symptoms. However, progesterone downregulates the estrogen receptor, and it has been suggested that, despite high circulating concentrations of estrogen, the luteal phase is a period of functional estrogen withdrawal, with concomitant effects on the serotonergic system. Recent evidence indicates that the abrupt decline of progesterone and allopregnanolone in the luteal phase results in increased production of the a4 subunit of the $GABA_A$ receptor and changes in receptor sensitivity that could account for the typical behavioral symptoms noted. Although the specific susceptibility that characterizes women with premenstrual dysphoric disorder remains to be described, treatments based on these hypothetical neurotransmitter effects are available. Selective serotonin reuptake inhibitors (SSRIs), particularly fluoxetine (Prozac), have demonstrated efficacy in the majority of women studied, and up to 50 percent of women may respond to fluoxetine administered only in the second half of each cycle. Alprazolam (Xanax), a $GABA_A$ agonist, is significantly more effective than placebo in women who do not respond to treatment with SSRIs. In women with severe symptoms that are not responsive to these treatments, the long-term use of a GnRH agonist to abolish menstrual cycling, with added estrogen-progestin, may be required.

The bulk of psychological symptoms associated with the menopause are actually reported during perimenopause rather than after complete cessation of menses. Although studies suggest no increased incidence of major depressive disorder, reported symptoms include worry, fatigue, crying spells, mood swings, diminished ability to cope, and diminished libido or intensity of orgasm. Hormone replacement therapy is the treatment of choice at this time. Although most advocate estrogen replacement, combination androgen-estrogen replacement therapies may be superior for reinstating energy, a sense of well-being, and libido. In women with an intact uterus, the addition of progestin is necessary to protect against endometrial hyperplasia; this can reportedly attenuate the beneficial effects of estrogen on mood, so the lowest possible progestin dosage necessary is recommended.

PROLACTIN

Since its identification in 1970, the anterior pituitary hormone prolactin has been examined as a potential index of dopamine activity, dopamine receptor sensitivity, and antipsychotic drug concentration in studies of CNS function in psychiatric patients, and as a correlate of stress responsivity. The secretion of prolactin is under direct inhibitory regulation by dopamine neurons located in the tuberoinfundibular section of the hypothalamus. Prolactin also inhibits its own secretion by means of a short-loop feedback circuit to the hypothalamus. In addition, prolactin-releasing factors have been identified, including estrogen, serotonin, opiates, TRH, and oxytocin.

Prolactin is primarily involved in reproductive functions. During maturation, prolactin secretion participates in gonadal development. In adults, prolactin contributes to the regulation of the behavioral aspects of reproduction and infant care, including estrogen-dependent sexual receptivity and breastfeeding. In female rats, prolactin secretion is strongly stimulated with exposure to pups. In women, basal prolactin levels are elevated in the postpartum period prior to weaning, and prolactin release is stimulated by suckling. In line with these functions, hyperprolactinemia is associated with low testosterone in men and reduced libido in both men and women. In rodents, prolactin is increased along with corticosterone in response to such stressful stimuli as immobilization, hypoglycemia, surgery, and cold exposure. A recent report suggests that prolactin increase may be specifically associated with the use of passive coping in the face of a stressor.

Although prolactin metabolism is not clearly altered in psychiatric disorders, hyperprolactinemic patients often complain of depression, decreased libido, stress intolerance, anxiety, and increased irritability. These behavioral symptoms usually resolve in parallel with decrements in serum prolactin when either surgical or pharmacological treatments are employed. Serum prolactin concentrations have also been positively correlated with severity of tardive dyskinesia, particularly in women who have been exposed to antipsychotic medication. Studies in psychiatric populations have attempted to use prolactin response to infusions of dopaminergic agonists as an index of central neurotransmitter activity. Thus far, the conclusions to be drawn from this strategy are not clear because widely discrepant and contradictory results have been reported.

HYPOTHALAMIC-PITUITARY-THYROID AXIS

Thyroid hormones are involved in the regulation of nearly every organ system, particularly those integral to the metabolism of food and the regulation of temperature, and are responsible for optimal development and function of all body tissues. Moreover, rates of secretion and metabolism of all other major hormones and catecholamines (cortisol, gonadal hormones, insulin) depend on thyroid status. The thyroid gland secretes two thyroid hormones: T_3 and T_4. T_3 is the more potent of the two, and most of the T_3 circulating in the blood is created by the peripheral metabolism of T_4. The brain relies on its own conversion of T_4 to T_3, rather than on circulating T_3. The hypothalamus secretes TRH into the capillaries of the pituitary portal venous system, and the pituitary responds with synthesis and secretion of TSH, which stimulates thyroid cells. Negative feedback regulation occurs when T_3 and T_4 act in the pituitary and hypothalamus to inhibit TSH and TRH respectively. Finally, a corticotropinrelease–inhibiting factor (CRIF) has recently been identified in the rat that inhibits both synthesis and secretion of ACTH. This peptide, prepro-TRH 178-199, is derived from the prohormone TRH and may play a role in integrating the regulation of the hypothalamic-pituitary-adrenal and hypothalamic-pituitary-thyroid axes.

There is general agreement that central noradrenergic systems are primarily stimulatory to TSH secretion and that central dopamine neurons inhibit TSH release. Thyroid hormones in turn are important regulators of central adrenoreceptor function, generally decreasing presynaptic noradrenaline release and increasing postsynaptic b-adrenergic receptor number. Hypothyroidism is conversely associated with decreased b-receptor number. These changes parallel the alteration in a- and b-receptor sensitivity associated with pharmacological and electroconvulsive antidepressant treatments and may explain the therapeutic efficacy of supplemental thyroid hormone in treatment-resistant depression. In addition to its prime endocrine function, TRH has direct effects on neuronal excitability, behavior, and neurotransmitter regulation, particularly on central cholinergic systems located in the septo-hippocampal band and on mesolimbic and nigrostriatal dopamine systems. In lower animals, TRH possesses mild stimulant properties. Initial reports of its mood-elevating effects in normal human subjects led to a number of projects investigating its short-term and long-term antidepressant effects in clinical populations. Despite some initial enthusiasm, the degree of mood alteration does not seem to be great nor is its occurrence reliable.

Given these observations, it is not surprising that alterations in behavioral function have been observed in patients with primary thyroid gland dysfunction, beginning with the earliest reports in the medical literature. It has been noted that thyroid disorders may induce virtually any psychiatric symptom or syndrome, although regular associations of specific syndromes and thyroid conditions are not consistently found. Hyperthyroidism is commonly associated with fatigue, irritability, insomnia, anxiety, restlessness, weight loss, and emotional lability; marked impairment in concentration and memory may also be evident. Such states can progress into delirium or mania or they can be episodic in ature. On occasion, a true psychosis develops, with paranoia being a particularly common presenting feature. In some cases psychomotor retardation, apathy, and withdrawal rather than agitation and anxiety are the presenting features. Symptoms of mania have also been reported following rapid normalization of thyroid status in hypothyroid individuals and may covary with thyroid level in individuals with episodic endocrine dysfunction. In general, behavioral abnormalities resolve with a normalization of thyroid function and are responsive symptomatically to traditional psychopharmacological regimens. Caution should be exerted, however, regarding use of antidepressant medications in hyperthyroid states because of possible synergistic cardiotoxicity. In several case reports, haloperidol (Haldol) has been linked to increasing thyrotoxicity, and hyperthyroidism has been linked to an enhancement of the neurotoxic effects of antipsychotic medications.

The psychiatric symptoms of chronic hypothyroidism are generally well recognized. Most classically, fatigue, decreased libido, memory impairment, and irritability are noted, but a true secondary psychotic disorder or dementia-like state can also develop. Suicidal ideation is common and the lethality of actual attempts is profound. In milder, subclinical states of hypothyroidism, the absence of gross signs accompanying endocrine dysfunction may result in its being overlooked as a possible cause of a mental disorder. Accordingly, the evaluation of basal TSH concentration or the TSH response to TRH infusion is necessary to arrive at the proper diagnosis. Figure 1.11-1 illustrates a characteristic physical sign of advanced hypothyroidism.

FIGURE 1.11-1 Hands of a patient suffering from hypothyroidism (myxedema), illustrating the swelling of the soft parts, the broadening of the fingers, and their consequent stumpy or pudgy appearance. (Reprinted from Waterfield RL: Anæmia. In *French's Index of Differential Diagnosis,* ed 7, AH Douthwaite, editor. Williams & Wilkins, Baltimore, 1954.)

A blunted response of TSH to TRH infusion has been found in a significant percentage of patients with a variety of disorders including eating disorders, alcoholism, and schizophrenia, and, most commonly, major depressive disorder, and probably reflects a transient hyperthyroxinemia. Large-scale studies suggest that such subjects are in fact euthyroid, and predictive sensitivity of the test is low. Antithyroid antibodies are found more frequently in women with depression than control subjects, and may contribute to relative treatment resistance. In recent years, several investigators have presented evidence that attention-deficit/hyperactivity disorder may be associated with a generalized resistance to thyroid hormone due to a genetic mutation of the b-thyroid receptor.

Most antidepressant therapies have some influence on thyroid concentrations at baseline; T_4 and T_3 concentrations have been correlated with antidepressant response, as have antidepressant-induced changes in thyroid hormones as well as changes induced by ECT. Lithium increases antithyroid antibodies, and inhibits iodine uptake into the thyroid, iodination of tyrosine, release of T_3 and T_4 from the thyroid, and peripheral breakdown of thyroid hormones. It also blocks the thyroid-stimulating effects of TSH through interference with adenylate cyclase and may, in certain circumstances, precipitate a rebound thyrotoxicosis. About 30 percent of patients receiving lithium will have an elevated TSH level during treatment, and approximately one sixth of these will go on to develop frank hypothyroidism. Attention to subtle alteration in thyroid status induced by lithium treatment is important in the clinical evaluation of symptomatic complaints such as fatigue, memory impairment, and anhedonia. Carbamazapine (Tegretol), an anticonvulsant shown to have antimanic properties akin to lithium, also decreases peripheral thyroid hormone concentrations while increasing TSH. Administration of T_3 is sometimes helpful in patients with treatment-resistant depression, while adjunctive T_4 contributes to decreasing cycling in patients with rapid-cycling bipolar I disorder.

PARATHYROID HORMONE

Parathyroid hormone (PTH) was originally isolated as an endocrine factor having effects on bone, gut, and kidney and contributing to calcium and phosphorus homeostasis. However, the frequent and often profound neuropsychiatric changes that can result from altered parathyroid gland function are consistent with other central actions of PTH that have been described in recent years.

Although PTH is known to increase calcium uptake leading to enhanced neurotransmitter release, PTH administration can impair the active uptake and release of both norepinephrine and dopamine through a variety of other actions. Consequences of exogenously administered PTH include adrenergic-like effects (not blocked by b-adrenergic antagonist), learning and memory problems, and a state of hyperalgesia.

Lithium treatment can raise the concentrations of serum calcium and may increase PTH. When such effects are associated with somatic or behavioral change, discontinuation of lithium should result in rapid symptomatic improvement. When this does not happen, a parathyroid adenoma is sometimes discovered fortuitously. Primary hyperparathyroidism most commonly occurs secondary to a single parathyroid adenoma, the removal of which almost invariably results in a lysis of behavioral symptoms, regardless of severity or chronicity. Animal studies suggest that long-term lithium administration can stimulate the development of extant parathyroid tumors but does not induce tumors in normal parathyroid tissue. Thus, reinstitution of lithium treatment after surgical removal of the tumor should be possible.

GROWTH HORMONE

Most psychiatric studies of the regulation of somatotropin or growth hormone (GH) have utilized strategies similar to those described for prolactin. Accordingly, studies of GH response to various provocative stimuli, such as to GHRH or psychotherapeutic drugs, have been seen as a means to evaluate central neurotransmitter function. Augmentation of GH secretion in response to GHRH, LH-releasing hormone (LHRH), and TRH in patients with schizophrenia or dementia of the Alzheimer's type has been interpreted as reflecting an alteration in catecholamine and possibly prostaglandin regulation, which facilitate the secretion of human GH. In general, however, there is a large variation in GH response to GHRH; a blunted response has been variably linked to length of illness, presence of negative symptoms, and platelet monoamine oxidase activity, but the validity of the conclusions drawn from this test is controversial.

The stress responsivity of somatotrophs is well established but species dependent, with increases in circulating GH noted in humans and inhibition of secretion noted in rodents. Case reports have documented reversible GH deficiencies and marked growth retardation and delay of puberty secondary to stressful experience. Administration of GH to individuals with GH deficiency has a beneficial effect on cognitive function in addition to its more obvious somatic effects, but there is evidence for poor psychosocial adaptation in adulthood for children who were treated for GH deficiency. Nearly one third of patients with major depressive disorder and dysthymic disorder may have a GH deficiency. Some prepubertal as well as adult patients with diagnoses of major depressive disorder show hyposecretion of GH-releasing hormone during an insulin tolerance test, a deficit that has been interpreted as reflecting alterations in both cholinergic and serotonergic mechanism. A number of GH abnormalities have been noted in patients with anorexia nervosa. Secondary factors such as weight loss, however, in both major depressive disorder and eating disorders, may be responsible for such alterations in endocrine release. Nonetheless, at least one study has reported that GHRH stimulates food consumption in patients with anorexia nervosa and attenuates elevated food consumption in patients with bulimia. Administration of GH to elderly men results in an increase in lean body mass and improved vigor.

SOMATOSTATIN

SRIF is a hypothalamic tetradecapeptide that is located principally in the nerve endings of the median eminence and in neurosecretory neurons located in the paraventricular nucleus. SRIF inhibits anterior pituitary secretion of ACTH, thyrotropin, GH, and prolactin and alters release of catecholamine neurotransmitters. Five receptor subtypes have been cloned and receptor-specific ligands developed. SRIF was so named because of its action in inhibiting the release of immunoreactive GH, a function that is subserved by somatostatin-2 receptors.

In rats, SRIF delays the extinction of active avoidance behavior and antagonizes amnesia induced by electric shock. Alterations in the concentration of SRIF have been associated with a number of conditions in which cognitive dysfunction is present, including Huntington's disease, Parkinson's disease, multiple sclerosis, and particularly Alzheimer's Disease. Decreases in SRIF are highly correlated with decreases in acetylcholinesterase, suggesting a close relationship between the cholinergic and somatostatinergic systems. Decreased concentrations of SRIF in CSF are inconsistently found in patients with depression, and central injection of SRIF in rats causes decreased slow-wave and rapid eye movement (REM) sleep, altered appetite and locomotor activity, impaired cognition, and decreased sensitivity to pain. Early stressful experiences have also been related to sustained elevations of CRF and somatostatin in the CSF of adult primates.

CHOLECYSTOKININ

In addition to its presence in pancreas and the gastrointestinal tract, cholecystokinin (CCK) has been identified in mammalian brain, with high concentrations found in the cerebral cortex, limbic system, and hypothalamus. In animal studies CCK is involved in the regulation of such behavioral functions as inhibition of intake of both solid and liquid food, production of satiety, and pain relief. Of the two identified receptor subtypes, CCK type A (CCK-A) is found primarily in the periphery and in some discrete brain areas, whereas CCK-B is plentiful in the brain. The primary form of CCK, CCK-8S (a sulphated octapeptide), coexists with dopamine in the ventral tegmental area and substantia nigra, and its interactions with dopamine are to be context- and location-specific. Both CCK-A and CCK-B receptors have a high affinity for CCK-8S. CCK-B receptors also have high affinity for CCK-8US (unsulphated), CCK-4, and pentagastrin, whereas CCK-A receptors do not.

Of particular interest to psychiatry is the coexistence of CCK with dopamine in mesolimbic and mesocortical but not in nigrostriatal systems. This suggests that CCK-8 activity might either be dysregulated in psychiatric syndromes thought to involve altered dopamine transmission or that CCK-8 analogues could be used therapeutically in the treatment of these syndromes. CCK-A receptor antagonists has been proposed for the treatment of schizophrenia, and initial evidence suggests that CCK agonists may be useful for decreasing the severity of parkinsonian symptoms. Evidence is stronger for a role of CCK-B receptor antagonists in the treatment of anxiety. Several small-scale human studies have demonstrated that administration of CCK-4 or pentagastrin can induce panic attacks in a significant percentage of normal volunteers. Panic attacks in subjects with preexisting panic disorder can be elicited at doses of CCK-4 that do not reliably induce panic in normal subjects, indicating the enhanced sensitivity of patients with panic disorder to CCK-4. Not only can selective CCK-B antagonists completely abolish the anxiogenic effects of CCK-4, but in animal models of anxiety used to evaluate the efficacy of benzodiazepines CCK-B antagonists also demonstrate anxiolytic properties.

MELATONIN

Melatonin is a pineal hormone that is derived from the serotonin molecule and controls photoperiodically mediated endocrine events (particularly those of the hypothalamic-pituitary-gonadal axis). It also modulates immune function, mood, and reproductive performance and is a potent antioxidant and free-radical scavenger. Melatonin has a depressive effect on CNS excitability and is an analgesic and has seizure-inhibiting effects in animal studies. These effects may occur via a GABA-potentiating action, although they may be secondary to the antioxidant or antiexcitotoxic actions of melatonin. Although some researchers have found low melatonin in depression, confounding factors exist, and suppression of melatonin is not necessary for the efficacy of light therapy in seasonal affective disorder. However, melatonin can be a useful therapeutic agent in the treatment of circadian phase disorders such as jet lag. Intake of melatonin increases the speed of falling asleep, as well as its duration and quality.

ARGININE VASOPRESSIN

AVP or (antidiuretic hormone [ADH]) is a posterior pituitary hormone that maintains plasma osmolarity through regulation of renal water excretion. AVP release is triggered by pain, emotional stress, dehydration, increased plasma osmolarity, or decreases in blood volume.

Profound alterations in fluid ingestion and excretion have been observed in psychiatric patients throughout most of the twentieth century. Polydipsia occurs in 10 to 15 percent of hospitalized psychiatric patients and is unrelated to diagnosis. In many cases the syndrome is secondary to inappropriate secretion of AVP, which occurs as a feature of the altered behavioral state itself and resolves with treatment or, conversely, is precipitated by a variety of antidepressant or antipsychotic agents.

Animal and normal human studies of AVP administration (or longer-acting synthetic analogue compounds) have indicated that the hormone may enhance both the consolidation and retrieval of memory, particularly that associated with aversive learning. Clinical studies in assessments of attention, concentration, and memory in the elderly, those with depression, or those with dementia have had more mixed results. Although positive results exist, the effect is small and has yet to be consistently reproduced; it may be that such reported effects are secondary to a general arousal effect. However, AVP has also been shown to prevent the loss of tolerance to alcohol and to delay the loss of sexual behavior following castration, both of which suggest involvement of a learning mechanism.

Altered AVP function has been reported in depression and in eating disorders. Anorexic patients show hypersecretion of centrally directed AVP, and patients with bulimia nervosa or depression may have an attenuated AVP response to hypertonic saline. An inverse relation between AVP concentration and motor activity in depression and an increased number of vasopressin and oxytocin neurons have also been reported in the hypothalamus of depressed patients.

OXYTOCIN

Oxytocin is also a posterior pituitary hormone that is involved in osmoregulation, the milk ejection reflex, food intake, and female maternal and sexual behaviors. The majority of studies of oxytocin have so far been conducted in animals. Convergent evidence using a range of methodologies indicates that oxytocin inhibits food and sodium intake. Oxytocin binding in the hypothalamus is increased by estrogen and glucocorticoids, and in estrogen-primed females, oxytocin has anxiolytic activity and promotes the initiation of maternal behaviors. Oxytocin induces a variety of reproductive (grooming, arousal, lordosis, orgasm, nesting, birthing) and maternal behaviors (breast-feeding, mother-infant bonding), although the former may be restricted to nonmonogamous species. Infusion of oxytocin in females of monogamous species facilitates pair bonding in the absence of mating, and administration of an oxytocin antagonist prevents pair bonding. AVP serves a similar pair-bonding function in males, and promotes monogamy and paternal behavior in male prairie moles. Oxytocin can also act as a neuromodulator of limbic dopamine concentrations and thus may be involved in adaptation to substances of abuse.

SUBSTANCE P

Substance P, an 11 amino acid peptide discovered originally in 1930, has neurotrophic effects and acts as an excitatory transmitter in primary afferent nerve terminals in mammalian spinal cord, helping to regulate sympathetic noradrenergic function. Depending on the pain paradigm utilized, administration of substance P can produce either hyperalgesia or analgesia. Substance P also has been found to have memory-promoting and reinforcing effects, which may be produced by the N- and C-terminal fragments respectively. Although substance P has been implicated in the pathogenesis of several neuropsychiatric disorders, evidence for any specific role is mixed.

NEUROTENSIN

Neurotensin is a tridecapeptide in the substantia nigra, limbic system, and hypothalamus that has a close neuroanatomical relation with dopaminergic pathways. It is involved in the control of anterior pituitary activity and affects release of prolactin and TSH at both hypothalamic and pituitary concentrations. Several lines of evidence suggest that neurotensin may have a possible antipsychotic role. Psychotogenic drugs (e.g., methamphetamine [Desoxyn]) inhibit the release of neurotensin via an inhibitory effect of the dopamine type 1 (D_1) receptor. All antipsychotic drugs increase neurotensin concentrations in the nucleus accumbens and dopamine receptor antagonists also increase concentrations in the caudate nucleus. Central administration of neurotensin produces a range of pharmacological effects similar to those produced by antipsychotic drugs in animals, and such effects may be specific to the mesolimbic-cortical and not the nigrostriatal-dopamine system.

Neurotensin may exert its antipsychotic action through intramembrane receptor interactions that reduce affinity of the D_2-agonist binding site.

MELANOCYTE-STIMULATING HORMONE

Melanocyte-stimulating hormone (MSH), an anterior pituitary peptide, controls the secretion of melatonin (and melanin) and, in some paradigms, exerts opposite effects on behavior. Intraperitoneal administration of a-MSH delays extinction in a passive-avoidance paradigm and increases emotional response. In a double-blind crossover trial in humans, an infusion of a-MSH resulted in a significant improvement in verbal memory but little change in mood. Because phenothiazines increase pituitary MSH secretion and pigmentation in patients in proportion to their therapeutic potency, it has been suggested that MSH peptides may possess some therapeutic properties. A dose-related biphasic effect on mood has also been reported for MSH-release–inhibiting factor. Recent data indicate that MSH interacts with leptin to counteract Neuropeptide Y, decrease food intake, and increase energy expenditure.

SUGGESTED CROSS-REFERENCES

Section 1.12 on the immune system contains information on the interaction between endocrine, immune, and neural systems. Section 2.5 provides more detail on the psychiatric effects of endocrine disorders. Chapter 14 discusses further aspects of mood disorders and section 31.28 presents the therapeutic use of thyroid hormones.

1.12 IMMUNE SYSTEM AND CENTRAL NERVOUS SYSTEM INTERACTIONS

ANDREW H. MILLER, M.D., BRADLEY D. PEARCE, PH.D. AND CARMINE M. PARIANTE, M.D.

An ever-growing database demonstrates that interactions between the immune system and the central nervous system (CNS) play a critical role in the maintenance of bodily homeostasis and the development of diseases, including psychiatric disease. Alterations in CNS function brought about by a variety of stressors have been clearly shown to influence both the immune system as well as diseases that involve the immune system. Moreover, many of the relevant hormonal and neurotransmitter pathways that mediate these effects have been elucidated. Of considerable interest is recent data outlining the impact of soluble factors (cytokines) derived from immune cells and glia, which in turn have profound effects on the CNS. The relative roles of these factors in the various psychiatric diseases is an area of active investigation, as is the role of infectious and autoimmune diseases in the pathophysiology of psychiatric disorders. Taken together, these findings highlight the importance of interdisciplinary efforts involving the neurosciences and immunology for gaining new insights into the etiology of psychiatric syndromes.

OVERVIEW OF IMMUNE SYSTEM

The immune system has the capacity to protect the body from the invasion of foreign pathogens, such as viruses, bacteria, fungi, and parasites. In addition, the immune system can detect and eliminate cells that have become neoplastically transformed. These functions are accomplished through highly specific receptors on immune cells for molecules derived from invading organisms and a rich intercellular communication network that involves direct cell-to-cell interactions and signaling between cells of the immune system by soluble factors called *cytokines*. The body's absolute dependence on the efficient functioning of the immune system is illustrated by the less than 1-year survival rate of untreated infants born with severe combined immunodeficiency disease and the devastating opportunistic infections and cancers that arise during acquired immune deficiency syndrome (AIDS).

CELLS AND TISSUES

The immune system must be able to survey all tissues of the body for the presence of infectious agents or neoplastic cells and to mobilize its effector components to specific sites in the body where infectious agents may invade. Therefore, an important requirement of the immune system is that it be systemic and mobile. Cells of hematopoietic origin largely accomplish this function. Like all other blood cells, immune cells are derived from hematopoietic precursor stem cells, which in the adult originate in the bone marrow. The stem cells are pluripotent and are capable of differentiating into any one of the various mature hematopoietic cells. There are two major paths of differentiation that are regulated in part by cytokines and other factors (Fig. 1.12-1). The lymphoid path leads to the formation of the mature lymphocytes—B cells, T cells, and natural killer cells; the myeloid path of differentiation leads to the other cells of the blood (some of which participate in the immune response), including monocytes and granulocytes, which include neutrophils, eosinophils, and basophils. Monocytes and basophils may further differentiate into macrophages and mast cells, respectively, which take up residence in tissues throughout the body.

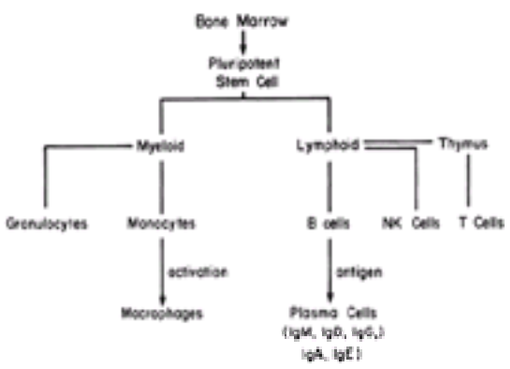

FIGURE 1.12-1 All cells are ultimately derived from a pluripotent stem cell of bone marrow, which gives rise to myeloid or lymphoid progenitors that undergo further differentiation to mature cell types indicated in the schematic diagram. NK = natural killer; Ig = immunoglobulin. (Reprinted with permission from Norin AJ: Introduction to immunobiologic concepts. In *Depressive Disorders and Immunity*, AH Miller, editor. American Psychiatric Press, Washington, DC, 1989.)

Lymphocyte maturation occurs in *primary immune tissues*. In humans the bone marrow serves as the primary site for B-cell maturation, and the thymus is the primary site for T-cell maturation. An important part of the maturation process is the screening out of cells that are reactive to the body's own constituents *(self-reactive)*. On maturation, lymphocytes exit the primary immune tissues and circulate through the bloodstream and the lymphatic system into and out of the secondary immune tissues, including the spleen and widely distributed lymph nodes. *Secondary immune tissues* provide a structure for interactions between different immune cells and circulating pathogens.

NATURAL AND ACQUIRED IMMUNITY

The immune system is often divided on a functional basis into two separate categories: natural or innate immunity and specific or acquired immunity (Table 1.12-1). The components of natural immunity act in a relatively nonspecific manner against pathogens or infected cells and may be evolutionarily more primitive than the specialized T and B lymphocytes that mediate specific immunity; operationally, however, the two modes of immunity interact and cooperate.

Feature	Natural	Specific (Acquired)
Physicochemical barriers	Skin, mucous membranes	Cutaneous and mucosal immune systems; antibody in mucosal secretions
Circulating molecules	Complement	Antibodies
Cells	Phagocytes (macrophages, neutrophils), natural killer cells	Lymphocytes
Soluble mediators active on other cells	Macrophage-derived cytokines, (e.g., interferon alpha and beta, tumor necrosis factor)	Lymphocyte-derived cytokines, (e.g., interferon gamma)

Reprinted with permission from Abbas AK, Lichtman AH, Pober JS: Cellular and Molecular Immunology, ed 2. Saunders, Philadelphia, 1994.

Table 1.12-1 Features of Natural and Specific (Acquired) Immunity

Natural Immunity The cells mediating natural immunity do not require prior activation to be functional; they therefore provide an important first line of defense against infectious agents during the early stages of an immune response. Mononuclear phagocytic cells and natural killer cells are examples of immune cells that mediate nonspecific immunity. Mononuclear phagocytic cells, such as macrophages, microglia, certain endothelial cells, and reticular cells of lymphoid organs, are collectively referred to as the *reticuloendothelial system*, and these cells destroy extracellular pathogens (e.g., bacteria and parasites) by engulfing and degrading them. Mononuclear phagocytes also release type I interferons (IFN), which have direct antiviral properties, and proinflammatory cytokines including tumor necrosis factor (TNF), interleukin (IL-1), and IL-6. TNF is the principal mediator of the response to gram-negative bacteria and is one of the earliest cytokines released in the proinflammatory cascade that includes IL-1 followed by IL-6. TNF is an endogenous pyrogen that along with IL-1 is capable of inducing fever by increasing the synthesis of prostaglandins by cytokine-stimulated hypothalamic cells. TNF also leads to cachexia, characterized by wasting of muscle and fat cells, in part secondary to appetite suppression.

The combination of liver-derived plasma proteins induced by TNF and IL-1 with those induced by IL-6 constitutes the acute-phase response (Fig. 1.12-2). The acute-phase response is designed to limit tissue damage, isolate and destroy invading organisms, and set repair functions in motion. These objectives are achieved by rapid changes in plasma protein composition characterized by increases in the so-called “acute phase reactants”: C-reactive protein (which coats bacteria to facilitate phagocytosis-opsonization), macroglobulin and other antiproteases (which neutralize tissue destructive proteases), and the clotting protein fibrinogen. Albumin and transferrin, the iron transport protein, decline during the acute-phase response and are therefore called *negative acute phase reactants*.

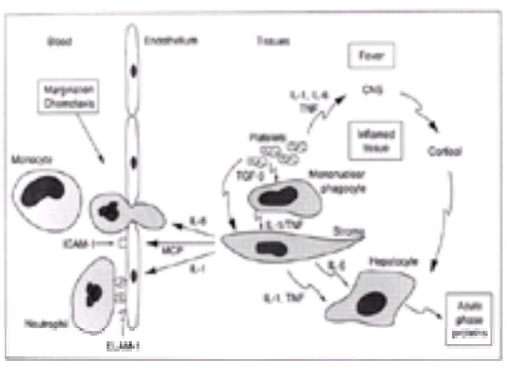

FIGURE 1.12-2 Scheme for cell and cytokine interaction in the acute phase response. Mononuclear phagocytes release early cytokines, such as IL-1 and TNF, at the site of tissue damage. These cytokines activate adjacent stroma and endothelium to elicit other chemotactic cytokines and initiate the accumulation of inflammatory cells. The hepatic response is activated by other cytokine mediators, as is the activation of the adrenal-pituitary axis to release ACTH and subsequently cortisol. (Reprinted with permission from Baumann H, Gauldie J: The acute phase response. Immunol Today *15:*74, 1994.)

Complement factor proteins, which are produced by the liver, provide another important humoral component of nonspecific immunity. These functionally linked proteins interact with one another in a highly regulated manner and subserve many of the effector functions of the immune system, including cell lysis, opsonization, activation of inflammation by attracting inflammatory cells (chemotaxis) and stimulating immune cells to release chemical mediators of inflammation, and neutralization of antigen-antibody complexes that can damage tissues.

Natural killer cells are also an important component of natural immunity. These cells can destroy virally infected cells by binding to them and releasing cytolytic factors, including perforin. Natural killer cells also have the ability to recognize and destroy neoplastically transformed host cells, especially those of hematopoietic origin, thus providing protection against some cancers.

Acquired Immunity T and B lymphocytes are the crowning achievement of immune cell specialization and evolution. These cells account for both the diversity and the specificity of the immune response and for the adaptive aspect of the immune system. Furthermore, T and B cells are responsible for directing the immune response against foreign targets, rather than self components. An effective specific immune response includes three conceptually separate phases: an induction phase, in which the presence of an infectious agent or antigen is detected; an activation phase, which includes the proliferation and the mobilization of the immune cells relevant to the eradication of the infectious agent; and an action or effector phase, in which the infectious agent is neutralized and eliminated.

INDUCTION PHASE Recognition of pathogens or neoplastically transformed cells is achieved through specialized receptors for antigens on the surface of B and T lymphocytes. Antigens are foreign substances that induce specific immunity and typically include molecules derived from pathogens, such as viral subunits, enzymes, and bacterial cell wall glycoproteins. The B-cell antigen receptor is a membrane-bound form of immunoglobulin. A related form of immunoglobulin is secreted as antibody by mature B cells (plasma B cells). Antibodies play a central role in humoral immunity and help to kill a variety of pathogens. Each immunoglobulin or antibody molecule has two identical antigen-binding sites, and those binding sites can recognize the tertiary structure of specific proteins and other molecules, such as polysaccharides and lipids, which are important components of infectious agents (Fig. 1.12-3).

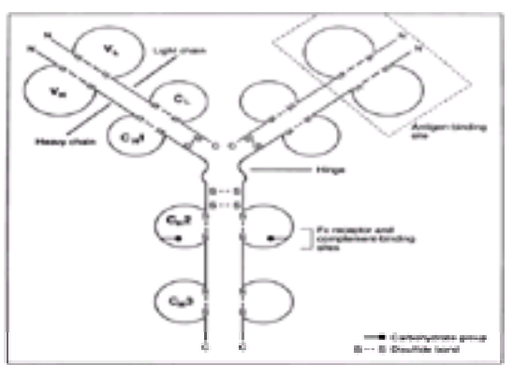

FIGURE 1.12-3 Schematic diagram of an immunoglobulin molecule. In this drawing of an IgG molecule, the antigen binding sites are formed by the juxtaposition of V_L and V_H domains. The locations of complement and Fc receptor-binding sites within the heavy chain constant regions are approximations. S--S refers to intrachain and interchain disulfide bonds; N and C refer to amino and carboxy termini of the polypeptide chains, respectively. (Reprinted with permission from Abbas AK, Lichtman AH, Pober JS: *Cellular and Molecular Immunology*, ed 2. Saunders, Philadelphia, 1994.)

The T-cell antigen receptor has a single antigen-binding site. Antigen recognition by T cells takes on an added level of complexity not inherent to B cells. The T-cell receptor recognizes only fragments of protein antigens. In addition, the antigen fragments must be present in association with a class of cell surface molecules called *major histocompatibility (MHC) molecules* (Fig. 1.12-4). Virtually all nucleated cells of the body express MHC molecules on their surface. Most cells express class I MHC molecules; some cells, usually of immune system origin, also express class II MHC molecules. The induction of a T-cell response depends on the ability and the effectiveness of MHC molecules to bind and present antigen. Therefore, the repertoire of MHC molecule genes that a person inherits can contribute significantly to antigen presentation and ultimately to susceptibility to infectious diseases and autoimmune disorders. T cells are MHC class-restricted—that is, T-cell receptors recognize antigen only in association with one or the other class of MHC molecules. All MHC class I-restricted T cells also express an invariant surface glycoprotein, referred to as *clusters of differentiation (CD) 8*. All MHC class II-restricted T cells express a different invariant surface glycoprotein, referred to as *CD4*. CD8 and CD4 molecules assist the binding of T cells to antigen-MHC complexes and assist in subsequent T-cell activation. Most $CD8^+$ T cells are cytolytic T lymphocytes (CTLs) that have the ability to lyse cells to which they bind, whereas most $CD4^+$ T cells are helper T cells that secrete cytokines on activation. Antigen-presenting cells (APCs), including macrophages, B cells, dendritic cells, Langerhans' cells of the skin and human endothelial cells, all have the ability to engulf, degrade, and process extracellular proteins and then display the processed bits of protein in conjunction with surface class II MHC molecules (Fig. 1.12-4). Therefore, these cells play an important role in presenting antigen to $CD4^+$ T cells.

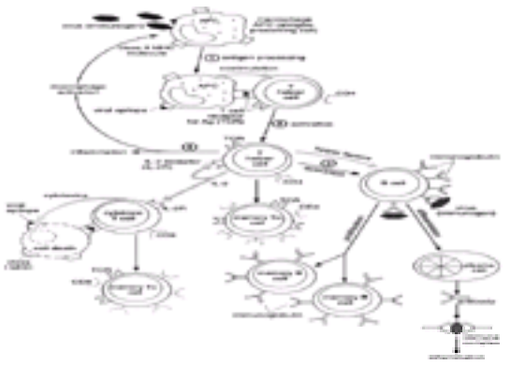

FIGURE 1.12-4 Sequence of events in a prototypical acquired immune response. Antigen presenting cells (APCs) present processed immunogen to helper T cells, which are central to the development of acquired immune responses. Through their T cell receptors (TCRs), T cells recognize particular epitopes of the immunogen in association with a Major Histocompatibility Complex (MHC) molecule. T helper cells in turn can help B cells make antibody and activate other effector cells including cytotoxic T cells, T and B memory cells, and natural killer cells, macrophages, granulocytes and antibody dependent cytotoxic (K) cells (not pictured). (Reprinted with permission from Stites DP, Terr AI, Parslow TG: *Medical Immunology*, ed 9. Appleton & Lange, Stamford, CT, 1997.)

All the receptors for an antigen on a particular B or T cell are identical and unique to that cell and its decedents *(clones)*. A family of lymphocytes with identical antigen receptor specificity is called a *clonal line*. Diversity in antigen recognition is derived from the vast number of different B-cell and T-cell clonal lines present in each person. Such diversity is achieved by semirandom mixing and matching of sequences of deoxyribonucleic acid (DNA) that code for the antigen-binding portion of the T-cell and B-cell receptors. That process of genetic diversity has been estimated to have the capacity to generate in each person more than 10^8 different receptors with functionally distinct antigenic specificity. Such high diversity makes it likely that each person possesses some clonal line of lymphocytes with an antigen receptor specificity capable of binding to a portion of any pathogen that may be encountered. Thus, the specific recognition of pathogens by the immune system entails the clonal selection of lymphocytes that are specifically responsive to the infectious agent.

ACTIVATION PHASE The binding of foreign antigens by B cells and T cells is usually not sufficient to produce cell activation; an accessory signal must also be provided. Important accessory signals are generated by a group of cytokines called *interleukins* that are secreted by T helper cells and antigen presenting cells, such as macrophages. T helper cells and APCs cooperate (Fig. 1.12-3); APCs secrete IL-1 and other cytokines that stimulate T helper cells to secrete a host of cytokines including interferon gamma (IFN-g), which then increases the phagocytic ability of APCs and increases their class II MHC expression, thus improving their antigen-presenting capacity. IFN-gamma also has direct antiviral properties. In addition, IL-1 stimulates T cells to produce IL-2 and express IL-2 receptors on their surface; IL-2 is an important cytokine that activates multiple lymphocyte functions (Table 1.12-2).

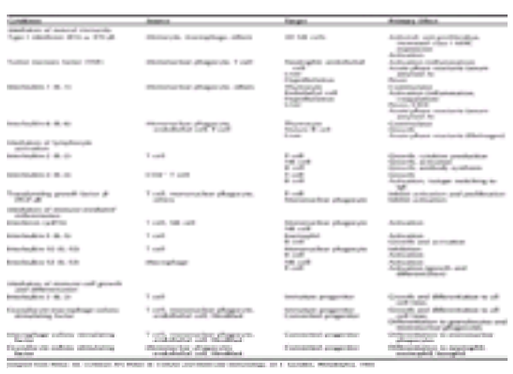

Table 1.12-2 Cytokines and Their Effects

Recent evidence indicates that two subclasses of T helper cells secrete different cytokine profiles after stimulation. These T helper subsets have been best characterized in the mouse. T helper-1 (Th-1) cells primarily secrete IL-2 and IFN-g and are involved in cell-mediated inflammatory reactions and result in activation of CTL. T helper-2 (Th-2) cells primarily secrete IL-4, IL-5, IL-6, and IL-10, and encourage antibody formation, particularly immunoglobulin E (IgE) responses. Thus, Th-2 cytokines are found in association with strong antibody responses and allergic responses. Various cytokines and their effects are listed in Table 1.12-2.

After binding antigen in the presence of stimulatory cytokines, T and B lymphocytes with the appropriate binding sites are activated, leading to cell growth, division, and proliferation. Activation also results in the clonal expansion of immune cells with the identical high-affinity specificity for the foreign antigen. Some of the progeny during clonal expansion undergo further differentiation into mature effector cells, such as antibody-secreting plasma B cells, and CTLs. By contrast, some descendents of activated B cells or T cells become memory cells that are primed for activation on further stimulation by the same antigen. Reexposure to that antigen results in a secondary immune response *(acquired immunity)*, which is usually more rapid and more robust than the first or primary immune response to that antigen. Memory cells may live for many years, thus providing long-lasting acquired immunity, as is evident in individuals who received a vaccine or had their first contact with a specific infectious agent during infancy.

EFFECTOR PHASE The ultimate aim of an immune response is the neutralization and elimination of pathogens. The principal effector mechanisms of acquired immunity are mediated by antibodies *(humoral immunity)* secreted from B cells, and by cytolytic T cells *(cellular immunity)*. Humoral immunity is especially effective in combating extracellular pathogens, such as bacteria and parasites; cellular immunity is effective in protecting against viral infection and, as with natural killer cells, may provide some protection against tumor cells.

The effector components of natural immunity are also recruited, enhanced, and directed toward specific pathogens as a result of the actions of B and T cells. For example, circulating antibodies can neutralize pathogens by binding to and coating the pathogens *(opsonization)*. Pathogens that are opsonized are made susceptible to lysis by complement factors and phagocytosis (Fig. 1.12-2). Natural killer cells and *phagocytic cells*, such as neutrophils and macrophages, have receptors for the

Fc fragment of antibodies. Furthermore, complement proteins bind to and are activated by the Fc fragments of some types of antibodies. Thus, antibodies can link effector cells and cytolytic proteins of natural immunity with pathogens, lending a level of specificity that is not inherent in the effector processes themselves. Although a large diversity of antigen-binding domains are present in different antibodies, the remainder of the molecule is highly conserved, and there are a limited number of different types of Fc fragments *(isotypes)* of the molecule. Because the Fc fragment of the antibody is the effector portion of the molecule, antibodies with different isotypes have different effector features (Table 1.12-3).

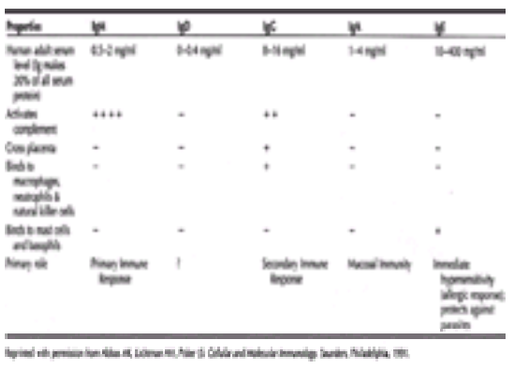

Table 1.12-3 Antibody Isotypes and Their Features

IMMUNE SYSTEM AND DISEASE

The general effectiveness of the immune system in protecting the body against pathogens has been made dramatically clear by the extensive pathology that characterizes AIDS in persons infected by the human immunodeficiency virus (HIV). HIV selectively binds to the CD4 molecule on T-helper cells via the gp120 protein on its membrane envelope and thereby gains entry and inhibits T-helper cell function. Since T-helper cells play a critical role in facilitating all aspects of specific immunity, the incapacitation of T-helper cells by HIV has catastrophic effects on the immune system. AIDS patients become susceptible to a wide spectrum of pathogens, such as protozoa *(Pneumocystis)*, bacteria *(Mycobacterium tuberculosis)*, fungi *(Candida)*, and viruses (herpes simplex). Furthermore, AIDS patients have a high incidence of malignant tumors, especially those known to result from virally induced cellular proliferation and transformation. The nervous system is also affected in many AIDS patients, as evidenced by memory loss and other nonspecific neuropsychiatric disorders. No evidence indicates that HIV directly infects neurons; however, the infection of macrophages in neural tissues may lead to the impairment of neuronal function through the release of cytokines.

At the other end of the spectrum from immunodeficiency is autoimmunity. A number of relatively common diseases—such as type I diabetes, rheumatoid arthritis, and systemic lupus erythematosus—have been shown to result from a specific autoimmune response directed against self-antigenic components. Clear genetic links to the expression of autoimmune disorders are often associated with specific types of MHC molecules. In most cases, however, a genetic background is not sufficient for the expression of disease. For example, the much greater prevalence of rheumatoid arthritis and systemic lupus erythematosus in women than in men suggests that, at least in some cases, there may be a hormonal component to the expression of these diseases.

The extent to which the immune system provides protection against cancer is still undetermined. Several effector mechanisms of the immune system are capable of destroying tumor cells in vitro (natural killer cells, CTLs, and TNF). The relatively rare occurrence of nonvirally induced tumors in immunodeficient patients suggests that the immune system plays a role primarily in protecting against tumor-inducing viruses, rather than providing widespread tumor surveillance and elimination. Nevertheless, the extensive use of a variety of cytokines and other immune modulators in the treatment of neoplastic diseases underlines the importance of these factors in cancer therapy.

METHODS USED IN STUDYING THE IMMUNE SYSTEM

In Vitro Assays Much of the understanding of the immune system has been derived from in vitro studies. In vitro assays may be especially useful in dissecting the direct and indirect mechanisms by which neurally controlled factors can influence immune cell function. Two of the most widely used assays in the study of neural-immune interactions assess the proliferative capacity of lymphocytes and determine the cytolytic capability of CTL and natural killer cells.

For proliferative assays, mononuclear cells, including lymphocytes, are removed from the experimental subject and are challenged in vitro with a mitogenic stimulus. Commonly used mitogenic stimuli (including concanavalin A, phytohemagglutinin, pokeweed mitogen, and lipopolysaccharide) are glycoproteins derived from plant lectins or bacterial cell walls that have been found to polyclonally stimulate lymphocyte proliferation. Proliferation is monitored by the incorporation of 3H-thymidine into the DNA of the dividing cells. The limitations of proliferative assays are their notorious interassay variability and a limited understanding of the relationship between the polyclonal proliferative response to a mitogen and the clonally selective proliferative response to a specific antigen or pathogen.

NK cell assays have been widely applied to studies of neural-immune interactions. Typically, immune cells isolated from a subject are incubated in vitro with chromium 51-labeled target cells. Lysis of target cells results in the release of chromium 51 into the incubation medium, which is then collected and measured.

Flow Cytometry The development of monoclonal antibodies against specific immune cell surface markers, such as the various CD determinants, has been useful in monitoring and sorting subclasses of immune cells (Table 1.12-4). Fluorescently tagged monoclonal antibodies and the cells to which they bind can be detected by a laser-controlled flow cytometer. Clinically, flow cytometry has important applications in monitoring the proportion of subsets of immune cells in patients' peripheral blood. For example, a diagnostic feature of the onset of AIDS is the precipitous decline in the proportion of circulating $CD4^+$ cells. Experimentally, flow cytometry may be useful in studying the effects of various treatments and environmental factors on the proportion or number of immune cell subpopulations present in the various immune compartments. However, changes in the number and the percentage of a given subset are independent phenomena and may involve different mechanisms: for example, the increased percentage of one subset may actually be related to a decrease in the percentage of other subsets of lymphocytes.

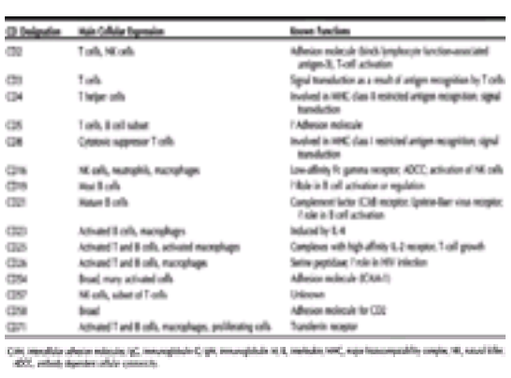

Table 1.12-4 Some Defined Clusters of Differentiation (CD) Molecules and Their Known Functions

In Vivo Assays Results from in vitro assays can be difficult to interpret because the relation between changes in these assays and the capability of the immune system to exert effective responses in vivo is still unclear. To address this issue, studies exploring the immune system in humans (e.g., evaluating the consequences of stressors) have used at least three different assays for the examination of the immune system in vivo: (1) the antibody response to antigen challenge such as a vaccination, (2) antibody titers to latent viruses, and (3) cutaneous delayed-type hypersensitivity. Examining the antibody response to a vaccine allows evaluation of all phases of the immune response including antigen presentation, B- and T-cell cooperation, and humoral immunity. Alterations (notably increases) in antibody titers

to latent viruses (herpes viruses in particular) has been considered a marker of viral reactivation secondary to impairment in cellular immunity. Finally, cutaneous delayed-type hypersensitivity is based on the intradermal injection of one or more protein antigens (e.g., from tetanus, diphtheria, streptococcus, tuberculin, or candida). The antigens induce a rapid accumulation of neutrophils followed by a more persistent infiltration of T cells and monocytes, and the reaction is interpreted by measuring the induration at 48 hours.

REGULATION OF THE IMMUNE RESPONSE

An effective immune response requires the cooperation of many components of the immune system, often resulting in the augmentation of each component's contribution to the overall immune response. However, the simultaneous indiscriminate amplification of all aspects of the immune system would not be efficient and could even be disastrous. An overactive immune system may contribute to autoimmunity; furthermore, the inflammatory component of immune responses can be damaging if not controlled, as is seen in immune complex diseases and septic shock. Therefore, regulation of the immune response is necessary to make sure that the response is energy efficient, focused on the infectious agent, counterbalanced in a fashion that does not cause self-damage, and reversible once the pathogen has been eliminated.

Probably the most important form of *intrinsic regulation* of the immune system is mediated by the various cytokines. Several examples of the facilitatory effects of cytokines have been cited; however, some cytokines, such as transforming growth factor b (TGF-b), also produce potent inhibitory effects on lymphocyte activation and proliferation (Table 1.12-2). In addition, there is clear evidence for the existence of a subclass of CD4+ and CD8+ T cells (T suppressor cells) that act primarily to suppress the function of other T cells, either by secreting inhibitory cytokines or by cytolysis. However, the isolation of a unique subset of T cells that have a predominant suppressor action has been elusive. Another important mode of intrinsic regulation results from the production of antibodies or T cells that bind to determinants (idiotypes) in the antigen-binding domain of other antibodies or T-cell antigen receptors and serve to influence (inhibit) further antigen-antibody interactions.

The relative significance of *extrinsic regulation* of the immune response remains to be fully established. However, the increasing evidence of neural-immune interactions indicates that extrinsic factors of central nervous system origin plays an important role in the modulation of the immune system.

EVIDENCE OF NERVOUS SYSTEM AND IMMUNE SYSTEM INTERACTIONS

Immune Cell Receptors As outlined in Table 1.12-5, cells from the immune system express receptors for a wide variety of molecules that are, in part, regulated by or derived from the nervous system. One of the first receptors to be characterized in lymphocytes was the b-adrenergic receptor. Subsequently, receptors for the other classic neurotransmitters have been described. As in the nervous system, receptors for the neurotransmitters in immune cells are located in the cell membrane and in most cases are coupled to G proteins and associated second-messenger pathways. Nevertheless, the biochemical mechanisms for the receptor-mediated activity of the majority of the molecules listed in Table 1.12-5 has yet to be fully elucidated.

Neurotransmitters	Neuropeptides	Steroid Hormones
β-adrenergic	Growth hormone	Glucocorticoids
α-adrenergic	Prolactin	Mineralocorticoids
Dopamine	Corticotropin	Estrogens
Serotonin	CRH	Progesterones
Acetylcholine	Substance P	Androgens
Histamine	Somatostatin	
Vasoactive intestinal peptide		
Endorphins and enkephalins		
Vasopressin	Thyroid hormone	

CRH, corticotropin releasing hormone.

Table 1.12-5 Receptors for Chemical Messengers in Cells and Tissues of the Immune System

Several important concepts from research on receptors in immune cells and tissues are central to understanding the effects of neurally derived molecules on immune function. First, the expression of receptors is heterogeneous. For example, of the two types of receptors for adrenal steroids, mineralocorticoid receptors and glucocorticoid receptors, only glucocorticoid receptors are expressed in the thymus, whereas both glucocorticoid and mineralocorticoid receptors are expressed in the spleen. Related to heterogeneity in receptor expression in immune cells and tissues is heterogeneity in receptor density. For example, of the subsets of T cells, the number of b-adrenergic receptors is highest for T suppressor cells (CD8+, CD28–), followed by T cytotoxic cells (CD8+, CD28+) and then T helper cells (CD4+).

Heterogeneity of both receptor expression and receptor density is relevant for understanding the sensitivities of the various immune cells and tissues to circulating hormones and is important for determining the net effect of these agents on immune function in vivo. Thus, even though b-adrenergic receptor agonists generally inhibit lymphocyte function in vitro, the increased susceptibility of T suppressor cells to the inhibitory effect (secondary to increased receptor density) may paradoxically lead to an enhancement of the immune response in vivo.

Another important concept is that a change in circulating concentrations of a hormone or transmitter is not necessarily reflected equally in all immune compartments. For example, stress-related increases in glucocorticoids are more effective in activating glucocorticoid receptors in the peripheral blood and the thymus than in the spleen. Thus, the microenvironment of any given tissue is critical in determining hormonal or neurotransmitter influences on immune function. Taken together with the heterogeneity in receptor density and expression, the data demonstrate that the influence of any given molecule on the immune system is a function of (1) the type of cell that exhibits the relevant receptor, (2) the density of the receptors on that cell, and (3) whether that cell is located in an immune compartment that allows access of the relevant molecule to the receptor under the conditions being studied.

Cross talk between receptor-associated second-messenger systems is another important mechanism by which neurally derived or regulated molecules influence the immune response (Fig. 1.12-5). For example, dual signaling through the b-adrenergic and T cell receptors can lead to a synergistic rise in cyclic adenosine monophosphate (cAMP), which may alter the early events in T cell activation. Changes in these early events may then influence the transcription of multiple genes, including the genes for IL-2 and the IL-2 receptor, as well as genes for other cytokines.

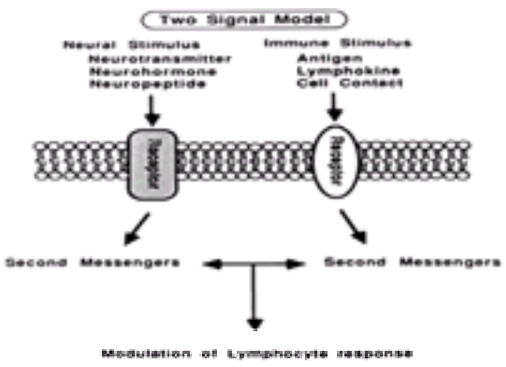

FIGURE 1.12-5 Schematic representation of two signal model of the interaction of neurally and immune-derived substances with their respective receptors on lymphocytes. The figure shows the potential crosstalk between second messengers with resulting modulation of lymphocyte function. These models assume that the lymphocytes are in G_0 of the cell cycle. (Reprinted with permission from Rozman TL, Carlson SL: Neural-immune interactions: Circuits and networks. Prog Neuroendocrin Immunol *4:*22, 1991.)

IN VITRO AND IN VIVO EFFECTS

Numerous chemical messengers derived from or regulated by the nervous system are capable of altering immune cell function and distribution. Table 1.12-6 provides a necessarily simplified, representative listing of selected molecules and their effects. The immunological effects of the agents depend on a number of factors aside from those involving the relevant expression, density, and activation of receptors on target immune cells. For example, the effect of any given molecule on the immune system depends on the phase of the immune response that is involved. As previously noted, the major phases of an immune response include the induction phase, the activation and proliferation phase, and the effector phase. Norepinephrine, for example, promotes immune function during the induction phase, both potentiates and inhibits immune function during the activation and proliferation phase, and inhibits the effector phase (Fig. 1.12-6). The potentiation of the proliferative phase occurs at low concentrations of norepinephrine, but inhibition occurs at high norepinephrine concentrations. These findings indicate that both the timing of exposure as well as the dose are important.

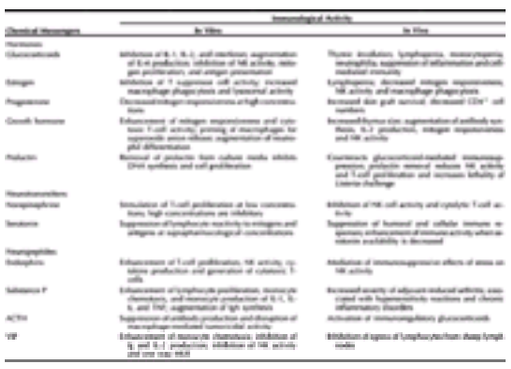

Table 1.12-6 Representative Listing of Chemical Messengers and Their Immunological Effects

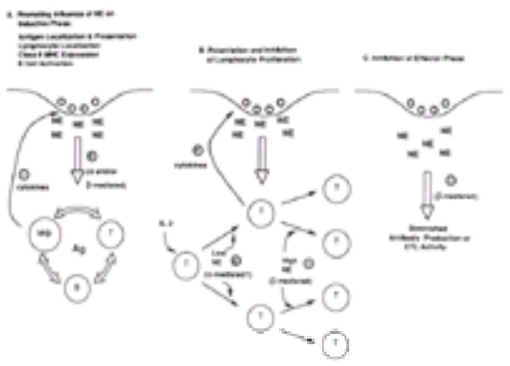

FIGURE 1.12-6 Working model for bidirectional communication between norepinephrine and cells of the immune system. This diagram depicts the potential modulatory effects of norepinephrine (NE) during different phases of an immune response. The capacity for cellular responsiveness to NE will depend on the presence of adrenoceptors, on cell type, and on the activational state. (A) In the presence of antigen, NE may have an enabling influence on lymphocyte and accessory cell function. To achieve the proper balance between a- and b-mediated effects, regulation of NE levels may be critical. (B) Low levels of NE may stimulate a-adrenoceptors and thus potentiate lymphocyte proliferation. (B,C) With increasing NE, b-adrenoceptor-mediated inhibition of lymphocyte proliferation and effector function may occur. The response to NE may be influenced by, and alter the production of cytokines (such as IL-2) and neuroendocrine peptides (not shown for clarity). Finally, products of the immune system may modulate NE availability by altering release or turnover. Ag, antigen; MO, macrophage. (Reprinted with permission from Madden KS, Livnat S: Catecholamine action and immunologic reactivity. In *Psychoneuroimmunology*, ed 2, R Ader, DL Felten, N Cohen, editors, Academic Press, New York, 1991.)

Issues of timing are also relevant in terms of development and aging. In aged rats, for example, a progressive loss of noradrenergic innervation of the spleen is accompanied by a progressive increase in the density of b-receptors on splenic lymphocytes. However, there is also an age-related dysfunction that involves impaired coupling between the b-receptor and adenylate cyclase, indicating that noradrenergic agents may have variable, unpredictable effects on immune function in old animals.

Related to the phase of the immune response and developmental stage of the animal is the type of immune response as it relates to pathophysiology. Substances that are primarily inhibitory to immune function may promote tumor development in animals with cancer but may attenuate the development of autoimmune disease. For example, the administration of glucocorticoids accelerates the growth of tumors in mice. But glucocorticoids inhibit the development of several types of autoimmune disorders, including experimental allergic encephalitis (a model of multiple sclerosis) and streptococcal cell wall-induced polyarthritis (a model of rheumatoid arthritis). Another important factor in determining the immunological effect of a particular molecule is its indirect effects, as well as its direct effects, on the immune system. In vitro studies provide important information on the direct effects of the various chemical messengers, but the influence of those agents in vivo may be completely different. For example, a number of in vitro studies have shown that opioid peptides are capable of enhancing natural killer cell activity. However, in vivo, opioid peptides play an important role in mediating the inhibitory effects of shock stress on natural killer cell activity, most likely through effects in the brain. In vivo, neurally derived molecules act against a complicated background of multiple hormones that may have synergistic or antagonist effects or both. For example, prolactin antagonizes the effects of glucocorticoids on spleen mitogen responses in mice. Furthermore, many of the hormones and transmitters influence other bodily systems, including the cardiovascular system, which may influence the traffic of immune cells to various organs, immunological and otherwise. Changes in immunocyte distribution may ultimately have effects on cellular function.

NEURAL INNERVATION OF LYMPHOID TISSUES

Historically, the identification of nerve fibers derived from the sympathetic nervous system in immune tissues was one of the first indications that communication between the CNS and the immune system was possible. Sympathetic nerve fibers have been identified in organs that are responsible for the development, education, and function of lymphocytes. Specifically, nerve fibers are found in the bone marrow, thymus, spleen, and lymph nodes. The nerves that innervate the thymus gland are derived from the vagus, phrenic, and recurrent laryngeal nerves and from the stellate and other small ganglia of the thoracic sympathetic chain. The nonmyelinated nerves that innervate the bone marrow arise from the level of the spinal cord associated with the location of the bone. The spleen obtains its sympathetic nerves from the celiac ganglion. Autonomic nervous system innervation of the lymph nodes is not as dense or as uniquely distributed as noted for the spleen and the thymus. In general, sympathetic nerve fibers enter the lymphoid tissues in association with the vascular supply. Because those nerves play an important role in vascular tone, their presence in association with the smooth muscle cells of the blood vessels is not unexpected. However, the nerve fibers travel with small blood vessels devoid of smooth muscle cells and are present in the parenchyma of the lymphoid tissue, associated not only with blood vessels but with lymphocytes and other immune cells (Fig. 1.12-7). The existence of noradrenergic nerve terminals in the parenchyma of lymphoid tissues suggests that the release of norepinephrine in these areas may interact with the neurotransmitter receptors on nearby cells and ultimately influence their function.

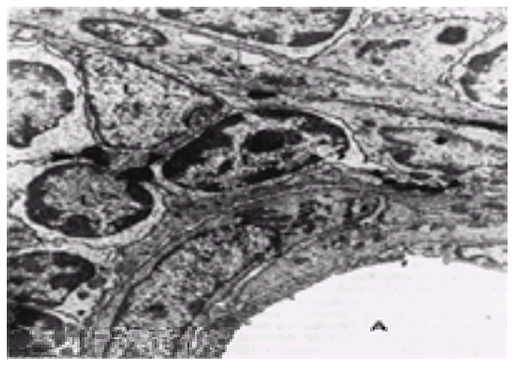

FIGURE 1.12-7 Tyrosine hydroxylase-immunoreactive nerve processes (small arrowheads) in contact with the smooth muscle (S) of the central arteriole (A), and nerve processes (large arrowheads) in direct contact with lymphocytes (L) in the periarteriolar lymphatic sheath of the rat spleen. Transmission electron micrograph, X6732. (Courtesy of Denise L. Bellinger, Department of Neurology and Anatomy, University of Rochester School of Medicine and Dentistry, Rochester, NY.)

Since catecholamines (including norepinephrine) have stimulatory effects on immune function at low concentrations and inhibitory effects at high concentrations, differential sympathetic nervous system effects on the immune response are possible, depending on local concentrations of catecholamines and the location of the immune cell relative to the point of neurotransmitter release. Chemical sympathectomy has variable effects on immune function, depending in part on the phase of the immune response studied. The reported effects of sympathectomy include suppressed antibody responses to sheep red blood cells, suppressed cytolytic T-cell activity, and enhanced natural killer-cell activity. Splenic sympathectomy also leads to an upregulation of b-adrenergic receptors on lymphocytes and a decrease in suppressor lymphocyte function. Aside from the phase of the immune response, other factors that may influence the effects of nervous innervation on immune function include the animal's age, sex, and strain.

Colocalization of neurotransmitters with a variety of neuropeptides—including neuropeptide Y, substance P, vasoactive intestinal peptide, and calcitonin gene-related peptide—has also been identified in nerves innervating immune tissues. The distribution of these peptides have not been extensively studied, and their relative significance has yet to be determined.

Finally, data suggests that local immune responses within the microenvironment of the immune tissues may be able to interact directly with nerve fibers through the effects of cytokines on neurotransmitter release. Neurotransmitters may in turn regulate immune function or the sensitivity of cells to local immunomodulatory factors. Although earlier studies have focused on efferent nerve fibers, more attention is now being paid to sensory afferent fibers and their relevance to immune system communication with the brain. For example, sensory afferent fibers appear to relay immune signals through the vagus nerve, to the nucleus of the solitary tract. From the nucleus of the solitary, there are pathways to other brain regions that may be relevant to the CNS response to immune system activation.

CNS LESIONS AND CELLULAR IMMUNITY

Some of the earliest studies demonstrating CNS involvement in the regulation of immune phenomena were those involving lesions in specific areas of the brain in laboratory animals. In a series of experiments in the early 1960s, lesions of the anterior hypothalamus were found to protect guinea pigs from death by anaphylactic shock when compared with sham and control lesions. Such protection was not apparent with median and posterior hypothalamic lesions. Lesions of the anterior hypothalamus were also accompanied by decreases in thymus and spleen cell number, splenic mitogen responsiveness, antigen responsiveness, and natural killer cell activity. In contrast, bilateral electrolytic lesions of the hippocampus and the amygdala have been associated with increases in thymic and splenic mitogen responsiveness and no change in thymus and spleen cell number. Left-sided neocortical lesions have been associated with decreases in spleen T-cell numbers, T-cell mitogen proliferation, T-cell cytotoxicity (measured in mixed lymphocyte cultures), and natural killer cell activity; these immune parameters were either unchanged or enhanced by right-sided lesions. B-cell and macrophage responses were not affected by right-sided or left-sided neocortical ablations.

Some investigators have reported an increased prevalence in humans of immune disorders, especially those involving the thyroid and the gastrointestinal tract, in association with atypical cerebral dominance (left-handedness). The relation between cerebral dominance and immune dysfunction in humans lends support to the notion that lateralized alterations in CNS function may have differential effects on the immune response. However, some patients with brain tumors and head injuries have gross disturbances of in vitro lymphocyte function, and there is no evidence that the immune changes are related to the laterality of the lesion.

BEHAVIORAL CONDITIONING

Demonstration that learning processes are capable of influencing immunological function is another example of interactions between the immune system and the nervous system. Several classical conditioning paradigms have been associated with the suppression or enhancement of the immune response in various experimental designs. The conditioning of immunological reactivity provides further evidence that the CNS can have significant immunomodulatory effects.

Some of the first experiments on immunological conditioning were derived from the serendipitous observation that animals undergoing extinction in a taste-aversion paradigm with cyclophosphamide, an immunosuppressive agent, had unexpected mortality. In that taste-aversion paradigm, the animals were simultaneously exposed to an oral saccharin solution (the conditioned stimulus) and an intraperitoneal injection of cyclophosphamide (unconditioned stimulus). Since the animals experienced considerable physical discomfort from the cyclophosphamide injection, through the process of conditioning they began to associate the ill effects of cyclophosphamide with the taste of the oral saccharin solution. If given a choice, the animals avoided the saccharin solution (taste aversion). Conditioned avoidance can be eliminated or extinguished if the saccharin is repeatedly presented in the absence of cyclophosphamide. However, it was observed that animals undergoing extinction of cyclophosphamide-induced taste aversion unexpectedly died, leading to the speculation that the oral saccharin solution had a specific conditioned association with the immunosuppressive effects of cyclophosphamide. Repeated exposure to the saccharin-associated conditioned immunosuppression during extinction might explain the unexpected death of animals. To test that hypothesis the researchers conditioned the animals with saccharin (conditioned stimulous) and intraperitoneal cyclophosphamide (unconditioned conditioned stimulous) and then immunized them with sheep red blood cells. At different times after immunization the conditioned animals were reexposed to saccharin (conditioned stimulous) and examined. The conditioned animals exhibited a significant decrease in mean antibody titers to sheep red blood cells as compared with the control animals. Thus, the evidence demonstrated that immunosuppression of humoral immunity was occurring in response to the conditioned stimulous of saccharin alone.

Because the immunological effects of conditioned immunosuppression were not large, the influence of immunological conditioning on the development of a spontaneously occurring autoimmune disease in New Zealand mice was investigated. These animals provide a standard model for the study of systemic lupus erythematosus, a fatal autoimmune disorder that is similar to that found in humans. Death in the New Zealand mice can be delayed by weekly injections of cyclophosphamide. In the initial studies the animals were first conditioned with saccharin and cyclophosphamide and then divided into three groups: (1) saccharin only (conditioned stimulous group), (2) saccharin and cyclophosphamide (conditioned stimulous plus unconditioned conditioned group), and (3) no treatment. As shown in Figure 1.12-8, animals given saccharin alone had a mortality rate as low as the animals receiving saccharin plus weekly injections of cyclophosphamide; these findings supported the notion that conditioned immunosuppression was occurring in response to saccharin alone, and the effects were of sufficient magnitude to powerfully influence disease expression.

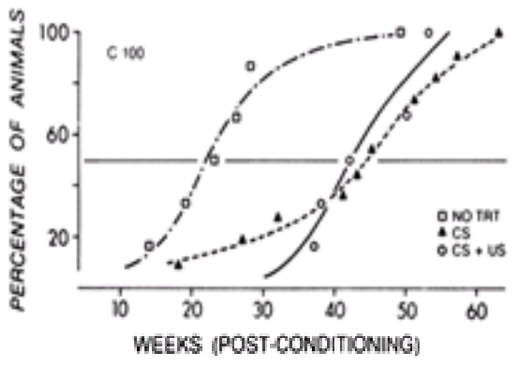

FIGURE 1.12-8 Mortality rate in NZB × NZW F_1 female mice treated with saccharin and CY weekly and then continued on a regimen of saccharin and CY (group CS + US, N = 6), continued on saccharin alone (group SD, N = 11), or deprived of both saccharin and CY (no treatment, N = 6). (Reprinted with permission from Ader R: Behaviorally conditioned modulation of immunity. In *Neural Modulation of Immunity*, R Guillemin, M Cohen, T Melnechuk, editors. Raven, New York, 1985.)

The ability to condition immunosuppression using T–cell–independent antigens and a graph-versus-host response (T cells present in transplanted bone marrow attack the host) has indicated that conditioned immunosuppression generalizes to both humoral and cell-mediated immunity. Furthermore, conditioned enhancement of natural killer cell activity in response to the conditioned stimulous, camphor, has been found after repeated pairing of the immunostimulant poly I:C with camphor odor. Finally, Studies of conditioning of immune responses have been expanded to include demonstrations that environmental stimuli, such as those inherent in passive avoidance paradigms, can be associated with conditioned immunosuppression.

STRESS AND THE IMMUNE RESPONSE

Interest in the effects of stress on the immune system grew out of a series of animal and human studies that suggested that stressful stimuli can influence the development of immune-related disorders including infections, cancer, and autoimmune diseases. Experiments conducted on laboratory animals in the late 1950s and the early 1960s, for example, indicated that a wide variety of stressors—including isolation, rotation, crowding, exposure to a predator, and electric shock—increased morbidity and mortality in response to several types of tumors and infectious diseases caused by viruses and parasites. Critical variables in the effects of stress on illness in animals involved the timing of the stressor application and the type of infectious agent or tumor. For example, mice subjected to electric grid shock 1 to 3 days before the injection of Maloney murine sarcoma virus-induced tumor cells exhibited a decreased tumor size and incidence. In contrast, mice exposed to grid shock 2 days after tumor cell injection exhibited an increase in tumor size and number.

Fewer studies have been carried out on the relation between stress and immune-related illnesses in humans, and in general they are difficult to interpret because of the many factors that can influence illness and illness behavior. Nevertheless, from prospective studies on upper respiratory infections verified either by physician diagnosis or by biological methods, evidence indicates that stressful life events can increase the susceptibility to infectious diseases in humans. For example, investigators have found that infection rates by five separate rhinoviruses administered intranasally are significantly greater in persons experiencing a high degree of psychological stress than in those under low stress. Prospective studies in humans on the development of cancer are mixed. Some studies have indicated a relation between depressive symptoms (presumably secondary to increased stress and inability to cope) and cancer development; others have been unable to replicate these findings. Once cancer has developed, however, data on women with metastatic breast cancer indicate that supportive group therapy may increase the time of survival by more than 1 year, although group therapy did not alter the mortality rates in the patients. Similar findings of increased survival have been found in patients diagnosed with malignant melanoma who were provided with a 6-week structured psychiatric group intervention.

In an attempt to understand the potential mechanisms of the effect of stress on illness involving the immune system, researchers have focused considerable attention on the effects of stress on a variety of immune parameters in laboratory animals and humans.

Animal Studies Early studies using 19 hours of tail shock have shown that intense stress inhibits mitogen-induced lymphocyte proliferation in the peripheral blood of rats. Subsequent studies have indicated that this stressor also inhibits natural killer cell activity and the production of interferon and IL-2 in the blood and spleen of rats. Since the early studies on tail shock, there has been an explosion of reports on the effects of many types of stress on virtually every aspect of immune function; in general, the stressors inhibit immune responses (Table 1.12-7). However, several studies using either chronic stressors or mild or brief stressors have noted an enhancement of both cellular and humoral aspects of the immune system. For example, in a study of mice exposed to 0.3, 0.8, or 1.2 mA of electric foot shock over a 1-hour period, there was a graded enhancement of the proliferative response of T cells to the mitogen concanavalin A as the shock level increased. Interestingly, proliferative assays using the B-cell mitogen poke weed did not show any significant effect of the shock treatments, suggesting that the type of immune response may dictate the relative influence of stress. Differential effects of stress on various measures of the immune system have been further demonstrated in a study in which physical restraint in mice significantly depressed the cellular immune response to influenza virus infection without affecting the humoral response as measured by antiviral IgG antibody levels.

Stressor	Subject	Immunological Effect
Restraint	Rat	Involution of the thymus
Restraint	Mouse	Decreased macrophage cytotoxic activity
Noise	Mouse	Decreased lymphocyte proliferation to mitogenic stimulation, reduced lymphocyte cytotoxicity; prolonged noise-enhanced immune responses
Noise	Rat	Leukopenia
Isolation	Rat	Decreased lymphocyte proliferation to antigenic stimulation
Crowding	Rat	Increased lymphocyte stimulation to antigenic stimulation
Avoidance learning task	Mouse	Decreased interferon production, delayed allograph rejection, decreased antibody response to challenge, increased death rate following antigenic challenge
Uncontrollable shock	Rat	Decreased NK cell activity, decreased interleukin-2 production, decreased IL-2 receptor expression
Heat stress	Mouse	Diminished delayed-type hypersensitivity

Table 1.12-7 Stress-Induced Changes in the Immune System of Rodents

Stress-induced alterations in immune function may be related to the psychological state of the animal. One study suggested that coping is an important variable in stress effects on the immune system. Whereas phytohemagglutinin and concanavalin A stimulation of lymphocytes was suppressed in rats exposed to inescapable, uncontrollable electric shock for 80 minutes, followed by several minutes of tail shock 24 hours later, animals receiving the same total amount of shock using a yoked paradigm but able to terminate the stressor did not have decreased lymphocyte activity compared with nonstressed controls. These findings are consistent with the hypothesis that the ability to cope with a stressor may mitigate against some of its noxious effects.

Finally, different mild stressors like electric foot shock and restraint have been found to elevate plasma levels of cytokines, including IL-6 in rats. Peripheral IL-6 release during stress may be related to catecholamines, given that epinephrine administration is also capable of inducing IL-6 secretion. Of note, is that stressor administration found to elevate IL-1b protein levels in the brain of stressed animals who were rendered glucocorticoid deficient by adrenalectomy. The ability of stressors to stimulate cytokine production and the ability of cytokines to alter CNS function in turn suggests that the immune system may contribute to the behavioral and neuroendocrine response to stress, even in the absence of a formal immune challenge (i.e., a pathogen).

Human Studies The effect of stress on measures of the immune system in humans has attracted considerable attention. In studies on academic stress among medical students, a decrease in natural killer cell activity was found during the final examination period as compared with a preexamination baseline. Examination stress has also been associated with decreased number of T cells, mitogen responses, interferon production, and antibody responses to recombinant hepatitis B vaccine. In addition, increases in antibody titers to latent herpes viruses, presumably secondary to impaired cellular immunity have been observed. Investigators have

also reported decreased measures of immune function in persons exposed to chronic life stressors, such as divorce and the taking care of patients with Alzheimer's disease. For example, caregivers to Alzheimer's disease patients showed alterations in lymphocyte subpopulations, increased antibody titers to herpes simplex virus, decreased proliferative response to mitogens, more days of illness from infectious disease, impaired antibody responses to an influenza virus vaccine, and longer latency for wound healing.

Conjugal bereavement is one of the most stressful of commonly occuring life events, and has been associated with increased medical morbidity and mortality. One group investigated the effects of bereavement on immune measures in a prospective longitudinal study of spouses of women with advanced breast carcinoma. Lymphocyte stimulation was measured in men before and after the deaths of their wives. Lymphocyte stimulation responses to phytohemagglutinin, concanavalin A, and pokeweed mitogen were significantly lower during the first 2 months after bereavement compared with prebereavement immune responses. However, the number of peripheral blood lymphocytes and the percentage and the absolute number of T and B cells during the postbereavement period were not significantly different from those in the prebereavement period. Follow-up during the remainder of the postbereavement year revealed that lymphocyte stimulation responses had returned to prebereavement levels for the majority of the men. Prebereavement mitogen responses did not differ from those of age-matched and sex-matched controls.

Advancing age has been shown to increase responsivity to the physiological effects of stress and depression on the neuroendocrine and immune systems. Age has been shown to interact with chronic stress and social support in determining the cardiovascular reactivity to stress, and the largest study to date investigating immune abnormalities in major depressive disorder revealed significant age-related differences between depressed patients and age- and sex-matched controls. For example, in contrast to age-related increases in mitogen responses in the controls, the depressed patients did not show increased lymphocyte responses with advancing age. Similar age-related differences between depressed patients and controls were found for $CD4^+$ lymphocytes. Finally, in a recent study on female caregivers of handicapped people, caregivers had a significantly lower percentage of T cells, a significantly higher percentage of $CD8^+$ cells, and a significantly lower T $CD4^+/CD8^+$ ratio; however, older caregivers (>45 years, median of age) also had lower numbers of T cells and $CD4^+$ cells and higher antibody titers to cytomegalovirus. The interaction between stress, depression, and age is important, since older people also show age-related alterations in immune function *(immunosenescence)*, which may leave them more vulnerable to stress-induced immune alterations and the development of immune-related diseases including infectious diseases and cancer. Whether stress-induced immune alterations will include clinically relevant changes in the ability of the organism to respond to infections or other in vivo immune challenges affecting health outcome is an active area of investigation. Several recent animal studies have begun to address the issue of direct evidence of a causal relation among stress, immune alterations, and disease states. One study found that rats exposed to an acute swimming stress exhibited decreased natural killer cell activity against a mammary tumor in vitro and an increase in tumor lung metastasis when the same tumor cells were injected in vivo. In addition, investigators have shown that restraint stress in mice not only suppressed measures of the cellular immune response to a specific herpes simplex viral infection but also was associated with an increased herpes simplex virus local infection. These animal studies support the hypothesis that stress effects on tumors and infection are a result of stress-induced suppression of the immune system.

Immunological Mechanisms Only recently have investigators begun to examine the immunological mechanisms through which stress may affect the immune system. In general, a stressor can alter immune function in two major ways. First, the stressor can lead to changes in the distribution of immune cells in any given part of the body, second, stress can alter the function of the immune cells themselves. Because the immune response depends on the interplay of various immune cell subtypes, a redistribution of relevant cell types into or out of a particular immune compartment can directly influence the local immune response. For example, significant and selective changes in peripheral blood cell distribution have been described in rats undergoing a mild acute stress (2 hours of restraint), including decreased numbers of white blood cells and decreased numbers and percentages of monocytes and lymphocytes including B cells, natural killer cells, and, to a lesser degree, T cells. Interestingly, cells leaving the blood during stress return when the stressor is discontinued; also, based on stress-induced enhancement of immune responses in the skin it appears that cells leaving the blood during stress may migrate to the skin where they would be more likely to encounter pathogens. Studies also have shown that stressors can alter a variety of cell-specific activities, including IL-2 production and the expression of the IL-2 receptor gene. In a study examining the biochemical mechanisms of stress-induced impairment of T-cell mitogenesis, spleen cells isolated from rats exposed to two brief stressors (5 minutes of restraint or 2 minutes of foot shock) exhibited a diminished response to both T-cell mitogens and a combination of the phorbol ester tetradecanoylphorbol acetate and the calcium ionophore ionomycin. Since stimulation with the latter two agents mimics early signals generated by mitogen surface receptor binding, including increased intracellular calcium and protein kinase C activation, the data indicate that stress-related defects in T-cell proliferation occur at sites beyond or in addition to the early events in cellular activation. Production of nitric oxide (NO) by macrophages has also been recently shown to be involved in the biochemical mechanisms underlying the stress-induced decrease in the lymphocyte proliferative response; both the depletion of macrophages and the inhibition of NO synthesis have been shown to attenuate stress-induced immune changes.

PUTATIVE MECHANISMS AND MEDIATORS

A number of studies have focused on the neuroendocrine mechanisms by which stress or alterations in CNS function may influence the immune response. The two systems that have received the most attention are the endocrine system, especially the hypothalamic-pituitary-adrenal axis, and the autonomic nervous system (Fig. 1.12-9). These two systems are intimately associated with the organism's response to stress, and immune cells and tissues not only express receptors for the transmitters and hormones emanating from those systems but also receive direct innervation from autonomic nervous system fibers.

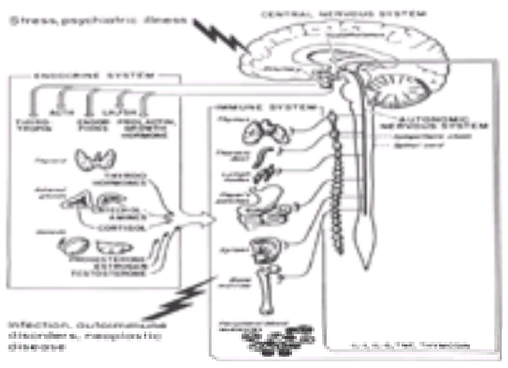

FIGURE 1.12-9 Diagram of bidirectional communication between the central nervous system and the immune system. The endocrine system and the autonomic nervous system are depicted as important mediators of CNS effects of the immune system. Inflammatory cytokines including IL-1, IL-6, and tumor necrosis factor (TNF) are shown closing the loop and interacting with the brain. CRH - Corticotropin-releasing hormone, ACTH - corticotropin, LH - luteinizing hormone, FSH - follicle stimulating hormone. (Drawn by Ellen Felten, Medical Arts Department, Mount Sinai Medical Center, NY.)

The interplay of the hypothalamic-pituitary-adrenal axis and autonomic nervous system with the immune system has been the focus of numerous recent experiments. The data indicate that both the hypothalamic-pituitary-adrenal axis and the autonomic nervous system have specific and selective effects on the immune system that are determined in part by which immune compartment and which immune response is examined. For example, after mild foot shock, investigators have found suppression of both splenic and peripheral blood lymphocyte responses to nonspecific T-cell mitogens. Removing endogenous corticosteroids by adrenalectomy prevents shock-induced suppression of the proliferative response of T cells in the peripheral blood. However, adrenalectomy has no effect on the stress-induced suppression of T-cell proliferation in the spleen. The b-adrenergic receptor antagonists propranolol (Inderal) and nadolol (Corgard) attenuates the shock-induced suppression of T-cell proliferation in the spleen but has no effect on stress-induced suppression of T-cell mitogen responses in the peripheral blood. The findings that stress-induced changes of immune parameters in the peripheral blood are adrenal dependent or pituitary dependent whereas stress effects on immune parameters in the spleen are related to catecholamine release has been demonstrated in a number of laboratories using a variety of paradigms.

A central factor in the regulation of the response to stress is *corticotropin-releasing hormone* (CRH). Aside from its ability to modify the expression of a number of animal behaviors, CRH is a pivotal molecule in mediating the hypothalamic-pituitary-adrenal axis and the sympathetic nervous system (SNS) outflow of the stress response to peripheral tissues. The immunological effects of CRH on a wide range of immune functions have been well characterized. CRH-administered icv was first shown to have a powerful immunosuppressive effect on NK-cell activity in the rat spleen. Follow-up studies have shown that CRH is also capable of inhibiting in vivo antibody formation, specifically the generation of an IgG response to immunization with keyhole limpet hemocyanin. The influence of CRH on antibody responses is also apparent in CRH-overproducing mice whose immune deficits are characterized by a profound decrease in B-cell number and severely diminished primary and memory antibody responses. Chronic icv administration of CRH and acute infusion of CRH into the locus ceruleus have been shown to suppress

lymphocyte-proliferative responses to nonspecific mitogens and antibody to the T cell receptor (anti-CD3).

Interestingly, CRH has also been found to stimulate the release of proinflammatory cytokines in laboratory animals and humans. Long-term intracerebroventricular administration of CRH to rats led to induction of IL-1b messenger ribonucleic acid (mRNA) in splenocytes, and intravenous infusion of CRH in humans led to an almost fourfold induction of IL-1a. Both treatments also led to significant increases in the immunoregulatory cytokine, IL-2. Finally, the proinflammatory effects of CRH are manifest in the direct autocrine or paracrine inflammatory actions of this peptide at peripheral sites of inflammation such as in an inflamed arthritic joint. Taken together, these results demonstrate that CRH has well-documented immunosuppressive effects on in vivo cellular and humoral responses while having a stimulatory effect on cytokine production and local inflammation.

The mechanism by which centrally administered CRH influences the immune response has been considered. Two of the major outflow pathways that are stimulated by CRH in the hypothalamus are the hypothalamic-pituitary-adrenal axis, which ultimately releases glucocorticoids, and the SNS, which releases catecholamines. Both these factors (glucocorticoids and catecholamines) are known to influence multiple aspects of the cellular and humoral immune response as well as the production and release of cytokines. Activation of the SNS by intracerebroventricular CRH has been found to be a major regulator of the effects of CRH on splenic natural killer activity, in particular by use of the sympathetic ganglionic blocker, chlorisandamine, which reverses the inhibitory effect of intracerebroventricular CRH on natural killer activity in the spleen. The hypothalamic-pituitary-adrenal axis is also involved in CRH immune effects as demonstrated by the finding that the effects of chronic icv CRH on splenocyte proliferative responses were eliminated by adrenalectomy. In addition, the B-cell decreases found in CRH-overproducing mice are very consistent with the marked reduction of rodent B cells found following chronic exposure to glucocorticoids.

Endorphins also appear to play a role in stress effects on natural killer cell activity in the spleen. Rats subjected to a foot-shock paradigm known to be associated with opioid analgesia exhibited a decreased natural killer cell activity that was prevented by injections of the long-acting opioid antagonist naltrexone (ReVia).

Much of the focus of CNS-immune system interactions has been on the inhibitory immunological effects of neurally derived or regulated molecules, but several pituitary hormones, including prolactin and growth hormone, seem to have immune-enhancing or immunoprotective properties. For example, removal of the pituitary before stress results in an augmented inhibitory effect of stress on a variety of immune parameters, suggesting that pituitary hormones may restrain stress-induced effects.

Finally, the effects of cytokines on the nervous system and the endocrine system close the loop between the brain and the immune system and indicate that neural-immune interactions are bidirectional (Fig. 1.12-9).

IMMUNE SYSTEM EFFECTS ON CNS AND ENDOCRINE FUNCTION

A tremendous amount of interest has been generated in the neurosciences by the discovery that cytokines are capable of exerting profound effects on the CNS and neuroendocrine system. Acting at the level of the CNS, the pituitary, and the adrenal glands, cytokines appear to play a role in the regulation of sleep, temperature, feeding behavior, neurotransmission, and the secretion of multiple peptides and hormones, including CRH, ACTH, prolactin, leutinizing hormone, follicle stimulating hormone, growth hormone, thyroid stimulating hormone and glucocorticoids.

By making electrophysiological recordings from individual neurons in the ventromedial hypothalamus at various time intervals after an antigenic challenge, investigators in the early 1980s found that the hypothalamic neuronal firing rate was maximally increased at the time of the peak of the immune response, when presumably the release of immunological mediators was greatest. Furthermore, blood concentrations of glucocorticoids were noted to be increased at the time of peak immune responsivity, whereas norepinephrine concentrations in the hypothalamus were found to be decreased. To determine whether cytokines were influencing hypothalamic norepinephrine concentrations and ultimately glucocorticoid secretion, the researchers injected supernatants from mitogen-stimulated lymphocytes into rats and measured hypothalamic norepinephrine concentrations; a significant drop in norepinephrine concentrations 2 hours after injection was seen. That decrease was similar to the decrease in norepinephrine seen during a normal immune response except that, as anticipated, the kinetics were much accelerated. Those studies have been repeated, using IL-1, with similar results, and subsequent studies have characterized the capacity of numerous cytokines to influence a host of monoamine and other neurotransmitter pathways. IL-1 also has been shown to exhibit potent stimulation of the secretion of hypothalamic CRH and therefore is capable of activating the neuroendocrine cascade, resulting in increased glucocorticoid release. In addition, IL-1 b and its mRNA (as well as other cytokines including TNF-a, IL-6 and IL-2) have been found in nerve cell bodies and nerve fibers within the hypothalamus, the hippocampus, and other regions in human and rodent brain, suggesting that IL-1 and other cytokines may play a role in neurotransmission.

Further evidence that the immune system may exert a powerful regulatory influence on neuroendocrine function is provided by data showing the effects of cytokines on the pituitary gland. For example, in vitro studies have shown that IL-1 is capable of enhancing the release of corticotropin (adrenocorticotrophic hormone [ACTH]), luteinizing hormone, growth hormone, and thyroid-stimulating hormone while inhibiting the release of prolactin from rat pituitary cells. Those effects occur at concentrations between 10^{-9} and 10^{-12} mol and are eliminated by incubation with antibody to IL-1.

Evidence of direct interaction between the immune system and the adrenal gland also exists. Virus-infected lymphocytes produce hormones concomitantly with human leukocyte interferon. Two of the products are structurally similar to pituitary-derived ACTH and b-endorphin on the basis of antigenicity, molecular weight, and retention time on reverse-phase high-pressure liquid chromatography. In addition, the two products demonstrate the appropriate biological activity—that is, stimulating primary cultures of adrenal tumor cells to secrete glucocorticoids, binding opiate receptors in vitro, and causing analgesia and catatonia in mice. The simultaneous release of ACTH-like and b-endorphin-like products in response to a variety of stimuli, including CRH, indicates that immunocytes (probably macrophages), like pituitary cells, are capable of transcribing the proopiomelanocortin gene, which is responsible for coding the precursor protein from which ACTH and b-endorphin are derived. Lymphocyte production of an ACTH-like hormone suggests that immunocytes may be capable of tapping directly into the hypothalamic-pituitary-adrenal axis at the level of the adrenal gland, giving rise to a so-called lymphoid-adrenal axis. Nevertheless, the physiological relevance of the lymphoid-adrenal axis has not been established. Other hormones found to be secreted by immunocytes include somatostatin, vasoactive intestinal polypeptide, thyrotropin, prolactin and growth hormone.

Finally, based on recent data from mice infected with a virus, it appears that depending on the type of immune stimulus (e.g., bacterial versus viral), different cytokine pathways may be involved in neuroendocrine activation. Early glucocorticoid responses to viral infections and virus-type stimuli, for example, seem to preferentially involve IL-6, whereas TNF and IL-1 b may play a greater role in glucocorticoid release during bacterial infections.

Aside from the potent effects of cytokines (especially IL-1) on neuroendocrine function, mounting data has indicated that cytokines play an important role in the mediation of ‘sickness behavior.' Sickness behavior is a syndrome that includes weakness, malaise, listlessness, anhedonia, hypersomnia, anorexia, social isolation, hyperalgesia, and poor concentration. This syndrome typically occurs during infections, but may occur in a wide variety of clinical settings, including any medical condition or treatment that leads to significant inflammation or the release of proinflammatory cytokines (e.g., TNF, IL-1, and IL-6).

One of the first indications that cytokines might be involved in this syndrome in humans came from the behavioral effects of cytokines administered in clinical trials for immunological conditions including cancer. The ability of cytokine antagonists such as the IL-1 receptor antagonist (which is also expressed in the brain) to block symptoms of sickness behavior in laboratory animals has confirmed the role of IL-1 (and possibly other cytokines) in this syndrome. a-Melanocyte–stimulating hormone and vasopressin are capable of opposing the ability of cytokines to induce sickness behavior, suggesting that the brain exhibits several opposing processes for limiting the effects of these factors on CNS function.

Many of the behavioral effects of IL-1 are mediated within the CNS and since cytokines do not cross the blood-brain barrier, considerable attention has been paid to the mechanism by which peripherally released cytokines communicate with the brain. Four major hypotheses have been advanced including (1) active transport of cytokines across the blood-brain barrier, (2) access of cytokines to the brain in areas where the blood-brain barrier is weak, such as the organum vasculosum of the lamina terminalis, (3) conversion of cytokine signals into secondary signals, such as prostaglandin or nitric oxide signals, by endothelial cells that line the blood vessels of the brain, and (4) transmission of cytokine signals (through cytokine receptor binding) along sensory afferents to the nucleus of the solitary tract and then via ascending catecholaminergic pathways onto relevant brain regions including the paraventricular nucleus of the hypothalamus. There are data to support each of these mechanisms, and it appears that the various effects of cytokines on the CNS may each be mediated by one or more of these pathways. Once peripheral cytokine signals reach the brain, there is reason to believe that in many instances these signals are turned back into cytokine signals (peripheral cytokines beget new central cytokines). For example, peripheral administration of IL-1–inducers or IL-1 itself, is associated with an increase in IL-1 immunoreactivity and bioactivity in several brain regions, including the hippocampus and hypothalamus. Cytokines mediate their effects through specific receptors, that are members of several classes of receptor gene families, including the immunoglobulin family (for IL-1 and IL-6), the hemopoietin family (for Ils 2-7), and the nerve growth factor (NGF) family (for TNF and nerve growth factor). There is widespread and unique distribution of cytokine receptors in the brain. For instance, especially high concentrations of IL-1 and

its receptors are found in the rat hippocampus. Of note is that soluble receptors exist for many cytokines as well as decoy (inactive) receptors (such as the type II IL-1 receptor) both of which serve to limit cytokine action. A specific endogenous IL-1 receptor antagonist has also been described.

RELEVANCE OF IMMUNE-CNS INTERACTIONS TO PSYCHIATRY

There are at least two major considerations when examining the potential psychiatric relevance of nervous system-immune system interactions. First, it is important to consider the potential impact that psychiatric disorders may have on immune function. Given that CNS processes appear to be involved in immune regulation, it is logical to consider that disorders of CNS function as manifested by psychiatric disease may contribute to the development, course, or outcome of diseases involving the immune system. Second, given the potential impact the immune system may have on the nervous system both through direct (e.g., infections or autoimmune disease) or indirect (release of cytokines) actions, it is important to consider that the pathophysiology of some psychiatric disorders may involve significant contributions from the immune system. This area of inquiry is often referred to as *neuroimmunology* and involves the investigation of the potential causative role of infectious, paraneoplastic, and autoimmune processes in psychiatric and neurological syndromes.

PSYCHIATRIC DISORDERS, IMMUNOCOMPETENCE, AND HEALTH AND ILLNESS

The psychiatric disorder that has been most investigated in terms of the competence of the immune system is major depression. More than 30 studies and several meta-analyses have examined immune parameters in depression. Although a number of investigators have reported depression-related alterations in peripheral blood immune cell numbers and decreases in peripheral blood mitogen responses and natural killer cell activity, these findings have not been reliably replicated from study to study. Nevertheless, when results are pooled across studies more consistent results are apparent. Depressionrelated immune changes may occur in association with other variables that characterize persons with depression, such as age, sex, and symptom severity. For example, in a large study of 91 depressed patients and 91 controls, investigators found no mean differences in immune measures between the groups. However, in that study both advancing age and severity of depression were associated with decreases in $CD4^+$ -cell numbers and mitogen responsiveness of peripheral blood lymphocytes in depressed patients as compared to controls. Moreover, studies have reported sex differences in the relationship between immune function and depression. One study reported decreased natural killer activity in males and no changes in females; two other studies have reportedly found increased natural killer activity in depressed women compared with controls. Other important factors that appear to significantly influence immunologic responses in depressed patients are sleep and cigarette smoking. For example, disruption of sleep has been found to have a suppressive effect on natural killer cell activity. Nutritional considerations are also important.

Because depressed patients frequently exhibit alterations in cortisol secretion and since cortisol has potent immunoregulatory effects, a number of studies have examined the relation between measures of cortisol secretion and the immune response in depressed patients; however, no clear association between these variables has emerged.

Finally, epidemiological data have provided only limited support for the idea that depressive symptoms or mood disorders are associated with an increased mortality from immune-related diseases. For example, several studies have examined mortality in large numbers of patients with psychiatric disorders; in general, the results suggest that psychiatric disorders are significantly associated not with death from natural causes but rather with unnatural mortality such as suicide and accidental death. Furthermore, a 1994 meta analysis of 7 large prospective studies on the relative risk of developing cancer as a function of baseline depression found a small but marginally statistically significant increase (1 to 2 percent) in cancer rates in individuals with depressive symptoms versus nondepressed controls. Taken together with the inconsistent findings across studies of immune dysfunction in depressed patients, these results indicate that persons with depression do not clearly exhibit evidence of impaired immunocompetence and are not clearly at high risk for immune-related conditions. Nevertheless, these reports primarily focused on persons free of physical illness at the time of study, and considerable evidence suggests that persons with physical illness complicated by depression have a worse outcome than persons without depression. This evidence of increased morbidity and mortality in depressed patients with comorbid medical illnesses (e.g., neoplastic and cardiovascular disorders), emphasizes the notion that the effects of depression on disease development and outcome are ultimately determined by the genetic predisposition of the individual. Based on this predisposition, the pathophysiology of depression serves to interact and exacerbate disease-specific processes as opposed to having a specific association with a given disease.

Finally, a great deal of attention has been directed to the notion that stress and depression may influence immunocompetence in HIV-seropositive persons, thereby serving as cofactors in the progression of HIV infection to AIDS. The scientific evidence for an association between psychosocial factors and disease progression, however, remains somewhat elusive, and contrasting findings have been reported on the effects of stress on immune parameters in this population. For example, several studies have explored the relationship between psychosocial factors and the number of T-cell subsets among HIV-seropositive adults. In at least two studies no relation was found between life stress or depression and counts of $CD4^+$ cells, $CD8^+$ cells, or helper-suppressor T-cell ratios in a cohort of HIV-seropositive homosexual men. Furthermore, stress and depression measures were not related to advanced illness or mortality over time. In contrast, other studies have found that HIV-positive subjects who experienced severe stress have relevant changes in immune parameters, including lower $CD8^+$ and lower natural killer cell counts, increased levels of serum neopterin (a marker of immune activation), and decreased proliferative responses to the mitogen phytohemagglutinin. To complement these findings, a well-controlled 1997 study reported that severe life stress in people infected with HIV increased the odds of undergoing HIV disease progression nearly fourfold. This finding supports the notion that the previously observed stress-related immune changes translate into greater vulnerability for disease development. Ongoing studies examining psychosocial variables and immunological and clinical endpoints in individuals with HIV infection may shed more light on these important issues.

NEUROIMMUNOLOGY

Disorders that are typically associated with the immune system, including infectious diseases and autoimmunity, can influence CNS function. Microbial pathogens can invade the brain and either infect neural cells directly, such as the infection of neurons by polio virus, or grow locally outside the brain as in bacterial meningitis. If the infection results in the destruction of neurons, the consequences can be particularly devastating because, unlike glia or cells in the periphery, neurons have minimal capacity for regeneration. Thus, the brain has developed a specialized immune system to maintain the tenuous balance between protecting neurons from invading pathogens on the one hand, and preventing damage mediated by the immune response on the other. As an initial defense, the blood-brain barrier prevents the entry of microbial organisms, which may explain why most infections with blood-borne neurotropic viruses do not result in encephalitis.

The brain has historically been considered “immune privileged” because it lacks conventional lymphatics, has extremely low levels of MHC expression, and is resistant to the transmigration of immune cells. Nevertheless, a pronounced inflammatory response can be elicited by invading pathogens or other forms of injury. During CNS infection extracellular antigens are thought to drain to cervical lymphatics, glia are induced to express MHC class I and II, and activated T cells enter the CNS. Local induction of cytokines helps to orchestrate the immune response, and adhesion molecules are upregulated on endothelium and perivascular glia to facilitate the entry of macrophages and other leukocytes. Besides being a major source of proinflammatory cytokines, astrocytes and microglia become activated during inflammation and can produce other diffusible mediators such as NO, prostagladins, and excitatory amino acids. Such inflammatory reactions can occur even in the absence of an infectious agent as exemplified in postischemic brain injury in which there is a rapid induction of cytokines, extravasation of leukocytes, and gliosis. Which aspects of this immune reaction are deleterious and which aspects are the immunological accouterments of repair remains to be determined.

The idea that alterations of CNS function result from a combination of the direct effects of an injurious event on various cell types and the effects of cytokines and other inflammatory mediators on neurons and supporting cells is a cornerstone of neuroimmunology. The idea that infectious agents can lead to psychiatric disorders has been well established. Obvious examples include the mental retardation that may develop after congenital infection with rubella or cytomegalovirus, the delirium that accompanies acute meningoencephalitis after CNS infection by herpes simplex virus type I, dementias due to slow viruses, such as kuru and Creutzfeldt-Jakob disease, and the neuropsychiatric manifestations that occur during neurosyphilis.

Schizophrenia Several lines of evidence suggest that virus infection during neural development may be involved in the pathogenesis of some cases of schizophrenia. The data include (1) an excess number of patient births in the late winter and early spring, suggesting possible exposure to viral infection in utero during the fall and winter peak of viral illnesses; (2) an association between exposure to viral epidemics in utero and the later development of schizophrenia; (3) an increased likelihood for schizophrenic patients to have had older siblings in the household (a potential source of viral infections) as compared to controls; and (4) geographical variation of prevalence, with schizophrenia being more common at greater distance from the equator.

Investigators have reported various alterations in immune markers in patients with schizophrenia including increased levels of interferon, decreased IL-2 production, and increased IL-2 receptors. Cerebrospinal fluid (CSF) immunoglobulins have also been increased in some studies. Although these immune findings in schizophrenia patients may indicate evidence of immune system activation secondary to infection, it should be noted that they may also indicate that an autoimmune process is involved in the disorder. Attempts to isolate infectious agents, especially viruses and viral DNA, from schizophrenia patients have been unsuccessful. For

example, the polymerase chain reaction has been used to amplify virus-specific nucleic acids for cytomegalovirus, Borna disease virus, HIV, bovine viral diarrhea virus and influenza A in brain tissues from schizophrenia patients; no evidence of virus-specific nucleic acids was found in any of the tissue samples. Nevertheless, because the initial neuronal abnormalities in schizophrenia have been proposed to arise during neurodevelopment, a perinatal viral infection could insidiously disrupt development and then be cleared by the immune system prior to clinical diagnosis. In such a scenario, host factors such as cytokines could be responsible for causing the developmental abnormality by interacting with growth factors or adhesion molecules. Viral infections can also cause alterations in neurotransmitters and neuronal circuitry. For example, neonatal infection of rats with the lymphocytic choriomeningitis virus manifests in a loss of inhibitory neuron function in the hippocampus. This decrement of inhibitory control could release excitotoxic influences impinging on other neuron populations, and result ultimately in a complex cascade of selective neurodegeneration.

As previously noted, an autoimmune cause has been suspected in some patients with schizophrenia. Nevertheless, attempts to isolate autoantibodies to CNS tissue constituents in schizophrenia patients have failed to yield consistent results. Furthermore, since schizophrenia may involve various forms of CNS tissue damage, with the resultant release of brain antigens, autoantibodies to CNS tissues in those instances may be the result of CNS pathology rather than the cause. Nevertheless, several autoimmune disorders, including autoimmune disorders of the thyroid and such collagen vascular diseases as systemic lupus erythematosus and Behcet's syndrome, are capable of indirectly or nonspecifically altering CNS function, but only a few autoimmune conditions directly involve brain antigens. Neural cells are the target for autoantibodies in the paraneoplastic syndromes. For example, autoantibodies to cytoplasmic proteins of Purkinje cells are associated with subacute cortical cerebellar degeneration, which is a rare complication of breast or ovarian cancers. Autoantibodies to g-aminobutyric acid (GABA)-ergic neurons in the serum and the CSF appear to be the mechanism behind the stiff-man syndrome, a rare disorder characterized by progressive rigidity, accompanied by recurrent painful muscle spasms. Antineuronal antibodies can also arise following infection with group A b-hemolytic streptococcal infections, as exemplified by Sydenham's chorea. Considering that children with Sydenham's chorea frequently exhibit obsessive-compulsive symptoms, emotional lability, and hyperactivity, there may be a spectrum of pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections (PANDAS). In particular, sudden onset of obsessive-compulsive disorder, tics, attention-deficit/hyperactivity disorder, and other psychiatric syndromes has been characterized in children following infection with group A b-hemolytic streptococcus. These findings in conjunction with the indication of a genetic vulnerability to this condition (high frequency of binding of a monoclonal antibody designated D8/17) represents an exciting new development in the etiology and possible treatment of these disorders.

Major Depressive Disorder There has been increasing interest in the possibility that immune activation may contribute to the pathophysiology of depression. For example, elevated serum concentrations of the proinflammatory cytokines IL-1 and IL-6 as well as increased acute-phase proteins including C-reactive protein, haptoglobin, and alpha 1-acid glycoprotein have been found in patients with major depressive disorder. In addition, cellular markers of immune activation have been described. The source of immune activation in major depressive disorder is unknown, although studies have shown that both stress and CRH are capable of inducing proinflammatory cytokines in the absence of a formal immune challenge. Administration of a variety of cytokines in clinical trials also has been associated with the development of depressive syndromes (sickness behavior).

It has been suggested that the acute-phase response may contribute to decreases in the availability of L-tryptophan, thus contributing to reduced serotonin in the brain. The findings that stressors may be able to activate the release of proinflammatory cytokines and an acute-phase response in the absence of an immune challenge further supports the notion that the immune system may be recruited to participate in the behavioral response to stress, and therefore may contribute to the biochemical and molecular biological changes that characterize depression.

As for infectious diseases contributing to the pathophysiology of major depressive disorders, the potential contribution of a virus to the etiology of depression has long been considered. There has been renewed interest in this area based on the isolation of Borna disease virus from immune cells of patients with depression. Borna disease virus was primarily of interest as a pathogen of horses and sheep until recent serological and virological data demonstrated that it can infect humans and may be associated with psychiatric diseases. The neurotrophic and immunopathogenic capabilities of Borna disease virus have been well studied in the rat model. During the initial phase of Borna disease in rats, the infection of neurons and glia is accompanied by a robust inflammatory response with participation of T cells, B cells, and macrophages. Rats that recover from the initial phase may develop chronic symptoms including behavioral abnormalities and obesity; further studies are needed to clarify the importance of Borna disease virus in human neuropsychiatric disorders such as major depression.

Alzheimer's Disease Although Alzheimer's disease is not considered primarily an inflammatory disease, emerging evidence indicates that the immune system may contribute to its pathogenesis. The discovery that amyloid plaques are associated with acute-phase proteins such as complement proteins, a1-antichymotrypsin, and c-reactive protein, suggests the possibility of an ongoing immune response. Furthermore, gliosis and increased levels of proinflammatory cytokines are found in and around plaques. Interestingly, the induction of IL-6 has been proposed to precede neuritic degeneration in nascent (diffuse) plaques, and IL-1b can increase mRNA for amyloid precursor protein. Thus, immune mediators have been theorized to have an early role in plaque formation. The idea that inflammatory processes are involved in Alzheimer's disease has been bolstered by recent studies showing that the long-term use of nonsteroidal antiinflammatory drugs is negatively correlated with the development of Alzheimer's disease. Studies are underway to determine whether immune suppression with glucocorticoids can improve disease outcome.

HIV Infection Infection with HIV is an immunological disease associated with a variety of neurological manifestations including dementia. Although some neurological symptoms may be a consequence of opportunistic infections, accumulating evidence indicates that HIV itself can produce encephalitis. Infected microglia can be readily identified in the brain while infection of neurons does not appear to occur in vivo. Nevertheless, HIV encephalitis results in synaptic abnormalities and loss of neurons in the limbic system, basal ganglia, and neocortex. Current research examining the mechanism of this neurodegeneration has focused on a network of interactions between viral products (e.g., gp120, tat), glia, macrophages, and neurons. In this regard, soluble factors such as cytokines (IL-1, IL-6, TNF, TGF-b), free radicals, and excitatory amino acids have all been proposed as intermediaries in HIV-induced neuropathology. Studies in rodents have demonstrated that viral gp120 can induce IL-1b expression, activate glia, and cause neuronal damage. Antagonists of the *N*-methyl-D-aspartate (NMDA) excitatory amino acid receptor can ameliorate this damage although many aspects of this neuropathogenic pathway are unclear. Neuroendocrine abnormalities have also been described following HIV infection, perhaps as a result of cytokine activation. Thus, while the complex interactions between viral and host factors in HIV encephalitis may be perplexing, current research is revealing a variety of potential targets for therapeutic intervention in the disease.

Multiple Sclerosis Multiple sclerosis is a demyelinating disease characterized by disseminated inflammatory lesions of white matter. Since the mid-1970s considerable progress has been made in elucidating the immunopathology of myelin destruction that occurs in multiple sclerosis, and the animal model for the disease, *experimental allergic encephalomyelitis*. Although the initial step in lesion formation has not been determined, disruption of the blood-brain barrier, and the infiltration of T cells, B cells, plasma cells, and macrophages all appear to be associated with lesion formation. Proinflammatory cytokines, notably TNF-a, IFN-g, and IL-1 are believed to participate in the immunopathology by activating glia, inducing MHC class II, or mediating cytotoxicity by stimulation of free radical formation. Conversely, treatment with IFN-b decreases lesions and has been used clinically in multiple sclerosis. Current therapeutic strategies are focusing on preventing the transmigration of leukocytes into the brain by targeting chemokines (a type of cytokine that mediates chemoattraction), or by blocking adhesion molecules on endothelium or glia. Several viruses have been suggested to trigger multiple sclerosis, most recently human herpesvirus-6. One mechanism by which a virus could trigger multiple sclerosis is by molecular mimicry in which a shared epitope between a virus and the host allows for self tolerance to myelin to be broken. The selective depletion of autoreactive T cells or induction of immune tolerance by oral administration of myelin proteins is also under investigation.

Finally, there are several disorders in which neural-immune interactions are suspected but not well documented. Chronic fatigue syndrome is an illness with controversial etiology and pathogenesis. Besides persistent fatigue, symptoms frequently include depression and sleep disturbances. Tests of immune function have found indications of both immune activation and immunosuppression. Neuroendocrine assessments indicate that patients with chronic fatigue syndrome may be hypocortisolemic because of impaired activation of the hypothalamic-pituitary-adrenal axis. Although an acute viral infection frequently precedes the onset of CFS, no infectious agent has been definitively identified as causing the disease. In contrast, Lyme disease, in which sleep disturbances and depression are also common, is clearly caused by infection with the tick-borne spirochete, *Borrelia burgdoferi*. The organism can invade the CNS and cause encephalitis and neurological symptoms. Lyme disease is remarkable because it appears to produce a spectrum of neuropsychiatric disorders including anxiety, irritability, obsessions, compulsions, hallucinations, and cognitive deficits. Immunopathology of the CNS may be involved because symptoms can persist or reappear even after a lengthy course of antibiotic treatment, and the spirochete is frequently difficult to isolate from the brain. Gulf War syndrome is a controversial condition with inflammatory and neuropsychiatric features. The condition has been attributed variously to combat stress, chemical weapons (e.g., cholinesterase inhibitors), infections, and vaccines. Given the impact of stress on neurochemistry and immune responses, these pathogenic mechanisms are not mutually exclusive.

IMMUNOCYTES AS TOOLS FOR EXPLORING THE NEUROBIOLOGY OF PSYCHIATRIC SYNDROMES

Unlike brain cells, immune cells are readily available from the peripheral blood and express receptors for hormones and transmitters that are altered in a variety of psychiatric disorders. Immune cells may therefore provide useful receptor models for exploring the molecular and biochemical mechanisms that may be involved in altered neuroendocrine or neurotransmitter function.

For example, adrenal steroid receptors are expressed in immune tissues and, after long-term exposure to glucocorticoids in rats, those receptors in immune tissues exhibit downregulation in parallel with adrenal steroid receptors in multiple brain regions, including the hypothalamus and the hippocampus. During major depression, abnormalities in hypothalamic-pituitary-adrenal axis activity, including hypercortisolemia and nonsuppression of the hypothalamic-pituitary-adrenal axis by dexamethasone, are believed to be partly related to reduced glucocorticoid receptor responsiveness to feedback inhibition by glucocorticoids at the level of the hippocampus, the hypothalamus, and the pituitary. Therefore, several studies have been conducted investigating glucocorticoid receptors in lymphocytes from depressed patients. Nevertheless, results have been inconsistent; in some studies, decreased receptor number in depressed patients has been observed; others have obtained discordant results. Fewer studies have investigated the functional sensitivity of cells to the inhibitory effects of glucocorticoids, but they have been more consistent, showing increased resistance of cells from depressed patients to the inhibitory effects of glucocorticoids on immune function. Evidence of altered glucocorticoid receptor function in lymphocytes from depressed patients indicates that the glucocorticoid resistance in this disorder may be reflected in the readily accessible cells from the immune system. Abnormalities in lymphocyte glucocorticoid receptor expression have also been found in patients with posttraumatic stress disorder. In contrast to patients with depression, patients with posttraumatic stress disorder exhibit significantly higher numbers of glucocorticoid receptors than in controls; these findings are accompanied by significantly lower concentrations of plasma cortisol in posttraumatic stress disorder patients. Immune cells may therefore provide a useful receptor model both for identifying persons with hypothalamic-pituitary-adrenal axis alterations and exploring the molecular mechanisms involved.

Another lymphocyte receptor that has been evaluated in the depressive disorders is the b-receptor. In the majority of studies, b-adrenergic receptors of peripheral immune cells from depressed patients have exhibited evidence of diminished b-adrenergic responsiveness. The decreased responsivity may be the result of desensitization (diminished function, normal number) or downregulation (diminished number) of leukocyte b-receptors. Because postmortem brain b-receptors from depressed patients (death by suicide) have been shown to be upregulated (increased receptor binding), brain and lymphocyte b-receptors appear to have an inverse relationship in the depressive disorders. However, whether the decreased responsivity of immune cell b-receptors is caused by an increase in plasma catecholamines or whether a decrease in peripheral sensitivity to catecholamines leads to an increase in brain catecholamine production is unknown. Nevertheless, as with glucocorticoid receptors, immune cells may be an important tool for identifying and evaluating b-receptor alterations in the depressive disorders.

SUGGESTED CROSS-REFERENCES

Functional neuroanatomy is discussed in Section 1.2; and neuroimaging is covered in Section 1.15 and Section 1.16. Schizophrenia is covered in Chapter 13, mood disorders in Chapter 14, and anxiety disorders in Chapter 15. Behavior and immunity is discussed in Section 25.10. Alzheimer's disease is presented in Chapter 10 and Section 51.3e.

1.13 CHRONOBIOLOGY

THOMAS A. WEHR, M.D.

Chronobiology is the study of biological rhythms. Such rhythms span a spectrum of periods from the fraction-of-a-second fluctuations of the electroencephalogram to multiyear cycles in populations of predators and their prey. Two types of biological rhythms, circadian (daily) rhythms and seasonal rhythms, enable the organism to anticipate and adapt to corresponding cycles in the environment.

PHYSIOLOGY

Circadian Rhythms Because the Earth rotates on its axis, it presents two different environments—a daytime world and a nighttime world—to the organisms that live on it. In the course of their evolution, most animals have specialized in the active engagement of only one of those two environments. Because adaptations that make animals fit for one environment are liable to make them unfit for the other, animals have also adopted ways of withdrawing from the unfavorable environment (e.g., by sleeping in secure refuges) to avoid danger and to prevent the inefficient use of energy.

Thus, as the world alternates between phases of light and of darkness, animals alternate between phases of active engagement and of withdrawal. That alternation of behavioral states is not simply a passive response to the alternation of day and night. Animals possess clocklike mechanisms that automatically switch them from one state to the other in anticipation of the transitions between day and night. Those mechanisms also switch back and forth between contrasting physiological states that are geared to engagement or to withdrawal. For that reason, circadian rhythms in animals' behavior and physiology often exhibit two distinct phases, a diurnal phase and a nocturnal phase, with relatively discrete transitions between them. In humans, for example, the *diurnal phase* is one of active engagement of the environment, high body temperature, and decline or cessation of the secretion of several hormones, including pineal melatonin, pituitary thyrotropin, pituitary prolactin, pituitary corticotropin, and adrenocortical steroids. Conversely, the *nocturnal phase* is one of withdrawal from the environment, rest, sleep, low body temperature, and augmentation of the secretion of the above hormones.

The best evidence that circadian rhythms are not simply passive responses to cyclic changes in the external environment but are generated by endogenous processes is the fact that the rhythms persist when organisms are placed in constant conditions. In that situation the rhythms continue to oscillate but with an intrinsic period that differs slightly from 24 hours (hence the name “circadian,” about daily). In humans, for example, the period is slightly longer than 24 hours. In a normal environment the circadian system responds to external stimuli that serve as time cues, *zeitgebers*, in such a way that the period of its oscillations is adjusted to 24 hours and a characteristic *phase relationship* to the day-night cycle is maintained. Thus, in humans external time cues advance the phase of their longer-than-24-hour circadian rhythms several minutes each day, so that sleep recurs every 24 hours and recurs at night. Otherwise, humans would go to sleep later and later each day and would make a full circuit around the clock every few weeks.

Light, acting on the retina, is the most important stimulus for phase-resetting of the circadian system. The direction and the magnitude of the phase-resetting effect of light depends on the circadian phase at which it is applied. For example, early-morning light shifts the oscillations of the circadian system to an earlier *advanced-phase position*; late-evening light shifts the oscillations to a later *delayed-phase position*. Light in the middle of the day has little or no effect. Thus, in humans, evening light delays the time of sleep onset, but morning light advances it. The dependence of light's phase-resetting effects on the circadian phase at which it is applied can be shown quantitatively in a *phase-response curve* that indicates the magnitude and the direction of phase shifts induced by light pulses at each circadian phase (Fig. 1.13-1). The phase-resetting properties of light have led to its use in the treatment of certain types of sleep and mood disorders and of jet lag.

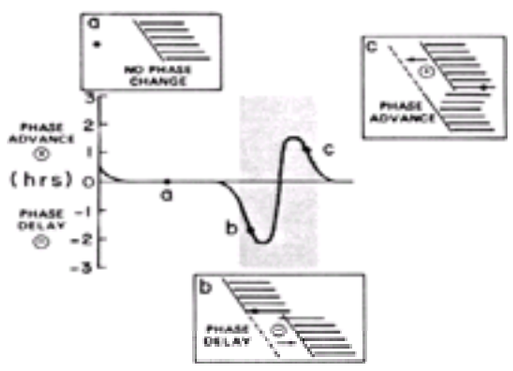

FIGURE 1.13-1 The derivation of a phase-response curve for the phase-resetting effect of light pulses in an animal whose circadian locomotor activity rhythms are free-running in constant darkness. Light pulses result in no phase change **(a)**, a phase delay **(b)**, or a phase advance **(c)**, depending on the phase of the circadian cycle at which the stimulus was presented. Sleep *4:*1, 1981.)

Light-Oriented Rhythms and Behavior-Oriented Rhythms Circadian rhythms in animals appear to be of two types: (1) rhythms whose phase relations to the external light-dark cycle are similar in day-active and night-active species, but whose phase relations to the endogenous activity-rest cycle are opposite (Type I) and (2) rhythms whose phase relations to the external light-dark cycle are opposite in day-active and night-active species but whose phase relations to the endogenous activity-rest cycle are similar (Type II).

Type I rhythms have the same orientation to the light-dark cycle in both day-active and night-active species. They include the rhythms in the circadian pacemaker's responses to light pulses, which reaches its maximum at night (Fig. 1.13-1); the rhythm in the hypothalamic suprachiasmatic nucleus's electrical multiple-unit activity and glucose utilization (Fig. 1.13-2), which reaches its maximum in the daytime; the rhythm in retinal disk shedding, which reaches its maximum in the morning; the rhythm in melatonin secretion, which reaches its maximum at night (Fig. 1.13-3); and the rhythm in cerebrospinal fluid arginine vasopressin secretion, which reaches its maximum in the daytime. Most of these rhythms are intimately connected with mechanisms responsible for the generation and entrainment of circadian rhythms, and one of their most important functions appears to be the transmission of information about the timing of day and night to other parts of the organism.

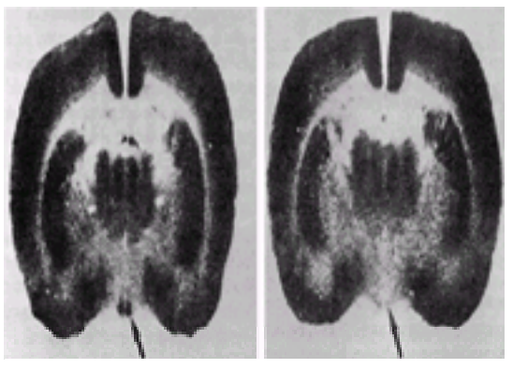

FIGURE 1.13-2 In autoradiographs of coronal sections of rat brain, 2-deoxyglucose uptake in the suprachiasmatic nuclei of the hypothalamus (indicated by arrows) is higher during the light phase **(left)** than during the dark phase **(right)** of a 24-hour light-dark cycle. (Reprinted with permission from Schwartz WJ, Smith CB, Davidsen LC: In vivo glucose utilization of the suprachiasmatic nucleus. In *Biological Rhythms and Their Central Mechanism*, M Suda, O Hayaishi, H Nakagawa, editors. Elsevier, New York, 1979.)

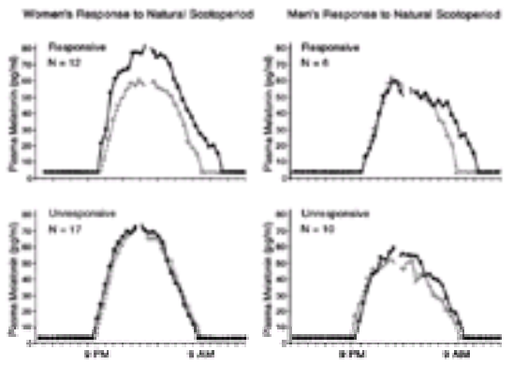

FIGURE 1.13-3 The intrinsic duration (the duration in constant dim light) of nocturnal melatonin secretion becomes longer in winter (black lines) than in summer (hatched lines) in some individuals living in a modern urban environment **(top)** but not in others **(bottom)**. In that environment, women are more likely to respond to seasonal changes in duration of the natural scotoperiod than men (maximum melatonin level also increases in winter compared with summer in women, but not in men). (Reprinted with permission from Wehr TA: Melatonin and seasonal rhythms. J Biol Rhythms *12:*517, 1997.)

Type II rhythms have the same orientation to the activity-rest cycle in both day-active and night-active species. They include the rhythm in sleep, which reaches its maximum during the rest phase; the rhythm in body temperature, which reaches its maximum during the activity phase; and the rhythms in pituitary thyrotropin secretion, pituitary corticotropin secretion, and adrenocortical steroid secretion, which reach their maximums during the rest phase. These rhythms seem to be directly connected with the maintenance of internal conditions that serve active engagement of and withdrawal from the environment.

If Type I rhythms are directly connected with clock mechanisms and Type II rhythms are directly connected with the expression of behavioral rhythms that are driven by those clock mechanism, it is likely that Type II rhythms occupy a more subordinate position that Type I rhythms in the hierarchical organization of the circadian system.

Sunrise and Sunset To coordinate the timing of the diurnal and nocturnal periods of circadian rhythms with the timing of day and night, organisms must track and anticipate the transitions between day and night. That task is complicated by the fact that the Earth's axis of rotation is tilted, causing the interval between dawn and dusk to vary during the course of the year. Animals appear to deal with this situation by using two separate mechanisms to track and to anticipate the changing times of dawn and dusk. In that way they are able to modify the durations of diurnal and nocturnal periods of their circadian rhythms to match the changing durations of day and night outside. According to one model, this is accomplished by a circadian pacemaker that consists of two coupled oscillators. One oscillator, entrained to sunset, controls the timing of the transition from the diurnal period to the nocturnal period of the circadian system; a second oscillator, entrained to sunrise, controls the timing of the transition from the nocturnal period to the diurnal period of the circadian system. According to this model, in humans the dusk-entrained oscillator controls the onset of sleep and the onset of nocturnal melatonin secretion, and the dawn-entrained oscillator controls the offset of sleep and the offset of nocturnal melatonin secretion. Thus, when nights become longer in winter, the sleep period and the melatonin secretion period become longer, too (Fig. 1.13-3).

The fact that activity or sleep in animals and humans tends to be bimodally distributed, with a peak near dusk and a peak near dawn (Fig. 1.13-4) seems consistent with a two-oscillator model. The strongest support for the model comes from the phenomenon of splitting of activity-rest cycles: when nocturnal rodents are exposed to constant light, their activity sometimes splits into two circadian components that seem to oscillate independently. A phenomenon that resembles splitting has also been described in human sleep-wake cycles.

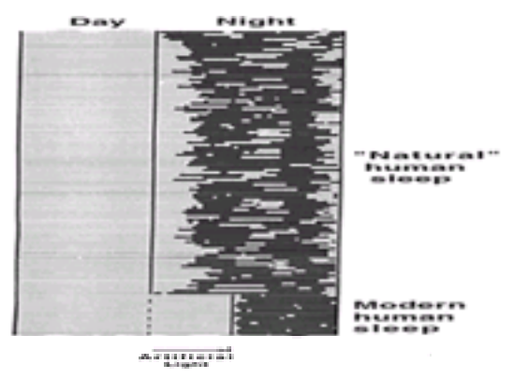

FIGURE 1.13-4 In long (14-hour) nights, human sleep is no longer consolidated, but divides into an evening bout and a morning bout that are separated by a period of quiet wakefulness. The graph shows nightly patterns of sleep (dark, horizontal bars) and wakefulness (horizontal lines), with data for each night plotted successively beneath the night that preceded it, in a young woman who rested and slept in 14-hour nightly dark periods for 15 weeks and then returned to a conventional 8-hour sleep schedule. The fact that many types of animals exhibit similar bimodal patterns of distribution in their nocturnal behavior suggests that this pattern of human nocturnal behavior is a natural one. Consistent with this idea, diaries and other historical records from the preindustrial era typically contain references to a “first sleep” and a “morning sleep.” Modern humans use artificial light to extend their waking activities into the first hours of the night (arrow). This practice causes their sleep to become consolidated and reduced in duration. (Reprinted with permission from Wehr TA: Seasonal photoperiodic responses of the human circadian system. In *Handbook of Behavioral Neurobiology: Circadian Clocks*, JS Takahashi, FW Turek, RY Moore, editors. Plenum, New York, 1998.)

Seasonal Rhythms The system of dawn-tracking and dusk-tracking circadian mechanisms that adjusts the duration of diurnal and nocturnal periods of circadian rhythms to match the changing duration of day and night has a second important function. The timing of dawn relative to the timing of dusk is an indicator of the time of year. Taking advantage of that fact, animals also use dawn-tracking and dusk-tracking mechanisms as a kind of biological calendar so that they can anticipate conditions that will prevail at particular times of the year and can initiate responses that are likely to be adaptive. For example; animals respond to critical changes in

day length *(photoperiod)* by storing energy in anticipation of seasonal scarcity of food or by conceiving offspring in anticipation of seasonal abundance of food.

Melatonin as a Chemical Transducer of Change of Season The pineal hormone *melatonin* is an important chemical mediator of the effects of seasonal changes in the photoperiod on reproduction and other functions. In some animals the duration of nocturnal melatonin secretion appears to be regulated by separate circadian processes that are synchronized with dusk and dawn and that trigger the onset and the offset of secretion. Thus, in winter, during which nights are long, the duration of nocturnal melatonin secretion is long. In summer, when nights are short, the duration of melatonin secretion is short (Fig. 1.13-3). In many species these changes in the duration of melatonin secretion serve as chemical signals that convey information about the duration of night to target sites in the body that induce season-specific changes in behavior and physiology. For example, numerous experiments have shown that the effect of the photoperiod on breeding is mediated by changes in the duration of nocturnal melatonin secretion.

Elements of the reproductive system that respond to the seasonal melatonin message appear to possess *interval timers* that measure the duration of melatonin secretion. When the duration increases by a certain amount, winter-type reproductive responses are triggered. When the duration declines by a certain amount, summer-type responses are triggered. Further research has shown that the direction of change in the duration of melatonin secretion is also important in determining the nature of the response. Intermediate durations of melatonin secretion can elicit either summer-type responses or winter-type responses, depending on whether the durations to which an animal was previously exposed were long or short.

The exact nature of an animal's reproductive responses to photoperiod-induced changes in melatonin secretion depends on its species and the length of its gestational period. For example, short photoperiods and long melatonin durations induce breeding in sheep, but long photoperiods and short melatonin durations induce breeding in hamsters. Because the gestational period of sheep is long, the gestational period of hamsters is short, the offspring of each species tend to be born at approximately the same time of year, the late spring—a time when conditions are favorable for their survival. Thus, melatonin is generically neither progonadal nor antigonadal. Rather, it conveys information about the duration of the photoperiod, and that information is used in different ways by different animals.

A 420-amino acid melatonin receptor has been identified and cloned. Structure analysis revealed that the receptor protein is a member of the guanine nucleotide binding protein-coupled receptor family. Melatonin receptors are concentrated in the suprachiasmatic area of the hypothalamus and the pars tuberalis of the pituitary. It seems likely that the effects of melatonin on reproductive function are mediated, at least in part, by interval timers associated with melatonin receptors in those areas.

The retinohypothalamic-pineal axis's responses to light are highly conserved in humans. Like other animals, humans secrete melatonin exclusively at night, and they interrupt its secretion when they are exposed to light during the period of nocturnal secretion. In many individuals, the retinohypothalamic-pineal axis also is capable of detecting changes in the length of the night and making proportional adjustments in the duration of nocturnal melatonin secretion, producing the type of melatonin message that other animals use to trigger seasonal changes in their behavior. This response has been shown both in naturalistic studies and in experiments in which melatonin profiles were compared after chronic exposure to long and short artificial “nights.”

The effect of changes in photoperiod on the melatonin message do not depend solely on the acute melatonin-suppressing effects of light; that is, differences in the duration of nocturnal melatonin secretion that are seen under different photoperiods are not simply a function of differences in the extent to which the beginning and end of the light period encroaches on the nocturnal period of melatonin secretion and directly suppresses its initial and terminal phases. Changes in the length of the night to which an individual is exposed alter the intrinsic duration of nocturnal melatonin secretion that is programmed by processes within the organism (presumably within the suprachiasmatic nucleus). That this is the case can be seen when the duration of melatonin secretion is measured in constant dim light following exposures to photoperiods of different duration. Under these conditions the aftereffects of the photoperiod to which an individual has been exposed can be detected in the duration of melatonin secretion even though the individual is no longer being exposed to that photoperiod.

Individuals who live in modern urban environments differ in the degree to which, or even whether, the intrinsic duration of melatonin secretion (the duration measured in constant dim light) responds to seasonal changes in the length of the solar night. Approximately 1 in 3 healthy women living in the District of Columbia area respond unequivocally to seasonal changes in the length of the solar night. By contrast, only 1 in 8 healthy men respond unequivocally. Women also differ from men in that the maximum level of their nocturnal melatonin secretion increases in winter compared to that in summer.

Response to morning light seems to be critical in determining an individual's response to seasonal or experimental changes in the length of the night. Changes in the intrinsic duration of melatonin secretion that are induced by changes in night length are highly correlated with changes in the intrinsic timing of the morning offset of secretion. By contrast, they are only weakly correlated with changes in the intrinsic timing of evening onset of secretion.

Animals use photoperiod-induced changes in the duration of nocturnal melatonin secretion as a chemical signal to trigger seasonal changes in reproduction and other functions. Although humans can produce this signal, it is unclear whether they are capable of responding to it in similar ways. It is difficult to know whether the human reproductive system, for example, is able to respond to the seasonal melatonin message given that only a minority of modern humans who live in urban environments unequivocally respond to seasonal changes in the length of the night by making proportional adjustments in the intrinsic duration of melatonin secretion; investigators who have looked for seasonal influences on human reproduction have studied populations that were not selected for this response. Nevertheless, there are some indications that some humans may respond to this signal. For example, rates of human conception exhibit clear and reproducible patterns of seasonal variation.

Unicellular algae also produce melatonin at night, and they use photoperiod-induced changes in the duration of their nocturnal production to trigger encystment, an adaptive response to conditions that prevail in winter. The fact that humans and algae both use changes in the duration of nocturnal melatonin secretion to code for seasonal changes in the duration of the night points to an ancient evolutionary origin for the mechanism.

Effect of Night Length on Sleep Because modern humans use artificial light to extend their period of wakefulness and activity into the evening hours, they adhere to a short-night sleep schedule throughout the year for most of their lives. In these circumstances, individuals fall asleep shortly after lying down and sleep without interruption until they arise in the morning. This type of sleep, which we tend to regard as the only normal type of sleep, is highly consolidated and efficient, occupying almost all of the nightly period of bed rest.

The sleep of most other animals is quite different. Their sleep and activity are polyphasic, exhibiting multiple bouts per day. Moreover, in many species, including insects, birds, and mammals, average daily profiles of sleep or activity exhibit two prominent peaks, one near dusk and one near dawn. Such bimodal patterns are not necessarily present in all circumstances; they tend to emerge when the relevant behavioral phase (sleep or activity) expands, as can occur after a change in photoperiod.

Until recently, humans were considered to be fundamentally different from all other animals in having sleep that is consolidated into one continuous nocturnal bout. In long nights, however, human sleep resembles that of other mammals to a much greater extent than has been appreciated. In these conditions, humans typically lie awake for one or more hours and then sleep in bouts of several hours' duration that are separated by extended periods of quiet wakefulness. The bouts of sleep are distributed in such a way that when nightly profiles of sleep are averaged, a remarkably symmetrical bimodal pattern emerges, as occurs in other animals.

Circannual Rhythm Certain types of seasonal rhythms in animals, such as rhythms in hibernation, persist in experimental conditions when the duration of the photoperiod and all other conditions are held constant. Apparently those seasonal rhythms are not simply passive responses to seasonal changes in the photoperiod; they are endogenous and capable of self-sustainment. In constant conditions, their intrinsic period is slightly different from one year (hence the name “circannual,” about yearly). In the natural environment the circannual rhythm responds to zeitgebers in such a way that its period is adjusted to 1 year, and a characteristic phase relationship to the seasons is maintained. Annual changes in light, temperature, and diet have been shown to serve as zeitgebers for various types of circannual rhythms.

Feedback Some outputs of the circadian system feed back onto its rhythm-generating mechanisms and modify their oscillatory behavior. For example, pharmacological studies suggest that the onset of melatonin secretion in the evening, which is triggered by the circadian system, may feed back on the system and phase advance it. This effect of melatonin may be mediated by high-affinity melatonin-binding sites that are found in the suprachiasmatic nucleus of the hypothalamus, which is the site of a circadian pacemaker. Experiments have shown that arousing stimuli—such as forced exercise, social interactions, and novel environments—when applied near the time of onset of the activity phase, advance circadian rhythms. This finding suggests that the daily onset of the activity phase, which is triggered by the circadian system, may also feed back on the system and phase advance it.

NEUROBIOLOGY

The circadian system consists of three elements: (1) a rhythm generator or pacemaker, (2) visual inputs to the pacemaker that mediate its entrainment to the photoperiod, and (3) efferent connections that drive and coordinate numerous physiological and behavioral output rhythms. Research over the past three decades has revealed that the retinohypothalamic-pineal axis contains all those elements and is the core of the mammalian circadian system (Fig. 1.13-5).

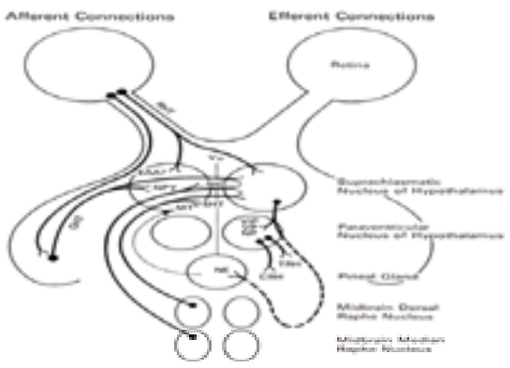

FIGURE 1.13-5 Important pathways and neurotransmitters of the retinohypothalamic-pineal/midbrain raphe axis (schematic drawing, not to scale). Anatomical structures: V_m, third ventricle; RHT, retinohypothalamic tract; GHT, geniculohypothalamic tract. Neurotransmitters: ACh, acetylcholine; EAA, excitatory amino acids; GABA, g-amino butyric acid; NPY, neuropeptide Y; 5HT, serotonin; VIP, vasoactive intestinal peptide; VP, vasopressin; NP, neurophysin; NE, norepinephrine; OXT, oxytocin. Hormones: MT, melatonin; CRH, corticotropin-releasing hormone; TRH, thyrotropin-releasing hormone.

Pacemaker The mammalian brain has a least two circadian pacemakers, but only one, the suprachiasmatic nucleus of the hypothalamus, has been identified. (A second oscillator, which can be entrained by feeding and which survives suprachiasmatic nucleus lesions, has not been localized.) The suprachiasmatic nucleus consists of bilateral compact cell groups lying above the caudal third of the optic chiasm on either side of the third ventricle (Fig. 1.13-2 and Fig. 1.13-5). The evidence that the suprachiasmatic nucleus generates and coordinates circadian rhythms in mammals includes the following:

1. The suprachiasmatic nucleus is directly innervated by the retinohypothalamic tract, a pathway that originates in the retina and is necessary and sufficient for the entrainment of circadian rhythms by light.
2. Suprachiasmatic nucleus lesions disrupt many types of circadian rhythms.
3. The suprachiasmatic nucleus exhibits circadian rhythms in multiunit electrical activity, even when it is isolated from the rest of the brain by knife cuts that create a hypothalamic island in vivo.
4. Suprachiasmatic nucleus explants continue to exhibit circadian rhythms in multiunit electrical activity, vasopressin release, and metabolic activity in vitro.
5. Fetal suprachiasmatic nucleus transplants restore circadian rhythmicity to animals whose circadian rhythms have been disrupted by suprachiasmatic nucleus lesions.
6. When such suprachiasmatic nucleus transplants are obtained from mutant donors whose circadian rhythms oscillate unusually rapidly, the recipient's circadian rhythms also oscillate unusually rapidly.

Intact suprachiasmatic nucleus's have also been shown to be necessary for the expression of photoperiodic seasonal rhythms.

The suprachiasmatic nucleus of a variety of mammalian species share a number of common properties. The suprachiasmatic nucleus can be divided into dorsomedial and ventrolateral subdivisions. The *dorsomedial* subdivision contains neurons exhibiting vasopressinlike and somatostatinlike immunoreactivity. Most vasopressin-containing cells and somatostatin-containing cells seem to be local circuit neurons that do not project beyond the confines of the suprachiasmatic nucleus. The *ventrolateral* subdivision contains a large number of vasoactive intestinal polypeptide-immunoreactive neuronal perikarya. The majority of those cells also appear to be local-circuit neurons confined to the boundaries of the suprachiasmatic nucleus, although there is a small projection to the periventricular and anterior hypothalamic area.

The normal neuroanatomical organization of the suprachiasmatic nucleus is not necessary for its cells to generate circadian rhythms. Dispersed cultures of suprachiasmatic nucleus cells are capable of generating circadian rhythms in vasopressing release, and transplants of those cultures are capable of restoring circadian rhythms in animals whose circadian rhythms have been disrupted by suprachiasmatic nucleus lesions. Those results suggest that circadian rhythm generation in the suprachiasmatic nucleus may be a property of individuals cells. The fact that all successful transplants included vasoactive intestinal polypeptide-containing cells may indicate that those particular suprachiasmatic nucleus cells play an important role in the generation of circadian rhythms.

Circadian rhythm generation by the suprachiasmatic nucleus pacemaker is reflected in changes in multiple-unit electrical activity and metabolism, which increase in the daytime in both day-active and night-active mammals (Fig. 1.13-2). Furthermore, circadian rhythms in that activity persist when knife cuts isolate tissue containing the suprachiasmatic nucleus from the rest of the brain. When splitting occurs in hamsters, the pattern of glucose metabolism becomes asymmetrical in the two suprachiasmatic nucleus.

Clock Genes Recently, two genes that govern the frequency of oscillations of the circadian pacemaker in animals were identified and cloned in humans. One of the genes, *per*, had already been identified and extensively investigated in *Drosophila*. In the fly, positive and negative feedback between the *per* gene and the product of its expression, the *per* protein, appear to be part of a mechanism that generates circadian rhythms. The other gene, *clock*, was first identified in mice. Flies and mice bearing mutations in these genes exhibit alterations in the timing of their daily activity-rest cycles that are phenotypically similar to circadian sleep disorders in humans. Daily rhythms in behavior are abnormally delayed in animals with some types of mutations and abnormally advanced in animals with other types of mutations.

Afferents to the Suprachiasmatic Nucleus Pacemaker The suprachiasmatic nucleus receives three major afferents, a direct visual pathway, an indirect visual pathway, and a pathway from the raphe nuclei of the brainstem (Fig. 1.13-5). All three pathways terminate on cells in the ventrolateral subdivision of the suprachiasmatic nucleus, and all three pathways have been shown to affect the expression of rhythms generated by the suprachiasmatic nucleus.

Direct Visual Pathway Entrainment of circadian rhythms in animals requires intact visual pathways. If the eyes are removed or the optic nerves cut, the circadian pacemaker expresses its own intrinsic rhythms and free runs, even in the presence of a light-dark cycle. The pathways responsible for photic entrainment are unusual in some respects. The threshold for photic effects on entrainment is rather high and resembles that of cone photoreceptors. Genetic mutant mice that lack rods can be entrained perfectly normally to light-dark cycles, suggesting that cones or some novel photoreceptors are responsible for phase resetting by light. The photic entrainment system is also unusual in that it can integrate light over long durations; it responds optimally to pulse durations of 5 minutes.

The retinohypothalamic tract—which passes from the retina along the optic nerve, exits from the optic chiasm, and enters the suprachiasmatic nucleus—is both necessary and sufficient for photic entrainment of circadian rhythms. If the optic tracts, which are distal to the chiasm, are cut, entrainment is preserved.

Neurophysiological studies have shown that the suprachiasmatic nucleus contains many cells whose electrical activity is modified when the retina is exposed to light. The visual fields of those cells are wide, and they code exclusively for luminance (as opposed to spatial characteristics of light that be useful for image processing). With light stimulation, electrical activity is enhanced in some cells and suppressed in others.

Which neurotransmitters mediate retinohypothalamic tract input to the suprachiasmatic nucleus is still not known. Currently, several lines of evidence point to excitatory amino acids. They have been found in the retinohypothalamic tract and its terminals, and their levels are reduced by optic nerve ransection. Furthermore, an *N*-methyl-D-aspartic acid (NMDA) glutamate receptor antagonists can block light-induced phase shifts in rodents.

Photic entrainment may depend on transcriptionally regulated signal transduction processes in the suprachiasmatic nucleus. Light triggers production of mRNA and protein products of the proto-oncogene c-*fos* in the suprachiasmatic nucleus. That stimulation exhibits the same circadian-phase dependence and the same photic threshold as circadian-rhythm phase-shifting effects of light, and the stimulation can be blocked with an NMDA antagonist. Light also stimulates the *jun*-B protooncogene family, which forms a dimer with c-*fos*, called *activator protein-1* (AP-1), which serves as a transcription factor.

Indirect Visual Pathway An indirect visual pathway reaches the suprachiasmatic nucleus through the lateral geniculate nucleus and the intergeniculate leaflet. That pathway is not necessary for entrainment; nevertheless, it appears to be capable of modifying the responses of the suprachiasmatic nucleus circadian pacemaker to photic and nonphotic entraining stimuli. In hamsters, destruction of the intergeniculate leaflet prevents lengthening of the intrinsic period of circadian rhythms that is normally caused by constant light, reduces the magnitude of phase shifts that are induced by light pulses, and advances the time of onset of the nocturnal activity period under conditions of entrainment to light-dark cycles. Furthermore, electrical stimulation of the lateral geniculate nucleus causes phase shifts of circadian rhythms.

Geniculohypothalamic tract input to the suprachiasmatic nucleus appears to be mediated by neuropeptide Y, which is present in cells of the tract and is released in terminals in the suprachiasmatic nucleus when the lateral geniculate nucleus is stimulated. Moreover, injections of neuropeptide Y into the suprachiasmatic nucleus produce phase shifts that resemble those produced by electrical stimulation of the lateral geniculate nucleus. In nocturnal rodents the phase shifts produced by electrical stimulation of the lateral geniculate nucleus and by applications of neuropeptide Y to the suprachiasmatic nucleus resemble phase shifts produced when dark pulses are applied against a background of constant illumination.

In humans neuropeptide Y cell bodies do not appear to be present in the lateral geniculate nucleus. Instead, they are found within the suprachiasmatic nucleus itself, which may indicate that in humans the indirect visual input to the suprachiasmatic nucleus is circumscribed and bypasses the lateral geniculate nucleus.

Pathway From the Raphe Nuclei From the serotonergic raphe nuclei, extensive projections terminate in the suprachiasmatic nucleus, mainly on the vasoactive intestinal polypeptide-containing cells. Further, the suprachiasmatic nucleus show a diurnal rhythm of serotonin uptake and sensitivity. In contrast to excitatory amino acids and neuropeptide Y, which are excitatory neurotransmitters, serotonin is inhibitory and suppresses spontaneous electrical activity of suprachiasmatic nucleus cells.

Although lesion studies have shown that raphe input is not necessary for photic entrainment, the raphe cells do appear to influence the rhythmic behavior of the suprachiasmatic nucleus pacemaker and its responses to light-dark cycles. For example, in rodents housed in constant darkness, lesioning of the raphe causes activity rhythms to disintegrate, which suggests that raphe input may be necessary to maintain the coherent expression of suprachiasmatic nucleus rhythms.

The raphe nuclei also appear to modulate animals' responses to the photoperiod. Animals adjust the durations of the diurnal and nocturnal periods of the circadian systems to match seasonal changes in durations of the photoperiod and scotoperiod. In rodents exposed to a fixed light-dark cycle, lesioning of the raphe nuclei causes the onset of locomotor activity to advance to an earlier time and the offset to delay to a later time such that the duration of the nocturnal activity period increases (as also occurs when the photoperiod is shortened). Lesion studies suggest that the effects of serotonergic input on the times of onset and offset of activity may be mediated by separate tracts—a tract from the dorsal raphe nucleus that modulates the time of activity offset and a tract from the median raphe nucleus, lateral to the other tract, that modulates the time of activity onset.

The idea that serotonergic input from the raphe nuclei modulates or reinforces the SCN circadian pacemaker's responses to the entraining light-dark cycle is also supported by observations that serotonin and the serotonin agonists, quipazine and buspirone, can induce phase shifts in the circadian rhythm of spontaneous electrical activity of the suprachiasmatic nucleus in vitro. Because increases in serotonergic activity have been shown to be correlated with increased arousal in rats, phase shifts induced by arousing stimuli may be mediated by serotonergic input to the suprachiasmatic nucleus from the raphe nuclei. The effects of serotonin on the circadian pacemaker appear to be mediated by a novel receptor, the serotonin (5-hydroxytryptamine [5-HT]) type 7 (5-HT $_7$) receptor.

Other afferent connections to the suprachiasmatic nucleus have been described, but their function and physiological significant are obscure. A few dopamine-containing terminals are present in the suprachiasmatic nucleus, and there are afferents from the anterior hypothalamic nucleus, ventromedial nucleus, arcuate nucleus, and paraventricular thalamic nucleus. There are also numerous commissural projections between the suprachiasmatic nucleus.

Efferent Connections The suprachiasmatic nucleus drives circadian rhythms in locomotor activity, food intake, water intake, sexual behavior, deep body temperature, sleep, adrenocorticotropic hormone (ACTH) secretion, prolactin secretion, melatonin secretion, and gonadotropin secretion. The imposition of rhythmic variation on those functions is probably mediated by efferent pathways from the suprachiasmatic nucleus to networks that regulate those functions.

Efferent projections of the suprachiasmatic nucleus are confined mainly to the hypothalamus. Besides the commissural connections, six efferent pathways to fiber terminals can be identified.

The principal efferent from the suprachiasmatic nucleus is a dense plexus of fibers that terminates in the subparaventricular zone, below the posterior part of the paraventricular nucleus of the hypothalamus. A few of those fibers continue through the paraventricular nucleus and midline thalamic nuclei and end in the paraventricular nucleus of the thalamus. Fibers from the suprachiasmatic nucleus to the paraventricular nucleus and subparaventricular zone contain vasoactive intestinal polypeptide, vasopressin, and neurophysin. The hypothalamic paraventricular nucleus is a way station in the multisynaptic pathway that connects the suprachiasmatic nucleus to the pineal gland and that mediates the effects of light and pacemaker activity on nocturnal melatonin secretion (Fig. 1.13-3). The pathway proceeds through the intermediolateral cell column of the spinal cord and the superior cervical ganglion and terminates in noradrenergic sympathetic fibers on the pineal gland. At night the suprachiasmatic nucleus triggers the release of norepinephrine, which stimulates the synthesis and the release of melatonin by the pineal gland. Lesions of the paraventricular nucleus and the superior cervical ganglion abolish the nocturnal rhythm of melatonin secretion and abolish seasonal photoperiodic reproductive rhythms. The fact that melatonin inhibits spontaneous electrical activity and glucose metabolism in the suprachiasmatic nucleus suggest that the SCN modulates its own activity through a pineal neuroendocrine feedback loop.

Since the paraventricular nucleus contains cell bodies of thyrotropin-releasing hormone neurons and corticotropin-releasing hormone neurons that regulate pituitary thyroid-stimulating hormone secretion and pituitary ACTH secretion, the connections between the suprachiasmatic nucleus and the paraventricular nucleus may also be the route through which the suprachiasmatic nucleus pacemaker imposes daily rhythms on the secretion of thyroid-stimulating hormone and ACTH by the pituitary. Paraventricular nucleus lesions do not interfere with the expression of activity and sleep circadian rhythms.

Other pathways consist of relatively fewer fibers. One pathway runs rostrally and ends in the ventral part of the medial preoptic area. Probably through this connection the SCN imposes circadian rhythms on water intake, deep body temperature, and reproductive behavior. Another pathway runs rostrally through the medial preoptic nucleus and ends in the intermediate lateral septal nucleus. Other fibers terminate in the bed nucleus of the stria terminalis, the parataenial nucleus, the paraventricular nucleus of the thalamus, the midbrain central gray nuclei and raphe nuclei, the lateral geniculate nucleus, a zone near the arcuate nucleus, and the lateral hypothalamic area. Interruption of this last pathway by lesions of the dorsomedial nucleus interrupts the circadian control of food intake without affecting rhythms in body temperature, drinking, and locomotor activity.

Efferent projects from the suprachiasmatic nucleus terminate in the intergeniculate leaflet and in the raphe nuclei, areas from which afferents to the suprachiasmatic nucleus arise. Through those feedback loops, the SCN may modify its own inputs.

Parallels exist between the closely related indoles serotonin and melatonin (serotonin is a precursor of melatonin). The suprachiasmatic nucleus drives daily rhythms in the synthesis and the release of each indole, and each feeds back on the suprachiasmatic nucleus—one acting as a neurotransmitter, the other as a hormone. Each appears to be capable of inducing phase shifts in rhythms generated by the suprachiasmatic nucleus pacemaker, and each appears to play a role, as mediator or modulator, in the pacemaker's responses to seasonal changes in the photoperiod.

BIOLOGICAL RHYTHMS IN PSYCHIATRY

Delayed Sleep Phase Syndrome and its Treatment With Light Abnormalities in the timing of the oscillations of the circadian pacemaker may play an important role in the pathogenesis of some sleep and mood disorders. The evidence for such a role is clearest in the case of *delayed sleep phase syndrome*, a type of circadian rhythm sleep disorder in which individuals have difficulty falling asleep until late at night, but once asleep, tend to sleep soundly and have difficulty arising in the

morning. If they force themselves to rise early, they function poorly during the morning hours and become increasingly sleep-deprived as the week progresses. On weekends, they may sleep late into the afternoon to recover the sleep that they have lost during the week. These individuals appear to suffer not from a disorder of sleep per se, but from a disorder in the timing of the sleep-wake cycle, which remains stubbornly delayed relative to the sleep and work schedule that they wish to follow. Such individuals report that it is difficult or impossible to advance the timing of their sleep to earlier hours. In these individuals the circadian pacemaker seems unable to adopt a normal phase position when it entrains to the day-night cycle; instead, the pacemaker adopts an abnormally delayed phase position. Using principles derived from the human phase response curve for light, clinical researchers have successfully treated delayed sleep phase syndrome by exposing patients to bright light in the morning, which advances their rhythms, and by shielding them from light in the evening, which delays their rhythms.

Some individuals, especially the elderly, suffer from an opposite condition, *advanced sleep phase syndrome*, in which they find it difficult to remain awake in the evening, fall asleep early, and wake up early in the morning. In principal, advanced sleep phase syndrome could be treated by an opposite approach that employs light treatment in the evening and avoidance of light in the morning.

Animals bearing mutations in clock genes exhibit abnormalities in the phasing of their circadian rhythms that are phenotypically similar to circadian sleep disorders in humans. Now that the genes *per* and *clock* have been identified and cloned in humans, it will be possible to examine the frequencies of polymorphisms in these genes and determine whether delayed sleep phase syndrome and advanced sleep phase syndrome are associated with specific variants that affect the frequency of oscillations of the circadian pacemaker.

Treatment of Depression by Phase-Advancing the Sleep-Wake Cycle It is well known that depression and mania are often accompanied by dramatic changes in the amount and timing of sleep. For example, many patients with bipolar I disorder awaken later and sleep more when depressed and awaken earlier and sleep less when manic. In some of these cases, the timing of the sleep-wake cycle shifts later in depression (as in delayed sleep phase syndrome) and shifts earlier in mania (as in advanced sleep phase syndrome).

Experiments have shown that these state-dependent changes in the amount and timing of sleep are not merely symptoms of the illness, but feed back on the illness and play a role in its pathogenesis. For example, it is well known that sleep deprivation can temporarily improve depression and can sometimes trigger mania. Conversely, sleep can trigger or worsen depression, at least in individuals whose depressions improved after sleep deprivation. Less well known is the fact that experimentally altering the timing of sleep, without altering its duration, can also alter mood. Shifting the timing of sleep earlier than usual (e.g., sleeping from 5 PM to 1 AM) can improve depression and can sometimes trigger mania. Conversely, scheduling sleep in the morning can trigger depression, at least in patients whose depressions have improved after sleep deprivation (sleep in the afternoon and evening is much less likely to have this effect). These findings seem to indicate that sleep is depressant and wakefulness antidepressant, especially when they occur in the morning hours. Thus, the timing of the sleep-wake cycle, relative to other circadian rhythms, appears to influence the clinical state of patients with mood disorders.

These observations led to the development of an adjunctive treatment for depression. Patients who have just begun treatment with antidepressant medications are sleep-deprived for one night, then allowed to return to sleep but on an altered sleep schedule in which they sleep from 5 PM to 1 AM (Fig. 1.13-6). Among patients whose depressions improve after a night of sleep deprivation (about 60 percent), the relapse that typically occurs when they resume their customary sleep schedule seems to be prevented when their sleep is shifted to the earlier hours. On subsequent nights, their sleep can gradually be shifted later until they are again sleeping at their customary hours. As patients shift back to their normal schedule, the medication begins to exert its antidepressant effects. This approach to treatment combines the immediate antidepressant effects of total deprivation of sleep, the gradual antidepressant effects of phase-advance of sleep, and the long-term antidepressant effects of medications, so that the patient experiences an improvement that is both rapid and sustained. Some depressed patients respond to the sleep manipulations alone, without adjunctive antidepressant medications.

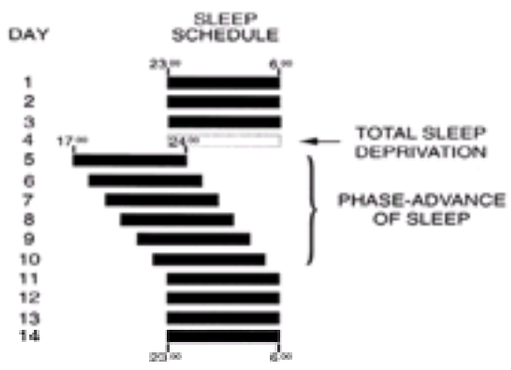

FIGURE 1.13-6 Treatment of depression by shifting the sleep-wake cycle earlier (phase-advancing it), relative to other circadian rhythms, then gradually shifting it back to a normal schedule. The phase-advance treatment is based on experimental observations that sleep is depressant when it coincides with late night and early morning circadian phases, but not when it coincides with late afternoon and early evening circadian phases. (See Wehr TA, Wirz-Justice A, Duncan WC, Gillin JC, Goodwin FK: Phase-advance of the circadian sleep-wake cycle as an antidepressant. Science *206:*710, 1979; Berger M, Vollmann J, Hohagen F, König A, Lohner H, Voderholzer U, Riemann D: Sleep deprivation combined with consecutive sleep phase advance as a fast-acting therapy in depression: An open pilot trial in medicated and unmedicated patients. Am J Psychiatr *154:*870, 1997.)

Light, Melatonin, and Seasonal Affective Disorder In animals, photoperiod-induced changes in the duration of nocturnal melatonin secretion can induce changes not only in reproductive function, but also in activity, aggression, sleep, food intake, weight, metabolism, and other behaviors and functions. Thus, at one time of year an animal may become more active and aggressive, eat more, sleep less, become interested in sex, and interact more with its physical and social environment. At another time of year, it may become less active and aggressive, eat less, sleep more, lose interest in sex, and withdraw from its physical and social environment. It may be relevant that similar seasonal changes in behavior occur as pathology in humans who are afflicted with *seasonal affective disorder* (classified as depressive disorder, seasonal type, in the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* [DSM-IV]).

Seasonal affective disorder is characterized by recurrent depressions that usually begin in November and end in March. Symptoms of winter depression commonly include lethargy, decreased activity, social withdrawal, loss of interest in sex, oversleeping, overeating, carbohydrate cravings, and weight gain. Sometimes the picture changes to an opposite one in the spring, with increased energy, increased activity, social engagement, increased libido, decreased need for sleep, decreased appetite, and weight loss. The ubiquitous role of melatonin as a chemical mediator of seasonal change in animals and the similarities between patients' symptoms and behaviors that melatonin triggers in animals led clinical investigators to hypothesize that photoperiod-induced changes in the duration of melatonin secretion are part of the mechanism that drives the seasonal cycles of this disorder.

This hypothesis has been tested in a number of naturalistic studies and experiments. For the hypothesis to be tenable, however, its assumption that the duration of nocturnal melatonin secretion is longer in winter than in summer in patients with seasonal affective disorder would have to be shown to be true. Recent research shows that this assumption is true for men with seasonal affective disorder but not for women with seasonal affective disorder. Thus, there is a gender difference in responsiveness of the retinohypothalamic-pineal axis to seasonal changes in the natural scotoperiod in patients with seasonal affective disorder. Curiously, this gender difference is opposite to the one found in healthy volunteers. The results in men are consistent with (but do not prove) the classic melatonin hypothesis of seasonal affective disorder. The results in women, however, appear to be inconsistent with the hypothesis as originally formulated.

The classic melatonin-duration hypothesis of the pathogenesis of seasonal affective disorder has been tested in a number of experiments, with inconsistent results. Supporting the hypothesis are findings that exposure to light improves winter depression, and that exposure of the eyes (not the skin) to light is necessary for this improvement to occur. Also consistent with the hypothesis is the finding that morning treatment with the beta blocker drug propranolol, which suppresses the terminal portion of nocturnal melatonin secretion and thereby shortens its duration, is associated with improvement of winter depression, and the finding that administration of melatonin to patients who have improved during light treatments induces some of the most characteristic symptoms of winter depression. Observations that suppression of melatonin secretion by light is not necessary for improvement to occur during light treatment, however, are inconsistent with the hypothesis.

In future studies of the melatonin-duration hypothesis seasonal affective disorder, it will be necessary to investigate men and women separately, and to determine why patients respond to seasonal changes in the natural photoperiod differently than their sex-matched controls. In the latter effort, the effect of morning light on

processes that regulate the timing of offset of nocturnal secretion are of particular interest, because changes in the intrinsic duration of nocturnal melatonin secretion are mostly a function of changes in the timing of offset of secretion (Fig. 1.13-3).

Monitoring Bipolar Disorders With Continuous Recording of the Activity-Rest Cycle Instruments and data displays that were developed for research on biological rhythms in animals are proving to be valuable tools for automated assessment of the course of bipolar I disorder. To study the behavior and physiology of the circadian pacemaker, researchers have relied primarily on analyses of the expression of its rhythm in longitudinal recordings of locomotor activity (the activity-rest cycle) in animals. These researchers found it convenient to display activity data in the form of a raster plot, in which horizontal 24-hour segments of the recordings are shown consecutively beneath one another. Typically, the data are double-plotted to the right to compensate for the artificial interruption that is created when the data are cut into segments and to facilitate visual inspection of the courses of the activity-rest cycle. This format yields a series of stacked horizontal lines in which Line 1 consists of data for Day 1 plus Day 2, Line 2 consists of data for Day 2 plus Day 3, and so on (Fig. 1.13-7).

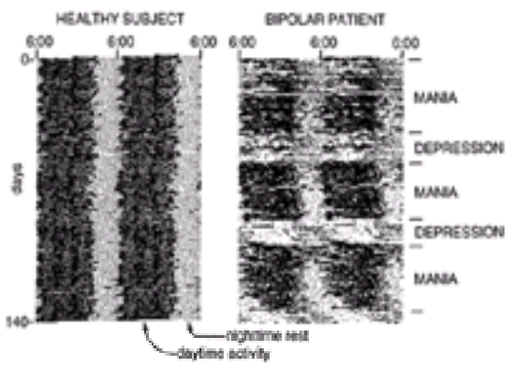

FIGURE 1.13-7 Longitudinal raster plots of wrist motor activity in a healthy individual **(left)** and in an individual with rapid cycling bipolar illness **(right)** (see description of format of plot in text). Activity levels are unchanging in the healthy individual, but change dramatically in the patient, as he switches back and forth between manic (dark areas) and depressive (light areas) phases of his illness. Changes in the timing of the activity-rest/sleep-wake cycle (phase-advanced in mania and phase-delayed in depression) and in the duration of rest and sleep (shorter in mania and longer in depression) can also be detected in the tracing. (Data from Wehr TA, Turner EH, Clark CH, Barker C, Leibenluft E: Treatment of a rapidly cycling bipolar patient by using extended bed rest and darkness to stabilize the timing and duration of sleep. Biol Psychiatry *43:*822, 1998.)

Portable electronic devices can be used to obtain similar motor activity recordings in patients with bipolar I disorder (Fig. 1.13-7). Such recordings provide a continuous, quantitative, and objective recording of the course of illness that reveals the longitudinal changes in the activity-rest and sleep-wake cycles that are such characteristic features of the disorder. A clinician becomes familiar with gestalt of the raster plot and can readily detect and monitor these features in the compressed and ordered display in which the data are presented. Recently, electronic wrist-activity recording devices that are small, light, and inconspicuous have become commercially available. These devices probably represent a methodological breakthrough for the clinical assessment of bipolar disorders. With their capacity to continuously and inexpensively monitor the course of illness, they could prove highly useful in diagnosis and in the evaluation of response to treatment.

SUGGESTED CROSS-REFERENCES

Sleep and the REM-non-REM sleep cycle are discussed in Section 1.19 on the basic science of sleep. The menstrual cycle and the neuroendocrine systems are discussed in Section 1.11 on psychoneuroendocrinology. Excitatory amino acids are discussed in Section 1.5 on amino acid neurotransmitters; neuropeptide Y is discussed in Section 1.6, and the serotonergic system is discussed in Section 1.4 on monoamine neurotransmitters. Textbook of Psychiatry

1.14 APPLIED ELECTROPHYSIOLOGY

EDWARD L. REILLY, M.D.

HISTORY AND OVERVIEW

Electrophysiological changes in biology are now taken for granted by the medical community but the first recognition that there was an electrical action potential in nerves was made by Dr. Du Bois-Reymond in 1848. The first report of electrical activity of the brain was made in August 1875 by Richard Caton, who recorded electrical activity from the brain of a rabbit and a monkey. It would be more than another 50 years before a relatively unknown psychiatrist in Jena, Germany, would record electrical activity from the brain of humans as seen from recordings from the skull surface. Hans Berger first wrote on the electroencephalogram (EEG) of man in 1929, but his work remained essentially unrecognized until the far better known Lord Adrian reported at several meetings in 1934 that Berger's work was to be taken seriously and that his “Berger rhythm” was not just artifact or noise.

Expected frequencies and standards of normal were developed in the 1930s and early 1940s. These standards as currently viewed were frequently overly rigid and led to a higher “abnormal” rate than such observation of normal range of variation yields now.

In some cases it took 20 or 30 years to make a decision as to whether infrequent patterns were indeed abnormal or merely rare. As one looks at patterns such as the 14 and 6 per second positive spike or the 6 per second spike and wave it is clear that this is not a debate that ends easily or with precision.

Alpha rhythm was defined, but its place in normalcy would remain debatable and many studies would be attempted to see whether or not the actual frequency in the alpha range correlated with some aspect of personality, neurosis, introversion, extroversion, intelligence, and other specific features. No replicated correlation was very robust.

Studies were made of normal groups and psychiatric patients or target populations on various features. Sometimes the trait of aggressiveness could be definable or viewed analytically even though observable behavior did not show this feature. In many of these studies various differences were found and correlations were made that other studies were unable to replicate.

Some of these early studies suggested that as much as 15 percent of a normal population had a nonspecific abnormal EEG. In the 1940s better screened, well-controlled populations were found to have a 5 percent nonspecific abnormality rate. Hospitalized psychiatric populations have a higher rate of abnormality (generally twice the rate of a control population) but no specific or consistent feature “identifies” a psychiatric patient, much less a particular diagnosis.

ELECTROPHYSIOLOGY

Reading an electrocardiogram (ECG) of heart action is entirely different from eading an EEG or brainwave test. This is also true for the ability to read sleep studies (polysomnograms), evoked potentials (EPs), or electromyograms (EMGs) (electrical activity generated by muscular activity).

Between the 1940s and the 1960s when there were very few neurologists, it was much more common for psychiatrists to know how to read an EEG, but they often did not perform or read EMGs. In the mid-1940s evoked potentials were recorded. Quantified EEGs are a much newer development, and research is being conducted by psychiatrists, neurologists, and Ph.D. recipients in a number of areas.

Some neurologists are skilled at reading EMGs, EEGs, evoked potentials, and polysomnograms, but not all neurologists can read EEGs. Neurologists are much more likely to have received training in electroencephalography than are psychiatrists, which gave rise to the perception that all neurologists could read EEGs and that all psychiatrists could not. From the 1950s to the 1970s the American Board of Psychiatry and Neurology (ABPN) did not wish to have further subspecialization and still refuses to qualify individuals in regard to a test rather than an area of skill.

The need to demonstrate training and skill in electroencephalography was so great that the American EEG Society in the 1950s developed an independent examination by a separate American Board of Qualification in EEG, now called the American Board of Clinical Neurophysiology, to demonstrate competency in reading EEGs. The exam requires understanding of EEG, EPs, polysomnography, and the basic science and clinical implications of these tests.

In 1972 the American Medical EEG Society, which is more clinically oriented, developed a separate Board to test competency in EEG reading skills. The American Board of EEG and Neurophysiology expects all readers to have an understanding of clinical EEGs and has added qualifications for those interested only in polysomnography, EPs, or quantitative EEG. In the author's opinion the latter Board probably meets the style of training and interest in both clinical practice and research for psychiatrists.

These two Boards, spin-offs from medical organizations that started them, are not sanctioned by the American Board of Medical Specialists (ABMS). Both Boards test candidates predominantly on central nervous system (CNS) electrophysiology. There are differences in the criteria and expectation of breadth of the ability to read CNS activity or more general neurophysiological activity between the two non-ABMS Boards.

In 1997 the American Board of Psychiatry and Neurology decided that neurophysiology did merit a special added qualification. The ABPN developed a written neurophysiology examination leading to an added qualification for candidates who have passed the American Board of Psychiatry and Neurology in either Psychiatry or Neurology. Very soon it will be open only to people who have taken a postgraduate 5th year fellowship in a Neurology program. The exam covers operating room neurophysiology, electromyography, polysomnography, evoked potentials, and EEG. The ABPN examination is a written exam only, and the candidates do not have to prove that they can actually interpret a record that they had never seen before nor do they have to defend how good or bad their readings are as is required in both the non-ABPN examinations.

In the author's opinion it was a mistake for the ABPN, which received little or no supervision from the chairs of psychiatry departments until after the decision was inevitable, to require a postgraduate 5th year of training as a fellow in a Neurology program in order to take the examination. Electrophysiology training leading to Board eligibility should be allowed in Psychiatry Accreditation Council for Graduate Medical Education (ACGME) programs.

ELECTROENCEPHALOGRAPHY

An EEG is a test producing an analog graph of very low voltage electrical activity produced by the brain as viewed from the surface of the skull. The value of EEG increases as the physician ordering and using it recognizes the strengths of the test and learns how to compensate for its weaknesses.

Many new tests are available to evaluate brain structure but EEG remains one of the very few objective tests of brain function. Mental status examination, EPs, positron emission tomography, single photon emission-computed tomography (SPECT), functional magnetic resonance imaging, and psychological tests are others,

but only the mental status examination is quicker than and as safely repeatable as the EEG.

The EEG is produced by cortical activity near the electrodes. Each wave is probably the cumulative result of the activity from 7 square centimeters of tissue. The waves are believed to be a reflection of the excitatory and inhibitory postsynaptic potentials in the dendrite portion of the neurons. The exact source and direction of spread of the measured activity remains controversial. The resultant activity recorded is dependent on the output of the surface gray matter, which is a layer of neurons varying in thickness from 1.5 to 4 mm.

To be reflected in the EEG, disturbance of function must occur or be reflected in the surface cortical neuronal activity. An early tumor or vascular disorder involving the cortex of the convexity of the cerebral hemispheres may cause clear EEG abnormality in the presence of slight clinical signs. A subcortical lesion such as a hemorrhage involving only the internal capsule may produce profound clinical change (dense hemiplegia) in the face of a normal or minimally disturbed EEG. EEG change is manifest early after stroke or trauma and usually subsides; computed tomography (CT) change may not be seen as early as EEG change.

Because the electrical signal is small and depends greatly on the application of the electrode, technique is a crucial issue in the reliability of the activity recorded. A year of training is recommended for the technologist and the interpreting electroencephalographer, but frequently this is not the case. A recent marketing campaign informs physicians that they and an employee can be trained in hours or days to use new and usually expensive equipment to run examinations that the untrained physician will then “read.”

The quality of EEG procedure varies greatly in different laboratories. The American EEG Society and the American Medical EEG Society have outlined minimum standards on EEG but well-defined higher expectations exist and should be used.

Recording

A. Position of Electrodes. The positions internationally recommended are those of the International 10/20 System as outlined by Jasper in 1958 (Fig. 1.14-1). Measurement is made from the front at the nasion to the inion (a ridge below the occipital portion of the skull), and electrode points are at 10 percent and then 20 percent intervals along the total distance, ending with another 10 percent jump in distance. A similar measurement across the coronal or transverse plane from the preauricular notch of each ear allows placement of mid-temporal and central electrodes. Measurement around the head along the 10 percent line locates the occipital, posterior temporal, anterior temporal, and frontal-polar electrodes. Filling in this system over the convexity of the hemisphere allows us to compare a chain of parasagittal electrodes and the midline electrodes to a chain over the temporal region on each side. Odd numbers are on the left and even numbers on the right. The letter refers to the area involved. *C* stands for *central* and the lateral central electrodes are over the central sulcus or Rolandic fissure. This places those two electrodes (C3 and C4) over the motor and sensory strip and on the anterior border of the parietal lobe and posterior border of the frontal lobe. Because the fissure also runs in a postero-superior direction, the midline central (vertex) electrode (CZ) is anterior to the central fissure

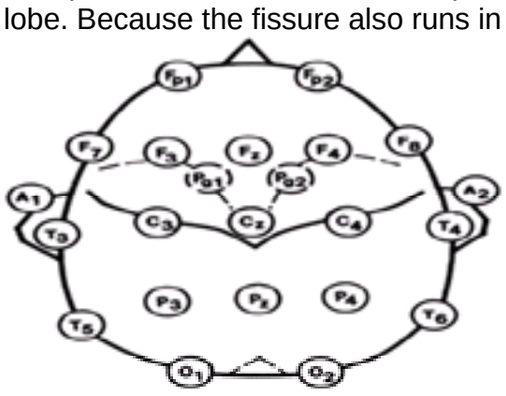

FIGURE 1.14-1 International 10/20 system.

The P3 and P4 electrodes are placed over the posterior parietal lobe. The middle and posterior temporal electrodes are not a source of confusion but the electrodes referred to as *F7* and *F8* (postero-inferior-frontal) are referred to clinically as *anterior temporal electrodes*. They are referenced as such because the activity recorded in abnormal records is generally reflected from the anterior temporal region in spite of the fact that the electrodes are placed over the posterior frontal lobe, which is rarely as active or abnormal as the temporal region.

The increasing use of computer-assisted evaluation of tests in quantified electroencephalography has led to more situations where a greater number of electrodes is believed to be useful. The Electrode Position Nomenclature Committee of the American EEG Society has developed a nomenclature for an expanded number of electrodes that they have designated as “modified combinatorial nomenclature” (Fig. 1.14-2). It will take some time for any standardization on how many additional electrodes will be used in particular tests, such as Fourier Transforms and digital EEGs. The development of the modified nomenclature provides a specific position and name for 75 electrodes that can be placed on the scalp.

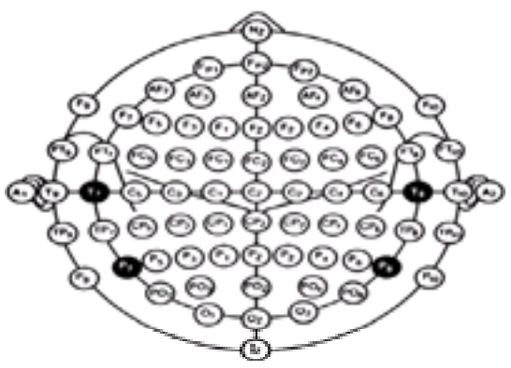

FIGURE 1.14-2 Modified Combinatorial Nomenclature. In this designation four electrode positions in black are given a new name. This system allows for 75 electrode placements clearly designated and defined. The T7 on the left and T8 is a change from the previous T3 and T4. The previous T5 and T6 in this nomenclature is P7 and P8.

For the moment, the use of more than the standard 21 electrodes in the 10/20 system will probably be more research oriented than routine, but that may change as the value of using additional positions becomes better understood.

B. Electrode Type. Cerebral activity is picked up from the skull with metal electrodes, several types of which are in general use.
   1. Disc—silver or gold. These can be attached with paste or glued in place with collodion. The first is removed with hard rubbing and the second with acetone.
   2. Needles—small platinum. These offer fast application but they fall out if the head is moved or sometimes just by their own weight. At one time these were the most commonly sold type of electrodes, but fewer are used now because of concern about the transmission of the human immunodeficiency virus (HIV).
   3. Special
      a. Nasopharyngeal—inserted in the nostril and closer to the temporal region than scalp electrodes. No actual penetration of tissue occurs.
      b. Sphenoidal—needles are inserted between the zygoma and the sigmoid notch until they come in contact with the base of the skull close to the foramen ovale. The needle insertion can reach unintended areas and produce complications. These electrodes are generally used only when surgery for seizure disorders is being considered.
      c. Cortical—surgical implantation of electrodes may involve a subdural grid of electrodes that can be left in place for several days or weeks for further study. Electrodes have been stereotactically planted at various locations in the depth of the brain. Again such surgical involvement most commonly is related to seizure disorder patients who may require surgery for intractable seizures.

C. Record. The EEG machine compares the difference in electrical voltage and amplitude between electrodes; clinical machines do not measure absolute values at a single electrode. Newer computer methods attempt to calculate such absolute value at individual electrodes with an attempt to get a reference-free estimate of activity at each electrode.

Each laboratory sets up patterns of electrodes in runs that are called *montages* (Fig. 1.14-3). These let the reader see activity from different areas of the cortex. Rarely is actual abnormal activity specific to a single electrode.

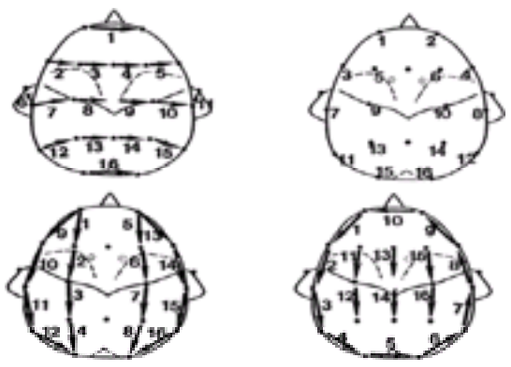

FIGURE 1.14-3 These are four common montages for 16 channel machines. The upper left is considered a “coronal” montage, which is especially useful in seeing subtle temporal asymmetries. The upper right montage is referential, generally done either to ipsilateral ears or linked ears or run to the vertex electrode. When run in left-right pairs, as in this diagram, subtle differences in the same electrode on each side of the head are evident. At lower left a longitudinal montage gives the reader an excellent view of the left and right parasagittal chain of electrodes and compares left and right temporal regional differences. The lower right montage covers the circumference of the head and simultaneously covers the parasagittal electrodes. It is particularly useful in seeing temporal and occipital asymmetries differences while not losing sight of the overall surface activity.

The page of EEG seen in most laboratories moves at 30 mm a second and has dark lines at 1-second intervals and light lines every 200 mm. The wave height indicates the µV involved. The number of μV per mm of pen deflection depends on the setting of the amplifier. The reader cannot identify the amplification unless the record is marked in some way. In most laboratories the letter “S” stands for sensitivity and the number following it indicates the μV per mm. Thus, a small number indicates that it takes fewer microvolts to move the pen one mm. The smallest numbers indicate the highest amplification. Normally, S7 is used to indicate 7 μV per mm but the machine can reach S1 or if needed, as in a “cerebral inactivity” recording, one may make the pen move 1 mm for a 0.5 μV response with S0.5 μV per mm as the amplification.

D. Recording Features. The components of value in an EEG record are:
   1. Frequency (mainly 0.5 cps and 40 cps)
   2. Symmetry
   3. Amplitude (recorded in μV—usually less than 100 μV)
   4. Distribution
   5. Reactivity
   6. Specific patterns

Most abnormal records have some variation in the first four features.

Frequency is the single most important feature of the listed variables.

Electroencephalographers use a shorthand for frequency bands.

Alpha (8 to 13 cps waves over the posterior regions with the patient awake but relaxed with eyes closed)

Beta (any rhythm over 13 cps)

Theta (waves 4 cps to under 8 cps)

Delta (less than 4 cps)

Alpha waves are the most common normal dominant activity in awake adults. Children have slower posterior dominant activity until 7 to 9 years of age, and continue to have slower activity mixed with alpha waves into the early 20s. Alpha waves are the dominant activity in 95 percent of normal adults in the awake resting state.

If the patient is asleep, concentrating, or even focusing with eyes open, alpha activity is absent or at least attenuated.

Beta activity is identified as 14 cps or more. Five percent of normal adults have beta activity as their dominant posterior frequency; it may be widespread, especially if drug induced, in which case it occurs with highest voltage anteriorly. A number of medications can add beta activity to an EEG. In particular, meprobamate (Equanil, Miltown), chlordiazepoxide (Librium), diazepam (Valium), flurazepam (Dalmane), and barbiturates do this. Drug-induced beta activity can turn a search for small spikes into a difficult task.

Theta waves refer to activity from 4 cps to less than 8 cps. Such activity is seen in limited amounts in normal awake adults, especially in the temporal and central region, but becomes more evident in drowsiness. In children under 8 years of age, theta activity is often the posterior dominant frequency.

Delta waves have a frequency less than 4 cps. Delta waves are seen normally in adults only in sleep but occur in a variety of disease states. Delta waves may be from a limited area or “focus.” Focal delta waves in an adult raises the possibility of a destructive process. Such destruction could result from any one of many causes such as infarction, hemorrhage, embolism, tumor, or abscess. All these causes may produce similar EEG changes, but the presence of a focus can be sufficient confirmation to be helpful in considering further, more expensive, and often more invasive testing.

The most common abnormality is slowing of the dominant posterior frequency. In diffuse disease, the frequency of activity slows over the entire brain. (Fig. 1.14-4); in a focal destructive process, the slowing is often localized or lateralized (Fig. 1.14-5).

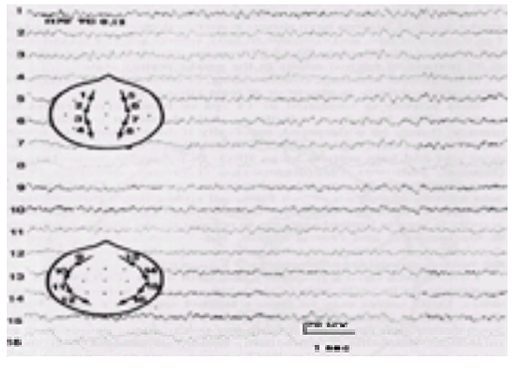

FIGURE 1.14-4 This is a record that is symmetrical but the dominant posterior activity is below normal limits. This is one of the most common abnormalities in EEG and is particularly seen in toxic or metabolic processes or CNS degenerative diseases.

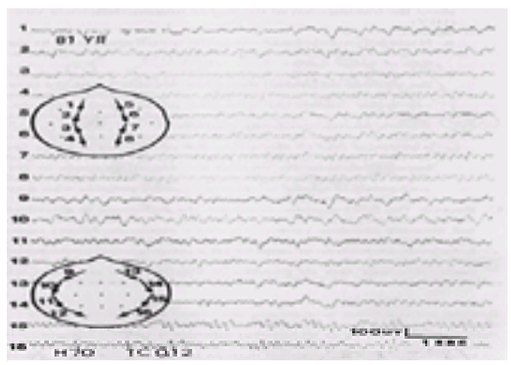

FIGURE 1.14-5 This woman had an infarction and in channels 1 and 2 higher-voltage delta waves are evident from the frontal central region than from the comparable area in channels 5 and 6 on the right. Similarly, there is delta activity from the left anterior temporal region reflected in channels 9, 10, and 11 with higher voltage and persistence than is seen on the right. This record is showing a lateralized abnormality maximal in the left anterior quandrant.

In an area of damaged cortical tissue the slow activity may be constant. If it recurs intermittently with normal activity seen between bursts, it raises the possibility of a subcortical source. As used in EEG, *subcortical* begins below the surface 4 mm of gray matter and extends caudally to the medulla. The EEG reader cannot define the subcortical distance because all activity seen is cortical but may be modified by different subcortical influences. The activity seen is compared with activity expected for the level of consciousness at the time of the EEG; there is a great difference between waking and sleeping activity.

Clinically, sleep is important as an activator of potential abnormalities, especially those seen in patients who have seizures. A great many individuals will show abnormality in sleep but not in the awake record. The abnormality most sensitive to sleep activation is epileptiform activity. *Epileptiform* means “the activity seen is similar to patterns observed between or during seizures in patients who have epilepsy” (Fig. 1.14-6). This type of activity is seen in a high percentage of patients with seizures and a very low percentage of normal individuals. The evaluation of a patient with possible seizures is not complete without sleep activation as well as awake recording.

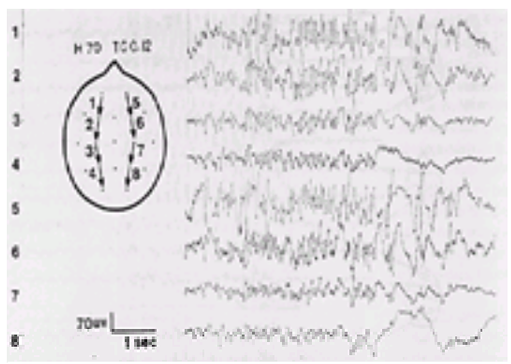

FIGURE 1.14-6 A sleeping patient develops bilaterally synchronous multiple-spike discharges developing over a 4-second period. The multiple spikes are what are seen in the tonic phase of a seizure and alternating spike and slow waves are what are seen in the clonic phase. This very short burst in a patient with such seizures was short and this is only epileptiform activity with no actual seizure and no motion occurring. Actual seizures are associated with a good deal of muscle artifact and the pattern is not as clearly readable during a clinical seizure.

Some reports imply that sleep deprivation is a better activator, but a well-controlled study suggests that recording sleep (natural or from sedation) rather than sleep deprivation is the important factor.

Epileptiform activity generally reflects cerebral irritative processes but does not have a one-to-one correlation with clinical epilepsy or seizures. The absence of epileptiform activity does not mean a patient does not have epilepsy. Persons with epilepsy show epileptiform activity in 50 to 60 percent of initial EEGs if sleep is recorded, and less if it is not. Serial records will demonstrate epileptiform activity in at least one record in 80 to 98 percent of seizure patients, depending on seizure type and if repeated testing is spread over a year or more. Special electrodes (such as nasopharyngeal electrodes for temporal lobe epilepsy) or reduction of anticonvulsant medication may be necessary to demonstrate epileptiform activity.

There are other ways to activate the EEG besides sleep. The two most common in routine testing are hyperventilation and photic stimulation. *Hyperventilation* consists of asking the patient to breathe rapidly with mouth open for a 3-minute period and then to breathe normally. Hyperventilation may stress the brain function just sufficiently to demonstrate a lateralized change or in children with an absence seizure may actually provoke a seizure with its characteristic changes in the record (Fig. 1.14-7).

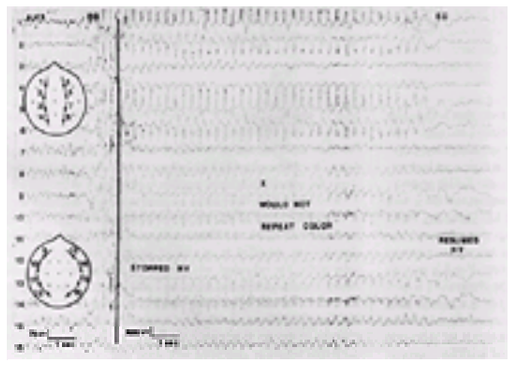

FIGURE 1.14-7 The slide begins with a patient hyperventilating with eyes closed. As the epileptiform burst begins, the patient's eyes open without command. There is increased voltage and amplification is rapidly decreased so it takes 200 μV, not 75 μV to move the pen 1 cm. The patient does not respond to the command. When the burst ends, the patient's eyes close and the patient begins hyperventilating again without command. This is a clinical absence seizure documented by EEG.

Photic stimulation similarly can provoke normal “driving” responses where the occipital dominant activity matches or is a harmonic of the frequencies. Flashes may provoke muscle responses, which are rare but not abnormal, or epileptiform discharges, which if prolonged beyond the flash tend to strongly indicate the possibility

that the patient has a potential for seizures and in most instances has a history of seizures (Fig. 1.14-8).

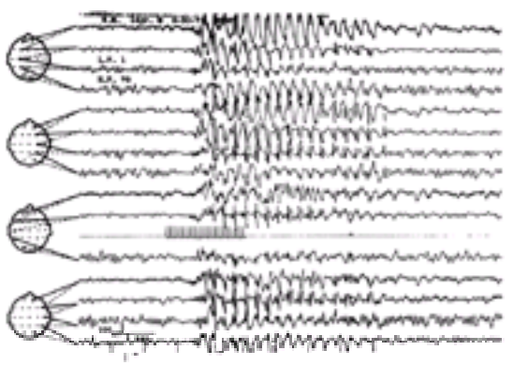

FIGURE 1.14-8 This is a patient with a paroxysmal response to flashes at a different rate than the flash rate. When the flash stops, the paroxysmal activity continues. Prolonged paroxysmal response to photic stimulation beyond the flash is highly correlated with seizure disorder but can be seen before the first spontaneous seizure in some patients.

Since the EEG is a reflection of function, it can change from day to day and at times from hour to hour. Serial tracings assist in sorting out the picture. Diffuse processes such as encephalopathies may show focal areas of slow activity superimposed on diffuse slow activity. Such lateralization raises the question of focal problems but in these patients the asymmetry is not consistent and it usually changes from record to record and day to day if it is really a diffuse process.

The basic posterior dominant frequencies tend to show a trend toward or away from normalization that is helpful in judgment about effectiveness of therapy.

Abnormality may be:

Diffuse—suggesting a process that involves the entire cortex or perhaps the thalamus or brainstem as suggested by “bilateral simultaneous slow waves anteriorly.” Only cortex activity is being recorded but bilateral symmetry suggests it is driven from subcortical sites (Fig. 1.14-9).

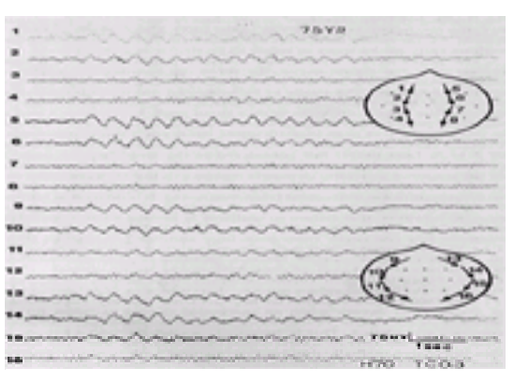

FIGURE 1.14-9 This record demonstrates bilaterally synchronous frontal central trains of 21/2- to 3-second delta activity referred to as *frontal intermittent rhythmic delta activity* (FIRDA). This synchronous activity in an awake individual raises the possibility of the involvement of deep midline structures somewhere from the medulla to the thalamus.

Focal—the majority of times the EEG can lateralize a focal process to a hemisphere. Often it can be further localized.

a. Quadrants—a lesion may involve the anterior or posterior half of one hemisphere and the lesion will be reported as maximal in a particular quadrant.
b. Temporal—parasagittal distinctions. Most often the temporal area reflects abnormality more than the parasagittal area. As a result it becomes necessary to weigh minor parasagittal changes heavily to compensate for this tendency of the temporal area to seem more involved.

Structural lesions have more stable asymmetries that persist in the same location; they may be increasing in serial records. An example of the latter would be an abscess that becomes more evident in serial records.

Another source of generally progressive focal change are tumors, but changes can be masked with treatments such as steroids. Tumors often show focal slowing. The abnormalities in the EEG cannot be distinguished in any definitive way from the changes from focal vascular problems. As a class, however, tumors are more apt to have sharp waves or spikes mixed with the slow activity than are vascular diseases (15 percent of tumor patients have seizures and only 7 percent of cases of even acute cerebral vascular accidents have them). Often the first EEG record, CT scan, and initial brain scan is abnormal in patients who have tumors. After 2 weeks the EEG is generally (but not always) worse or not improved in contrast to what is seen in patients with vascular disorders where the EEG generally shows a rapid trend toward improvement and perhaps normalization.

The EEG is immediately at its worst after a thrombosis or hemorrhage. It generally shows improvement with time. Possibly normalization will occur in a 2- to 6-week period. The abnormality is most often focal slow waves, which may be evident early at a point when the CT scan and brain scan results are still normal. In a day or so the CT scan and by 10 days or 2 weeks, a brain scan is apt to become abnormal and the EEG will already be improved. It is easy to suggest a vascular cause for any focal change in an adult population. It is better for the EEG reader to provide the characteristics and changes of the record and let a clinician knowledgeable in such subtle changes compare them to the clinical findings.

INITIAL USE OF EEG

It was recognized early in the recording of EEG that the patterns changed when patients went to sleep. The first classification of sleep was first suggested in 1937. In 1953 researchers noted periods of rapid eye movements, which were soon referred to as *REM*. It is when this activity is present that an individual experiences dream activity. Arousal during REM is usually associated with an awareness of the dream content but if the REM period is not interrupted, the dream will not be remembered later. Individuals who have been asked by their therapist to report dream activity and write down the dream as soon as they wake up often find that they wake up during dreams more frequently. They also find that they may not remember the dream content in the morning until they refer to their notes. Following the identification of this stage, much work was done on issues related to REM sleep versus non-REM (NREM) sleep. At one point there was some concern that lack of REM sleep might in fact provoke psychotic behavior. But those early suggestions were not replicated, and it is recognized that a number of medications can eliminate REM and not be associated with ill effects. Stages 3 and 4 sleep are characterized by high-voltage delta activity and these two stages are sometimes lumped together as *slow-wave sleep*.

Specialized sleep laboratories are used to identify disorders such as narcolepsy, sleep apnea, and nocturnal myoclonus (periodic leg movements of sleep). In 1986 an entity called *REM sleep behavior disorder* was identified as an unusual situation occurring often in older adults. The individual, while dreaming, does not have the usual loss of muscle activity and therefore could and often does act out the dream with activity involving jumping, pushing, hitting, or kicking. Sleep laboratories identify these syndromes and can then suggest effective treatments to minimize the loss of rest and the sometimes dangerous behaviors associated with some sleep

syndromes.

Sleep research is being done to compare medication effects in double-blind studies of long-term use of various treatments. Nortriptyline (Pamelor) used at maintenance doses in elderly patients with depression demonstrated increased REM activity generation and increase delta-wave production in the first NREM period of the night when compared to patients on placebo. It has become apparent that even antidepressant medications in the same class may have different effects on the sleep pattern. Better understanding and awareness of these differences will be useful in drug selection in the future.

In addition to laboratories designed to look at “disturbed sleep patterns,” there are laboratories designed to record ongoing EEG activity in the awake and sleep state as part of the investigation of epileptiform activity. More importantly, attempting to get better localization of the onset of actual clinical seizures. These laboratories tend to be distinct from the typical sleep laboratory, but a 24-hour EEG monitoring may be done in these specialized departments.

EVOKED POTENTIALS: BRAIN RESPONSES TO SPECIFIC STIMULI

Localization and lateralization are important aims of structural tests such as CT scanning and functional tests such as the EEG and psychological tests. Development of localizing and lateralizing techniques that are noninvasive, independent of patient cooperation, and specific as to location as well as cause has been a goal, but for electrophysiology this is only minimally realized.

The measurement of electricity from the surface of the skull provides a large array of ongoing activity of very low voltage. Buried under that already low-voltage signal there are some additional changes of extremely low voltage that can be demonstrated to occur in a very time-related fashion after a specific external or internal stimulus. The evoked potential after such a stimulus meets some localization goals. The response to a specific stimulus is called an *evoked response* (ER), an EP, or an *event-related potential* (ERP). The latter has a longer latency and is influenced more by level of arousal and medication than the shorter-latency ER or EP responses. The evoked potential is an attempt to separate specific reactions of the CNS to a stimulus from ongoing nonstimulus-related EEG activity. If one samples regularly from EEG and averages each time epoch recording, there is as much chance that the EEG wave will go up as down at any point in the epoch because EEG is a random wave form; it will average out to a flat line or 0. If the samples are not random but triggered by a stimuli, the event following and repeating each stimulus may stand out from the larger EEG signal, which averages out. Recently the increased degree of computer sophistication to average out some of these responses has made it possible to record these events easily. Newer methods have provided recordings as clinically relevant modalities. An EEG tends to be 30 to 60 μV, and the small evoked potentials are in the 0.1 to 0.5 μV range. Taken in the perspective that less than 2 μV of electricity was taken 20 years ago as the level suggesting no brain function or brain death because machine limits were reached, better amplification and artifact reduction was needed to demonstrate these responses. The measurement of this tiny activity is much easier to demonstrate with computers that average many responses, better amplifiers, and better techniques to avoid artifact.

The EEG depends on surface cortical activity, but the evoked potential can demonstrate transmission time through the brainstem with the *brainstem auditory evoked potential* (BAER) and the *somatosensory evoked potential* (SEP). Transmission through hemisphere pathways is measured by the *pattern reversal visual evoked potential* (PRVEP). Thus, EEGs that measure only surface function and the changes following stimulation, sleep, arousal, or drug effect can be complemented by an accurate measurement of the transmission time, and the consistency of the response to a specific sensory stimulus.

There are three major stimuli being used in the clinical electrophysiology setting.

1. pattern—reversal of a checkerboard—VEP (PRVEP)
2. click stimulus by earphone—BAER
3. electrical stimulation of the median nerve—SEP

These tests provide a measure of functional integrity or lack of it in situations where documentation often has been lacking in the past. Patients with multiple sclerosis display delayed transmission because of myelin loss, and the visual EP may show prolonged latency even in the absence of visual complaints; other causes affect these potentials as well.

There is a great rush to sell “easy, foolproof” equipment. Some of the machines are so good that they are easily and reliably operated, but no machine is immune to the “garbage in, garbage out” rule. If the data are bad, the most skilled reader is blind.

A basic problem is that the responses change with each variation of stimulus or equipment setting. The visual evoked potential with bright flashes to closed eyes is more complex and less reproducible than the pattern-reversal visual response, which is simpler in its shape and more replicable in repeat collections. This does not mean that the flash response is useless, but the sparse plain response to pattern reversal is easier to quantify as normal or abnormal (Fig. 1.14-10). It is valuable in clinical use, and standard deviations from normal by age exist.

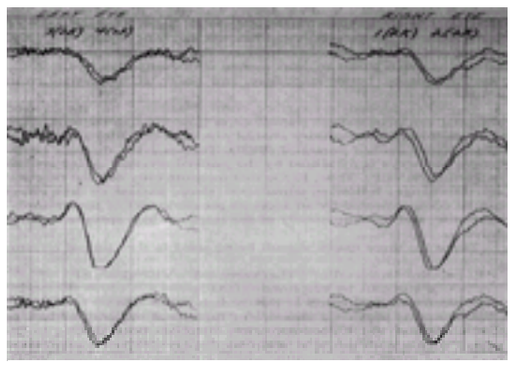

FIGURE 1.14-10 This is a visual evoked response to pattern reversal of a checkerboard. Notice that there are two lines in that the series of stimuli were given twice to each eye to see if the waves reproduced. The reproducibility is excellent and the latencies in this evoked potential are normal. The total field seen is 200 ms.

After the introduction of PRVEPs, the next clinically useful EP followed the observation that very early responses to clicks had identifiable waves that corresponded with anatomical generators in the auditory pathway. The response is suitable for measurement of brainstem function even more than it is a measure of hearing. This modality brought new terminology into the language. The visual EP is clearly dependent on the cortex underneath the electrode. Visual EPs in the midline occipital region are often different from lateral electrodes both in wave form and amplitudes, although not necessarily in latency. The cortex-dependent responses are “near field” and most responses 60 ms or more after a stimulus are near field, depending on the effect on the cortex under the electrode.

In contrast, the response averaged in the first 10 ms after auditory clicks is similar when recorded from almost any cortical location. The peaks are generated from sources so far from the cortex that they are equally far from all the electrodes and these are “far field” potentials. Far field potentials are short in latency and more reproducible than long latency responses. The BAER is much less sensitive to change from level of consciousness or drug effect. At the extreme, the BAER has been preserved in overdose situations severe enough to cause electrocerebral inactivity in the EEG. The anatomical correlations are far better than with the near field potentials in that the various early peaks seem to relate to particular brainstem areas.

The peaks in the BAER that are most replicable are the one representing the eighth nerve, the three representing the superior olivary level of the pons, and the five representing the inferior colliculus in midbrain. The peaks to be measured are those on the side stimulated. Because of cancellation effects, the wave referenced to the opposite side is different with a small peak 1 and peak 3 and a separated peak 4 and 5 (Fig. 1.14-11). The opposite response is useful to record to help in peak identification, but is not actually measured. Items of value are the latency between peak 1 and 3, and the latency of 3 to 5. Less useful but considered is the amplitude of peak 5 compared to peak 1. Reproducibility is critical. The significance of the response generally demands reproducibility between separate collections. Movement distorts the waves as does muscle activity without significant movement (clenched teeth). It follows that failure to replicate raises the possibility of significant artifact. It is not proven, however, that failure to replicate is always artifact; patients with stable early components followed by variability of later peaks suggests this can occur from pathology and not just artifact (Fig. 1.14-12). Differentiation is difficult, and extreme care must be taken to attempt to get records of relaxed, motionless patients.

Sedation may be necessary. Level of consciousness is not as critical as for EEG and long-latency EP because sedation effect does not change the BAER wave. Normal values must be determined in each laboratory.

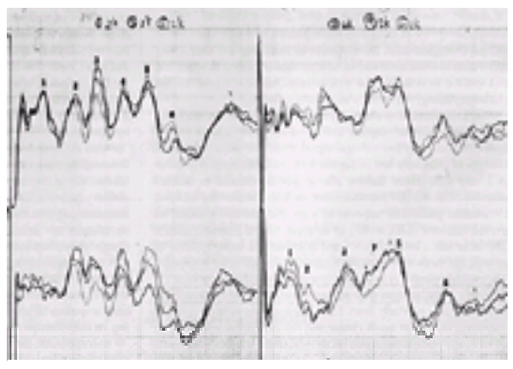

FIGURE 1.14-11 A brainstem auditory evoked potential (BAER). The top line is recorded from the side where the clicks occurred and the bottom line is from the opposite side of the head. The AER is a far-field response. The waves measured are on the side where the clicks occurred and the other side is used to help identify peak 1 and peaks 4 and 5, which look different on the two sides. Recording both sides makes peaks more easily identifiable. The recording is of the 10 ms after the clicks.

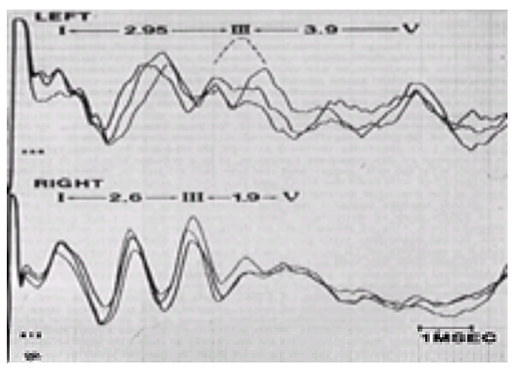

FIGURE 1.14-12 Abnormal BAER on one side. On one side there is a variable response. The early components replicate but the variability of later peaks is abnormal and the latency from peak 3 to peak 5 is prolonged compared to the right where reproducible waves occur at normal latency.

The P300 commonly used EP in psychiatric research populations is a wave that occurs when an individual is told to listen for or look for an infrequent stimuli mixed in with a much more frequent common stimulation. This is frequently a click or tone when done with sounds and may be a different symbol or visual cue. The attention to the rare oddball stimulus is associated with a widely distributed wave occurring about 300 ms after the stimulus. In alert attentive individuals, this is a bigger and earlier wave form than is seen in the populations that are less alert or not really interested. Testing for this particular wave has been done to assess for mental function as well as to test for interest and attention.

There is preliminary work that suggests that the P300 may have reduced amplitude in some patients with schizophrenia and seems to be associated with structural abnormality in the medial temporal lobe.

In a group of medication-free men with chronic alcohol dependence as compared to a control group, there was reduction in the P300 amplitude that may reflect a deficiency in an inhibitory mechanism that may underlie P300 generation.

In special instances, the following more limited and sometimes more controversial stimuli may be used:

1. tones at various frequencies (audiology)
2. electrical stimulation of peroneal and tibial nerves
3. visual stimulation with flashes, hemifields, or different colors.

There are major technical differences in machines and in the way responses are recorded. Machines designed by engineers tend to put positive up; EEG uses negative up. Both engineers and neurophysiologists put positive up in some specific instances. The BAER is usually positive up because the latencies used relate to the surface positive peaks.

The presence and absence of similar components that do or do not cancel is a major factor in what is displayed. Technique includes decisions about filters. A move from one high filter (eliminates higher-frequency activity from analysis) to another can cause a shift of several milliseconds in the apparent latency of evoked potentials.

Terminology may name a peak by its sequence or by its expected latency. As latencies change, it is difficult to identify the particular peaks and this remains a major problem at times in interpretation of long latency near field responses.

The P300 wave has been studied in many psychiatric and organically afflicted patients. Because of its long latency, it can be considered an ERP. The response is effected by incentive, significance of the stimulus, and other factors but can be recorded even in infancy (Fig. 1.14-13).

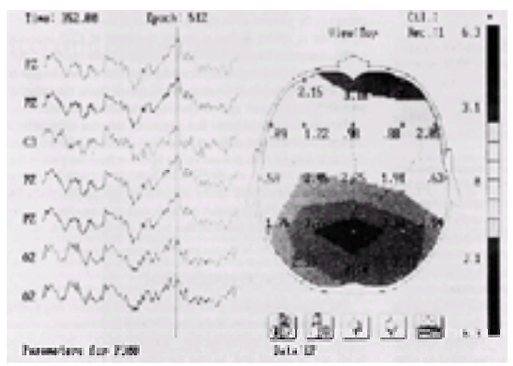

FIGURE 1.14-13 Brain map of the P300 peak. To the left is the evoked potential, to the right a map at the msec where a line is drawn on the potential. The p300 response to an oddball signal is fairly symmetrical and widespread. To read an evoked potentials look at the evoked potential to the left, it is not necessary to have a map. The map gives the viewer an idea of what is going on over the entire head and not just at the recording electrodes but it can be deceptive because it is a particular millisecond view of what is going on over 200 to 600 ms. Moving back 10 ms or forward 10 ms and the picture may change considerably; laterality can change a little bit. The skill of the person picking the point for the illustration is crucial in determining clinical accuracy or error.

Latency is prolonged in patients with dementia but amplitude changes are suggested in uninterested, depressive, and alcoholic patients. It is still of greater research than clinical value, but a useful tool.

MEDICATION

Medication changes in the EEG have been measured for many years, and some of the first computer analysis of drug effects on EEG by the early computers was done with ‘period analysis.' This methodology measured baseline crossings. The actual wave (how high it went, how fast it went, and whether it was pointed at the top or not) was not measured but a baseline of the EEG was determined for the electrical activity. Each time a wave passed above or below that baseline, a notation was made. With this period analysis computer methodology, changes were made before and after drug administration. This method used far less computer energy and memory than is now available. The methodology looked only at frequency change and yet was able to provide signatures of the effect an antidepressant drug had on the EEG as opposed to the effect of an antianxiety drug. By current standards this is a rather simplistic methodology, but it allowed drug companies to look at changes in the EEG in test animals and to identify potential antidepressants and antianxiety drugs to screen further. This EEG screening of drug effects on the brain by period analysis helped to enlarge the role of EEG in psychiatry. Period analysis suggested that changes in the electrophysiology of the cortex in response to drugs was of value.

Using a single-dose drug effect and looking at EEG changes to determine whether to use the medication or try another has not really been proven to be of significant value in clinical practice. Robust evidence that this can be done with a high enough sensitivity (the percentage of people with the disease who are so identified by the test) plus sufficient specificity (the percentage of people free of the disease to be so identified by the test) to be clinically useful does not yet exist.

However, some prediction can be achieved. The attempts to predict response to treatment, whether it be to medication or to cognitive therapy or to any other kind of therapy, certainly need to be continued as a source of interest and study. It is possible that in the future electrophysiological changes may prove to be helpful in determining whether a psychopharmacological drug that is known not to show significant clinical effect for 10 days to 2 weeks or 6 weeks is likely to be effective.

QUANTITATIVE OR COMPUTERIZED ELECTROENCEPHALOGRAPHY

The term “quantitative EEG” is generic and is probably currently the best term to apply to a wide range of analysis of EEG. Some of this analysis such as fourier transforms and spatial analysis has been conducted for several years but is now accomplished faster and for more patients by advanced computer analysis and digital recording so it is more cheaply available for the study of EEG and evoked potentials.

Some of the early studies were conducted without computers and with much more laborious quantifications on small numbers of patients. Much of that work was called *topographical mapping*. Currently, quantitative EEG includes evoked potentials analysis, spectral analysis, fourier transforms, digital EEG, discriminant function analysis, and other entities. Some of the changes in this part of the field are the result of technological changes in collecting data plus changes related to computer analysis of the recorded data.

Some mapping data is merely recording data that was available in the EEG since the 1930s, but such data is displayed as a color picture like a weather map. The latter is useful, probably accurate, but leaves the naive viewer in a position to misinterpret or to overvalue the changes if the display makes the changes look more important than they really are. Some early color maps were deceptive because the color changes were so abrupt as to appear more significant than the change between bands really represented. Some companies advertising their machines encourage psychiatrists in particular to use the responses as a way to make psychiatric diagnosis. These companies should warn physicians that they are required to have a fairly significant understanding of electroencephalography and be able to review the EEG and not just the printed map or discriminate function.

The misuse of quantitative EEG for unnecessary billing, or the misuse of discriminate function as a screen rather than a way to separate two carefully defined groups should not be interpreted as a weakness of discriminate function. It is a rebuke leveled at practitioners who do not understand the test and its limits. Assuming that a technician will read the EEG and that the psychiatrist only needs to look at the machine output is not good medicine or good psychiatry.

Some studies suggest that the combination of quantitative EEG and ERPs may contribute to better discrimination in schizophrenia populations. Use of these tests to differentiate between schizophrenia, mood disorders with psychotic features, and controls presently has a sensitivity of 78 percent and a specificity of 85 percent, which is encouraging but still not definitive in a clinical population. With additional components perhaps better sensitivity and specificity can be reached in some psychiatric populations.

While digital recording of EEG lends itself as a first step for further analysis in a variety of ways, digital EEG recording may be of value to a practitioner who wishes to use it for no purpose other than reading standard EEGs. With adequate size and detail from the monitor screen, the record can be recorded at one site and stored in nonpaper form such as on an optical disc. It can be read at another site either at the time recorded or some later date. Once the record is digitized, other manipulations such as montage change are available.

As psychiatrists become more knowledgeable about the strengths and limitations of these tests and the interpretation of them, quantitative EEG will add to the evaluation of psychiatric patients, but as yet it is not likely to determine an Axis I or Axis II diagnosis; it has been known for years that an EEG may suggest an Axis III component.

It is becoming apparent that the very sophisticated analysis of EEG changes in frequency where there is only medication or state change of the patient can be used much more in some patient populations than in others. Before a fourier transform of EEG becomes useful, it requires totally artifact-free recording of the cerebral activity. Chewing movement, eyeblink, and drowsiness all must be absent from the EEG that is to be interpreted, which limits the value of such tests in confused, agitated, heavily medicated patients.

Psychiatrists should know that a patient's behavior changes with different illnesses and different phases of emotional disturbances. Research designs must demand only a behavior from the patient that is reasonable for each emotional state. Inability to control a patient in the test situation may render an excellent test inappropriate for certain patients. The physician ordering such tests in clinical or research situations must consider that before any testing is done.

MAGNETOENCEPHALOGRAM

The magnetoencephalogram measures ionic currents originating from biochemical sources at the cellular level in the central nervous system. Instead of measuring the “electric fields,” the magnetic fields are measured and, as was the case with EEGs in the early years, there are technical problems. Sufficiently sensitive transducers were not available until the late 1960s. Present-day equipment and techniques do not draw great clinical utilization and may not do so until a number of questions are answered.

In the early 1970s a superconducting quantum interference device (SQUID) was developed that avoided the use of any electric reference and led to more rapid development. In the early 1990s there were only about 50 laboratories with magnetoencephalography capability and 24 channel magnetometers were in use. Helmets that cover the whole head involving as many as 122 channels are being developed and possibly as many as 150 channels could be used to cover the whole cortex in the not-too-distant future. The strengths of magnetoencephalography are:

1. Magnetoencephalography appears to be a better way to find the precise source of a response to stimulus or the cortical activating area provoking some sort of change.
2. Magnetoencephalography evaluations help to better demonstrate the origin of some of the electroencephalographic activity than can be determined by an EEG from the surface of the skull.
3. Some patterns may be specific to magnetoencephalography and are not seen in the EEG or at least are seen quite differently.
4. At present the clinical value of magnetoencephalography is relatively limited but its research value appears to be unlimited.
5. The greater accuracy in identifying source is going to make magnetoencephalography a major advance in identifying specific areas and in separating areas of

function such as speech that are near an area that needs to be excised because it is a seizure focus.

The so-called inverse problem is one particular area where magnetoencephalography seems to have a definite advantage over electroencephalography. It is crucial to find the intercranial sources of potentials recorded at the scalp and particularly to be able to relate them to particular neural generators and neural events. Magnetoencephalography techniques seem to be more accurate at finding the source on the cortex that is affected by a particular stimulus response or motor event. This alone makes this modality a significant and major tool to demonstrate true cortical response areas for sensory and motor events.

Magnetoencephalography is not yet a great threat to the usual clinical EEG recording because of the former's cost and limited availability, but it certainly offers the potential for greater localization when properly applied to research and clinical situations.

SUGGESTED CROSS-REFERENCES

Basic electrophysiology is discussed in Section 1.9, and Section 2.3 is on the neuropsychiatric aspects of epilepsy. Section 7.7 is on medical assessment and laboratory testing in psychiatry. Chapter 10 discusses delirium, dementia, and amnestic and other cognitive disorders and mental disorders due to a general medical condition.

1.15 PRINCIPLES OF NEUROIMAGING: RADIOTRACER TECHNIQUES

ROBERT T. MALISON, M.D., AND ROBERT B. INNIS, M.D., Ph.D.

Neuroimaging methodologies allow measurement of the structure, function, and chemistry of the living human brain. Although some of the methods such as structural magnetic resonance imaging (MRI) have been a standard component of the clinical assessment of patients with neurological disorders for more than a decade, similar applications have not yet been found for patients with psychiatric disorders; any methods are largely restricted to research studies. However, following the path established in neurology, neuroimaging of psychiatric disorders can be expected to have a similarly useful clinical application in psychiatry. In addition to the potential clinical applicability of neuroimaging, the current attraction of these methods in psychiatry is based on very promising results from all the methods described in this chapter to examine the physiology of healthy subjects and the pathophysiology of patients with psychiatric illnesses. These relatively recent studies, the vast majority of which have been performed since the late 1980s, have demonstrated that reliable measurements are feasible and that selection of the appropriate target parameters will provide key information on the pathophysiology of psychiatric illnesses. Such information may be useful for diagnosing and monitoring the illness and for developing new treatments. Neuroimaging is also attractive to the field of psychiatry because it provides direct measurements of the brain and thereby bypasses the limitations of peripheral measures (e.g., concentrations of plasma hormones or urinary catecholamine metabolites), which generate only indirect assessments of central nervous system function.

The two radiotracer methods of neuroimaging, positron emission tomography (PET) and single photon emission computed tomography (SPECT) entail the injection of radioactively labeled drugs. The imaging and measurement over time of the distribution of these radiotracers is used to assess the neurochemistry, blood flow, or metabolism of the brain. The three methods based on nuclear magnetic resonance are MRI, functional MRI, (fMRI), and magnetic resonance spectroscopy (MRS). In general terms, MRI provides exquisitely detailed images of brain structure; fMRI provides images of local neuronal activity with high spatial and temporal resolution; and MRS provides measurements of the concentrations of numerous chemicals in the brain without the radiation exposure of PET and SPECT but with much lower sensitivity.

BASIC PRINCIPLES

In PET and SPECT a biological process of interest is studied by synthetically incorporating a radionuclide into a molecule of known physiological relevance. The so-called radiopharmaceutical is then administered to a patient either by inhalation, ingestion, or most commonly by intravenous injection. As radioactivity distributes within the subject, the radiotracer's uptake into the brain is measured over time and is used to obtain information about the physiological process of interest. Because of the high-energy (g-ray) emissions of the specific isotopes employed and the sensitivity and sophistication of the instruments used to detect them, the two-dimensional distribution of radioactivity within a brain slice may be inferred from information obtained outside the head. For this reason, PET and SPECT are referred to as *emission tomographic* (from the Greek *tomos* for *cut*) *techniques*. In contrast to more conventional radiographic methods, like a chest X-ray, where an external source of radiation merely casts a shadow of the body's organs and cavities onto a planar film, PET and SPECT rely on more sophisticated principles to produce three-dimensional information. In order to understand this process, a basic understanding of the physics of photon emission is required.

Physics of Photon Emission Radioactive decay is a process whereby unstable nuclides, those possessing an excess number of protons, reduce their net nuclear positivity. For the radionuclides used in PET, a proton is converted to a neutron and a particle called a *positron* (denoted e_+ or b_+) is emitted. A positron may be thought of as the antimatter equivalent of an electron, possessing identical mass but opposite charge. When ejected from the nucleus, a positron travels until it collides with an electron. This collision results in the annihilation of both particles and the conversion of mass into energy (Fig. 1.15-1). The energy produced has a characteristic profile consisting of two g-photons (rays) of equivalent energy (511 keV) and opposite trajectory (180° apart). These dual photons distinguish PET from SPECT and have implications for camera design. The most commonly used positron-emitting nuclides in PET include 11-carbon (^{11}C), 13-nitrogen (^{13}N), 15-oxygen (^{15}O), and 18-fluorine (^{18}F).

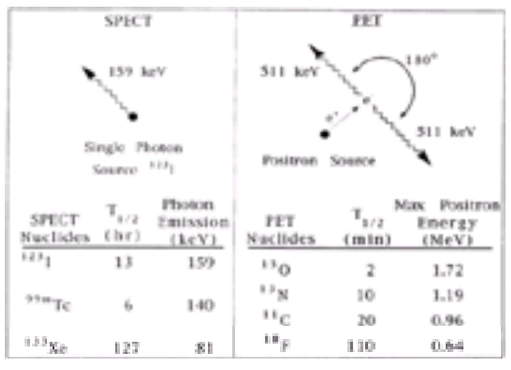

FIGURE 1.15-1 The decay of a SPECT radiopharmaceutical results in the emission of a high-energy photon directly from the radionuclide. In contrast, the decay of a PET radiopharmaceutical results in the emission of a positron (e^+) that travels a variable distance before annihilating with an electron (e^-), which then yields two 511 keV photons at an angle of 180 degrees to each other. The distance traveled by the positron decreases the resolution of PET images when using the typical nuclides listed by 0.2 to 1.3 mm, with resolution measured as FWHM. The longer-lived SPECT radionuclides emit single photons of different energies, whereas the PET radionuclides consistently yield two photons of 511 keV.

PET scanners take advantage of the unique spatial signature of back-to-back photons by using a method known as *coincidence detection* to locate the source of an annihilation event (Fig. 1.15-2). Coincidence detection is an efficient technique and contributes to PET's superior sampling rates and sensitivity. In a typical configuration, a PET scanner consists of a circular array of highly sensitive scintillation detectors that surround the head. These detectors are made of dense crystalline materials (e.g., bismuth germanium oxide, sodium iodide, or cesium fluoride) that trap the invisible, high-energy g-rays and convert them to visible light. This brief flash of light is then converted into an electrical pulse by an immediately adjacent photomultiplier tube, and the electrical pulse is then registered by the scanner's computer. When the scanner detects two electronic signals from two radiation detectors that coincide (to within 3-10 nsec), an annihilation event is presumed to have occurred at some point along an imaginary line connecting the detectors. In contrast, single events are ignored. Although any two crystal detectors may be activated by coincident photons, the most straightforward conceptual configuration for a PET camera is one in which only opposing detectors are electronically connected. Although it is true that two unrelated photons from spatially separate annihilation events can reach opposing detectors concurrently, such accidental coincidences are much less frequent than true ones. Nevertheless, random coincidences constitute one source of the background noise in PET images.

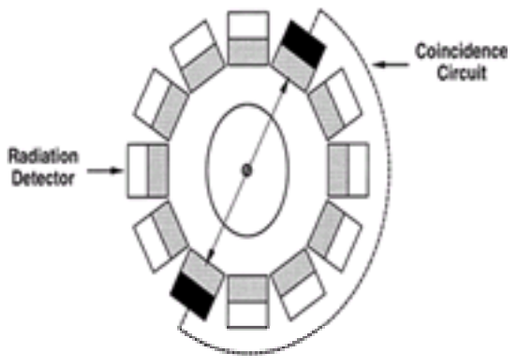

FIGURE 1.15-2 A PET scanner consists of a ring of radiation sensors that are designed to detect the simultaneously emitted, characteristically back-to-back (180 degrees apart) dual photons that are created by the annihilation of a positron and an electron. Opposing detectors are electronically coupled to form a coincidence circuit. Thus, when separate scintillation events in paired detectors coincide, an annihilation event is presumed to have occurred at some point along a line connecting the two. This information is registered by a computer and later used to reconstruct images using the principles of computed tomography. (Reprinted with permission from Malison RT, Laruelle M, Innis RB: Positron and single photon emission tomography: Principles and applications in psychopharmacology. In *Psychopharmacology: The Fourth Generation of Progress*, F Bloom, D Kupfer, editors. Raven, New York, 1995.)

Because PET detects the site at which a positron annihilates and not the site of its emission, there exists an intrinsic theoretical limit on the spatial resolution of PET. Specifically, a positron generally travels a finite distance before coming to rest in a tissue and colliding with an electron. Thus, an annihilation typically occurs some distance away from the site of radioactive decay. This distance is proportional to the positron's average kinetic energy as it is emitted from the nucleus and is characteristic of the specific isotope employed (Fig. 1.15-1). For example, the range for ^{11}C decay is roughly 2 mm. An additional limitation placed on PET is that sometime photons are emitted at an angle slightly more or less than 180 degrees. This typically occurs if the positron is not entirely at rest when it annihilates. Thus, both remote positron annihilation and photon noncollinearity are factors that theoretically limit PET's achievable spatial resolution (approximately 2 to 3 mm); modern PET instruments fall within this realm.

In the case of SPECT, the opposite occurs. Instead of a proton-rich radionuclide ejecting a positron (i.e., e+), it captures an orbiting electron (denoted e–). Once again, the net result is transformation of a proton into a neutron. Most commonly, the radioactive progeny of this process remains in a residually excited, so-called metastable state. With the dissipation of this metastable arrangement, the daughter nucleus achieves a ground state, and a single g-photon is produced. Thus, SPECT employs isotopes that decay by electron capture or g-emission or both, including both 123-iodine (^{123}I) and the long-lived metastable nuclide 99m-technetium (^{99m}Tc). No comparable theoretical limit on spatial resolution exists for SPECT because the site of g-emission and the site of radioactive decay are synonymous.

The emission of only a single photon fundamentally distinguishes SPECT from PET and necessitates an intrinsically different approach to ascertaining the origin of a decay event and therefore of camera design. Specifically, SPECT utilizes a method know as *collimation* (Fig. 1.15-3). In a manner analogous to the effects of a polarizing filter for visible light, a collimator is a physical filter that permits only g-rays of a specific spatial trajectory to reach the SPECT scanner's detector. Most commonly, a collimator is a lead structure that is interposed between the subject and the radiation detector. The collimator contains many holes of sufficiently long and narrow dimension so that only photons of a parallel trajectory are allowed through. In contrast to parallel photons, g-rays that deviate slightly are absorbed by the lead and go undetected (Fig. 1.15-3). Different collimators (e.g., parallel, fan-beam, and cone-beam) have holes of differing orientations (e.g., perpendicular to the detector, focused in two dimensions, and focused in three dimensions, respectively). Given a known geometric configuration for the specific collimator's holes, the original path of a detected photon is linearly extrapolated. Collimation is less efficient than coincidence detection because many potentially informative photons are lost. However, the sensitivity of SPECT has been largely enhanced by advances in collimator design and an increase in the number of detectors surrounding the body; SPECT is now sufficiently sensitive for routine use in nearly all the same applications as PET.

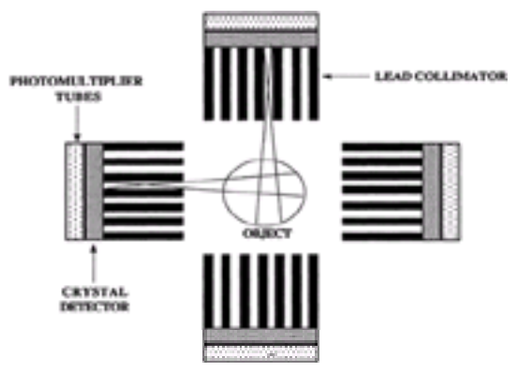

FIGURE 1.15-3 The method of image reconstruction from back projection in SPECT uses a collimator placed between the object and the crystal detector. The area of the object that is viewed by the underlying detector is decreased by having longer and narrower holes in the collimator. By moving the detector-collimator complex around the object, multiple views are obtained and provide the primary data for image reconstruction.

Image Reconstruction Although the nature of photon emission and detection are different in PET and SPECT, both techniques rely on the same principles of computed tomography when translating information about photon paths into brain images. Briefly, computed tomography is based on the premise that an appreciation of an object's two- or three-dimensional distribution in space may only be inferred by viewing it from multiple vantage points. Since information about a photon's direction, not depth, is known, views of photon trajectories from multiple angles around the entire head are required. In PET and SPECT, such a set of measurements from a given angle or viewpoint is referred to as a *projection*. A ring of essentially contiguous radiation detectors in a PET scanner provides multiple projections in this modality. In contrast, SPECT cameras usually rely on several (typically 2 to 4) detector “heads” that rotate around the subject in synchrony, collecting data over 360 degrees. A picture of the distribution of radioactivity within a given brain slice is then inferred by retracing or backprojecting the trajectories (typically thousands) of g-rays across the field of view for every imaging angle. Conceptually analogous to the simple childhood puzzle in which numbers in a square grid (e.g., 3 × 3) are inferred from their sums along each row, PET and SPECT images require fast computer coprocessors and efficient mathematical algorithms (fast Fourier transformations) to handle the considerably larger matrices (e.g., 128 × 128 or 256 × 256 elements) of radiation density values and the correspondingly more intensive calculations. In this manner, individual radiation values (i.e., counts of detected events) are determined for each cell of the matrix (also known as a *picture element* or *pixel*), corresponding shades of color assigned, and an image of the distribution of radioactivity within the brain produced (Fig. 1.15-4).

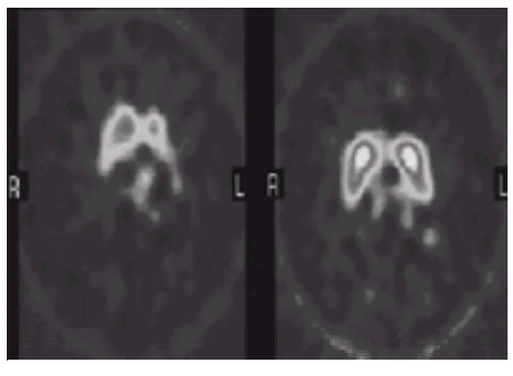

FIGURE 1.15-4 SPECT images of the distribution of [^{123}I]b-CIT (cocaine-iodo-tropane) in a healthy subject and a patient with Parkinson's disease. [^{123}I]b-CIT is a

radiolabeled cocaine analogue and is a probe of dopamine transporters in the striatum. These transporters are located presynaptically on terminals of dopamine neurons projecting from the substantia nigra to the striatum. These transverse images show a high density of dopamine transporters in striatum and a marked reduction of these sites in an age- and sex-matched patient with idiopathic Parkinson's disease. The transporters are lost because the entire dopaminergic neuron, including its terminal projections in the striatum, degenerate in this disorder. (Courtesy of John Seibyl, Yale University.) (See Color Plate 1.)

Despite its complexity and computational intensity, backprojection is an imperfect process and introduces known artifacts into the images themselves. As the backprojection algorithm retraces a photon's path, it cannot be sure of the actual point of decay. The algorithm is thus forced to assume an equal probability of radioactive decay and hence of radiation value for every point along the line of trajectory. Areas of the brain in which radioactivity is highly concentrated will stand out as many trajectories from multiple projections are superimposed and their probability values are summed. In the process, however, those areas containing no radioactivity now bear the statistical imprint of the algorithm's guess. Thus, small but finite values are ascribed to areas where none should exist. By increasing the density of spatial sampling through greater numbers of projections, the impact of these spurious values on image quantitation can be minimized but not eliminated. Therefore, a filter is still required to restore quantitative accuracy to images by “erasing” counts in those areas that should have none. Several filters have been developed (e.g., Ramp, Butterworth, and Hanning) in an effort to overcome these limitations, and these techniques remain the mainstay of the field of image reconstruction. Trade-offs exist with respect to the relative impact of filters on spatial resolution and noise amplification, and filter selection depends on the imaging context. Alternative reconstruction methods (e.g., restorative and iterative techniques) are the current focus of much research, and simple filtered backprojection is likely to be superseded by more quantitatively accurate methods in the near future.

Factors Affecting Image Quantitation Several physical factors affect the quantitative accuracy of PET and SPECT images. Among these are the statistics of radioactive decay, photon scatter, limited spatial resolution, and partial volume effects.

Statistics of Radioactive Decay Mathematically, radioactive decay is described by an exponential curve. The rate at which a specific radionuclide decays is expressed in terms of its radioactive half-life, or $T_{1/2}$ value, a parameter defined as the time required for half of the radioactive atoms to decay. Values of $T_{1/2}$ vary between species and are characteristic of a given nuclide. The characteristic $T_{1/2}$ values of several commonly used PET and SPECT isotopes are listed in Figure 1.15-1. Although a given isotope's half-life is constant, the nature of radioactive decay is intrinsically statistical. This phenomenon is most readily conceptualized by imagining an isotope of infinite half-life (i.e., unchanging levels of radioactivity). In struggling to measure the precise amount of radioactivity during a fixed period of time, variations in the individually recorded values invariably result. Only by taking the statistical average of multiple measurements is the true amount of radioactivity (and $T_{1/2}$ value) inferred. The variation in sampling derives from the intrinsic probabilistic nature (mathematically described by a Poisson distribution) of radioactive decay and the random fluctuation in individual decay events from moment to moment, and it occurs irrespective of detection method.

The manifestations of this effect are most readily appreciated by imaging an object which contains a uniform concentration of radioactivity. The swiss cheese appearance of the resulting images is the spatial equivalent of this temporal variation in PET and SPECT images. The probabilistic inaccuracies (or statistical noise) introduced is by virtue of its random nature easily surmountable through the collection counts. Longer sampling times and greater instrument sensitivity are the principle ways in which counting statistics are improved. Longer acquisition times improve statistical noise at the expense of temporal resolution. Conversely, increased sensitivity (e.g., larger collimator holes in SPECT) are traded for poorer spatial resolution (because slightly less than parallel photons are detected).

Photon Attenuation Although the high energies of photons emitted by PET and SPECT nuclides enable their penetration of brain structures, a significant number of g-rays escape detection by both types of scanners based on their interactions with surrounding tissues. These interactions fall into two general categories—Compton scattering and photoelectric absorption. In *Compton scattering*, a collision occurs between the photon and an atomic electron. The photon is deflected from its original trajectory and, in the process, loses a fraction of its original energy. Alternatively, in *photoelectron absorption*, the photon's energy is completely absorbed by the atom, and an electron may be ejected from its orbit. For this reason, g-radiation is said to be ionizing.

Because the chances of scatter or absorption decrease with increasing photon energy and increase with distance, photon attenuation is both energy- and depth-dependent. On both counts, PET has distinct advantages. Since photons in PET have higher energies (i.e., 511 keV) than those in SPECT (typically 80 to 160 keV), they are less prone to attenuation (Fig. 1.15-1). Moreover, linear attenuation is largely depth independent in PET because of coincidence detection. Nevertheless, activity at the brain's center is disproportionately underestimated (roughly fourfold to fivefold) in comparison to its surface for both PET and SPECT. Compensating for undetected photons is therefore crucial for comparing radioactive densities in different brain regions. The most commonly employed method with SPECT is uniform attenuation correction. In *uniform attenuation correction*, an ellipse is fitted to the brain's contour and the same attenuation value (typically equal to that of water) is assigned to all points within the ellipse. A commonly used method for attenuation correction in PET (and with some recent SPECT devices) is *nonuniform attenuation correction*, which relies on a preceding transmission study similar to a computed tomography (CT) scan. An external source of radiation is transmitted through the subject's head, creating a precise attenuation map for that individual. Because the sizes and shapes of patients' heads vary and because the attenuation properties of bone, tissue, fluid, and air differ, such an approach has clear theoretical advantages. Although commercially available PET and SPECT scanners now support this technology, the conditions under which nonuniform methods offer clear advantages over uniform approaches remain to be established for practical brain-imaging applications.

Photon Scatter In both PET and SPECT, instrumentation and image reconstruction are based on the underlying assumptions that detected photons retain their linear paths. However, Compton effects cause photons to deviate from their original trajectories. Although these photons lose energy to atoms in the tissue, many scattered photons retain sufficient energy to enable their escape from the brain. The detection of scattered events therefore leads to errors in image reconstruction as a result of false assumptions about the photon's original path. Much like accidental coincidences, scattered photons increase the background noise and compromise image contrast.

Because radionuclides emit photons of a known energy, scattered photons may be distinguished from true ones by the loss of energy they sustained from collisions with electrons. In an attempt to exploit this principle, PET and SPECT cameras measure the energy spectrum of their detected photons. In practice, however, accurately discriminating between true and scattered photons is often difficult because the energy resolution of current PET and SPECT scanners is limited. Also, the photopeak energies of true photons are not identical, but rather normally distributed about a mean value. Thus, scattered and photopeak photons inevitably overlap in their energy distributions. Current algorithms that subtract a *scatter fraction* from the photopeak counts are an attempt to compensate for this problem; however, these methods have obvious limitations. As for attenuation correction, advances in scatter correction offer the promise of incorporating *a priori* information about the head's structure and density in achieving more faithful image reconstruction.

Spatial Resolution In contrast to the fine visual detail seen in magnetic resonance images, pictures created using SPECT and PET appear blurred. The visual sense of imprecision is the qualitative consequence of limited spatial resolution. Equally important, however, is the quantitative impact of finite resolution on the measured radioactivity in individual brain regions. The latter partial volume effects have important consequences for image quantitation and require a clearer understanding of spatial resolution and its definition.

In PET and SPECT, spatial definition is defined in practical terms, the distance by which two objects must be separated to perceive them as discrete (Fig. 1.15-5). In a SPECT or PET camera with perfect resolution, a point source of radioactivity would be depicted as a vertical line of infinitely narrow width. In such an ideal device, two point sources could be distinguished from each other as long as they were not superimposed. In the real world, however, PET and SPECT scanners perceive the radioactivity from such a point source as a Gaussian curve and the radioactivity from the point is spread out. This *point spread function* characterizes a camera's resolving capacity. The spatial diffusion of imaged radioactivity is expressed in terms of the *full-width-at-half-maximum* (FWHM), or the width of the Gaussian curve at half of the curve's peak activity. The FWHM is the parameter most commonly used to define resolution in emission tomography because this is the distance at which the peaks of both sources become distinguishable from one another (Fig. 1.15-5).

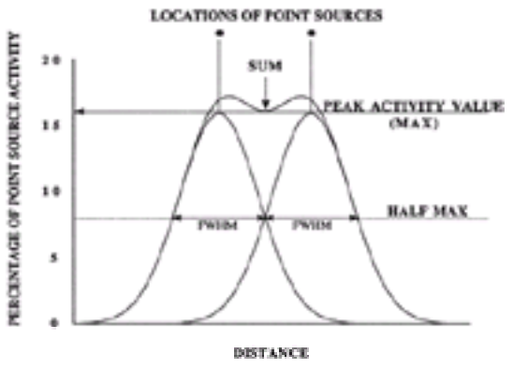

FIGURE 1.15-5 The limited resolution of PET and SPECT cameras blurs the activity of single point sources into adjacent regions with no activity. Viewed in just one dimension, a point source is visualized by the camera as a gaussian curve. Resolution is defined as the width of the curve at half maximum measured peak levels (FWHM). For two point sources of equal intensity separated by a distance equal to the FWHM of the camera, the sum of the activities begins to show a modest decrease at the midpoint. Thus, two point sources separated by a minimum distance equal to the FWHM will begin to appear as two separate points rather than just one.

Excluding issues of positron range, image resolution is primarily influenced by issues of instrumentation. For example, the precision of collimation, the number and size of detectors, and the accuracy with which scintillation events are localized within the crystalline elements all contribute to limited spatial resolution. In the case of PET, state-of-the-art devices have yielded resolutions close to the theoretical limits of accuracy (3 mm). However, the average PET and SPECT camera is currently capable of 5 to 6 mm and 7 to 9 mm FWHM, respectively.

Partial Volume Effects In the simplest terms, partial volume effects create one of two problems for image quantitation: the appearance of radioactivity where there was none, and the impression of less radioactivity than truly exists. For example, just as the brightness in a part of a room depends on the intensity and distance separating two lamps, so too will the measured radioactivity in a given brain region reflect the relative activity and proximity of nearby structures. Thus, brain regions with relatively lower concentrations of radioactivity will appear “hotter” in PET and SPECT images as imaged activity “spills over” from adjacent (more active) areas. Conversely, as the size of a radioactive region becomes smaller than two to three times the FWHM resolution, true activity is effectively diluted by nonradioactive areas within the field of resolution. In the latter case, regions containing equal concentrations of radioactivity will appear to have declining levels with decreasing size. Metaphorically speaking, together these two effects result in sharp peaks and steep canyons of brain activity being rendered as short hills and shallow valleys in PET and SPECT images.

Several approaches are currently taken to compensate for errors resulting from limited spatial resolution and partial volume effects. One method attempts to simulate errors created by partial voluming by creating a plastic model or phantom. Models can be designed to approximate the structures or activity distributions of interest in the brain. For example, finely machined, polycarbonate brain phantoms are commercially available and can recreate the geometry of gray and white matter. Once imaged, regionally specific correction factors, or *recovery coefficients*, are derived that relate units of measured activity to known activity. Such methods, however, are unable to account for inter-subject variations in brain anatomy, whether pathological or nonpathological. For this reason, researchers are now beginning to use structural information (e.g., CT or MRI scans) to quantify functional information. More specifically, partial volume errors may be mathematically compensated for by registering subjects' MRI scans with their own PET or SPECT scans and incorporating a priori functional (e.g., relative blood flow ratios in gray and white matter) and physical information (e.g., a PET or SPECT camera's three-dimensional point spread function). The latter approach is more complicated than the former but has obvious advantages for conditions such as Alzheimer's disease, in which cortical atrophy is present.

Radiopharmaceuticals The versatility and sensitivity of PET and SPECT arise largely from the ability of talented radiochemists to synthesize a radiopharmaceutical of high chemical purity, high radioactive yield, and small mass dose. Expressed differently, in order to ensure that a specific biological system of interest is adequately measured yet unperturbed by the tracer, high purity and high specific activity (expressed in units of radioactivity per chemical quantity: Ci/mmol) are paramount. However, the physical nature of radioactive decay and the short half-lives of most suitable radionuclidic species (Fig. 1.15-1) constantly challenge the radiochemist's efforts. Chemical yield generally improves with increasing reaction times; however, radioactivity and specific activity diminishes with increasing decay times. Thus, an optimal synthetic scheme is a balanced one in which chemical yield is maximized, radioactive byproducts are minimized, and the final product is capable of prompt purification. Given the high affinity of many radiopharmaceuticals (e.g., neurotransmitter receptor ligands) for their physiological targets, specific activities of greater than 2000 Ci/mmol are generally required. Most radiopharmaceuticals are still manually prepared by radiochemists racing against the clock of a nuclide's decay; however, a limited number of radiochemical syntheses are now automated and performed in robotically controlled hot cells (e.g., [^{18}F]-2-fluoro-2-deoxyglucose; [^{18}F]FDG).

In the case of positron-emitting radionuclides (e.g., ^{15}O, ^{13}N, ^{11}C, and ^{18}F), the particularly short half-lives (2, 10, 20, and 109 minutes, respectively) have special implications for the design of PET imaging facilities. Most PET centers have an on-site cyclotron that generates radionuclides for “real-time” utilization. An exception to this is ^{18}F, whose nearly 2-hour half-life permits a “local” regional facility to produce quantities for large metropolitan centers. The significant expense of a cyclotron (typically $1 to $2.5 million) and its highly skilled support staff are relative disadvantages for PET. In contrast, SPECT isotopes like ^{99m}Tc ($T_{1/2}$ = 6 hours) may be obtained from inexpensive molybdenum generators located in many hospital radiopharmacies. Alternatively, ^{123}I has a sufficiently long half-life (13 hours) to permit centralized production at distant (>3000 miles) commercial reactors. The radionuclide may then be delivered via overnight express mail and still meet the radiochemical needs of high specific activity.

The choice of a candidate molecule for radiopharmaceutical development depends primarily upon the physiological process under investigation. In the case of regional cerebral blood flow, relatively nonspecific and often nonorganic, diffusible tracers may be employed (e.g., the gaseous tracer ^{133}Xe). In contrast, the measurement of aspects of brain neurochemistry require much greater biochemical selectivity. Thus, PET and SPECT radiopharmaceuticals are most often naturally occurring substances, structural analogues, or ligands that selectively label a particular brain target. In this regard, PET has significant advantages over SPECT because ^{11}C can be directly substituted for ^{12}C in existing organic molecules without altering their intrinsic biochemical properties. Alternatively, fluorine is frequently substituted for native hydrogen atoms without significant isotopic effects (e.g. [^{18}F]FDG). In contrast, SPECT nuclides (i.e., ^{123}I and ^{99m}Tc) are uncommon elements of organic substrates. The metallic nature and multiple valence states of ^{99m}Tc necessitate bulky complexing groups for its molecular stabilization. These barriers have largely limited the initial uses of ^{99m}Tc to nonselective processes (e.g., the blood flow agent [^{99m}Tc]-hexamethyl propyleneamine oxime; [^{99m}Tc]HMPAO). However, in 1997, ^{99m}Tc-labeled probes of the dopamine transporter were developed, and SPECT imaging has demonstrated appropriate labeling in human and monkey brain. Extension of these efforts is certain to result in the development of many other ^{99m}Tc-labeled probes in the future.

Many ^{123}I-containing radiopharmaceutical agents have been developed as a result of rapid advances in iodode metallation procedures and increasing knowledge of the structure-activity relationships of pharmacologically active compounds. The lipophilic nature of ^{123}I may actually facilitate transfer across the blood-brain barrier and, in some instances, improve affinity of the parent compound at its site of action. In particular, SPECT imaging of brain receptors and uptake sites with ^{123}I-containing radiopharmaceuticals is routine at several university medical centers.

Successful in vivo radiopharmaceuticals must fulfill several stringent pharmacokinetic criteria. Because a radiopharmaceutical must easily enter the brain, tracer binding to plasma proteins must be readily reversible, and its transport across the blood-brain barrier must be favorable. Although some tracers (e.g., [^{18}F]-FDG) may have facilitated carriers, most ligands must be sufficiently lipid-soluble to permit passive diffusion across the blood-brain barrier. However, as the tracer's lipophilicity increases, its “signal-to-noise” properties may be degraded because nonspecific binding increases. Thus, lipophilicity (nonspecific binding) and affinity (specific binding) are important factors influencing an imaging agent's signal-to-noise ratio. Lastly, tracer metabolism may also limit a ligand's in vivo utility. For example, rapid degradation, lipophilic radioactive metabolites, and pharmacologically active metabolites may all confound central measurements.

Safety With regard to studies in humans, PET and SPECT methods give rise to similar safety concerns for radiation exposure and pharmacological toxicity of the injected radiopharmaceutical. The radiation exposures from typical PET and SPECT scans are thought to be reasonably safe within the context of the present knowledge of radiation biology. The Food and Drug Administration (FDA) has established limits of radiation exposure to various organs of the body and to the body as a whole, these limits are applied to research studies and are often lower than exposures in routine clinical nuclear medicine procedures. Although the FDA limits are

presently thought to provide adequate safety, the long-term biological effects of ionizing radiation are an area of active investigation and even controversy. The estimation of the dose received by the body depends on multiple factors (including the amount of activity, the type of emission, and the residence time in the body), but the shorter half-lives of PET radionuclides and the higher sensitivity of the method generally yield lower radiation burdens than did a comparable SPECT study. A useful guideline is to employ doses of radiotracer that are "as low as reasonably allowable" to provide useful results.

Fortunately, the pharmacological toxicity of radiopharmaceuticals is usually not a significant issue. The sensitivity of functional imaging is so high that minuscule mass doses of compound may be injected, although that small mass is associated with significant levels of radioactivity. For example, some radiopharmaceuticals are injected at mg/kg doses that are a millionfold lower than the minimal dose required to have any pharmacological effect. In such situations no pharmacological toxicity would be expected and only an unusual immunological adverse effect could be anticipated. Nevertheless, the potential pharmacological effects and toxicity of radiopharmaceuticals needs to be evaluated relative to previously established criteria for nonradioactive pharmaceuticals. The final formulation of any radiotracer must meet established guidelines for purity, sterility, and lack of pyrogenicity.

RESEARCH APPLICATIONS

The uses of PET and SPECT brain imaging can be roughly divided into measurements of local neuronal activity, neurochemistry, and in vivo pharmacology.

Local Neuronal Activity Local neuronal activity is associated with energy consumption and can be directly measured with glucose metabolism or indirectly with cerebral blood flow. Local cerebral blood flow is coupled with glucose metabolism and neuronal activity via mechanisms that are not completely elucidated. PET tracers for measurement of local neuronal activity include [^{18}F]FDG (fluoro-deoxyglucose for glucose metabolism) and [^{15}O]H_2O (blood flow). SPECT does not have a comparable tracer for glucose metabolism but does have ^{99m}Tc- and ^{123}I-labeled agents, as well as ^{133}Xe to provide measures of blood flow.

Neuronal metabolic demands are believed to primarily reflect terminal rather than cell body activity. In any given volume of brain, the majority of [^{18}F]FDG uptake is believed to be in terminals rather than in cell bodies, a conclusion that is based upon a limited number of studies in which the cell bodies are anatomically distant from their terminals. Metabolic rate will not distinguish activity of excitatory and inhibitory neurons. Although increased [^{18}F]FDG uptake is usually interpreted as increased functional activity of a region, it may reflect an overall decreased activity based upon increased firing of inhibitory interneurons.

The clinical uses of PET and SPECT imaging to measure local neuronal activity are largely restricted to neurological disorders and include localization of cerebral ischemia, localization of epileptic foci, and distinguishing radiation necrosis from tumor growth. These imaging results can directly impact clinical care. For example, the neurosurgical treatment of patients with medically refractory epilepsy critically depends upon accurate localization of the seizure focus, which is often distant from the surface of the brain and poorly localized by scalp electrode EEG. The seizure focus is hypometabolic with decreased blood flow during the interictal period, but is hypermetabolic with increased blood flow during the ictal period. PET and SPECT imaging has been used either as a primary means of localization or as a confirmation of other diagnostic tests to select the portion of the brain that is subsequently resected.

PET imaging using [^{15}O]H_2O has been elegantly combined with neuropsychological activation studies to localize cognitive and sensory functions, including reading, speaking, word associations, visual identification, and spatial localization. The short half-life of ^{15}O ($T_{1/2}$ of 2 minutes) allows multiple (often 8 to 10) bolus injections of the tracer in one experimental session. Thus, both baseline scans and those following neuropsychological tasks can be repeated and averaged.

Recently developed techniques in functional fMRI offer great promise to provide measures of local neuronal activity similar to that from PET and SPECT imaging. The primary signal from functional MRI is believed to derive from the concentration of deoxyhemoglobin. Functional MRI is superior to PET and SPECT in that it involves no radiation exposure and has greater temporal (<1 second) and spatial (<1 mm) resolutions. If these methods are fully developed with adequate quantitation, they may supplant PET and SPECT for measures of local neuronal activity.

Neurochemistry Two major attributes of both PET and SPECT are high sensitivity and chemical selectivity, both of which are critically important for in vivo neurochemical measurements. The sensitivity of PET and SPECT to detect radiotracers is less than 10^{-12} M, which is several orders of magnitude greater than that of nuclear magnetic resonance (NMR) methods. "Sensitivity" refers to the minimal concentration of the target compound that can be reliably measured. For example, the minimal concentration of [^{11}C]chlorpromazine that can be measured with PET in the human brain within a reasonably acceptable imaging time (e.g., 15 to 30 minutes) is less than 10^{-12} mol. In contrast, the minimal concentration of g-aminobutyric acid (GABA) that can be measured with MRS is about 10^{-4} mol.

In a manner exactly analogous to nonradioactive drugs, radiotracers that label specific target sites in the brain can be developed. These specific tracers can thereby provide measures of multiple neurochemical pathways in the brain, including synthesis and release of transmitters, receptors, reuptake sites, metabolic enzymes, and possibly even second messenger systems. Of these multiple neurochemical systems in the brain, the greatest effort has been devoted to imaging of dopaminergic transmission; it is an example of the types of measurements provided by these methods.

Synthesis 6-[^{18}F]Fluoro-L-3,4-dihydroxyphenylalanine ([^{18}F]-FDOPA) has been successfully used in animal and human studies to provide a measure of dopamine terminal innervation of the striatum. These studies have demonstrated decreased striatal uptake in parkinsonian patients as compared to healthy subjects. Furthermore, these studies have questioned the widely held notion that symptoms develop only after 85 to 90 percent depletion of endogenous dopamine levels. Imaging studies of patients with early signs of the disorder suggest that symptoms may begin with only a 50 to 60 percent decrease in striatal dopamine terminal innervation.

Release A potential method for the measurement of transmitter release involves the displacement of receptor radiotracers by the endogenous transmitter. On first consideration, this displacement may seem impossible because the endogenous transmitter tends to have a much lower affinity than the tracer for the receptor. For example, [^{11}C]raclopride has a IC_{50} value (concentration of drug required to occupy 50 percent of sites) for the dopamine type 2 (D_2) receptor of approximately 1 nM. In contrast, the IC_{50} value for dopamine itself may be as high as 1 μm. How then could dopamine effectively compete with [^{11}C]raclopride for binding to the D_2 receptor? Different affinities, which are inversely related to IC_{50}, will influence the speed at which equilibrium is achieved. However, after equilibrium is achieved, dopamine demonstrates effective competition with high-affinity tracers. In an equilibrium state, if the displacer dopamine is present at a concentration equal to its IC_{50} value, then 50 percent of receptors will be occupied by the drug and 50 percent of the radioligand (which is associated with only tracer receptor occupancy) will be displaced. Thus, the real questions of feasibility will be determined by physiological concentrations of dopamine in the synapse, the in vivo inhibition constant (K_i) of dopamine for the receptor, and whether adequate time has elapsed to establish equilibrium binding conditions. Several investigators have provided evidence from in vivo labeling studies in rodents that both the resting levels of synaptic dopamine and stimulant-induced dopamine release are associated with significant D_2 receptor occupancy, which is mirrored by comparable displacement of radiotracer from the receptor. Recent PET and SPECT D_2 receptor imaging studies in humans and monkeys have been combined with a pharmacological challenge of dextroamphetamine (Dexedrine), which causes a massive release of dopamine into the synapse. The release of dopamine can be monitored by displacement of tracer binding to the D_2 receptor. These studies have shown that the amount of displacement in healthy subjects is correlated with psychological reports of activation and feeling high. Similar studies in patients with schizophrenia have shown that the amount of dopamine released is two and a half times higher and that the amount of the release is correlated with a transient increase in positive symptoms. These dopamine receptor imaging studies combined with amphetamine challenge have provided further evidence of dopamine playing a role in psychotic symptoms.

Receptors Receptor studies have probably received the greatest effort among the various targets of neurochemical imaging. If a receptor is selectively altered in a specific disease, then imaging of this site may provide diagnostic information about the disorder. For the dopamine receptor system, the Johns Hopkins PET group has reported that drug-naive schizophrenia patients have an elevation of D_2 receptor density in the striatum of two and a half times as measured by the virtually irreversible tracer [^{11}C]N-methylspiperone and kinetic modeling. In contrast, the PET group at the Karolinska Institute, Sweden has reported normal levels of D_2 receptor densities in drug-naive schizophrenia patients using the reversible radiotracer [^{11}C]raclopride and an equilibrium approach. Reasons for these disparate results have been investigated but remain disappointingly elusive. Elevated D_2 receptors are certainly not a sine qua non of schizophrenia but may be associated in an as yet unknown way with aspects of psychosis in subsets of patients. Research imaging of the D_2 receptor has more recently focused on the interaction with synaptic dopamine, both basal levels and stimulant-induced release.

Transporters The transporter is located presynaptically on terminals of dopamine projections from substantia nigra to striatum. Thus, the transporter is a marker for dopamine terminal innervation, which is decreased in patients with idiopathic Parkinson's disease. Several radiotracers for the dopamine transporter have been developed: [^{11}C]cocaine, [^{11}C]methylphenidate, [^{11}C]CFT (also designated WIN 35,428), and [^{123}I]b-CIT (also designated RTI-55). The striatal uptake of both [^{11}C]CFT

and [^{123}I]b-CIT have recently been shown to be markedly decreased in patients with Parkinson's disease in comparison to healthy subjects of similar mean age (Fig. 1.15-4). Imaging with these tracers may be useful research tool for early diagnosis and for monitoring the progression of the disorder.

Metabolism The fate of a neurotransmitter can be studied by injection of selective inhibitors of the catabolic enzymes. For example, selegiline (Edepryl) is an irreversible inhibitor of monoamine oxidase (MAO) type B, and imaging with ^{11}C-labeled selegiline has been reported to provide a measure of regional enzyme activity in the brain. PET scanning with [^{11}C]selegiline may provide useful dosage-response measurements in patients treated with MAO inhibitors (MAOIs). Furthermore, reversible MAOIs such as [^{11}C]Ro 19-6327 may have advantages relative to the irreversible agents in terms of data analysis and ease of performing in vivo occupancy studies.

In Vivo Pharmacology Since receptors are frequently the targets of therapeutic medications, several investigators have argued that receptor imaging may be used to monitor drug treatment more accurately than is possible with measurement of plasma levels of the medications. However, the rationale for this argument is flawed from a theoretical perspective. Under steady-state conditions achieved with long-term treatment, the level of free (i.e., not protein bound) drug in plasma should be in equilibrium with the free level of drug in the extracellular space of the brain. Thus, under steady-state conditions there is little apparent value in performing expensive neuroreceptor imaging studies instead of simple measurements of the free level of drug in plasma. However, for non–steady-state conditions (e.g., beginning or discontinuing treatment), receptor imaging can provide valuable kinetic information. The brain uptake and washout of many psychoactive agents can be markedly delayed compared to a rapid peak and fast clearance of the drug from plasma. For example, the maximal brain uptake of the potent cocaine analogue cocaine-iodo-tropane occurs about 12 hours after intravenous administration as compared to plasma levels, which peak at 2 minutes. In addition, significant D_2 receptor occupancy has been reported to last for several weeks following discontinuation of antipsychotic agents, even when plasma levels are almost undetectable.

Several pharmaceutical companies and academic researchers have begun to explore the role of receptor imaging in new drug development. The two basic methods are the radiolabeling of the target compound (e.g., with ^{11}C) or the in vivo screening of the effects of the intravenously administered nonradioactive compound with previously developed radiotracers. An example of the first method would be the use of ^{11}C-labeled fluoxetine (Prozac); an example of the second method would be the use of nonradioactive fluoxetine to interact with a different radiolabeled probe (e.g., [^{11}C]citalopram) for the 5-HT transporter. The first method is probably better suited to PET radiochemistry, which can more easily provide a pharmacologically identical radiolabeled form of the target compound than SPECT, which would probably use an iodinated analogue. However, the second method may be equally well performed with PET or SPECT provided that an appropriate radiotracer has been developed for each method.

Brain imaging studies of antipsychotic medications provide an example of the advantages and limitations of the PET and SPECT methods. Several pharmaceutical companies are trying to develop so-called atypical medications like clozapine (Clozaril) and risperdol (Risperidone) that would have superior efficacy and fewer adverse effects than older antipsychotic medications. Studies with [^{11}C]clozapine have been relatively disappointing because of the high nonspecific uptake of the radioactivity. These results may prove to be typical, since only a small percentage of potential compounds prove to be useful in vivo radiotracers with low nonspecific binding. Studies of nonradioactive antipsychotic medications with established and selective receptor tracers have provided valuable information on the receptor occupancy profiles and the pharmacokinetics of brain uptake. For example, researchers have shown that, in comparison to several typical antipsychotic medications, clozapine is associated with a disproportionately high occupancy of D_1 relative to D_2 receptors. Novel therapeutic compounds could be examined for both the pharmacokinetics of entry into the brain and their receptor occupancy profiles, which will provide the combined effect of the parent compound and any active metabolites; this potential application is receiving growing attention.

SUGGESTED CROSS-REFERENCES

Brain-imaging techniques, including electroencephalography and magnetoencephalography, are discussed in Section 1.16. Neuroimaging in clinical practice is discussed in Section 2.13, and neuroimaging in geriatric assessment is discussed in Section 51.2e and Section 51.2f. The other sections of Chapter 1 discuss related neural sciences, particularly Section 1.2 on functional neuroanatomy and Section 1.14 on applied electrophysiology.

1.16 PRINCIPLES OF NEUROIMAGING: MAGNETIC RESONANCE TECHNIQUES

CRAIG N. KARSON, M.D., AND PERRY F. RENSHAW, M.D., ĦH.D.

Most atoms have a nuclear magnetic moment. A strong external magnetic field will align the magnetic moment of atoms along the axis of the magnetic field. The magnetic moment of atoms aligned with a strong external field can be deflected off axis by a radiofrequency pulse at the *nuclear resonant spin frequency* or *Lamour frequency*. In turn, a detectable radiofrequency signal will be generated by the realignment of magnetic moments with the external magnetic field once the radiofrequency pulse is turned off. The detection of this signal forms the basis of all magnetic resonance experiments. In *magnetic resonance imaging* (MRI), magnetic field gradients are used to encode the locations from which these radiofrequency signals arise. In *magnetic resonance spectroscopy* (MRS), slight differences in the resonance frequencies of particular atoms in different molecular environments can be used to measure the concentrations of specific neurochemicals.

Once the magnetic moment of an atom has been deflected off the axis of the main magnetic field, it will return to its equilibrium orientation. The rate at which the magnetic moment returns to equilibrium is described by two relaxation time constants. The realignment of atomic spins with the external magnetic field is characterized as T1 (spin-lattice) relaxation; T2 relaxation describes the rate at which the coherence of the magnetization decays after an initial radiofrequency pulse deflects the spins off axis. In MRI, images may be collected using different acquisition parameters and the resulting images may be described as being either T1-or T2-weighted.

MRI first became available for clinical studies in the 1980s and allows for detailed in vivo study of brain structure. Today, the use of MRI to rule out overt structural changes in the brain resulting from neurological illness remains the only agreed-upon clinical use for any magnetic resonance technique in the practice of psychiatry.

Magnetic resonance spectroscopy constitutes a second group of relevant magnetic resonance techniques. The first magnetic resonance experiments involved the spectroscopic detection of MRS signals from in vitro samples more than 50 years ago. At the present time, both in vitro and in vivo MRS experiments are feasible, and clinical scanners may be used to measure the concentration of many molecules in virtually any organ system based on the detection of radiofrequency signals from magnetic resonance-visible nuclei (Table 1.16-1). An example of an in vitro application would be the study of extracts from frozen brain tissue. In vivo MRS studies to evaluate human neurochemistry typically exploit the magnetic properties of the principle isotopes of hydrogen (^{1}H or proton) or phosphorus (^{31}P) atoms. Proton MRS can provide information about the concentration of several neurochemicals in tissue, including *N*-acetyl aspartate (NAA), an established neuronal marker. Phosphorus MRS provides data about the concentration of bioenergetic phosphates such as phosphocreatine (PCr) and adenosine triphosphate (ATP) in the brain. Finally some MRS-visible atoms like fluorine (^{19}F) and lithium (^{7}Li) are found in the molecular structure of psychotropic medications, that is, fluoxetine (Prozac) and lithium (Eskalith), respectively, and the concentration of these medications and their metabolites may be determined spectroscopically.

Nucleus	Spin Quantum Number	NMR Frequency at 10 kG (Mhz)	Relative Sensitivity at Constant Field
^{1}H	1/2	42.58	1.00
^{19}F	1/2	40.05	0.83
^{7}Li	3/2	16.55	0.29
^{23}Na	3/2	11.26	0.09
^{31}P	1/2	17.25	0.06
^{13}C	1/2	10.71	0.02
^{39}K	3/2	1.99	0.0005

Table 1.16-1 Relative NMR Sensitivities

Since the late 1980s ultrafast scanning techniques such as echo planar imaging that allow the collection of complete image planes in less than 100 ms have become clinically available. It has been demonstrated that by exploiting the high-temporal resolution of these methods, it is possible to construct images that are sensitive to changes in regional cerebral metabolism. This family of MR techniques is often referred to as *functional MRI* (fMRI). Current interest in fMRI methods for psychiatric research reflects the opportunity to probe brain activity in vivo without the need for ionizing radiation. Repeated studies of individual subjects, as well as studies of women and children, are now feasible. Additionally, there will be widespread availability of fMRI because every high-field MRI scanner can be equipped with a high-speed imaging coil.

Clinical MRI, MRS, and fMRI have evolved as separate disciplines. The rate of technical development continues at a rapid pace. Improvements in signal-to-noise ratios continue, not only with the fast scanning techniques, but with the introduction of human magnets that operate at higher field strengths, such as 3 or 4 tesla. And, unlike other neuroimaging techniques, the end of this evolution is not in sight, suggesting that MRI may eventually dominate psychiatric neuroimaging in a way that could not have been imagined only a short time ago.

MAGNETIC RESONANCE IMAGING

Psychiatry was introduced to MRI via the striking images of the human brain obtained in vivo by MRI scans. The appearance of these images is heavily dependent upon the scan acquisition parameters. In practice, images are often referred to as being either T1-weighted or T2-weighted. In T1-weighted images, water is dark; in T2-weighted images, water is bright (Fig. 1.16-1). While examinations of brain involve both T1- and T2-weighted images, T1-weighted images are best for anatomical studies. Neoplasia and inflammation are often associated with increased water content, most vividly rendered on T2-weighted images. Magnetic resonance images may be acquired both before and after the administration of a contrast agent, which is typically a strongly paramagnetic gadolinium chelate. These agents work by altering the local magnetic environment and, by extension, tissue relaxation times. Magnetic resonance contrast agents will diffuse from the intravascular to the extracellular space when there is some compromise of the blood-brain barrier (e.g., in the case of cerebral neoplasm or inflammation).

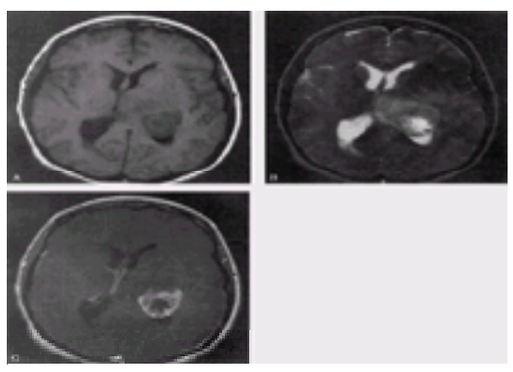

FIGURE 1.16-1 Three axial images from a 46-year-old woman who was hospitalized for the first time for depression and suicidality following the end of a longstanding relationship. A malignant neoplasm extending into the posterior aspect of the left lateral ventricle is clearly seen in all three images. Images **A** and **B** are T1-and T2-weighted, respectively. Image **C** demonstrates the effects of postcontrast enhancement.

Relatively few studies have substantiated the utility of MRI for the evaluation of organic brain pathology in patients with mental illness. Initial studies have suggested that 10 to 17 percent of subjects with a primary psychiatric disorder have evidence of a focal abnormality on brain MRI. More recently, investigators focused on unanticipated findings that might lead to a change in treatment in a cohort of 6200 consecutively referred psychiatric inpatients in a single institution. Ninety-nine subjects (1.6 percent) were noted to have findings that might lead to a change in clinical management. The most common new diagnosis was that of multiple sclerosis, which was present in approximately 0.8 percent of all subjects, a rate that is roughly 13 times higher than the prevalence of multiple sclerosis in the general population. The majority of subjects with unsuspected multiple sclerosis had been diagnosed as having refractory affective illness.

On the basis of existing data it has been suggested that structural brain imaging may be most appropriate for subjects with a new-onset psychosis, a new-onset dementia or delirium, or for subjects with other acute mental status changes in the presence of specific risk factors (i.e. advanced age, history of head trauma, or neurological signs). Data supporting the use of MRI for the detection of intracranial pathology in patients with longstanding psychotic disorders comes from large-scale autopsy studies of patients who had been hospitalized long-term. Intracranial neoplasms are approximately 60 percent more common at death in patients with psychotic disorders (3.7 percent) than in age-matched individuals who die of general medical illness (2.3 percent). A recent review of reversible dementia concluded that treatable conditions were likely to be found in approximately 1 percent of patients. Although normal-pressure hydrocephalus, neoplasm, and subdural hematoma may be detected on brain MRI in patients with dementia, the most common reversible causes of new-onset memory loss are depression, medication effects, and metabolic derangements.

In clinical practice structural brain imaging may be performed using either computed tomography (CT) or MRI. Given the fact that MRI provides more detail with regard to different brain tissues (e.g., gray versus white matter), it probably provides a higher yield when investigating possible central nervous system pathology. CT may be more widely available than MRI and is less expensive. In some circumstances, such as acute trauma, possible acute intracranial bleeding, or when MRI is relatively contraindicated, CT may be the preferred imaging modality. For each individual case it is most helpful if the referring psychiatrist specifies the clinical questions to be addressed by the scan to the local neuroradiologist. The better the information provided, the better the chances that an optimal study will be performed.

Neuromorphometry of Psychiatric Disorders MRI has largely succeeded CT as the psychiatric research tool of preference for the evaluation of structural changes in the brain in patients with psychiatric disorders, particularly schizophrenia. Software improvements have now made such neuromorphometric studies easier to perform, although many of the limitations of the older CT research still present confounds for MRI studies. Specifically, there may be evidence of diffuse change, such as atrophy, and many pathological findings on MRI, such as white-matter hyperintensities, that do not suggest specific causes.

Schizophrenia CT studies of patients with schizophrenia provided compelling evidence that a substantial fraction of these patients had reduced cerebral mass, as evidenced by enlargement of the brain ventricles and cortical sulci. Because of its very high spatial resolution and absence of exposure to radiation, MRI was introduced as a psychiatric research tool that might better resolve the specific nature of the structural abnormalities of the brain in schizophrenia. Since the late 1980s, improvements in image-processing tools have made in vivo computerized neuromorphometry a reality.

However, even with the increased resolution provided by MRI scanning, it remains unclear whether there are relatively specific structural brain changes in substantial fractions of patients with schizophrenia or if cerebral mass reduction is nonspecific. Several studies have provided convincing data regarding reduced volume in specific cortical regions, including prefrontal cortex and temporal cortical regions. Such changes have even been found in patients early in the course of illness, suggesting that the structural changes observed in the cortex are present at the onset of the illness and do not stem from progression of the illness or from iatrogenic factors. Enlargement of caudate volume has also been reported early in the course of the illness, but multiple studies suggest that caudate enlargement may be secondary to treatment with typical dopamine receptor antagonist agents. More recently it has been suggested that this enlargement recedes with clozapine (Clozaril) treatment.

Eloquent studies now combine structural imaging through MRI scans with functional imaging techniques, including positron emission computed tomography (PET) and single photon emission computed tomography (SPECT), using computerized coregistration of the image sets. For example, one study found that a sample of patients with schizophrenia had reduced metabolic activity in the anterior left portion of the thalamus as measured by ^{18}F-fluorodeoxyglucose PET and also had reduced volume in the same area as measured by MRI scan. As the thalamus has extensive afferent and efferent projections throughout cortex and receives massive input from structures in the brainstem reticular formation, these observations of altered thalamic architecture and activity are difficult to interpret in isolation. Resulting neural network hypotheses about schizophrenia have gained primacy and require that changes in volume (usually reduction) and activity be demonstrated consistently over a constellation of structures in the disorder.

Mood Disorder Although there have been fewer studies of mood disorders than of schizophrenia, some consistent findings have emerged. In major depressive disorder, smaller volumes of the frontal lobe, the cerebellum, the caudate, and the putamen have been reported. On the basis of these observations, neuroanatomic models of mood regulation involving specific frontosubcortical circuits have been proposed.

In patients with bipolar I disorder, the most commonly reported finding is the presence of an enlarged third ventricle. As the third ventricle lies adjacent to the hypothalamus, some researchers have suggested that hypothalamic dysfunction may play a role in the pathogenesis of bipolar I disorder. Less commonly, decreased volumes of the cerebellum and temporal lobes have also been noted.

In terms of pathological findings, several groups have reported an increased incidence of white matter hyperintensities in individuals with bipolar I disorder; unfortunately, neither the cause nor the clinical significance of these hyperintensities has been clearly established.

Obsessive-Compulsive Disorder Because of theoretical constructs suggesting caudate nucleus involvement and an early report of right caudate enlargement in patients with obsessive-compulsive disorder several MRI studies have focused on this structure, but compelling evidence for any change in caudate volume does not exist. A suggestion that this disorder is associated with nonspecific reductions in white matter as well as increases in cortical volume awaits replication.

Substance Abuse Investigations of structural brain changes in the various forms of substance abuse are confounded by two main issues. First, many types of substance abuse also involve behavior patterns that place patients at substantial risk for serious brain injury (i.e., fighting, motor vehicle accidents, and severe malnutrition). Separating the relatively subtle brain-toxic effects of a single substance, such as alcohol, from such direct and major brain injury is very difficult. In addition, polysubstance abuse tends to prevail in patients who are dependent on multiple illicit or prescription drugs, making it very difficult to attribute a subtle change to a single agent.

Of the substance abuse disorders, alcohol dependence has been the most thoroughly studied using computerized MRI scan neuromorphometry. Current evidence suggests that alcohol dependence leads to generalized reductions in brain mass as reflected by decreases in cortical gray and white matter and increased cerebrospinal fluid volume of the cerebral ventricles, particularly the lateral ventricles. Many of the changes may be at least partially reversed during sustained periods of abstinence. Reduction in the mass of the corpus callosum has been reported in one study, and a reduction of volume in the anterior lobe of the cerebellar vermis in the offspring of alcoholic mothers has also been noted.

Psychiatric Disorders in Childhood To date, the number of MRI studies in childhood psychiatric disorders is relatively small, and the early studies clearly suffered because they did not employ standardized morphometric analysis methods. In turn, some early findings, such as reduced volume of the cerebellar vermis in childhood autism, proved difficult to replicate. Disorders that have received special attention include autistic disorder, fragile X syndrome, Down syndrome, schizophrenia, obsessive compulsive disorder, Tourette's disorder, attention-deficit/hyperactivity disorder, and reading disorder.

Early studies of patients with attention deficit hyperactivity disorder suggested that the disorder was associated with reduced volume in the right prefrontal cortex and corpus callosum. A well-controlled study of 57 patients with attention deficit hyperactivity disorder and 55 age-matched controls using computerized morphometry finds attention deficit hyperactivity disorder associated with reduced volume of the right anterior frontal cortex and globus pallidus and loss of the normal right-left

asymmetry of the caudate. Based on these data, dysfunction of right prefrontal-striatal neural systems is hypothesized for attention deficit hyperactivity disorder.

In childhood schizophrenia the structural abnormalities in the brain mimic those seen in the adult disorder. These include lateral ventricular enlargement and a trend towards decreased cerebral volumes.

MAGNETIC RESONANCE SPECTROSCOPY

Under the right conditions, the actual concentration of an element with certain magnetic properties can be measured in specific brain regions by MRS. In human studies, several issues determine whether the capacity for MRS detection can be translated into an actual application. Identification and reliable measurement of cerebral metabolites requires the compound of interest to have a sufficiently high concentration and to give rise to a distinct MRS resonance. The concentration of the molecule also determines the spatial resolution that may be obtained.

When an element of interest not normally present in the human body (no background signal) is introduced into the human body and has a strong radiofrequency signal, MRS resonances may be detectable. The most common route of introduction for such elements is as a constituent element of pharmacotherapeutic molecules. For example, ^{19}F has a very high MRS sensitivity (see Table 1.16-1). Trifluorinated medications, including fluoxetine, trifluoperazine (Stelazine), and fluphenazine (Permitil) reach sufficiently high concentrations during routine pharmacotherapy to yield a signal of sufficient intensity for MRS detection in vivo in human brain. Polycyclic fluorinated drugs typically achieve brain concentrations on the order of 1 to 50 mmol, and ^{19}F MRS signals are usually recorded from the whole brain. ^{7}Li has a modest MRS sensitivity, but is present in brain at concentrations ranging from 0.1 to 1.0 millimolar when plasma lithium concentrations are within the therapeutic range. In a typical ^{7}Li MRS study, signals may be detected from brain regions ranging in volume from 100 to 1000 cm^3. Historically, one of the first research applications of MRS in psychiatry was to examine the pharmacokinetics of fluoxetine, antipsychotic medications, and ^{7}Li in the human brain.

Different issues arise when attempting to apply MRS to elements that are intrinsic to the human body. The contrast between signal from the molecule of interest and other molecules containing the MRS nucleus may be limited. For example, sodium (^{23}Na) has a strong magnetic moment, but is present at similar concentrations throughout the human body, and very few MRS applications have been developed for measuring ^{23}Na concentration in the human brain. ^{1}H is virtually ubiquitous in the human body, both in water as well as in a wide range of biomolecules. By suppressing the ^{1}H MRS signal from water protons, signals from endogenous metabolites with concentrations in the millimolar range may be detected in brain regions as small as 0.25 cm^3. Compared to ^{23}Na MRS, in which only a single resonance line is observed, hydrogen atoms that are present in different magnetic environments have slightly different resonance frequencies. Thus, the concentrations of several different compounds are typically detected in a ^{1}H MRS study. In addition, a family of sophisticated data acquisition techniques, known as *spectral editing*, facilitates the observation of resonance lines from some compounds, such as g-aminobutyric acid (GABA), which might not be detected otherwise. The concentration of proton MRS visible compounds vary throughout different brain regions and can be affected by disease processes or medications.

In vivo MRS may also be used to measure the concentration of high-energy phosphate metabolites using ^{31}P MRS. In studies of neuropsychiatric disorders, it is of relevance to explore which brain regions have altered concentrations of nucleoside triphosphate, ATP in brain, and phosphocreatine. Although the signal contrast principles are similar to proton MRS, the relatively weak contrast achieved has limited the use of ^{31}P MRS to very large brain regions. At 1.5 tesla, ^{31}P MRS data is usually obtained from brain regions on the order of 25 to 50 cm^3.

MRS has several unique features in contrast with other neuroimaging techniques, some of these are advantageous, others are not. One advantage is that the potential for signal detection for an element at a given concentration in the brain can be modeled by dissolving the molecule of interest in water and then placing it in a 1-liter flask, which is studied as if it is the human head; this is called a *phantom*. Another advantage is that MRS can be applied directly in animal or in vitro experiments that are related to in vivo work in human subjects. If the effect of a medication on the proton spectrum is being examined in a group of human subjects, it would be possible to examine the proton spectrum in the brain of a rat treated with the same medication or in the extracted cytosolic or membrane fractions of brain tissue taken from the same treated rat. Post mortem samples of human brain tissue taken from a deceased subject who was treated with the same medication could also be studied in vitro. The final and perhaps most important advantage of MRS when compared to other in vivo neurochemical measurement techniques is that the patient is not exposed to ionizing radiation. In subjects free of body metal or those implanted with biomedical devices such as pacemakers, MRS can be performed an unlimited number of times and at any interval required by the clinical or experimental situation.

A disadvantage of MRS is the requirement for specially built detection coils; only the in vivo proton MRS uses the standard clinical MRI apparatus for signal detection. ^{19}F MRS, ^{7}Li MRS, and ^{31}P MRS require the construction of a separate radiofrequency detection coil for each separate element. This time-consuming exercise requires considerable resources and expertise that are not normally available in clinical MRI units. Thus, much of the current focus in MRS is in the area of proton MRS.

Proton MRS The hydrogen atom is the most sensitive nucleus for MRS (Table 1.16-1). Proton MR spectra document signals from a number of compounds including NAA, cytosolic choline-containing compounds, Inositol and lactate (Fig. 1.16-2 and Fig. 1.16-3). Studies designed to identify alterations in brain levels of each of these compounds have been reported in patients with neuropsychiatric disorders.

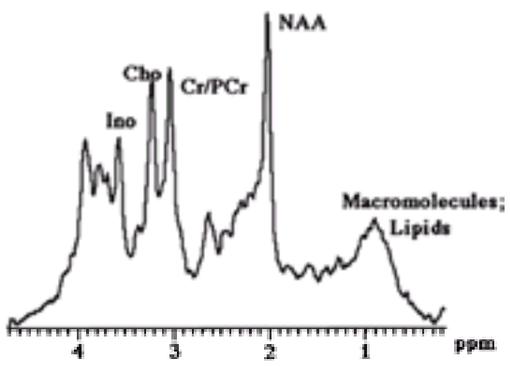

FIGURE 1.16-2 Proton magnetic resonance spectra. A is a short echo time (TE = 30 msec) STEAM spectrum from a 32-year-old healthy volunteer. Data was acquired from an 8-cm^3 volume located in the left, anterior frontal lobe. Note the prominent Inos resonance. Cho = cytosolic, choline-containing compounds; Cr/PCR = creatine and phosphocreatine; NAA = *N*-acetyl-L-aspartate.

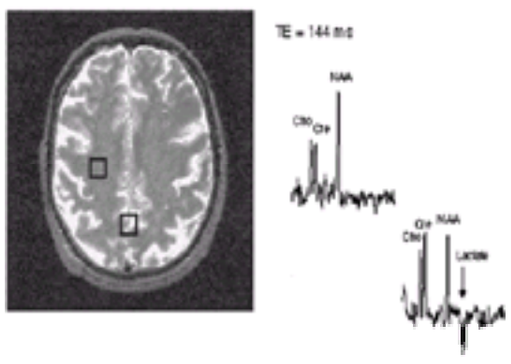

FIGURE 1.16-3 B displays two long echo time (TE = 144 ms) spectra from two locations (**A**) obtained from a 56-year-old man with mitochondrial myopathy, encephalopathy, lactacidosis, and stroke (MELAS). This disorder has been associated with increased brain lactate concentrations, best seen in the inverted pair of resonance lines at 1.4 PPM in the occipital region. (Courtesy of Lawrence L. Wald, Ph.D.)

Schizophrenia The most intensively studied ^{1}H MRS resonance line arises from NAA. One of the most consistently reported ^{1}H MRS findings in the psychiatric literature is the observation of decreased NAA resonance intensities in the hippocampus and frontal lobes of patients who have schizophrenia. Decreased NAA concentrations have also been observed in the temporal lobes of individuals with a first episode of psychosis, suggesting that this finding is present early in the course of illness. Further studies are necessary to clarify the degree to which this deficit increases with illness progression and to determine the degree to which this finding is specific to schizophrenia. An in vitro study of postmortem brain samples done on a 7-T unit suggests that concentrations of some amino acids such as glutamate, are reduced in schizophrenia. In vivo study of these lower concentration compounds will be facilitated by new human magnets that are 3 and 4 T.

Mood Disorders To date, most MRS studies relevant to mood disorders have employed either ^{19}F or ^{7}Li MRS in order to evaluate brain levels of pharmacological agents such as fluoxetine and lithium. However, another prominent brain ^{1}H MRS resonance line arises from cytosolic, choline-containing compounds. The vast majority of brain choline is present in the phospholipids phosphatidylcholine and sphingomyelin, which have restricted molecular motion and so do not contribute to the ^{1}H MRS resonance.

A role for altered choline metabolism in the pathophysiology of mood disorders was first proposed as an “adrenergic-cholinergic balance” manifested in mania by cholinergic underactivity and adrenergic overactivity. Several clinical studies have also demonstrated that the oral administration of both phosphatidylcholine and choline provides a moderate antimanic effect. Additionally, ^{7}Li exerts a potent and specific inhibitory effect on membrane Cho transport in man. Accumulating evidence has demonstrated that phosphatidylcholine hydrolysis by phospholipases A $_{2}$, C, and D is a widespread response elicited by many factors. These include growth factors, cytokines, neurotransmitters, hormones, and other extracellular signals. The molecules produced by this cleavage play an important role in intracellular message transduction.

Proton MRS provides a window on choline metabolism in the human brain that may have special relevance for the study of mood disorders illness. In this regard, a recent study of individuals with major depression has suggested that the intensity of the ^{1}H MRS choline resonance is altered in the basal ganglia and frontal lobes of depressed individuals. Future studies will be needed in order to determine the extent to which the ^{1}H MRS choline resonance is altered in other brain regions, as well as the degree to which these alterations are mood-state dependent.

Substance Abuse A limited number of ^{1}H studies relevant to substance use disorders have been conducted. Most attention has been paid to the fact that brain ethanol can be readily observed using ^{1}H MRS and that the relaxation or visibility of ethanol seems to be greater in tolerant than in nontolerant individuals. Extensions of this work might ultimately lead to diagnostic tests for ethanol tolerance and, by implication, for ongoing consumption. Elevated concentrations of creatine and myoinositol in abstinent cocaine users suggest that ^{1}H MRS may have a role in studying cocaine-related disorders, as well.

Panic Disorder A series of carefully designed ^{1}H MRS experiments in subjects with panic disorder have been undertaken that demonstrate that the intravenous infusion of lactate is associated with an excess increase in brain lactate levels in patients who experience a panic attack during the infusion. Later studies find that controlled hyperventilation increases brain lactate and does so disproportionately in subjects with panic disorder. Taken together, these studies have provided direct evidence that an important pathophysiological component of panic disorder may consist of an elevated cerebrovascular response to hypocapnia.

Dementia A number of research groups have used ^{1}H MRS to investigate possible neurochemical changes in patients with probable Alzheimer's disease. The most consistently reported observation has been that of decreased brain NAA concentrations. This decrease has been noted in many brain regions and may be most severe in the medial temporal lobe. Decreased concentrations of NAA in subjects with probable Alzheimer's disease most likely reflect a loss of neurons, which is consistent with structural neuroimaging studies that have generally noted progressive brain atrophy as being characteristic of the illness.

A more surprising finding has been the observation of increased brain inositol concentrations in patients with Alzheimer's disease. In occipital lobe gray matter, concentrations of inositol may be increased by as much as 50 percent relative to values obtained from matched comparison subjects. Although the cause of the observed increase in inositol is not clear, some clinical imaging centers now perform ^{1}H MRS as a diagnostic test for patients with memory loss. Additionally, some investigators have suggested that the ratio of NAA to inositol may serve as a useful measure of disease progression for following subjects with probable Alzheimer's disease over time.

Finally, a selective decrease in cholinergic neurons has been a consistent finding in postmortem studies of Alzheimer's disease brain tissue. Given that it is used for the synthesis of membrane lipid as well as of the neurotransmitter acetylcholine in cholinergic neurons, brain choline is almost exclusively dietary in origin. Recent studies have demonstrated that brain choline uptake may be directly observed by ^{1}H MRS following the oral administration of choline salts and that this uptake decreases markedly with increasing age, an observation that may provide a rationale for the fact that of the Alzheimer's dementia type is a disorder that almost always begins in late life. Additional studies are required to determine the relationship between decreases in brain choline uptake with advancing age and the development of dementing illness.

^{31}P MRS: DIRECT LOOK AT BRAIN BIOENERGETICS Much of the energy for biochemical reactions in the human brain is supplied when ATP is metabolized to adenosine diphosphate, a phosphodiester, in a reaction that also releases inorganic phosphate. ^{31}P MRS is able to detect and differentiate signal characteristics from the phosphorus moiety on each of these molecules and therefore to provide a window into the bioenergetic state of the brain (Fig. 1.16-4). In addition, this technique can also detect resonance lines arising from phosphomonoesters, which serve as membrane precursors, and from phosphodiesters, which consist largely of membrane catabolites. Alterations in the relative levels of phosphomonoesters and phosphodiesters provide some insight into the state of the brain membranes. However, MRS studies are severely limited by the problem of poor signal-to-noise contrast. Until recently, the most practical method for increasing ^{31}P MRS signal involved increasing the volume of measurement. As a result, the first generation of ^{31}P MRS studies did not provide the spatial resolution to make compelling anatomic correlates, and most neuropsychiatric studies focused on very large brain areas such as the entire frontal cortex. The recent development of methods for proton decoupling makes it possible to obtain brain ^{31}P MRS spectra with narrower resonance lines and increased signal-to-noise ratios. Additionally, the installation of three and four tesla whole-body magnets will also increase the utility of ^{31}P MRS for studies of cerebral metabolism.

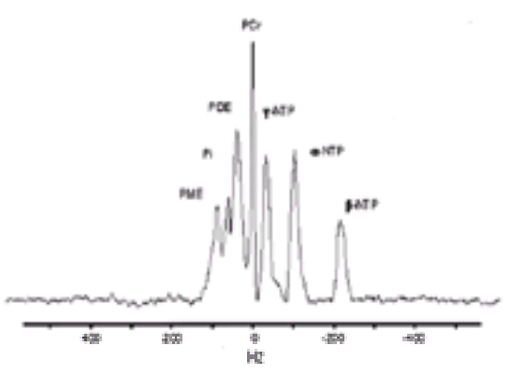

FIGURE 1.16-4 Phosphorus (^{31}P) MR spectrum. Data is acquired from an axial brain slice 50 cm in thickness. PME, phosphomonoesters; PDE, phosphodiesters; Pi, inorganic phosphate; PCr, phosphocreatine; NTP, nucleoside triphosphate. (Courtesy of Marc J. Kaufman, Ph.D.)

Schizophrenia Many studies suggest that schizophrenia seems to be associated with an increase in the concentration of phosphodiesters in the broadly defined frontal lobes. Based on the complementary finding of reduced phosphomonoester concentration in the frontal region, it has been suggested that the increase in phosphodiesters reflects a decrease in their activity and an increase in the activity of some phospholipase species. Alternatively put, schizophrenia patients may have decreased synthesis and increased breakdown of membrane phospholipids. These results, obtained in patients who had never been medicated as well as those who had been medicated recently suggest that the changes of the ^{31}P spectrum are present early in the course of the disease and may not relate to iatrogenic factors such as long-term treatment with antipsychotic medications. Increased concentration of phosphodiesters is also found in Alzheimer's disease, leading some to speculate about potential similarities in some aspects of the pathophysiology of Alzheimer's disease and schizophrenia. Although the neuropathological changes of Alzheimer's

disease are not found in schizophrenia, the high incidence of severe dementia in elderly institutionalized schizophrenia patients suggests that it is premature to dismiss the notion of pathophysiological commonalities between these two disorders.

Mood Disorder Low concentrations of phosphomonoesters and increased concentrations of phosphodiesters also occur in samples of patients with bipolar I disorder. Whether this suggests that at least in some cases schizophrenia and bipolar I disorder may share common pathophysiological markers or that treatment with ^{7}Li, which strongly impacts ^{31}P metabolism via its actions on inositol metabolism and choline transport, may alter other elements of phosphate metabolism is unclear.

Alcohol Abuse A limited number of ^{31}P MRS studies in patients with substance dependence limits the capacity to draw firm conclusions. Preliminary results may suggest that, in contrast to the other neuropsychiatric disorders noted, alcohol-dependent patients may have reductions in concentrations of phosphodiesters in the brain.

^{19}F MRS: TOWARDS BRAIN PHARMACOKINETICS OF ANTIDEPRESSANT AND ANTIPSYCHOTIC AGENTS Serum concentrations of either antidepressant or antipsychotic medications have limited clinical utility. Moreover, these classes of medications often have long half-lives and are highly lipid soluble. These factors suggest that the ability to measure the concentration of either of these classes of pharmacotherapeutic agents directly in the brain may provide useful information about clinical efficacy and the incidence of adverse effects.

Animal studies first suggested the possibility that ^{19}F MRS could be used to measure the concentration of trifluorinated antipsychotic drugs such as fluphenazine and trifluoperazine. Shortly thereafter, in vivo detection of such drugs in the human brain was accomplished by this technique. However, enthusiasm was limited by the very low signal-to-noise ratios and the unstable signal achieved in vivo: patients on low and moderate dosages of trifluoperazine often had large, easily detectable signals in contrast to patients on oral dosages of 120 mg a day who had no signal.

Brain Fluoxetine and Fluvoxamine Concentrations In contrast to the inconsistent signals achieved from the trifluorinated antipsychotic agents, a very consistent and robust signal was obtained from the ^{19}F constituent of the trifluorinated selective serotonin reuptake inhibitor, fluoxetine, the most prescribed antidepressant in the United States. In the first large study involving 21 subjects on routine doses ranging from 20 to 40 mg a day, brain concentrations initially reflected cumulative dose and reached steady state only after 6 months or more of treatment at concentrations ranging up to 11 μg per ml, about 20 times the concentration detected in plasma. These results have been widely replicated and probably reflect the long half-life of fluoxetine and its highly lipophilic nature.

Later studies have focused on the T1 and the anatomic origin of the nuclear magnet resonance (NMR) signal from ^{19}F in fluoxetine. To do this requires a specialized quadrature volume coil built in the laboratory. This contrasts to earlier work using a flat surface 16 cm in diameter placed on the front of the head, which was later modified to conform to the surface of the forehead.

In an experiment involving five subjects treated with fluoxetine, there was substantial variation in the T1 values, which apparently stems from real interindividual differences. Unfortunately, T1 is correlated with the corresponding brain fluoxetine concentration (C_F) at a Pearson r of 0.57 (mean T1 = 240 mx ± 75), suggesting a possible confound for the determination of fluoxetine concentrations as T1 appears in both the numerator and denominator of the calculation equation. This correlation of T1 with brain C_F may stem from fast exchange between unbound and bound fluoxetine. In brain, fluoxetine will undoubtedly bind to a variety of sites, which can be assumed to be relatively immobile. Binding fluoxetine, a small molecule, to macromolecular sites will resist ^{19}F's ability to align with a magnetic pulse and will lower the T1; unbound fluoxetine will have a longer T1 by comparison.

To demonstrate the utility of in vitro MRS to address questions about the in vivo state, in vitro ^{19}F MRS was performed on extracted brain tissue obtained at autopsy from a patient who was being treated with fluoxetine at the time of his death from natural causes. In these cytosolic (unbound) extracts, fluoxetine concentrations ranged up to fourfold higher than those seen in the intact tissue, supporting the notion that a relatively long T1 in some subjects may be related to the bound fraction of fluoxetine or its metabolites. These fundamental questions about previously “hard” assumptions, such as that T1 is similar from subject to subject, illustrate that MR remains in its early development.

In vivo methods similar to those described for fluoxetine, have now been applied to fluvoxamine (Luvox). Measured concentrations range from 3.0 to 12.7 μmol in a sample of patients receiving a mean dosages of 217 ± 68 mg a day. Moreover, for this fast-acting drug, the mean elimination half-life from the brain is 58 hours and the mean brain to plasma elimination half-life ratio is 2.4.

Lithium (^{7}Li) MRS in the Brain Like the ^{19}F atom, ^{7}Li is an element found in a frequently used psychotropic medication that is also not normally present in the human brain. Exogenously administered, ^{7}Li easily creates a sufficient brain concentration to be measured by MRS. Current MRS studies find that brain ^{7}Li concentrations are about half those in serum and peak at around 4 hours after the last dose of ^{7}Li, compared with at around 2 hours in serum. However, the extent to which altered ^{7}Li pharmacokinetics contributes to the variable clinical response to ^{7}Li therapy in patients with bipolar I disorder has not been determined. Additionally, studies of clinical populations that may have altered ^{7}Li pharmacokinetics, such as children, the elderly, or those with medical illness, have not been concluded.

Also promising are animal studies that suggest that the strong ^{7}Li signal makes it possible to ultimately map ^{7}Li distribution in human brain, potentially identifying the site or sites of ^{7}Li action. Another approach may be to combine localized ^{7}Li MRS with proton MRS to relate the actions of ^{7}Li to changes in brain Cho metabolism.

FUNCTIONAL MAGNETIC RESONANCE IMAGING

Functional brain imaging studies have historically been limited both by the need to use radioactive tracers as well as by poor temporal resolution. Recent developments in the area of MRI may largely surmount these limitations. First the development of high-speed, echo planar imaging devices has greatly enhanced the temporal resolution of MRI. With echo planar imaging single-image planes can be acquired in 50 to 100 msec or multiple-image planes can be acquired each second. fMRI studies, which may be performed with or without a high-speed MR scanner, selectively detect image parameters that are proportional to cerebral blood flow or blood volume. This strategy capitalizes on the fact that focal changes in neuronal activity usually are closely coupled to changes in cerebral blood flow and blood volume.

fMRI studies may be divided into two separate classes: those that make use of endogenous physiological factors to detect changes in cerebral activation: the *noncontrast* techniques, and those that require the intravenous administration of a paramagnetic agent: the *contrast* techniques. Noncontrast techniques make use of either T1-weighted pulse sequences to detect changes in blood flow or, more commonly, T2-weighted pulse sequences to detect changes in the local concentration of paramagnetic deoxyhemoglobin. The latter method has been referred to as *blood oxygen-level dependent* imaging. In a blood oxygen-level dependent imaging experiment, regional brain activation is associated with changes both in blood flow and blood volume, generally leading to a washout of paramagnetic deoxyhemoglobin and an increase in local signal intensity.

Blood oxygen-level dependent imaging studies are limited in several important aspects from the perspective of performing clinical research studies. At 1.5 tesla, the magnitude of the observed changes in signal intensity is relatively small. For instance, photic stimulation, which induces a substantial increase in occipital cortical blood flow, produces only a 2 to 4 percent increase in magnetic resonance signal intensity. Recent work also suggests that the magnitude of changes in blood oxygen-level dependent signal intensity may vary with subject's age and gender. Further, many medications directly affect vascular tone and modify changes in blood oxygen-level dependent signals presenting an important confound for studies of subjects with psychiatric illness. Finally, the uncoupling of cerebral blood flow and volume that occurs following cerebral activation and produces the blood oxygen-level dependent effect appears to resolve with prolonged stimulation. In response to these problems, many research groups are developing noncontrast fMRI methods that have a greater sensitivity to changes in cerebral blood flow.

The contrast method is a tracer kinetic technique that utilizes the bolus injection of a paramagnetic contrast agent to produce changes in tissue magnetic susceptibility and magnetic resonance image intensity. During the first pass of the contrast agent, magnetic resonance signal intensity may decrease by as much as 20 to 40 percent. This method may be used to map the distribution of cerebral volume at rest or to measure changes in response to cerebral activation. Resting maps of cerebral volume (Fig. 1.16-5 and Fig. 1.16-6) have been shown to correlate well with PET images of fluorodeoxyglucose uptake and with SPECT images of cerebral blood flow. Additionally, the recent development of a multiple bolus method for performing dynamic susceptibility contrast studies is likely to facilitate the measurement of the drug's effects on cerebral hemodynamics.

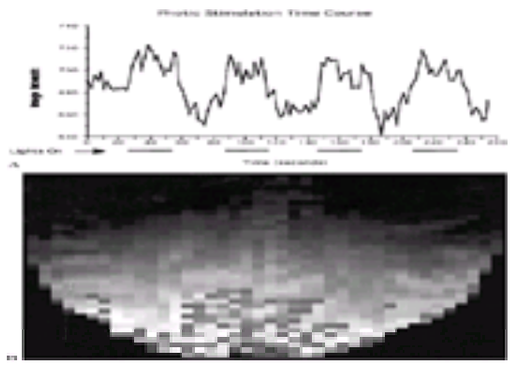

FIGURE 1.16-6 fMRI studies of photic stimulation. **A**, Change in image signal intensity in a single pixel during four alternating, 30-second epochs of flash photic stimulation. **B**, Activation maps demonstrating statistically significant increases in image signal intensity in primary visual cortex. Image data is acquired with a surface coil placed at the back of the head, thus explaining the decrease in image intensity with increasing distance from the occipital pole of the head. (Courtesy of Jonathan M. Levin, M.D., and Luis C. Maas.) (See Color Plate 1.)

Schizophrenia The promise that fMRI studies hold for the evaluation of patients with mental illness has recently been reviewed and schizophrenia is the disorder that has been studied the most intensively. Subjects with schizophrenia appear to have an increased blood oxygen-level dependent signal change in response to photic stimulation when compared to healthy volunteers. This finding, which was not anticipated, has been substantiated by recent PET studies in which an augmented cerebral blood flow increase was noted in schizophrenia subjects relative to comparison subjects during photic stimulation across a range of different frequencies. Additionally, a preliminary dynamic susceptibility contrast fMRI study has suggested that subjects with schizophrenia have an increased resting occipital blood volume. It is not clear to what extent these early findings result from altered vascular anatomy in the occipital cortex, altered cortical activation in response to photic stimulation, or the vasoactive effects of antipsychotic medication. Blood oxygen-level dependent signal changes in response to motor tasks have also been evaluated in schizophrenia patients. Finger-to-thumb opposition was associated with decreased activation of sensorimotor cortices and the supplementary motor area in subjects with schizophrenia relative to comparison subjects.

Although the use of blood oxygen-level dependent fMRI as a research tool is complicated by the large number of factors that can influence the magnitude of the signal change, altered patterns of cortical activation may serve as a more promising target for research. As an example, investigators have recently used blood oxygen-level dependent fMRI to evaluate changes in frontal and temporal lobe activation during word production in subjects with schizophrenia and in matched comparison subjects. Whereas the frontal lobe has decreased activation in subjects who have schizophrenia, the temporal lobe demonstrates increased activation. Similar findings have recently been demonstrated using PET blood flow studies and the identification of altered patterns of frontal-temporal circuitry in subjects with schizophrenia remains an active area of research.

Obsessive-Compulsive Disorder and Tourette's Disorder Patients with obsessive-compulsive disorder have been studied during symptom provocation using blood oxygen-level dependent fMRI. Brain regions that activated in the patient group in this study included the medial orbitofrontal, lateral frontal, anterior temporal, anterior cingulate, and insular cortices. These results are reasonably consistent with those reported by other groups using both PET and SPECT imaging.

fMRI has also been used to contrast the cerebral blood in Tourette's disorder patient, while they are suppressing tics versus when they allow the spontaneous expressions of their tics. Significant changes in signal intensity between the two states were demonstrated in the thalamus, and basal ganglia, and these changes correlated inversely with tic severity.

Alzheimer's Disease Dynamic susceptibility contrast MRI has also been used to evaluate changes in regional cerebral perfusion in patients with Alzheimer's disease. Based on the data from these studies, cerebral blood volume maps appear to provide data that is equivalent to that obtained by SPECT for establishing a diagnosis of probable Alzheimer's disease. However, data to generate cerebral blood volume maps is acquired over the course of 1 to 2 minutes and without the use of radiotracers. Thus, susceptibility contrast MRI may be particularly well suited, as compared to SPECT, for the evaluation of subjects with dementia. The ongoing development of therapeutic agents for Alzheimer's disease suggests that functional brain-imaging studies may play an important role in the evaluation of these drugs on cerebral metabolism. Additionally, it has recently been demonstrated that asymptomatic individuals at increased risk of developing Alzheimer's disease have decreased temporoparietal metabolism. These findings, if replicated, would bode very well for the use of dynamic susceptibility contrast fMRI as a safe diagnostic tool for the very large population of older adults at risk for developing dementing illness. Susceptibility contrast MRI is also being actively investigated as a tool for the evaluation of patients with a range of neurological disorders, including cerebral ischemia and infarction, cancer, and epilepsy.

Over time, fMRI will come to play an important role in psychiatric neuroimaging research. It offers an unprecedented opportunity for clinical neuropsychiatrists to directly evaluate many aspects of brain activity in both healthy and ill individuals. However, as with any new methodology, the promise that is so readily apparent must be balanced against the obstacles that will be identified with further research.

SUGGESTED CROSS-REFERENCES

Brain mechanisms of schizophrenia are discussed in Section 12.3, bipolar I disorder is discussed in Chapter 14, and obsessive-compulsive disorder is presented in Chapter 16. Chapter 35, Chapter 36, Chapter 37, Chapter 38, Chapter 39, Chapter 40, Chapter 41, Chapter 42, Chapter 43, Chapter 44, Chapter 45, Chapter 46, Chapter 47, Chapter 48 and Chapter 49 discuss childhood psychiatric disorders, substance abuse is discussed in Chapter 11, and Alzheimer's disease is discussed in Section 51.3e.

1.17 POPULATION GENETIC METHODS IN PSYCHIATRY

STEVEN O. MOLDIN, PH.D., AND IRVING I. GOTTESMAN, FH.D., F.R.C. PSYCH. (HON.)

The human genome consists of between 50,000 and 100,000 genes, of which over 20,000 have been identified. Over 5000 genetic disorders, each transmitted through a single mutant gene, have been characterized. The application of more powerful quantitative methods of analysis, new molecular technologies, and more detailed maps of the human genome have permitted localization to chromosomal regions of over 400 of these disease genes, with precise identification of more than 80.

There are major public health implications of identifying genes that influence an individual's risk for developing the more common familial mental disorders like schizophrenia, bipolar I disorder, alcoholism (alcohol abuse or dependent) and obsessive-compulsive disorder. Such findings may ultimately be of relevance to many affected individuals and their relatives, given the potential for developing a genetic test to identify individuals at risk and, most importantly, for providing the pharmaceutical industry with new drug therapy targets. Clinicians and researchers must understand the basic mathematical principles and quantitative methods of population genetics and genetic epidemiology so that they will be able to appreciate the relevance of new data derived from the genetic analysis of mental disorders.

MAIN SUBDIVISIONS OF GENETICS

The scientific study of heredity, which began with Gregor Mendel's work on peas in 1865, gradually developed into five major disciplines. *Biochemical genetics* is concerned with the biochemical reactions by which genetic determinants are replicated and produce their effects. *Developmental genetics* is concerned with the study of mutations that produce developmental abnormalities so that researchers can gain an understanding of how normal genes control growth and other developmental processes. *Molecular genetics* studies the structure and the functioning of genes at the molecular level. *Cytogenetics* deals with the chromosomes that carry those determinants. *Population genetics* may be subdivided into the partially overlapping fields of evolutionary genetics, genetic demography, quantitative genetics, and genetic epidemiology. Quantitative genetics and genetic epidemiology provide the mathematical methods to aid in the identification of genetic factors that influence risk to mental disorders.

DEFINITIONS

Population genetics deals with the mathematical properties of genetic transmission in families and populations. The primary goal of evolutionary genetics is to understand changes in gene frequency across generations. Genetic demography is primarily concerned with differential mortality and fertility (fitness) in human populations. Quantitative genetics and genetic epidemiology are the fields of population genetics that are of most relevance to the study of mental disorders. The goal of quantitative genetics is to partition variation in the observed differences between phenotypes into its genetic and environmental components. This area of study was developed largely to improve animals and plants through artificial selection and usually deals with continuous traits (e.g., milk yield or egg size), rather than discrete traits. Genetic epidemiology is explicitly directed toward understanding the causes, distribution, and control of disease in groups of relatives and the multifactorial causes of disease in populations. The mathematical principles of genetic epidemiology and quantitative genetics are central to *risk analysis*, which is the essential element in genetic counseling of familial disease, and to *linkage analysis*, which is a statistical procedure used to implicate a particular chromosomal region as containing a putative disease susceptibility gene. Figure 1.17-1 shows the focus of genetic epidemiology to be on genetic and environmental factors that interact in determining observed behavioral outcomes (disease). Differences between common and individual-specific environmental effects, and between genes of major versus minor effect, are discussed in the section on multilocus genetic models. *Psychiatric genetics* involves the specific application of genetic principles and methods to the study of mental disorders.

FIGURE 1.17-1 The network of genetic epidemiology.

BASIC ELEMENTS

A fundamental distinction in population genetics dating to Wilhelm Johannsen's work in 1909 is between *genotype* (an inferred set of genes) and *phenotype* (an observed effect of those genes); the distribution of the frequencies of the various phenotypes constitutes the essential description of a population. Gene frequencies are used to predict frequencies of genotypes and phenotypes and vice versa under a set of assumptions that include the following: (1) From the pattern of familial inheritance, the genotypes can be distinguished unequivocally, such that the frequencies of phenotypes are the same as those of the underlying genotypes. This relation between phenotypic and genotypic frequencies requires the related assumptions of negligible mutation rates and the occurrence of segregation of genes according to Mendel's laws. (2) There is no selection—that is, the expected number of fertile progeny from a mating that reaches maturity does not depend on the genotypes of the mates. (3) The population structure is such that all matings take place at random with respect to the genetic differences being considered in a population of infinite size. Consequently, the probability of mating between persons is in no way influenced by their genotype at a given locus.

A general theorem formulated in 1908 independently by Godfrey Harold Hardy and Wilhelm Weinberg is derived from these assumptions and fits the facts well in many cases. In its simplest form the *Hardy-Weinberg law* states that if respective gene frequencies of two alternative forms of a gene *(alleles) A* and *a* are *p* and *q*, the respective genotypic frequencies among progeny with genotypes *AA, Aa*, and *aa* are p^2, *2pq*, and q^2. This relation between gene frequencies and genotype frequencies is of the greatest importance because many of the deductions in quantitative and population genetics are based on it.

A basic distinction in population genetics of direct relevance to the analysis of mental disorders is that between *quantitative* and *qualitative* phenotypes. Can persons be classified to one of a small number of discrete classes, or can they be assigned a continuous score on an observed continuum? Disease phenotypes are qualitative—persons are classified as affected or unaffected. Contemporary genetic analysis usually posits an underlying but so far unobservable liability to affection that is continuous, with affected cases consisting of persons at an extreme end of the continuum. This is analogous to having height as the phenotype but only being able to measure tall versus nontall, rather than height in centimeters. Quantitative phenotypes are those in which an observable continuous scale is used to measure

the variable under consideration, e.g., enzyme levels, intelligence quotient (I.Q.) scores, and blood pressure.

A variable measured on a continuous scale has inherently greater information content than one measured as a dichotomous variable; therefore, quantitative traits that are highly correlated with liability to an illness can make important contributions to genetic analysis. Highly specific and sensitive biological measures of quantitative processes have not yet been found for mental disorders; rather, qualitative determinations (affected versus unaffected status) established through a structured diagnostic interview are the typical source of phenotypic data for genetic analysis.

GENETIC MODELS

Mathematical models are required in population genetics to represent the ways in which genes and the environment interact to form complex phenotypes transmitted within families (Table 1.17-1).

		Source of Familial Resemblance		
Genetic Model	Genes of Major Effect (N)	Genes of Minor Effect	Common Environment	Individual-Specific Environment
Single Major Locus	Yes (1)	No	No	Yes
Allelic Heterogeneity	Yes (1)	No	No	Yes
Locus Heterogeneity	Yes (>1)	No	No	Yes
Multifactorial	No	Yes	Yes	Yes
Mixed	Yes (1)	Yes	Yes	Yes
General multilocus	Yes (>1)	Yes	Yes	Yes

Table 1.17-1 Genetic Models of Disease Transmission

Single Major Locus Model The single major locus model assumes that all relevant genetic variation results from the presence of alleles at a single locus, and that environmental variation is unique to an individual. With two alleles, *A* and *a*, with respective frequencies *p* and *q*, three genotypes are possible: *AA, Aa*, and *aa*. When both alleles are the same, it is a *homozygous* genotype; when two alleles are different, it is a *heterozygous* genotype. The sum of the allele frequencies totals unity, so by definition, $p + q = 1$; thus, $1 - q = p$. If the environment is constant, such that each genotype corresponds to only one phenotype, the gene at a given locus is *completely penetrant*.

Diseases transmitted through a single major locus are referred to as *Mendelian diseases*, as the pattern of inheritance in families follows the rules of Mendelian segregation and can usually be recognized through visual inspection of pedigrees. Characteristic single locus diseases include retinitis pigmentosa, Duchenne dystrophy, Huntington's disease, phenylketonuria, and cystic fibrosis. The important discovery in 1991 of intraallelic expansion of highly unstable trinucleotide (triplet) repeat sequences helps to explain the variations in age of onset and severity without invoking an additional modifying locus. Huntington disease, fragile X syndrome, myotonic dystrophy, spinobulbar muscular atrophy, spinocerebellar ataxia type 1, and Machado-Joseph disease are all caused by the expansion of unstable repeat sequences in single major genes.

Familial patterns of simple Mendelizing inheritance can be characterized by whether the disease gene is on an autosome or on a sex chromosome and by whether both alleles are required for expression (recessive disease) or only one allele is sufficient (dominant disease). The liability distributions in the general population resulting from a diallelic major locus in Hardy-Weinberg equilibrium are shown in Figure 1.17-2.

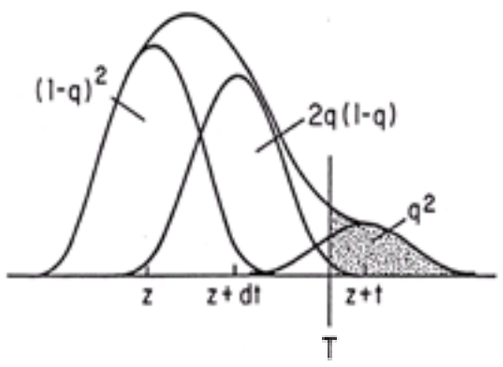

FIGURE 1.17-2 Liability distributions resulting from a single major locus in Hardy-Weinberg equilibrium. The locus has two alleles *A* and *a*, with frequency *p* and *q*. Given that $p + q = 1$, $p = (1 - q)$. The three genotypes *(AA, Aa, aa)* have respective means of z, z + dt, and z + t; d = 0 results in a recessive locus while d = 1 results in a dominant locus. The respective genotypic frequencies are $(1 - q)^2$, $2q(1 - q)$, and q^2. The shaded area gives the lifetime morbid risk of the disease (K_p). The proportion of persons with a given genotype who are above the threshold T gives the penetrance of that genotype.

Single Major Locus Modes of Inheritance The following criteria for different single locus models of disease transmission are required: (1) *Autosomal dominant*—(a) transmission continues from generation to generation without skipping; (b) except for freshly mutated cases (or nonpaternity), every affected child has an affected parent; (c) the two sexes are affected in equal numbers; and (d) in marriages of an affected heterozygote to a normal homozygote, the probability that a child born into that family will be affected (the segregation ratio) is [fr1,2]; (2) *Autosomal recessive*—(a) if the disease is rare, parents and relatives (except siblings) are usually normal; (b) all children of two affected parents are affected; (c) in marriages of two normal heterozygotes, the segregation ratio in offspring is ¼ and (d) the two sexes are affected in equal numbers; (3) *Sex-linked recessive*—(a) if the disease is rare, parents and relatives (except maternal uncles and other male relatives in the female line) are usually normal; (b) hemizygous affected men do not transmit the disease to children of either sex, but all their daughters are carriers; (c) heterozygous carrier women are normal but transmit the disease to their sons with a segregation ratio of ½, and half of the daughters are normal carriers; and (d) except for mutants, every affected male child comes from a carrier mother.

The concept of *incomplete penetrance* refers to persons with identical genotypes who have different phenotypes because of variability in nontransmissible environmental factors that contribute to the phenotype. The penetrance is the probability that a person with a given genotype will manifest the illness; probabilities are usually denoted by the letter *f*. The lifetime cumulative incidence or morbid risk of a disease is frequently denoted by the letters K_p. In the case of a disorder caused by a diallelic autosomal single major locus the respective gene frequencies of the *A* and *a* alleles are *p* and *q* and the respective penetrances associated with the *AA, Aa*, and *aa* genotypes are f_1, f_2, and $f_3 - K_p = f_1p_2 + f_2 2pq + f_3q_2$. Current generalized single major locus models allow for incomplete penetrance (i.e., one or more *f*s are not equal to 0 or 1), with transmission of a fully penetrant major locus contained as a submodel.

Elucidation of abnormal protein products and subsequent resolution of pathophysiology is theoretically more straightforward in the case of disease transmission through a single major gene than in the case of disease transmission through polygenes. However, the genetics of single major locus diseases can still be complicated, as exemplified by Huntington disease. Clinical characterization of this disease first occurred in the 1800s, a dominant disease locus was linked to genetic markers on chromosome 4 in 1983, and the precise gene was only identified in 1993.

Multilocus Models These models specify the effects of multiple loci, with or without contributions from environmental factors, on susceptibility to disease. It is useful to distinguish *familial (common) environmental effects* from *individual-specific (idiosyncratic) environmental effects*. The latter refer to environmental experiences

unique to the individual and not shared among family members; this is also called the *within-family environment*. The former refer to environmental influences that are common to, or shared by, family members; this is also called the *between-family environment*.

Genetic influences in multilocus models may arise from the effects of *genes of major effect* versus *genes of minor effect*. The former refer to genes that make a large relative contribution to the total variance in the disease attributable to genetic influences; the latter are genes that each make a small relative contribution to the total variance attributable to genetic factors. The individual unit for each—a gene—remains the same; the distinction between genes of major versus minor effect refers exclusively to the relative degree of influence that they have on the final behavioral outcome. Most common human diseases are inherited under a multilocus model; examples include hypertension, insulin-dependent diabetes mellitus, pyloric stenosis, rheumatoid arthritis, peptic ulcer, most cases of breast cancer, coronary artery disease, spina bifida, coronary artery disease, dementia of the Alzheimer's type late onset, with multiple sclerosis, and many mental disorders. Multilocus model variants may be distinguished in regard to the number of loci, if any, that exert a larger influence on the phenotype relative to the influence of other genes.

Multifactorial Model The multifactorial model assumes that all genetic variance is attributable to genes, called *polygenes*, that each exert a small relative effect. All relevant genetic and environmental contributions to variation can be combined into a normally distributed variable termed I>liability. There are one or more threshold values on the liability scale such that affected individuals are those with liability values that exceed the threshold. Familial inheritance is modeled through correlations in liability between family members, with the following assumptions: (1) relevant genes act additively and are each of small effect in relation to the total variation; (2) environmental contributions result from many events whose effects are additive; and (3) there may be multiple thresholds, such that individuals with scores between threshold values represent milder phenotypic or spectrum cases. When all transmissible effects are genetic (i.e., common environment exerts no influence), this is called the *polygenic model*. One or more threshold values are on the liability scale; affected persons are those with liability values that exceed the threshold. Familial inheritance is modeled through correlations in liability between family members. There may be multiple thresholds, such that persons with scores between threshold values represent mild phenotypic or spectrum cases. Normal traits inherited in this way include intelligence, stature, skin color, total dermal ridge count, and probably blood pressure. When the phenotype is qualitative (presence or absence of disease), a continuous liability distribution is unobservable but is assumed to underlie the discrete phenotypic events that are observed. Liability distributions in the general population for single-threshold and two-threshold multifactorial models are shown in Figure 1.17-3.

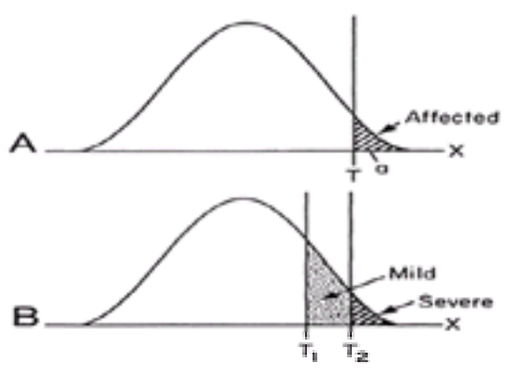

FIGURE 1.17-3 The unobserved liability *(x)* underlying a multifactorial disease with **(A)** a single threshold T and mean liability of affected persons denoted by *a*; **(B)** two thresholds T_1 and T_2, used to model severity, such that persons with a liability score above T_2 have a core (severe) phenotype, and persons whose liability is between T_1 and T_2 have a milder form of the illness (spectrum condition). The shaded areas give the lifetime cumulative incidences (K_p).

Mixed Model The mixed model is a marriage of the single major locus model and the multifactorial model. A distribution of liability is determined by the effects of a major locus, a multifactorial transmissible background (polygenes or environmental factors), and residual individual-specific environmental factors. The mixed model differs from the multifactorial model regarding the presence of a single genetic locus of major effect. Since both the single major locus model and the multifactorial model are submodels, the mixed model provides a statistical advance in permitting the rigorous testing of whether a single major locus or a multifactorial component (or both) contributes to familial resemblance.

General Multilocus Model The general multilocus model differs from the mixed model by the specification of more than one locus of relative major effect. The major assumption is that the marginal effects of these genes are etectable and separable from the background effects of other genetic loci of minor effect or environmental contributors. When multiple loci of small relative effect influence a phenotype measured on a continuous scale, they are commonly referred to as *quantitative trait loci*. Complex interactions among loci of major or minor effect *(epistasis)* may occur. Alternatively, each locus of relative major effect may be an independent and sufficient cause of disease; such multilocus models are termed *genetic heterogeneity models*—individuals can be affected if they possess a predisposing genotype at any one of the loci of relative major effect. Consequently, disease transmission in one set of families may be attributable to a locus that is different from the one predisposing to illness in another set of families.

The general multilocus model is the most comprehensive and realistic transmission model because common illnesses are likely to be influenced by major and minor genetic effects and by common environment. One way to quantify the relative effect of one locus versus others in multilocus models is to consider the proportion of disease risk that is attributable to that locus. This may be accomplished through consideration of the risks to different classes of relatives (i.e., siblings, monozygotic twins, cousins) of affected individuals conferred by that specific locus as compared to the population prevalence. Locus-specific risk ratios (frequently denoted as l) on the order of 1.5 to 2 may be expected for many mental disorders and other complex diseases. For example, analyses of recurrence risk patterns in first-, second-, and third-degree relatives and in monozygotic twins have suggested that multilocus models with gene effects of l = 2 are consistent with the familial transmission of schizophrenia and with cleft palate. Recently, variance-component methods for linkage analysis, which permit estimation of the magnitude of the effect of a detected locus within a multilocus system, have been developed.

RESEARCH DESIGNS

Population, family, twin, adoption, linkage, and association studies can each contribute evidence to evaluate the involvement of genetic factors in the cause of an illness (Table 1.17-2).

Study	Unit of Analysis	Goal
Population	Subjects in the general population	Establish lifetime incidence
Family	Pedigrees	Establish familiarity; estimate mode of transmission and risks to relative classes
Twin	Monozygotic and dizygotic twins	Distinguish genetic from environmental effects
Adoption	Adoptees; adoptive and biological relatives of adoptees	Distinguish genetic from environmental effects
Linkage	Nuclear or extended pedigrees or both	Establish chromosomal location of a disease susceptibility gene
Association	Unrelated affected individuals and controls	Identify a specific disease susceptibility gene
Transgenic	Gene expression and function in animals	Specify developmental outcomes/pathways

Table 1.17-2 Study Designs for Genetic Research on Mental Disorders

Population Studies Prevalence and incidence rates of mental and other disorders derived from community-based surveys have important scientific and health policy implications. Variations in such rates can provide clues to causes and can be used as base rates for comparative purposes in family genetic studies.

Family Studies If genetic factors are involved in illness transmission, the illness should occur in the families of affected members at a higher rate than in appropriate control populations. However, relatives who share a number of genes also tend to share common environments, so familial aggregation by itself does not necessarily implicate a genetic mechanism; culture, family environment, or infectious agents may be responsible. Family studies for mental and other disorders begin with affected persons *(probands)* selected from consecutive hospital inpatient admissions or a psychiatric case registry. Available relatives are located and assessed for psychopathology with structured or semistructured diagnostic instruments. Countries with national health insurance and psychiatric registers can provide morbidity information across generations. Recurrence risks are expected to increase as the degree of genetic overlap between relatives increases. The closest familial relationship is that of monozygotic twins, who share all their genes in common. Dizygotic twins, full siblings, parents, and children are first-degree relatives, who share half of their genes on average. Second-degree relatives of probands—grandparents, grandchildren, uncles, aunts, nieces, nephews, and half-siblings—share one fourth their genes.

A variety of factors tend to make comparisons of familial risk to mental disorders across studies difficult. Those factors include differences in sample characteristics, methods of age correction, ascertainment schemes, and diagnostic procedures. Such methodological concerns can explain how in different studies the risk for depression in first-degree relatives of depressive probands varies between 11 and 18 percent whereas the risk to relatives of normal controls varies between 0.7 and 7.3 percent. Comparison of normal controls and high-risk relatives by similar case-finding and diagnostic methods are essential when interpreting mean risk estimates. Similarly, the ideal family study uses double-blind, case-controlled methods in which diagnoses of relatives are made independently of the proband's diagnosis.

Age Correction Family studies permit determination of morbid risk estimates in different relative classes. A simple tally of the frequency of a disorder in relatives will underestimate the true morbid risks, because not all unaffected individuals have passed through the period of risk for mental disorders at the time of examination. Quantitative methods have been developed that permit estimation of morbid risks with suitable *age correction*, that is, morbid risk estimation that takes into account the fact that some of the unaffected individuals now observed as unaffected will develop illness at a later point in time. Wilhelm Weinberg's short method of age correction was the first devised early in the twentieth century; this simple procedure assigns weights to the number of unaffected individuals in different age groups. Weinberg's method was followed by one developed by Eric Strömgrer, and independently by Eliot Slater, which uses the ages at onset in the proband samples to obtain an age-at-onset distribution. All unaffected relatives are weighted by the proportion of the risk period through which they have passed, and the lifetime morbid risk is then computed as the number of affected individuals divided by the number at risk (the number affected plus the weighted sum of unaffected relatives).

Survival curve estimation methods are now applied to determine age-corrected lifetime morbid risks in relatives. *Survival analysis* is a mathematical technique that models time to an event (e.g., illness onset) while paying special attention to incomplete (censored) data in which the event is not observed for all individuals. Covariates that influence the time to the event may be modeled in the Cox proportional hazards model. The nonparametric Kaplan-Meier estimate of time to onset of illness is typically used to estimate lifetime morbid risk; only onsets in relatives (and not in the probands) are considered.

Twin Studies The twin method has been a popular research design to implicate or exclude genetic factors in the cause of a disease. Since monozygotic twins have identical genotypes, any dissimilarity between pair members must result from the action of the environment, either prenatally or postnatally. Consequently, anything less than 100 percent concordance among monozygotic pairs living through the period of risk excludes genetic factors as sufficient determinants of that disease.

If genetic differences are not important for the familial clustering of a disease, no differences should be seen in the monozygotic and dizygotic concordance rates. This is what occurs in twin studies of diseases caused by infectious agents (e.g., measles). Conversely, if genes are important in causing a disease, the monozygotic concordance rate is significantly higher than the dizygotic rate. A genetic basis is the most likely explanation for the higher monozygotic concordance rate if monozygotic twins are not more predisposed to having the disease and if monozygotic twin environments are not more alike in features that cause the disease. The twin method in psychiatry has also been useful in identifying spectrum conditions that are alternative manifestations of the disease genotype that occur in monozygotic twins discordant for the core illness. A variant of the twin design is to include the offspring of concordant versus discordant twins.

Critics of the twin method have argued that monozygotic pairs share more similar environments than do dizygotic pairs, and that is responsible for the higher monozygotic concordance rate for mental disorders. Three ways in which environmental factors may increase the rate have been advanced: (1) monozygosity per se, (2) the effects of identification by one twin with another, and (3) the sharing of a similar ecology, with enhanced exposure to triggering events. No conclusive evidence exists that those limitations have substantially or consistently biased the results of twin studies of mental disorders.

Adoption Studies Whereas monozygotic and dizygotic twin studies endeavor to hold the family environment constant to compare the resemblances between persons with the same and different genotypes, adoption studies permit the comparison of the effects of different types of rearing on groups who are assumed to be similar in their genetic predispositions. Such studies attempt to separate the effects of genes and the familial environment by capitalizing on the adoption process, in which children receive their environment from a source different from their gene source. Consequently, adoption study designs permit the disentangling of genetic and environmental factors that contribute to the familial aggregation of a disease. The ability to draw inferences from an adoption study is strongest when the adopted children are separated from their biological parents at birth.

Potential problems of the research design are that any parent-child interaction from the time of birth to the separation confounds a clear demarcation of genetic and environmental aspects and the environmental circumstances of biological parents may be associated with prenatal and perinatal events relevant to the cause of the disease.

Three major designs of adoption studies have been used to study mental disorders: (1) the parent-as-proband design compares the rate of illness in the adopted offspring of ill and well persons. Support for a genetic component is indicated if the risk of illness among adopted children of ill parents is greater than the risk of illness among adopted children of well parents; (2) the adoptee-as-proband design uses ill and well adoptees as probands. Genetic factors are implicated if (a) the risk of illness in the biological relatives of ill probands is greater than that in the adoptive relatives of ill probands and (b) the risk of illness is greater in the biological relatives of ill probands than that in the biological parents of well adoptees; and (3) the seldom used cross-fostering approach, which compares rates of illness in two groups of adoptees. One group has ill biological parents and are raised by well adoptive parents; the other group has well biological parents and are raised by ill adoptive parents.

A famous adoption study in psychiatry was started in the 1960s by David Rosenthal, Seymour Kety, Paul Wender, and their colleagues to study schizophrenia in Denmark. Major accomplishments of the project were to rule out some alleged environmental factors (e.g., being reared by a schizophrenic parent) as either necessary or sufficient for the development of schizophrenia in the offspring of parents with schizophrenia, and to confirm the validity of family and twin results in implicating genes. The data have held up remarkably well, even after probands and relatives were classified with criteria used in the third edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III). The data also provided an opportunity to develop operational criteria for schizotypal personality disorder as a spectrum condition genetically related to the core schizophrenic phenotype, since it occurred at a higher rate in the biological relatives of adopted-away schizophrenia patients than in the adoptive relatives of schizophrenia patients and the relatives of control adoptees.

Association Studies The standard method for mapping disease loci applies classic parametric or nonparametric methods to family data in a search for linkage between the disease and a marker locus (a gene or deoxyribonucleic acid [DNA] sequence of known location). An alternative approach is to look for statistical associations in the general population between the disease and a marker. Linkage analysis of family data implicates a chromosomal region by assuming a relationship between a disease locus and marker loci in that region; association analysis implicates a specific gene by assuming a relationship between a disease and alleles at a specific genetic locus.

Population associations can generally arise for three reasons: (1) the implicated locus is itself a disease susceptibility locus—possession of the particular allele associated with the disease is neither necessary not sufficient, but it increases the likelihood of becoming ill; (2) a disease locus and the associated marker locus are tightly linked, that is, physically close to each other. Nonrandom association of alleles at tightly linked loci is commonly called *linkage disequilibrium*. Linkage disequilibrium can persist for many generations as a function of the physical distance between the disease locus and the marker locus; or (3) people with the disease and those without may be genetically different subsets of the population that coincidently differ in allele frequencies *(population stratification)*—in this case, the implicated locus is likely to be unrelated to the disease.

Classic disease-marker studies have been conducted by studying a sample of unrelated affected persons and comparing the frequency of a particular marker allele in the affected group versus its frequency in a control sample. This is a *population-based case control study* of disease-marker association. Very strong associations have been found between the human lymphocyte antigen (HLA) system on chromosome 6 and a few diseases (e.g., ankylosing spondylitis); weaker associations

have more typically been found for complex diseases like insulin-dependent diabetes mellitus and multiple sclerosis. However, causal inferences based on genetic differences between cases and controls drawn from a heterogeneous population have been difficult to replicate or interpret in the study of mental disorders because: (1) problems with selections of controls lead to difficulties in distinguishing linkage disequilibrium from population stratification; and (2) inadequate statistical correction for the testing of association at many loci leads to an increased type I error rate and chance findings (i.e., falsely concluding that a disease-marker association exists when there truly is none).

Selecting suitable controls for population-based association studies is crucial to minimize the chances that the study and control groups are drawn from genetically distinct subpopulations. Methods have been recently applied to circumvent this problem, and the focus is on the use of association tests as a means of locating disease genes through detection of linkage disequilibrium. *Family-based association studies* use disease and marker data within families. Comparisons are made by comparing genetic material from a sample of patients with genetic material obtained from their two parents. A single affected individual and the individual's two parents identified for family-based association studies are frequently referred to as a *trio*. Given that data from parents may be difficult or impossible to obtain, methods for family-based association analysis have been extended to permit use of data from unaffected siblings.

QUANTITATIVE METHODS

Data from many of these research designs can be analyzed by using sophisticated mathematical models and high-speed computers. The methods most typically used in the study of genetic factors are presented in Table 1.17-3.

Method	Data Source	Goal
Path analysis	Twin, adoption	Distinguish transmissible environment from polygenes
Segregation analysis	Pedigree	Distinguish a major locus from polygenes or transmissible environment
Linkage analysis	Pedigree	Establish chromosomal localization of a putative disease susceptibility locus
Association analysis	Unrelated affecteds, controls	Implicate a specific gene as a disease susceptibility locus, given linkage disequilibrium

Table 1.17-3 Quantitative Methods of Genetic Analysis

Path Analysis Path analysis was introduced as a technique to explain the interrelations among variables by analyzing their correlational structure and to evaluate the relative importance of varying causes influencing a certain variable. The primary goal of path analysis in genetic epidemiology is to distinguish genetic effects from common environmental effects that contribute to the familial aggregation of a disease. Twin and adoptive data are necessary to separate nature from nurture in path analysis. When genetic transmission is present, additive genetic effects cannot be distinguished from other genetic effects (i.e., single major locus models and multilocus models cannot be distinguished).

Familial correlations are estimated through *maximum likelihood techniques*, statistical procedures for estimating parameters, such that the best-fitting estimates are those that maximize the probability of the observations. Comparisons of competing models are made by fitting a general model and alternative submodels. Since log likelihoods are calculated for the general model (L_1) and the submodel (L_2), $-2(L_1-L_2)$ is approximately distributed as a chi-square with the degrees of freedom equal to the difference in the number of estimated parameters. This is the *likelihood ratio test*, the test statistic for comparing alternate models. Both qualitative (affected or unaffected status) and quantitative phenotypes may be analyzed, and examples of the results of applying path models of multifactorial transmission to analyze several traits are given in Table 1.17-4.

Trait	Genes	Common or Family Environment	Individual-Specific or Unique Environment
Intelligence	0.52	0.34	0.14
Personality (extroversion)	0.60	0.00	0.40
Religious devotion	0.29	0.24	0.47
Bipolar I disorder	0.86	0.07	0.07
Major depressive disorder	0.45	0.00	0.55
Neurotic depression	0.08	0.54	0.38
Schizophrenia	0.63	0.29	0.08
Bulimia nervosa	0.04	0.24	0.72
Alcoholism (women)	0.50	0.00	0.50
Late-onset Alzheimer's disease	0.58	0.39	0.03
Tuberculosis	0.06	0.62	0.32

Table 1.17-4 Genetic and Environmental Contributions to the Variance in Liability of Several Traits, Assuming Etiological Homogeneity

A useful application of complex path models was exemplified by the analysis of twin and family data from a variety of published sources for tuberculosis and schizophrenia. The results showed that the major contribution to phenotypic variance for tuberculosis came from shared family environment, rather than from genes; that result is expected for an illness caused by an infectious agent. Results from twin data alone would have been misleading in implicating a significant genetic effect. By contrast, the largest contribution to the variance in schizophrenia and bipolar I disorder comes from genes, with suggestion of a modest role for the common environment.

Complex Segregation Analysis Complex segregation analysis is a method for resolving a single major locus effect, but it leaves cultural inheritance confounded with additive polygenes. The unit of analysis is an entire pedigree, and the goal is to statistically assess evidence for the segregation of a major gene in the presence of other sources of familial resemblance. The application of complex segregation analysis to psychiatric family data has led to disappointing results, in the sense that no single gene effect has been consistently identified for any mental disorder.

Linkage Analysis Complex segregation analysis is an analytic tool for identifying a major locus, but phenotypic segregation patterns alone do not provide opportunities for its localization and ultimate identification. Linkage analysis is a statistical procedure by which pedigree data are examined to determine whether a disease phenotype is co-segregating with a genetic marker of known chromosomal location. Linkage analysis allows an investigator to infer that two loci (a genetic marker locus and a putative disease susceptibility locus) are located close enough together on the same chromosome that their alleles tend to be transmitted together from parent to child more frequently than would occur by random assortment. The demonstration of linkage between a putative disease susceptibility locus and one or more genetic markers thus determines on which chromosomal region the disease locus lies.

Genetic markers are entities known to follow a simple Mendelian mode of inheritance with an identified chromosomal location. At least one parent must be doubly heterozygous for that mating to be informative for linkage. Therefore, the usefulness of a genetic marker for linkage depends on the number of alleles and the gene frequencies (its degree of *polymorphism*) in the sense that an increased polymorphism leads to an increased probability of heterozygosity.

In the late 1970s the number of available polymorphic genetic markers was severely limited to blood cell antigen loci (ABO, Rh, and HLA blood groups) now known to lie on chromosome 1, 6, or 9. Some of those markers were highly polymorphic, but their limited number and restricted coverage of the genome meant that even linkage studies with excellent family data had little prospect for success. However, in the late 1970s and early 1980s geneticists proposed to treat differences in the DNA sequence as allelic variants and to use them as genetic markers. Through molecular genetic techniques *restriction fragment length polymorphisms* (RFLPs) were

obtained and were well suited as genetic markers in linkage analysis. RFLP markers are highly polymorphic and are available in great numbers that saturate the genome. A variety of other types of genetic markers (e.g., microsatellite markers, variable number tandem repeats) have since been developed. The most common type of human genetic variation is the *single-nucleotide polymorphism*. There has been growing recognition that large collections of mapped single-nucleotide polymorphism would provide powerful information for genetic studies. Single-nucleotide polymorphism can serve as genetic markers for establishing linkage.

A common measure of the degree of marker polymorphism often used is the *polymorphic information content* (PIC) value, which is defined as the probability that the marker genotype of a given offspring will allow deduction of whichever one of the two marker alleles of the affected parent that were received. If a PIC value approaches 1, virtually all matings are informative for linkage; a PIC value of ½ means that 50 percent of matings are informative. Another common measure of the degree of polymorphism is called *heterozygosity*, which is the probability that a random individual is heterozygous for any two alleles at a given locus. A genetic marker's usefulness for linkage analysis is reflected in its PIC and heterozygosity values; the higher the values, the greater its utility.

A classic approach in human genetics has been to search for single locus effects underlying disease transmission once a Mendelian mode of transmission has been identified and then to apply linkage analysis. Chromosomal localization through linkage analysis is the first essential step in the process of identifying, isolating, and cloning a disease susceptibility locus.

Three analytical strategies (Table 1.17-5) are used to search for linkage to mental disorders and locate disease susceptibility genes: (1) apply parametric maximum likelihood methods to calculate LOD scores in small or extended pedigrees; (2) apply nonparametric methods to study allele sharing among affected sibling pairs; or (3) apply the transmission/disequilibrium test (TDT) or other family-based association tests to detect linkage given linkage disequilibrium.

Method	Unit of Analysis	Mode of Inheritance	Multipoint Analysis	Computational Load	Typical Statistic	Target
Parametric	Pedigree	Required	Yes (<14)	Intensive	LOD score	Chromosomal region
Allele-sharing	Affected sib pairs or pedigrees or both	Not required	Yes	Not intensive	IBD-sharing probability; nonparametric linkage statistic	Chromosomal region
Linkage disequilibrium	Unrelated affecteds, controls	Not required	No	Not intensive	χ^2	Individual gene

IBD, identity-by-descent. Multipoint analysis refers to the simultaneous use of information provided by more than one genetic marker.

Table 1.17-5 Quantitative Methods Used to Locate Disease Susceptibility Genes

Logarithm of Odds (LOD) Score Methods The alleles at different loci received by a person from one parent are called a *haplotype*. In principle, a doubly heterozygous person—for example, *Aa, Bb*—received the *A* allele with either the *B* or *b* allele from one parent. If two loci (with alleles *A* or *a* at one locus and *B* or *b* at the other) are inherited independently of each other, a father passes the four haplotypes *AB, ab, Ab*, and *aB* to his offspring in the ratio of 1:1:1:1. If the *AB* and *ab* haplotypes look the same as the ones he received from his parents, the children receiving them are called *parental types*. The other two haplotypes (*Ab* and *aB*) in this case are unlike any haplotypes received by the father from the grandparents of the child and contain one allele from each grandparent (a recombination of grandparental alleles must have occurred in the father). The nonparental types (*Ab* and *aB*) are called *recombinants*, and the other two haplotypes are called *nonrecombinants*. A recombination between two genes denotes the event that two different grandparents contribute one allele at each of the two loci to a haplotype in a person, whereas a nonrecombination is said to have occurred when a haplotype in a person contains two alleles that originated from the same grandparent of that person. A mating is potentially informative for linkage between two specific genes when at least one of the parents is a double heterozygote.

When two genes are inherited independently of each other, recombinants and nonrecombinants are expected in equal proportions among the offspring. Some pairs of genes consistently deviate from the 1:1 ratio of recombinant to nonrecombinant offspring; in other words, alleles of different genes appear to be genetically coupled. That is called *genetic linkage*. The extent of genetic linkage is measured by the *recombination fraction*, which is the probability that a gamete produced by a parent is a recombinant. The recombination fraction is frequently denoted by the Greek letter theta (q). Genes segregating independently are unlinked with q = ½, whereas linked genes are characterized by q < ½. Some pairs of genes are tightly linked, so that q approaches 0—that is, only rarely does a recombination occur between them. The estimation of q and the test of the hypothesis of free recombination (q = ½) versus linkage (q < ½) are the goals of linkage analysis.

Recombination fractions reflect genetic distance on a chromosome, which is not exactly the same as physical distance. Genetic distance refers to a mathematical estimate of distance between markers and reflects the number of recombinant events (values of q greater than ½ are not meaningful); physical distance reflect the actual number of base pairs on the chromosome. Two loci that show 1 percent recombination are defined as being 1 centimorgan (cM) apart on a genetic map. (100 cM define a Morgan, which was named in honor of Thomas Hunt Morgan; these are the units that measure genetic distance). However, for distances above 5 cM, genetic distance is not a simple reflection of the number of recombinant events. A mathematical equation called the *mapping function* defines the relationship between the recombination fraction and genetic distance.

A nonconstant relationship exists between genetic distance, as measured in cM, and physical distance, which is measured in DNA base pairs or megabases (Mb; 1 Mb = 1,000,000 base pairs). The entire human genome is 3000 Mb, or three billion base pairs. A sex-averaged figure that relates physical and genetic distance is 1 cM = 0.9 Mb, but the actual correspondence varies widely for different chromosomal regions.

Figure 1.17-4 shows in a simplified manner the chromosomal interpretation of recombination. In *meiosis* (cell division leading to the formation of gametes) homologous chromosomes pair up. At that point each homologous chromosome consists of two strands (*chromatids*), so that a chromosome pair consists of four. In the course of meiosis, the two homologous chromosomes separate from each other at most places but maintain one (1) or two (2) zones of contact *(chiasmata)*. Chiasmata reflect the occurrence of *crossing over* between chromatids. A single crossover generates two recombinant and two nonrecombinant chromatids (1) whereas a two-strand double crossover leaves four nonrecombinant chromatids (2). The overall effect averaged over all double crossovers is to generate 50 percent recombinants.

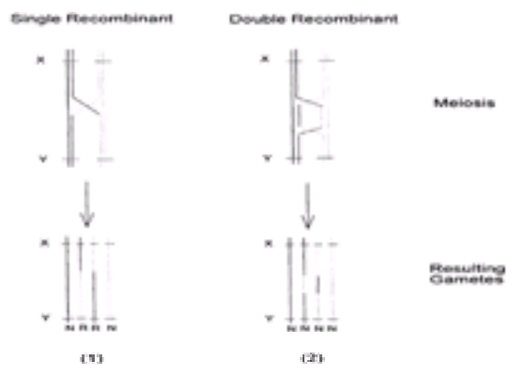

FIGURE 1.17-4 Schematic representation of a pair of homologous chromosomes, each consisting of two strands. Single (1) and two-strand double (2) crossovers involve two of the four chromatids; the solid line chromosome carries alleles X_1 and Y_1, at two loci, while the dotted one carries alleles X_2 and Y_2. Gametes (sperm, ovum) in which the chromatid is the same line type at the two loci are nonrecombinant (*N*) for these loci; those where the chromatids are different line types are recombinant (*R*).

Since recombination events can be recognized only on the basis of haplotypes passed from parents to children, linkage analysis requires phenotypic observations on

pedigree members. Estimating q is carried out by using the method of maximum likelihood. A relevant quantity is the likelihood ratio that is obtained by dividing the likelihood of a given family [L(q)] by its value under free recombination (L(½)). It is usually convenient to work not with the likelihood ratio but with its logarithm to the base 10. This is the *LOD score Z (q)*, such that $Z(q) = \log_{10}[L(q)/L(½)]$. The LOD score serves as a measure of the weight of the data in favor of the hypothesis of linkage. The critical value generally adhered to as the criterion for significant evidence for linkage to simple, monogenic diseases with unambiguous phenotypes and established modes of transmission is 3 for autosomal loci. The one-sided type I error rate associated with that value when q is the only estimated parameter (i.e., the mode of disease transmission is known) and when the linkage test is conducted at a single marker is 0.0001 in large samples.

The traditional advantages of LOD score methods for linkage analysis include the following: (1) because it is a parametric approach, LOD score methods have high power to detect a true linkage given knowledge of the true mode of disease inheritance; (2) if affected sib pairs are rare and etiological heterogeneity is likely, multigenerational pedigrees with multiple affected relatives of various classes (uncles, grandparents, cousins, and so forth) can be analyzed; (3) linkage to a particular chromosomal region can be excluded; and (4) a measure of the distance between two loci—the recombination fraction q—can be estimated.

A consideration when applying LOD score methods for linkage analysis is that the mode of inheritance is assumed to be known. When single major locus inheritance parameters (gene frequencies and penetrances) are estimated jointly with q in linkage analysis, the LOD score value does not have the same statistical meaning. One conservative correction for maximizing a LOD score over *t* different transmission models proposed by Neil Risch is to subtract $\log_{10}(t)$ from the result, (e.g., a LOD score of 3 maximized over 5 transmission models is reduced to about 2.3).

Allele-Sharing Methods Allele-sharing methods assume that a disease susceptibility locus can be identified given that a pair of affected relatives—typically a sibling (sib) pair, but other relative pairs may also be considered—will tend to inherit the same allele more often than expected under random Mendelian assortment. Each pair shares either 0, 1, or 2 alleles *identical by descent* (IBD) at a given locus, and the *allele-sharing proportion* is defined as the proportion of affected relative pairs that share a single allele IBD at that locus. Genotyping parents and other individuals in a pedigree allow determination of whether given alleles are actually inherited from a common ancestor, that is, IBD status can be deduced. In practice, the situation is more complicated because one cannot unambiguously determine the number of alleles shared IBD at all of the loci in the genome. In such cases, inferences are drawn based only on identity-by-state (IBS) information—that is, it is determined whether individuals show the same allele at a given locus, regardless of whether the allele came from a common ancestor. IBD methods have greater power to detect linkage and are less sensitive to misspecification of marker allele frequencies (which can lead to false-positive results) as compared to IBS methods.

Tracing the inheritance pattern in the affected sib pair method uses perturbations in the distribution of IBD scores at a marker locus to detect the presence of a linked disease locus. In the absence of linkage, the probability that two siblings share neither, one, or both marker haplotypes identical by descent is independent of their disease phenotypes. Consequently, if pairs of siblings are studied because they are both affected, the distribution of their IBD scores will be ¼, ½, and ¼ for IBD = 2, 1, and 0, respectively. The allele-sharing proportion z_{all} for sibs is $z_{all} = (z_1 + 2z_2)/2$, where z_1 and z_2 are the proportions of sib pairs sharing 1 and 2 alleles IBD; thus, $z_{all} = ½$ for sib pairs in the absence of linkage, i.e., $(½ + ¼\cdot2)/2$. When a disease locus is linked to a marker locus and pairs of affected sibs are studied, there is a perturbation in the IBD score distribution at that marker locus. New variance-component linkage analysis methods that utilize multipoint IBD information in pedigrees of arbitrary size have recently been developed.

The specific advantages of affected sib pair methods in the study of mental disorders are the following: (1) these semiparametric or fully nonparametric methods specification of complex, non-Mendelian modes of transmission is not required. Concomitantly, several confounding factors that make it difficult to accurately estimate the mode of transmission in segregation analysis (e.g., complex ascertainment strategies, cohort effects, sex effects, variable age of onset) do not have to be modeled; (2) the practice of testing for linkage under several transmission models—which necessitates some downward correction to the linkage statistic to prevent inflation in the type I error rate for testing across multiple disease transmission models—is now unnecessary; (3) large multigenerational families with many affected persons, which are typically difficult to locate and study, are not required; and (4) complete extraction of multipoint inheritance information and estimation of disease gene location is now possible using new nonparametric methods.

Linkage Disequilibrium Mapping Parametric and nonparametric linkage methods are very useful in the search for disease susceptibility genes. However, these methods may require very large sample sizes to detect the modest gene effects that are most likely to be operative in most mental disorders (recurrence risk ratios on the order of 1:6; Table 1.17-6). In addition, isolation of a specific disease gene knowing only its subchromosomal location *(positional cloning)* depends on high-resolution mapping of the chromosomal regions detected through linkage analysis. With current technologies, in the absence of fortuitous events like the presence of a trinucleotide repeat expansion or gross deletion, a gene most likely must be localized to a region of about 1 million base pairs before it is practical to identify it. Given the magnitude of the genetic effects found in mental disorders, localization to regions of this size may require 800 to 1600 affected sib pairs.

	Recurrence Risk Ratio*						
N	1.0	1.2	1.4	1.6	1.8	2.0	3.0
100	0	0	2	5	9	15	45
200	0	1	6	19	36	51	90
400	0	3	23	59	82	94	100
800	0	12	69	97	100	100	100

* Morbid risk conferred by a specific susceptibility locus to first-degree relatives of an affected individual, divided by the lifetime cumulative incidence of the disease. Figures displayed are percentages. (Adapted from Hauser ER, Boehnke M, Guo S-W, Risch N: Affected-sib-pair interval mapping and exclusion for complex genetic traits: Sampling considerations. Genet Epidemiol 13:117, 1996.)

Table 1.17-6 Power to Detect Linkage to a Disease Susceptibility Gene for *N* Affected Sib Pairs

The initial detection and positional cloning of genes of modest effect may be facilitated through application of family-based association tests. Linkage disequilibrium mapping using family-based association tests can also be accomplished using unrelated affected individuals and their parents. Such methods can have tremendous power in genetically isolated populations, where a significant fraction of affected individuals have inherited the disease susceptibility allele from a common ancestor. Such a strategy has been successfully applied to a simple monogenic disease, diastrophic dysplasia.

The *haplotype relative risk* (HRR) method has been proposed as a family-based test of association. The control sample is the alleles at different loci received from one parent (the parental haplotype) not present in the affected person, which represents a random sample of haplotype pairs from the same genetic population. These researchers did not focus on the use of the HRR method as a test for linkage. Richard Spielman and colleagues developed a related method—the TDT—as a test for linkage between a complex disease and a marker given an established disease-marker association (linkage disequilibrium).

The TDT employs the alleles not transmitted by parents to an affected offspring as the controls. Thus, DNA needs to be collected from unrelated affected subjects and their two biological parents. Table 1.17-7 shows the simple 2 × 2 contingency table that can be constructed given a marker with two alleles A^1 and A^2; the significance test employs the simple X_2 statistic. The TDT has been generalized to the case of an arbitrary number of marker alleles.

Transmitted Allele	Nontransmitted Allele		
	A_1	A_2	Total
a_1	a	b	a+b
A_2	c	d	c+d
Total	a+c	b+d	2n

* Combinations of transmitted and nontransmitted marker alleles A_1 and A_2 among 2n biological parents of n affected individuals. The notation is as follows: a, the number of times that an A_1A_1 parent transmits A_1 to affected offspring; b, the number of times that an A^1A_2 parent transmits A_1 to affected offspring; c, the number of times that an A_1A_2 parent transmits A_2 to affected offspring; and d, the number of times that an A^2A_2 parent transmits A_2 to affected offspring. For the hypothesis of no linkage (and no allelic association), χ^2 (one degree of freedom) = $(b - c)^2 / (b + c)$.

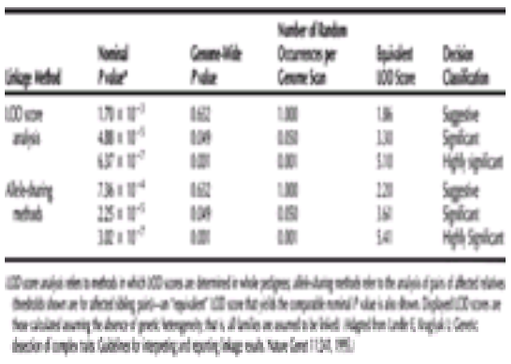
Table 1.17-7 Transmission/Disequilibrium Test: Detecting Linkage Given a Population Association*

Use of the TDT does not solve the problem of inadequate statistical correction given conduction of a large number of association tests at many loci. A conservative approach is to divide the desired type I error probability by the number of tests conducted. For example, maintenance of a 5 percent false-positive rate (significance level = 0.05) when 50 independent tests have been conducted would require a significance level of 0.001 for each test. Genomic screens have been recommended based on association studies using the TDT and the intriguing possibility of eventually testing for disease associations at all of the human genes that will eventually be identified by the beginning of the twenty-first century has been discussed. An efficient design for psychiatric genetic studies may be to employ a multi-stage strategy for genotyping and analysis of nuclear or small extended pedigrees that incorporates linkage and family-based association analysis.

Statistical Criteria for Declaring Linkage to Mental Disorders It is crucial in the genetic investigation of mental disorders that a sufficiently stringent standard be adopted for the declaration of linkage, in order to maintain a high likelihood that the assertion will be true and stand the test of time. The LOD score criterion for declaring a linkage is 3 in the study of classical Mendelian diseases with known modes of familial transmission.

Ever-evolving genetic methods and technologies now permit systematic screening of the entire human genome. The increased number of markers being tested inflate the type I error rate. A set of guidelines have been proposed for interpreting linkage results of complex disease. These guidelines distinguish the nominal significance level, which is the probability of encountering a linkage statistic of a given magnitude at one specific locus, from the genome-wide significance level, which is the probability that one would encounter such a deviation somewhere in a whole genome scan. A given linkage statistic like a LOD score has a corresponding nominal *P* value and a genome-wide *P* value.

It has further been proposed that genome-wide *P* values be interpreted to evaluate the magnitude of linkage evidence and classify it as “suggestive,” “significant,” or “highly significant.” Suggestive linkage reports will often reflect chance findings and will often be wrong, but are worth reporting as tentative findings. Table 1.17-8 shows equivalent LOD score values and associated nominal and genome-wide *P* values for these different categories. A more stringent LOD score criterion (3.3 for LOD score methods; 3.6 for allele-sharing methods) than the traditional value of 3 is required to claim significant linkage evidence in the analysis of mental disorders and other complex diseases. Confirmation of linkage requires a two-step process: (1) significant linkage is found in at least one study; and (2) evidence of linkage to the same region is obtained by an independent group of investigators in an independent sample.



Linkage Method	Nominal P value*	Genome-Wide P value	Number of Random Occurrences per Genome Scan	Equivalent LOD Score	Decision Classification
LOD score analysis	1.70×10^{-2}	0.632	1.000	1.86	Suggestive
	4.88×10^{-5}	0.049	0.050	3.30	Significant
	6.37×10^{-7}	0.001	0.001	5.10	Highly significant
Allele-sharing methods	7.26×10^{-4}	0.632	1.000	2.20	Suggestive
	2.25×10^{-5}	0.049	0.050	3.61	Significant
	3.02×10^{-7}	0.001	0.001	5.41	Highly Significant

LOD score analysis refers to methods in which LOD scores are determined in whole pedigrees, allele-sharing methods refer to the analysis of pairs of affected relatives [illegible] affected sibling pairs—an "equivalent" LOD score that yields the comparable nominal *P* value is also shown. Displayed LOD scores are those calculated assuming the absence of genetic heterogeneity; that is, all families are assumed to be linked. Adapted from Lander E, Kruglyak L: Genetic dissection of complex traits: Guidelines for interpreting and reporting linkage results. Nature Genet 11:241, 1995.)

Table 1.17-8 Criteria for Evaluating Reports of Linkage to Mental Disorders

MULTIVARIATE ANALYSIS INCORPORATING QUANTITATIVE TRAITS

Traditional approaches in genetic epidemiology focus on the qualitative determination of disease status as the exclusive source of data for genetic analysis. Such approaches are problematic in the case of mental disorders, in which phenotypic assessment through structured and semistructured interviews is potentially complicated by diagnostic error on misclassification. Quantitative traits that cosegregate with the disease phenotype provide greater information content than do groupings of individuals into affected or unaffected classes. The usefulness of pedigrees is increased because a greater range of information is available on unaffected persons who are not yet through the risk period. Thus, the power to initially map a susceptibility locus of small relative effect may be enhanced through consideration of the effects of such loci on quantitative traits correlated with disease. The application of such multivariate methods in the genetic analysis of mental disorders has yet to reach its full potential. Examples of such traits include psychophysiological abnormalities in alcoholism and attentional impairments in schizophrenia.

FUTURE DIRECTIONS

Table 1.17-9 shows a variety of relevant resources on the World Wide Web. As progress in the construction and completion of detailed genetic and physical maps continues, the ability to detect disease susceptibility genes for mental disorders will be enhanced. Complicating factors like multiple genes of small relative effect, common and individual-specific environmental effects, diagnostic error on misclassification, clinical heterogeneity, and etiological heterogeneity present challenges that can may be overcome in the following ways:

Table 1.17-9 Scientific Resources Related to Quantitative Genetics on the World Wide Web

1. Collection of a sufficiently large sample of pedigrees is required to obtain sufficient power to detect linkage and map loci to small chromosomal regions. Large-scale family-based association tests across the whole genome should be conducted in the sample;
2. Independent confirmation by at least one independent group of investigators remains the standard to establish the validity of an initial linkage report. The linkage evidence in at least one report needs to be significant, and must remain after sample augmentation (i.e., more families, or more subjects per family, are analyzed);
3. Resolution of genetic heterogeneity requires further work on phenotypic classification in order to identify clinical characteristics that can delineate genetically distinct subgroups;
4. Strict blindness on a project must be maintained as clinicians gather pedigree and diagnostic data and laboratory personnel establish genotypes. This necessitates close collaborative relationships between mental health clinicians, human biologists, genetic epidemiologists, and molecular geneticists in future

large-scale studies of mental disorders;
5. Diagnostic models and hierarchies, as well as a justification for classifying specific genotypes as “affected,” must be clearly specified prior to statistical genetic analyses;
6. Diagnostic and genotyping data should be made widely available to the scientific community so as to facilitate efforts to understand discrepancies between studies;
7. State-of-the-art techniques for molecular and quantitative analysis must continue to be rapidly applied to the genetic analysis of mental disorders. These include new nonparametric methods for multipoint linkage analysis, advances in high-throughput genotyping, the development and application of microchip DNA arrays, and the generation of abundant new genetic markers that reflect common human genetic variation.

SUGGESTED CROSS-REFERENCES

Epidemiological principles and methods are discussed in Section 5.1; mathematical concepts useful in understanding the fundamental principles of population genetics can be found in Section 5.2; and findings related to the epidemiology of schizophrenia and mood disorders are presented in Section 12.2 and Section 14.2, respectively. Section 12.5 and Section 14.3 present the findings from the study of the genetics of schizophrenia and mood disorders, respectively.

1.18 GENETIC LINKAGE ANALYSIS OF THE PSYCHIATRIC DISORDERS

CAROL A. MATHEWS, M.D., AND NELSON B. FREIMER, M.D.

In recent years genetic mapping techniques have been used to identify the underlying defects responsible for a number of important diseases, such as cystic fibrosis and Huntington's disease; such techniques are becoming increasingly important in studies of the psychiatric disorders as well, partly because attempts to find causes for these disorders using biochemical approaches have been largely unsuccessful. Genetic mapping studies are based on the idea that specific inherited mutations in the genetic material (the *genome*) of an individual are ultimately responsible for disease causation; such studies aim to isolate the responsible genes by identifying their chromosomal location within the genome through studies of affected individuals and their families. Each cell of all individuals contains two copies of each chromosome (called *homologues*), one inherited from the mother and one inherited from the father. During meiosis, the parental homologues cross over, or recombine, creating unique new chromosomes that are then passed on to the progeny. Genes that are physically close to one another on a chromosome are said to be *genetically linked*; those that are physically farther apart or are on different chromosomes are said to be *genetically unlinked*. Genes that are unlinked will recombine at random (i.e., there is a 50 percent chance of recombination). Genes that are linked will recombine less frequently than expected by random segregation; how much less often is proportional to the physical distance between them. Genetic mapping studies identify regions of the genome where recombination between two genetic loci is less than would be expected by chance, that is, areas of linkage. The chromosomal location of disease genes is identified by observation of inheritance patterns of diseases in conjunction with inheritance patterns of segments of deoxyribonucleic acid (DNA) of known chromosomal location (genetic markers).

Genetic markers are segments of DNA that contain known variations, called *polymorphisms*. Historically, a number of different types of markers have been used in genetic mapping studies, including the blood group antigens and other antigenic markers, as well as restriction fragment length polymorphisms (RFLPs), which are naturally occurring genomic sequence differences resulting in variations in restriction enzyme cutting sites in the genome. However, the low variability, small number, and uneven distribution of these markers has limited their power in linkage studies. Currently, microsatellite markers, or *simple sequence length polymorphisms* (SSLPs), are in wide use. Microsatellite markers are stretches of variable numbers of repeat units two to four base pairs in length, usually cytidine (C) - adenosine (A) repeats. Microsatellite markers have multiple advantages over other available genetic markers; they are distributed widely throughout genome, are highly polymorphic (the number of repeat units varies a great deal), and can be amplified with a technique called *polymerase chain reaction*.

Before the development of microsatellite markers, linkage was discovered for only a few Mendelian traits (i.e., traits for which a specific genotype at one particular locus is both necessary and sufficient to cause the trait). However, most medical and psychiatric diseases do not follow simple Mendelian inheritance patterns, but rather are examples of complex traits. A complex trait is any phenotype that does not exhibit classic inheritance (usually recessive or dominant) that can be attributed to a single locus. In other words, there is no one-to-one relationship between the genotype at a single locus and the phenotype in these disorders. This is caused by many factors, including incomplete penetrance (expression of the phenotype in only some of the individuals carrying the disease genotype), the presence of phenocopies (forms of the disease that are not caused by genetic factors), locus heterogeneity (different genes causing the same disease in different families or populations), or polygenic inheritance (the presence of multiple genes acting together to cause disease). Because it allows for close examination of virtually all chromosomal regions of interest using multiple markers, the construction of a genetic map that densely covers the genome with a large number of highly polymorphic markers (thousands are currently available) has been a pivotal development in the study of complex traits. Mapping a complex disorder involves several components; these include epidemiological studies to determine the likely mode of inheritance, definition of the phenotype to be studied, choice of an appropriate study population, and determination of correct technical and statistical approaches.

EPIDEMIOLOGICAL APPROACHES

The first step in identifying the gene or genes for a disorder is to determine whether or not the disease in question is in fact inherited. This is done using epidemiological approaches such as twin studies, relative risk determinations, and segregation analyses. In addition to indicating whether or not a disease is likely to have a genetic etiology, these studies are useful for estimating both the likely mode of transmission and the degree of genetic contribution, as well as for selecting appropriate families for further genetic studies.

Twin studies examine the concordance rates of a particular disorder (the percentage of twin pairs where both twins have the disorder) in monozygotic and dizygotic twins. For a disorder that is strictly determined by genetic factors, the concordance rate should be 100 percent in monozygotic twin pairs (because monozygotic twins share 100 percent in their genetic material in common) and 25 or 50 percent in dizygotic twin pairs (who are no more closely related than any siblings), depending on whether the disease is recessive or dominant, respectively. For a disorder where genetic factors are important but not exclusive, the concordance rates should be greater for monozygotic than for dizygotic twins; when genetic factors do not play a role the concordance rates should not differ between the twin pairs. This is based on the assumption that the environment for monozygotic twin pairs is no more similar than that for dizygotic twin pairs. Concordance rates for bipolar I disorder range between 65 percent and 100 percent in monozygotic twins and between 10 percent and 30 percent for dizygotic twins, indicating that it is highly genetic; concordance rates for schizophrenia, in contrast, are approximately 40 percent to 50 percent in monozygotic twins and 9 percent to 10 percent for dizygotic twins, indicating that although there is a genetic contribution to the disorder, it is weaker than that for bipolar I disorder.

Relative risk is defined as the rate of occurrence of the disease for the relatives of an affected individual divided by the rate of occurrence of the disease for the general population. A relative risk of greater than one suggests a genetic etiology; the magnitude of the measure gives an estimate of the genetic contribution to the disease. Relative risks can be calculated for sib pairs, parent-offspring pairs, and various other types of family relationships. The likely mode of transmission can be assessed by comparing the degree of relative risk for each type of relationship.

Segregation analysis compares the observed number of affected individuals within a given family to the expected number of affected individuals within that family, assuming a particular mode of inheritance, and then compares the likelihood of observing these data under the given genetic model to the likelihood of observing the data under other genetic models. These studies establish whether there is a genetic component to the disorder in question, and can also be used to estimate the likely genetic model (i.e., dominant or recessive). Because segregation analysis can be used to calculate the likelihood of a particular genetic model for individual families under specified parameters, it is useful both for choosing families for a genetic study when previous studies have indicated that the disease is Mendelian in only a proportion of affected families, and for choosing appropriate statistical models when studying a particular set of families.

Defining a Phenotype for Genetic Studies Because complex diseases, by definition, are not inherited in a simple Mendelian manner, they are often difficult to map. One approach to simplifying the genetic mapping process is to define the disease phenotype carefully. This is a particularly important step in the study of psychiatric disorders because they are defined empirically rather than on the basis of anatomic or physiological indices.

There are several elements to phenotype definition. The first involves deciding on the appropriate diagnostic criteria for the study in question, and deciding how these criteria will be applied to individuals in the study. For the psychiatric disorders there are several different sets of diagnostic criteria that are commonly used; these include the *Diagnostic and Statistical Manual of Mental Diagnoses* (DSM) diagnoses, the International Classification of Disease (ICD) schemas, and various research criteria such as the Research Diagnostic Criteria (RDC). Although these schemas overlap a great deal, there are significant differences between them. Because of the difficulty in precisely defining a disease phenotype for psychiatric disorders, the choice of a diagnostic schema can significantly influence the success of the study. It is preferable to use the most rigorous criteria available so as to minimize the likelihood of including individuals who do not actually have the disorder in question or who have a different form of the disorder.

It is also important to standardize the diagnostic procedures used to identify and classify individuals. One way of doing this is to use only experienced clinicians in the diagnostic process, and to train them in the administration of the instruments and the diagnostic criteria to be employed. Additionally, a best estimate procedure, a consensus diagnosis, or both are helpful. The best estimate process involves making use of every piece of information available, including medical records, interviews, and videotapes, where appropriate, to arrive at a diagnosis. For a consensus diagnosis, two or more diagnosticians independently review the material and make a diagnosis for each individual. The diagnoses are then compared; individuals for whom an agreement in diagnosis cannot be reached are not entered into the study.

The second element in phenotype definition involves making use of all available information about the genetic epidemiology of the disorder in order to choose a sample of affected individuals to study. It is often the case that a subset of affected individuals or families carry the disorder in what appears to be a simple Mendelian pattern whereas the inheritance pattern is less clear for other families or groups. When there are likely to be multiple genes contributing to a phenotype or disorder, it makes sense to begin with a study sample where there may be major loci. Redefining the disease phenotype can often simplify the mapping process by identifying such groups or families. For example, in the search for a genetic defect for Alzheimer's disease type, the process was advanced enormously by limiting the study population to those individuals who had early age of onset (before age 65); the early-onset trait segregated in an autosomal dominant fashion. Other ways of redefining the phenotype include focusing on specific ethnic groups, using family history as a prerequisite (it is common to require that there be at least two other affected individuals in a family), or restricting the study population to those with a particularly severe form of the disease. The rationale is that the severe forms of the disorder (early onset is thought to be an indicator of severity in many disorders) may be more genetically homogenous than the less severe forms and thus may be easier to map. This approach was successful in linkage studies of the long Q-T syndrome, in which the study group was limited to those affected individuals with a very severe form of the disorder.

Narrowing the phenotype is an effective way of increasing the chances of finding a genetic defect in complex diseases; however, it can greatly reduce the power of the study by limiting the number of affected individuals available. For this reason it has been argued that broadening the phenotype is an appropriate strategy for some disorders. The suggestion is that for some complex diseases the phenotype of interest may represent the extreme end of a spectrum, and that in order to have enough power to identify a gene, other disorders within the spectrum must also be included. This argument has been particularly favored in the study of schizophrenia. Family studies have indicated that there is an increased incidence of schizoaffective disorder, schizotypal personality disorder, and paranoid personality disorder in the biological families of schizophrenia patients, and individuals with these disorders are often included as affected subjects in genetic studies of schizophrenia. The same argument has been used in genetic studies of bipolar I disorder (using bipolar II disorder and major depressive disorder as alternate phenotypes), and Tourette's disorder, where chronic motor tic disorder and obsessive-compulsive disorder are considered alternate phenotypes. Although this strategy is often used, expanding the phenotype presumably leads to an increased rate of phenocopies, making detection of linkage more difficult. In addition, the theory that a disorder such as schizophrenia represents the extreme end of a spectrum of disorders also implies that the genetic effect for such a disorder may be too weak to be detected in mapping studies; this is supported by the concordance data from twin studies, which indicate a weak genetic effect for schizophrenia. So far, the strategy of using a broadly defined phenotype has not directly led to the identification of any disease genes. Another strategy that is similar to expanding the phenotype is to examine characteristics believed to be related to the disease in question, although not part of the diagnostic criteria. This technique was used in a study of non–insulin-dependent diabetes mellitus, which was mapped to chromosome 12 in a sample of affected individuals only after the phenotype was modified to account for mean insulin levels; although the overall genome screen provided no significant evidence of linkage, significant evidence of linkage was found on chromosome 12 when the study was limited to individuals with the lowest mean insulin levels.

Although the two approaches of narrowing the disease phenotype and broadening the disease phenotype may seem to be mutually exclusive, many groups studying complex disorders are attempting to incorporate both strategies into their study designs. One way to do this is to create stratified diagnostic categories, ranging from a narrow diagnostic category to a broad diagnostic category, and to test for genetic linkage under each of these schemas. There is currently a great deal of debate about whether this strategy is useful or not. Some investigators argue that for complex diseases that may actually be part of a spectrum, this strategy decreases the rate of false-negative results, that is, of missing an existing linkage because of misspecification. Others argue that using several models and picking the one that yields the highest scores statistically greatly increases the rates of false positives, that is, of identifying an area of linkage where none exists. One problem that clearly exists with the use of multiple diagnostic categories is that the level of significance attached to a particular statistical result drops with the use of more models.

The issues involved in phenotype definition are complicated, and within the field of genetics there is a great deal of disagreement about the best way to approach studies of complex traits. Because of the number of unknowns in other aspects of these studies, however, it is clear that the problem of how to define the disease to be studied is a serious one that should be addressed carefully.

Genome Screen Versus Candidate Gene Approach Once genetic epidemiology has provided as much information as possible about the genetic basis of a trait and the phenotype to be studied has been defined, the next step is to search for regions of the genome that may be linked to the disorder, either by examining candidate regions or by performing a screen of the entire genome. For disorders whose pathophysiology is known or partially understood, one or several candidate genes for the disorder may have already been identified. A candidate gene is usually a gene whose location has already been determined, whose protein product is known, and that is hypothesized to play a role in the pathophysiology of the disorder in question, although sometimes genes with unknown functions that are located in a particular chromosomal region of interest are also considered in this approach. Candidate genes for the neuropsychiatric disorders have traditionally been derived from obvious pharmacological information or from cytogenetic data (including translocations and deletions) indicating a candidate region. Examples of such potential candidate genes for neuropsychiatric disorders include the dopamine receptors and the serotonin receptors, as well as chromosomal translocations found in one or more individuals with the disease of interest.

The other approach to searching for linkage is to conduct a whole genome screen. This approach assumes that there are no known specific areas of interest within the genome (i.e., there are no candidate regions or any potential candidate genes have been excluded), and therefore involves screening the entire genome with evenly spaced markers in an attempt to find areas of potential linkage. Genome screens are becoming increasingly common for linkage studies involving psychiatric disorders, because of limited success with the candidate gene method in those cases where there are candidate genes, as well as a relative lack of candidate areas.

Several strategies have been developed to map disease genes; these methods are all based on identifying genetic marker alleles that are shared by affected individuals who are identical by descent. Marker alleles that are identical by descent are inherited from a common ancestor along with a linked disease gene. The optimal linkage method and type of analysis for a study sample is determined by the number of meioses separating the affected individuals in the sample via the common ancestor. These methods range from sib-pair studies, where affected individuals are separated from each other via a common ancestor by two meioses, to association studies in isolated populations, where affected individuals are separated from each other by up to about 100 meioses (Fig. 1.18-1). Alleles or haplotypes that are shared identical by descent must be differentiated from those that are shared identical by state; rather than being inherited from a common ancestor, these alleles are shared by affected individuals for a variety of other reasons, such as the same mutation in an allele occurring twice in a population. Dense, closely spaced marker maps are crucial for determining whether an allele is shared identical by descent or identical by state; markers closely surrounding an allele shared identical by descent will also be shared identical by descent, whereas markers closely surrounding an allele shared identical by state will not show sharing among those affected.

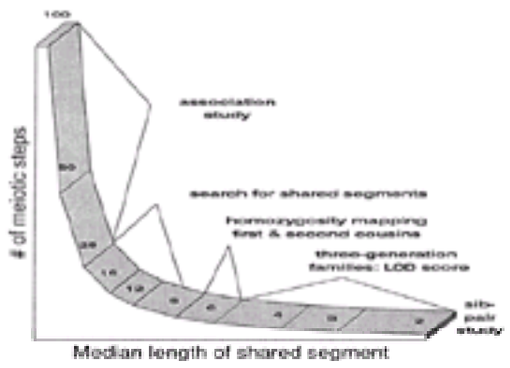

FIGURE 1.18-1 Depiction of the median lengths of the chromosomal segments inherited identical by descent around a disease gene by two individuals separated from a common ancestor by differing numbers of meiotic steps. (Reprinted with permission from Houwen RHJ, Baharloo S, Blankenship K, Raeymaekers P, Juyn J, Sandkuijl LA, Freimer NB: Genome screening by searching for shared segments: Mapping a gene for benign recurrent intrahepatic cholestasis. Nature Genet *8:*380, 1994.)

PEDIGREE ANALYSIS

Searching for areas of linkage to the disorder of interest, either in a whole genome screen or in a candidate area, has traditionally been done using pedigree analysis or logarithm of the odds (LOD) score analysis. This type of study is best done in families comprising three or four generations, where affected individuals are separated by two to six meiotic steps. The primary goal of pedigree analysis is to determine if two or more genetic loci (i.e., a genetic marker and the disease of interest) are cosegregating within a pedigree. For each marker locus the number of recombinants within the pedigree is compared to the number of nonrecombinants within the pedigree and a recombination fraction (q) is estimated. The recombination fraction represents the percentage of recombinations between two loci—in this case the hypothetical disease locus and the marker locus, and is equal to the genetic distance between the two loci [1 percent recombination is equivalent to 1 centimorgan (cM) in genetic distance and, on average, covers a physical distance of about 1 megabase (mB) of DNA]. A recombination fraction of 0.5 or 50 percent indicates that the two loci are not linked, but rather that they are segregating independently. An LOD score is then calculated to determine the likelihood that the two loci are linked at the distance suggested. The LOD score is calculated by dividing the likelihood of acquiring the data if the loci are linked at a given recombination fraction by the likelihood of acquiring the data if the loci are unlinked (q = 0.5), to obtain an odds ratio, and by then taking the $\log_{10}$ of this odds ratio to obtain an LOD score. The LOD score is calculated using the following equation:

$$\text{LOD score } Z(\theta) = \log_{10}[L(\theta)/L(0.5)]$$

where q is the recombination fraction from 0.0 to 0.5, $L(q)$ is the likelihood of the occurrence of the data if the loci are linked at a distance q, and $L(0.5)$ is the likelihood of the occurrence of the data if the loci are unlinked.

An LOD score can be obtained for various values of the recombination fraction, from 0.0 (completely linked) to 0.5 (unlinked). In addition, data from multiple family pedigrees can be combined to derive a cumulative LOD score (designated by Z). The value of q that gives the largest LOD score is considered to be the best estimate of the recombination fraction between the disease locus and the marker locus. This recombination fraction can then be converted into a genetic map distance. In general, the likelihood that any two given loci are linked (the prior probability of linkage) is expected to be approximately 1:50, based on the genetic length of the known genome. In order to compensate for the prior probability of linkage and bring the posterior (or overall) probability of linkage to about 1:20, the commonly accepted significance level of $p = 0.05$, a conditional probability of 1000:1 odds in favor of linkage (corresponding to an LOD score of 3 and a p value of 0.0001) is required. Therefore, under ideal conditions, for simple Mendelian disorders an LOD score of 3 is considered to be significant evidence of linkage.

A pedigree analysis consists of scanning the genome or a portion of the genome with a series of markers in one or more affected pedigrees, calculating an LOD score at each marker position, and identifying the chromosomal regions that show a significant deviation from what would be expected under the conditions of independent assortment. Because of the frequent use of multiple markers and multiple genetic models, as well as uncertainties in estimates of penetrance level and allele frequencies for many disorders, the question arises as to what represents acceptable evidence for linkage. In the instances where multiple genetic markers are tested, an LOD score of 3.4 has been suggested as providing sufficient evidence for linkage. The problem of using multiple genetic models is somewhat more difficult. One suggestion has been to use the formula 3 + log (t), where t is the number of tests performed. Under these parameters, an LOD score of 3.4 or higher would be required to provide significant evidence of linkage if more than one model is used, and an LOD score of 4 would be required if ten models are used. Many investigators argue that these criteria are too stringent because they assume that each model is independent of the others, which is not the case in mapping studies.

It is important, however, to account for the increased likelihood of obtaining a false positive in the context of multiple tests. In a standard genome screen of several hundred markers, false positives (regions that are significant at $p < 0.05$, corresponding to an LOD score of >1), can be expected approximately 24 times (once per chromosome) by chance alone (Fig. 1.18-2). This is important because some investigators have argued that an LOD score of >1 is a significant LOD score in genetic studies of a complex disease. For this reason, a classification system for reporting linkage based on dense genome scans has been proposed (Table 1.18-1). Although used by some investigators, these criteria are not universally accepted. Because the techniques and statistical methods used in the study of complex diseases are being developed at a rapid pace, there is currently no widely accepted standard for evaluating the significance of the findings of such studies.

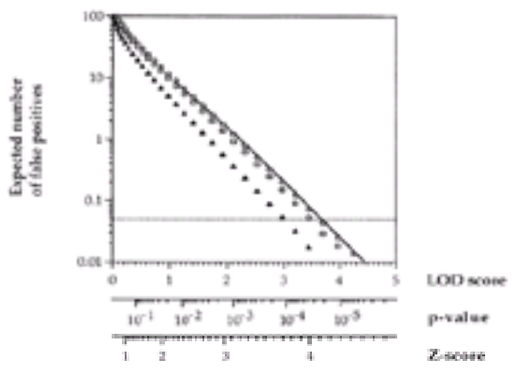

FIGURE 1.18-2 Number of false positives expected in a whole genome scan for a given threshold of LOD score. Solid line represents the expectation for a perfect genetic map. Symbols represent the results for 100 sib pairs using genetic maps with markers spaced every 0.1 cM (circles), every 1 cM (squares), and every 10 cM (triangles). The dotted line indicates the 5 percent genome-wide significance level. (Reprinted with permission from Lander E, Kruglyak L: Genetic dissection of complex traits: Guidelines for interpreting and reporting linkage results. Nature Genet *11*:244, 1995.)

Suggestive linkage Statistical evidence expected to occur once at random in a genome screen	$p \leq 0.001$
Significant linkage Statistical evidence expected to occur about 0.05 times in a genome screen	$p \leq 0.0001$
Highly significant linkage Statistical evidence likely to occur 0.001 times in a genome screen	$p < 0.00002$
Confirmed linkage Significant linkage from one or a combination of initial studies that has subsequently been confirmed in a further sample.

Table 1.18-1 Suggested Criteria for Statistical Evidence of Linkage in Genetic Studies of Complex Traits

Although these criteria suggest that replication of the finding in a separate sample is necessary to confirm linkage, it is important to note that failure to replicate a linkage finding in another population does not necessarily mean that there is no linkage at that locus. Failure to replicate the finding may be caused by genetic heterogeneity, diagnostic differences between the study populations, or statistical fluctuation; in such cases, extension studies in the original population or a meta-analysis of all studies may help to confirm or refute the initial finding.

NONPARAMETRIC APPROACHES

In addition to traditional parametric approaches such as the pedigree method, multiple nonparametric approaches have been developed to address the problem of searching for linkage in the presence of genetic heterogeneity, incomplete penetrance, and unknown modes of transmission. These model-free tests for linkage are so

named because they do not require the specification of a model or the attendant parameters (mode of inheritance, type of penetrance, allele frequencies, and mutation and recombination rates). Nonparametric methods are less powerful in their ability to detect linkage than a correctly specified linkage model, but are often more robust in the face of unknown parameters than linkage analysis; these methods should find allele sharing in the presence of incomplete penetrance, phenocopies, genetic heterogeneity, and high-frequency disease alleles. For this reason, they are best used when the genetic etiology of the disorder is complex (i.e., when simple Mendelian inheritance patterns are not observed and linkage analysis is not a feasible option). Another advantage of nonparametric methods is that LOD score analysis of a small number of large families can be very sensitive to small changes in a few data points (e.g., a change from unaffected status to affected status), whereas nonparametric analyses, because they are usually done on a large number of small families, tend toward normal distributions and are thus less affected by such changes. The most commonly used nonparametric methods in the study of psychiatric disorders are sib-pair analysis and affected pedigree member analysis.

Sib-Pair Analysis Sib-pair analysis, first proposed in 1935, is a nonparametric method that is widely used in genetic studies of complex traits. Sib-pair analysis examines the frequency with which sib pairs concordant for a trait share a particular region of the genome compared with the frequency that is expected under random segregation. Although it is possible to do this test using both affected and unaffected siblings, usually only affected-affected sib pairs are evaluated because little information is gained by including unaffected sib pairs; excluding these individuals alleviates the problem of incomplete penetrance.

Sib-pair analysis is based on the concept that siblings share approximately 50 percent of their genomes identical by descent. Therefore, if a group of unrelated sib pairs with a certain trait shares a particular area of the genome significantly more than 50 percent of the time (the proportion of sharing expected under conditions of random segregation), that area of the genome is considered likely to be linked to the trait in question. In this method, siblings are genotyped, and population frequencies and parental genotypes are used to estimate the proportion of genes shared identical by descent at each site for each sib pair. Those pairs concordant and discordant for each genetic locus can be compared via three statistical tests, the means test, the proportions test, and the goodness-of-fit test.

Affected Pedigree Member Analysis The *affected pedigree member method* uses relatives other than sib pairs (although it can also include sib pairs) to search for evidence of an association between a disease and specific alleles shared by affected individuals. The affected pedigree member method examines all affected individuals in a pedigree to determine the number of alleles shared identical by state in excess of what would be expected merely on the basis of allele frequencies and the relationships between family members. The percentage of alleles shared identical by descent and thus evidence for linkage can then be inferred from the percentage of alleles shared identical by state. Because allele frequencies can have an impact on the percentage of alleles shared identical by state, they must be estimated cautiously; fluctuation in these frequencies can have a major influence on significance levels.

Association Studies Whereas linkage studies attempt to find cosegregation of a genetic marker and a disease gene within a family or families, association studies examine whether a particular allele occurs more frequently in affected individuals within a population. In general, association studies are based on the idea that certain alleles at markers closely surrounding a disease gene will be in linkage disequilibrium with the disease gene; that is, that these alleles will be carried more often than expected by random segregation in affected individuals because they are inherited identical by descent. Association studies of candidate genes make a slightly different assumption—that a particular variant allele is actually causative of the disease, as with the association studies of dopamine receptors in thrill-seeking behavior.

Linkage disequilibrium studies have traditionally been used to complement traditional pedigree analyses, either to further narrow a region of interest that has already been identified or to confirm a previous finding. However, these methods are now being used for whole genome screens, particularly for diseases where traditional linkage studies have been unsuccessful. These studies have one great advantage over a traditional pedigree analysis: because affected individuals are chosen from an entire population rather than from one or a few pedigrees, the number of potential subjects is limited only by the size of the population and the frequency of the disease. For disorders where genetic heterogeneity or incomplete penetrance are likely to be factors, maximizing the potential number of affected individuals that can be included in the analysis is extremely important. In addition, expanding the potential sample pool allows investigators to define the disease phenotype more rigidly, thereby increasing the likelihood that the phenotype under investigation is caused by a major gene effect.

Linkage disequilibrium studies are best done in populations that are descended from a small number of original founders. As a population gets older, recombination across the generations will gradually diminish the length of the chromosomal regions that are shared identical by descent, and individuals several generations away from the founding of the population should therefore share very few regions of the genome by chance. Individuals who share a common trait or disease in such a population are likely to have inherited the same genetic defect as well as specific alleles for markers in the region surrounding the putative gene. In general, such linkage disequilibrium approaches require that the population under investigation has undergone rapid expansion from a small original founding population and that there has been minimal immigration subsequent to the founding. For a genome screen attempting to find shared segments of the genome, in order to maximize the likelihood of finding an association in modern-day affected individuals given current marker map densities, the ideal population should be approximately six to twenty generations distant from the founders. A population that is older than this is likely to have conserved areas that are too small to be identified using currently available marker maps (which have a resolution of a few centiMorgans), increasing the chances of a false-negative result, whereas a younger population is likely to have more areas that are conserved identical by descent by chance, increasing the likelihood of a false-positive result. For studies that attempt to further delineate an area already identified by a traditional linkage study by examining associations between the disease gene and particular alleles at one or a few markers, an older population is appropriate. It is likely, however, that by the early twenty-first century a new marker map will be available at very high resolution (<1 cM); it will then be possible to consider genome-wide association studies in a number of different types of populations.

The degree of linkage disequilibrium in a particular area of the genome can be assessed in several ways. These include haplotype inspection, where segments of the genome are visually inspected for segments shared by all or most affected individuals, and two statistical tests, the transmission disequilibrium test and the haplotype relative risk statistic, which examine the alleles or series of alleles at different markers (haplotypes) that are transmitted from a parent to an affected individual under the assumption that a particular allele or haplotype is associated with the disease.

For association studies, as for linkage and other types of studies, there is some risk of obtaining a positive result purely by chance. Whereas in linkage studies each marker or genetic model tested is not completely independent of the other markers and models tested, for association studies each test performed carries an independent risk of a false-positive result. Therefore, the statistical correction that is applied to prevent such false positives should be more straightforward. It has been suggested that the threshold for significance for these tests should be set at $p = 0.05/n$, where n is the number of independent tests, or in the case of testing for multiple alleles at multiple markers $p = 0.05/n(m-1)$, where n is the number of markers and m is the number of alleles per marker. Again, as for linkage studies, association studies should be confirmed in an independent sample whenever possible.

Genetic mapping has undergone a number of important advances in the 1980s and 1990s, making it possible to find the genetic basis for many complex traits, including familial breast cancer, diabetes mellitus, and, more recently, neuropsychiatric disorders such as dementia of the Alzheimer's type. For the neuropsychiatric disorders, as for other complex traits, however, geneticists are no longer searching for one definitive genetic defect, as was the case with simple Mendelian diseases. Rather, the search has shifted to susceptibility genes, with the understanding that there are likely to be several genes for each clinical entity, acting either in concert with one another within a population, or independently in different populations, and that these gene effects are likely to be modified by environmental or developmental phenomena. Several neuropsychiatric diseases that have been extensively studied genetically, with varying degrees of success, include Alzheimer's disease bipolar I disorder, schizophrenia, and Tourette's disorder. Each of these disorders has provided a somewhat different insight into the difficulties inherent in the genetic mapping of complex disorders.

ALZHEIMER'S DISEASE

Alzheimer's disease is an excellent example of how advances in available technologies and methods have aided genetic mapping studies of complex diseases. The search for the genetic basis of Alzheimer's disease began with a traditional linkage study using a candidate area on chromosome 21; this effort evolved over time into a study of a number of other areas of the genome using several different approaches, culminating in the identification of defects in three unique genes that are responsible for Alzheimer's disease.

Dementia of the Alzheimer's type characterized by progressive impairment of memory and intellectual functioning. The clinical signs and symptoms, although characteristic, are not limited to this disorder but are also found in several other types of dementia. For this reason, the diagnosis of Alzheimer's disease can only be confirmed histopathologically at autopsy; the presence of senile plaques (made up of a core of beta-amyloid fibrils surrounded by dystrophic neurites), neurofibrillary tangles, and congophilic angiopathy in the brain parenchyma and associated blood vessels are pathognomonic.

Alzheimer's disease occurs in both familial and sporadic forms; approximately 60 percent of cases appear to be sporadic (i.e., do not have a family history). A variable

age of onset has been noted, ranging from as early as age 50 to as late as age 95. The concordance rate for Alzheimer's disease in monozygotic twin pairs is approximately 50 percent, indicating a reasonably strong genetic component.

Although phenotypically Alzheimer's disease appears to be fairly homogenous, epidemiological studies have indicated that it is genetically heterogeneous. In order to more clearly define a phenotype that would be amenable to genetic studies, investigators have divided dementia of the Alzheimer's type into early-onset and late-onset categories; early-onset Alzheimer's disease consists of individuals affected before age 65, whereas late-onset Alzheimer's disease consists of individuals affected after age 65. No consistent phenotypic differences between the early and late-onset categories have been noted; however, in a significant number of families the early-onset form of the disorder appears to be inherited in an autosomal dominant fashion with age-dependent penetrance. In late-onset Alzheimer's disease the etiology is less clear—although some cases are probably inherited as an autosomal dominant, most are almost certainly not.

Chromosome 21 It has long been recognized that many individuals with Down's syndrome (trisomy 21) develop an early-onset dementia that is clinically and histopathologically indistinguishable from Alzheimer's disease. For this reason, chromosome 21 was considered to be an excellent candidate region for initial genetic studies of this disorder. In 1987 a group of investigators, using four large families that showed evidence of autosomal dominant transmission of early-onset Alzheimer's disease, looked at chromosome 21 using 10 restriction fragment length polymorphisms (RFLPs) as genetic markers. They found evidence for linkage (multipoint analysis gave an LOD score of 4.06) near two marker loci close to the centromere in the 21q11.2-21q22.2 region. Because amyloid b-peptide (a proteolytic product of amyloid precursor protein) is present in senile plaques and was known to map to chromosome 21, it was hypothesized that a defect in this gene, leading to either overexpression of normal b-amyloid, or expression of an abnormal form of b-amyloid, was responsible for Alzheimer's disease. Although the original linkage finding was later found to be a false positive, this hypothesis was strengthened when the gene coding for amyloid precursor protein was identified later in 1987 and shown to be located at 21q11.1-21q21.2. Mutations were subsequently found both in coding regions within the amyloid precursor protein gene, resulting in amino-acid substitutions, and in areas that lie outside the b-amyloid sequence, resulting in overproduction of b-amyloid or production of longer fragments in individuals with Alzheimer's disease. Transgenic mice with mutated amyloid precursor protein complementary DNA (cDNA) were shown to produce b-amyloid deposits and senile plaques, as well as showing synapse loss, astrocytosis, and microgliosis, all part of the pathology of the disorder. Although no neurofibrillary tangles were observed in these mice, these findings nevertheless represent striking evidence that mutations in the b-amyloid gene are indeed responsible for at least some of the histopathological elements of Alzheimer's disease. To date, there have been six missense mutations identified near or within the b-amyloid sequence of the amyloid precursor protein on chromosome 21 that are present in the families with early-onset Alzheimer's disease.

Chromosome 14 It is interesting to note that none of the families that were originally used in the studies of chromosome 21 and provided the first suggestion of linkage in this area ultimately showed linkage to the amyloid precursor protein gene. For this reason, and because linkage to chromosome 21 was excluded in number of other families evidencing early-onset Alzheimer's disease, further genome screening was done to search for evidence of linkage elsewhere. As result of these studies, linkage on chromosome 14 was independently identified in such families by four teams studying a large number of families from the general population, and was found to be the strongest at 14q24.3. Using traditional linkage studies, investigators were able to narrow the region of interest on chromosome 14 to 8.9 cM; haplotype inspection further delineated the region, and a physical map of this area was constructed using yeast artificial chromosomes. Exon trapping and direct selection of cDNA from the yeast artificial chromosomes then identified several new genes. Five missense mutations were found in early-onset Alzheimer's disease families in one of these transcripts, containing a previously uncharacterized gene that was subsequently named *presenilin-1 (PS-1)*. It is an integral transmembrane protein with at least seven transmembrane domains; its function is currently unknown. The *PS*-1 gene on chromosome 14 has since been recognized as a major locus for Alzheimer's disease in the early-onset familial form of the disorders contributing to up to 70 percent of cases. This area of chromosome 14 has also been examined in late-onset Alzheimer's disease families; however, there is currently no evidence for linkage in these families.

Chromosome 1 Although the *PS*-1 gene accounts for a significant proportion of families with early-onset Alzheimer's disease, it does not account for all such cases. In particular, *PS*-1 does not account for this disorder in a group of families of Volga-German descent. These families, which have a high incidence of the early-onset form of the disease, are known to be descended from one German family that emigrated to Russia from Germany, and then to the United States. In this group Alzheimer's disease segregates in an autosomal dominant fashion, and was hypothesized to result from a single gene defect inherited from a common ancestor. Initial linkage results from a genome search in several families of Volga-German descent did not show linkage to the chromosome 14 site or to the chromosome 21 site, but did identify yet another region, this time on chromosome 1 in the area of 1q31-q42. Following this linkage study and the identification of *PS*-1, a search of a publicly available cDNA database identified a cDNA sequence showing high homology to the *PS*-1 gene on chromosome 14, and which was found to map to within the chromosome 1 region of interest for Alzheimer's disease. This gene was subsequently named *presenilin-2 (PS-2)*. Two missense mutations have been found in *PS*-2 in the Volga-German families and in several talian families with early-onset Alzheimer's disease.

Presenilin-1 and Presenilin-2 Mutations The genes for *PS*-1 and *PS*-2 are expressed in most tissues in the body and share approximately 67 percent overall sequence homology, with the highest similarity being in putative transmembrane domains. The presence of high-sequence homology suggests that *PS*-1 and *PS*-2 have similar functions. However, the intronic sequences of *PS*-2 are not similar to those of *PS*-1, indicating that these genes are not the result of a recent gene duplication, but rather are two separate genes. In addition, as a mutation in only one of the two is sufficient to cause disease, it is clear that one gene cannot compensate for the other.

PS-1 mutations account for approximately 30 to 70 percent early-onset Alzheimer's disease families. To date, 47 missense mutations and one point mutation in *PS*-1 have been found; all but one of the mutations involve amino acids that are conserved between *PS*-1 and *PS*-2. *PS*-1 mutations are for the most part fully penetrant with a narrow age-of-onset range (35 to 55 years); it appears that for Alzheimer's disease caused by this gene, age of onset is determined by both the nature of the mutation and by the position of the mutation within the gene. In addition, although most mutations result in early-onset Alzheimer's disease, some *PS*-1 mutations may also result in late-onset Alzheimer's disease. Although less is currently known about *PS*-2 mutations, they do appear to result in a later and more variable age of onset (up to the 70s and 80s) than do *PS*-1 mutations.

Chromosome 19 For early-onset Alzheimer's disease traditional linkage studies were successful in identifying linkage to three genes, in part because careful phenotype definition allowed investigators to identify large families in which the disease appeared to segregate in a Mendelian fashion. However, these approaches were unsuccessful in studies of late-onset Alzheimer's disease in part because the mode of inheritance was less clear in individuals with this disorder. For this reason, investigators used a nonparametric approach, the affected pedigree member method, to search for evidence of linkage in a large number of small families with late-onset Alzheimer's disease. In 1991, the results of a linkage study using 36 markers in such families using the affected pedigree member method provided evidence (p <0.001) for a susceptibility gene on the long arm of chromosome 19. Subsequent multipoint LOD score analysis gave an LOD score of 4.60 on chromosome 19 between two markers in the area of 19q13.2. There were several candidate genes known to map to this area, including growth factors, proteases, and apolipoprotein E. The major known function of apolipoprotein E is in lipid transport, but other functions have also been suggested. Although it has no known specific causal relationship to Alzheimer's disease, it is found on postmortem in senile plaques, neurofibrillary tangles, and vascular amyloid deposits in the brain of individuals with this disorder. In addition apolipoprotein binds to b-amyloid in the cerebrospinal fluid with high affinity. For this reason, studies were undertaken to determine if an association between Alzheimer's disease and any of the expressed alleles of apolipoprotein E was present.

Apolipoprotein E In 1993 several epidemiological studies identified the e4 allele of the apolipoprotein E gene as a genetic risk factor for late-onset Alzheimer's disease. There are three known alleles of this gene—e2, e3, and e4. In most populations, the e3 allele is the most common. However, in the familial late-onset form of the disease the incidence of e*4* is approximately 50 percent and in sporadic late-onset Alzheimer's disease it is 40 percent, compared with 16 percent in normal controls. Studies have demonstrated that there is a gene dose effect for the e4 allele in families with late-onset disease, with the risk for disease increasing and the mean age of onset decreasing with increasing number of e4 alleles. In the late-onset families, those who are homozygous for e4 are affected 91 percent of the time, with a mean age of onset at 68.4 years. Those who are heterozygous for e4 are affected 47 percent of the time, with a mean age of onset at 75.5 years, and those with no e4 are affected 20 percent of the time with a mean age of onset at 84.3 years.

It has been shown that *apoE*-e4 binds more readily to b-amyloid than does *apoE*-e3, and that patients homozygous for *apoE*-e4 have more b-amyloid deposited in senile plaques and cerebral blood vessel walls than do those homozygous for *apoE*-e3. Although it seems likely that *apoE* is directly involved in the pathogenesis of Alzheimer's disease, it should also be noted that the possibility remains that *apoE*-e4 is a genetic marker for another gene located close by that is actually the susceptibility gene Alzheimer's disease, rather than having a role in and of itself.

Alzheimer's disease is a neuropsychiatric disorder with multiple causes, presumably both genetic and environmental. Although the genetics of this complex disorder are not fully elucidated, the history of the search for disease genes for this disorder illustrates how important each phase of the approach can be, from carefully defining the phenotype to making use of available epidemiological studies, as well as the importance of using all available data, including the public databases. To date, genes have been identified on chromosomes 21, 14, and 1, coding for the b-amyloid peptide of amyloid precursor protein, *PS*-1 and *PS*-2. Together, mutations in these genes account for about 10 percent of those affected, primarily those with familial early-onset disease. An additional 15 percent of affected individuals have sporadic early-onset disease, while 30 percent has the familial late-onset form and 45 percent the sporadic late-onset variant. In addition, a promising area on the

long arm of chromosome 19 has been identified as being potentially linked to the late-onset familial form of the disease. This area is promising because it is the location of the gene coding for apolipoprotein E, which has been previously shown to be related to Alzheimer's disease. Presence of the e4 allele of this gene in these families correlates both with increased risk of getting the disease and for decreased age of onset of the symptoms in a dose-effect manner (Fig. 1.18-3).

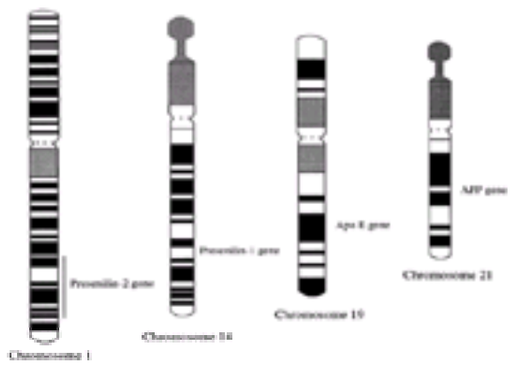

FIGURE 1.18-3 Chromosomal location of the genes implicated in Alzheimer's disease. Apo E = apolipoprotein E. APP = amyloid precursor protein.

Although the pathophysiology of the disease remains a mystery, b-amyloid appears to play a significant role in the course of the disease. The role of the presenilin proteins is unclear at this point; however, studies are currently under way to investigate the function of the presenilin proteins in normal individuals, as well as the effect at a cellular level of mutations in these genes in mice.

BIPOLAR I DISORDER

The search for the genetic basis of bipolar I disorder has been less successful than that for Alzheimer's disease; fraught with missteps and partial answers, the history of genetic mapping attempts for this disease illustrate not only the extreme complexity of the psychiatric disorders, but also the evolution of linkage studies of such diseases. Bipolar I disorder is an episodic illness characterized by recurrent periods of both mania and depression; psychotic symptoms are often a part of the clinical picture, particularly in more severely affected individuals. Although there continues to be disagreement the disorder is considered by many to be part of an affective disorders spectrum ranging from major depressive disorder, bipolar I and II disorders to schizoaffective disorder, bipolar type. Some epidemiological studies have indicated that there may be a single major gene with incomplete penetrance responsible for the disorder in some families; the mode of inheritance in these studies is inconsistent—some have indicated autosomal dominant inheritance whereas others have suggested X-linked or recessive inheritance. However, more recent studies indicate that the genetics of bipolar I disorder are more complex; these studies provide evidence for genetic heterogeneity, multifactorial inheritance, or both. Ongoing problems with linkage studies of bipolar I disorder have included difficulties with specification of genetic parameters such as phenocopy rate, model specification, and phenotype definition. Because using a narrowly defined phenotype often means using fewer individuals in a family or population and thus can result in an unacceptable loss of power, many studies done so far have used a broader definition of affected status that includes bipolar II disorder or major depressive disorder. Although intended to increase the ability to detect linkage, these methods often ultimately result in a decreased ability to detect linkage because of incorrectly specified parameters.

First-Generation Studies The first set of genetic studies following the introduction of DNA markers to report positive linkage to bipolar I disorder were published in 1987; they reported linkage on chromosomes X and 11. Like the initial studies of Alzheimer's disease, these studies used information about the clinical presentation of the disorder to identify likely areas of interest in the genome. In the first study of bipolar I disorder, investigators noted that in several families this and other mood disorders appeared to be inherited in an X-linked fashion and that they appeared to cosegregate with color blindness and G6PD deficiency, which map to the X chromosome. Linkage studies in several Israeli pedigrees with bipolar I disorder as well as color blindness or G6PD deficiency gave LOD scores between 4.75 and 9.17. The study of chromosome 11, which was based on previous studies that indicated a possible linkage to markers on this chromosome, was done in a population of Old Order Amish; two-point linkage analysis gave LOD scores of 4.08 and 2.63 with two RFLP markers on chromosome 11, and multipoint linkage analysis gave a peak LOD score of 4.9. Additionally, visual inspection of haplotypes showed that specific alleles for these two markers segregated with the illness in the three available generations.

Not surprisingly, these findings generated a great deal of interest; both studies showed high LOD scores and seemed to provide clear evidence for linkage. However, replication studies in other populations failed to produce positive results for either the X chromosomes or for chromosome 11. Following these attempts at replication, some members of each group extended and reanalyzed the data from the original studies, incorporating several important changes, in an attempt to confirm the linkage findings. The pedigrees in the Israeli study were reevaluated, and linkage studies were done using several DNA markers in the area. Using these markers, evidence for linkage disappeared in all but one family; in this family the LOD score dropped to 2.09. The most likely explanation for this is that the initial linkage studies used variations in phenotype (color blindness and G6PD deficiency) as markers rather than DNA polymorphisms; such markers are less informative and recombinations are frequently missed. In addition, the affection status of some individuals changed between the first and the second study; it was noted that some errors had been made regarding G6PD status in some individuals, and some individuals previously considered unaffected with bipolar I disorder later developed the disorder. These changes in phenotype also affected the linkage results. Although one family continued to have a suggestive LOD score, the pedigree could not be extended for further study, making confirmation impossible.

When the Amish pedigrees were reevaluated, the most significant change was a change in status from unaffected to affected in two members of the original pedigree. These two individuals did not share the alleles of interest in the original two markers, and this single change lowered the LOD scores for the few markers from 4.9 and 2.63 to 1.75 and 1.29, respectively. Adding data from 10 unaffected individuals who had not been previously included also decreased the LOD scores, although to a lesser extent.

In addition, in an attempt to extend the study, a new branch of the pedigree had been identified that contained both affected and unaffected individuals. As there was evidence that bipolar I disorder might segregate separately in this new branch, it was analyzed both alone and as a part of the larger kindred. In both instances, linkage of bipolar I disorder to the original area on chromosome 11 was excluded.

The failure to replicate or extend these linkage findings, which initially appeared to be so promising, illustrates the vulnerability of such studies to relatively small changes in affection status, as well as the problems inherent in using markers with low informativeness or only a few markers in an area of interest. The next generation of studies attempted to rectify these problems by using multiple markers in what could be considered partial genome screens. In a partial screen, markers widely spaced across the genome are tested, and any giving LOD scores above a certain low threshold are further investigated. Often in these studies, only a few markers are initially tested, and if these markers give evidence for areas of interest the areas are further investigated and the genome screen is postponed.

Second-Generation Studies The first partial genome screen that gave evidence for linkage to bipolar I disorder was completed in 1994 and gave initial results on chromosome 21. This study initially gave high LOD scores for ten markers on 21q22.3 in one family (the maximum LOD score was 3.41) under an autosomal dominant model, as well as significant results in this region using the affected pedigree member method. However, attempts at replication or confirmation of this finding were unsuccessful, as were those with chromosome 11 and X chromosome. Although both the LOD score analysis and the affected pedigree member method gave evidence for linkage that was significant or at least suggestive, they were found in only one pedigree, and attempts to strengthen the finding by adding other families to the sample significantly diminished evidence for this finding rather than enhancing it. In addition, there was no consistent haplotype for this region in the affected individuals. Other investigators have been unable to replicate this finding in other samples.

Another partial genome screen led to a possible area of linkage near the centromere of chromosome 18, although the results of this study are somewhat harder to interpret. This study examined 11 markers on chromosome 18 in 22 families and found several positive two-point LOD scores in individual families; the highest LOD score was 2.38. However, of these positive LOD scores, no clear pattern was observed; some of the markers gave positive LOD scores under a recessive model in some families, some gave positive LOD scores under a dominant model in other families, and some markers gave positive LOD scores in some families under both models. Nonparametric tests provided somewhat stronger evidence for linkage, with p values of less than 0.05 for 7 of the 11 markers, but again, no clear patterns

emerged.

Although these data may represent evidence for a susceptibility locus for bipolar I disorder in the pericentromeric region of chromosome 18, indicating either a small gene effect present in many families or a major locus responsible for the phenotype in a few particular families, the data do not clearly point to either a specific mode of inheritance or to linkage to specific markers in the area. Because multiple markers and multiple genetic models were tested, a statistical correction is necessary, reducing the statistical significance of the findings. In addition, the LOD scores were highest under a broad diagnostic category, which included bipolar I disorder, bipolar II disorder, schizoaffective disorder, and recurrent major depressive disorder; the LOD scores were lower when a narrow diagnostic category was used, calling into question the hypothesis that these LOD scores represent a susceptibility gene specific to bipolar I disorder. The fact that nonparametric methods supported the positive LOD scores suggests that the region should be further explored, but clearly these results in themselves are not sufficient evidence of linkage in this area.

Attempts to replicate this finding in other populations have for the most part been unsuccessful. One group was able to exclude linkage in the pericentromeric area of chromosome 18 in five families with bipolar I disorder using both linkage studies and nonparametric methods. Another group used one of the families from the original study (the same Old Order Amish kindred reported in the linkage studies) as well as five additional Amish pedigrees, and found no evidence for linkage except in the original kindred, where they obtained a maximum LOD score of 1.94. Nonparametric methods provided no evidence for linkage.

One group, however, did find evidence to support linkage to the chromosome 18 area. Hypothesizing that a parent-of-origin effect might play a role in the genetics of bipolar I disorder, the researchers divided their sample into those families where the disorder appeared to be inherited from the paternal side and those where the disorder appeared to be inherited from the maternal side, and analyzed these groups together and separately. Using nonparametric methods, the researchers found evidence for excess allele sharing in several markers in the pericentromeric area of chromosome 18 (18p11). This group also analyzed markers all along chromosome 18, and found excess allele sharing in the area of 18q as well. Two-point LOD score analysis, as well as multipoint LOD score analysis, provided some support for linkage in both areas, with LOD scores of 1.45 in one marker each in both regions. Interestingly, the evidence for linkage in the 18p area was obtained under a broad diagnostic category, which included bipolar I and II disorders and recurrent major depressive disorder, whereas the evidence for linkage in the 18q region was found under a narrow diagnostic category, which included only bipolar I and bipolar II disorder. The results for 18q were somewhat strengthened when the pedigrees were divided into paternal and maternal samples; two-point LOD scores in the area of 18q were between 2.6 and 3.5 in the paternal pedigrees, the peak multipoint LOD score in this area was 3.11, and there was evidence of excess allele sharing for several markers in the area. Again, however, the evidence for 18p was weaker, with evidence for linkage at only one marker. This group attempted to replicate their findings in a new sample of thirty pedigrees with bipolar disorders, using the same diagnostic criteria as the original study, they found evidence for excess allele sharing among affected sib pairs in two markers in the region of interest on 18q, but little evidence for linkage on 18p. In the new sample they found reduced evidence for the parent-of-origin effect that they noted in their original sample.

Third-Generation Studies The next step in the progress of linkage studies of BP was complete genome screening; because the results of the partial genome screens were difficult to interpret, and because of the ongoing difficulties in replication and extension of these studies, a more systematic search for susceptibility genes for bipolar disorder was initiated by several investigators. A complete genome screen provides an opportunity to compare the LOD scores (or *p* values) in potential areas of interest with those in other areas of the genome, thus giving an estimate of the level of background “noise” and the chances that the results of interest represent a false positive rather than a true area of linkage. For example, an LOD score of 1.5 would be of more interest in a genome screen where a few LOD scores are above 0.5 than it would in a genome screen where a large number of LOD scores are above 1.0.

Results of a complete genome screen in a kindred of Old Order Amish that subsumed the pedigrees from the earlier studies showed some promising sites, including markers in the areas of 6pter-p24, 13q13, and 15q11-qter, although there was no evidence for linkage on chromosomes 11 or X. One marker in each of these three areas gave *p* values of 0.001 or less using nonparametric methods; however, under LOD score analysis none of the markers had an LOD score greater than 3, and none of the flanking markers were strongly positive. In addition, there was no evidence of shared haplotypes. Although it may be very likely that these findings represent false positives, these areas should be more closely examined using additional markers and additional families in order to further explore the possibility that they contain susceptibility loci.

The genetic studies of bipolar disorders in the Amish illustrate many of the inherent difficulties of doing genetic analysis on complex disorders. The Amish appear to be a perfect population for such investigations; they are an isolated population with known genealogies, clean phenotypes with little comorbidity, and large extended families. However, the findings for bipolar disorders in this group have so far been inconsistent or contradictory, and even in this ideal population there has been no strong evidence for linkage that has withstood attempts at confirmation or replication.

Yet another susceptibility locus for bipolar disorders has been potentially located on chromosome 4. In 1996, as part of a genome search in twelve families with bipolar I, bipolar II, and recurrent major depressive disorder, investigators found evidence for linkage on chromosome 4p in one family, with a two-point LOD score of 4.1 at one marker, as well as positive LOD scores in the flanking markers under an autosomal dominant model. Three-point analysis with neighboring markers gave an LOD score of 4.8. In all cases, the LOD score was highest under the narrow phenotypic model, which included bipolar I and bipolar II disorder subjects only. Haplotype analysis showed a haplotype of seven markers that were shared by all 11 affected individuals and by 14 of 16 of those affected with recurrent major depressive disorder, and extended-relative pair analysis showed increased allele sharing at two markers that was suggestive but not significant.

When the other 11 families were added, the maximum LOD score, assuming genetic homogeneity, dropped to between 2.9 and 3.3. There was, however, evidence for locus heterogeneity in these families, with only approximately 30 to 35 percent of the families likely to be linked to this locus. Under the assumption of genetic heterogeneity, the maximum LOD score for the combined families was 4.1. Although it is important to be cautious in interpreting these results, the LOD scores in this study indicate that there may be a locus for bipolar disorders in some families at 4p16. The fact that haplotype analysis and extended-relative pair analysis support this finding to varying degrees, and that extending the study to several other families seemed to confirm the results, makes it worth further examination.

In 1996 a third genome screen, this time in two large Costa Rican pedigrees, gave evidence for linkage on the long arm of chromosome 18 somewhat below the area previously reported on 18q, as well as two other areas of potential linkage on 18p and 11p (Fig. 1.18-4). Under a narrow diagnostic model three consecutive markers on chromosome 18 in the area of 18q22-q23 had LOD scores that exceeded 1.6. When this area was further examined using haplotype evaluation, association tests, and joint linkage association tests, a haplotype (composed of several alleles that are relatively rare in the general population of Costa Rica) was found in 16 of 17 affected individuals in one family. A distinct but similarly sized haplotype in the same region was found in 7 of 9 affected individuals in the other family; 3 of the 9 individuals in this family also shared some portion of the first haplotype. In all, 23 of the 26 affected individuals in the two families shared some portion of a core haplotype in this area. Association-linkage scores (which provide joint evidence for linkage and association compared with the assumption of no linkage and no association) were significant for two markers, with LOD scores of 3.70 and 4.06. An independent sample of affected individuals in Costa Rica is currently under investigation in an attempt to confirm this finding and to further investigate the areas on 18p and 11p.

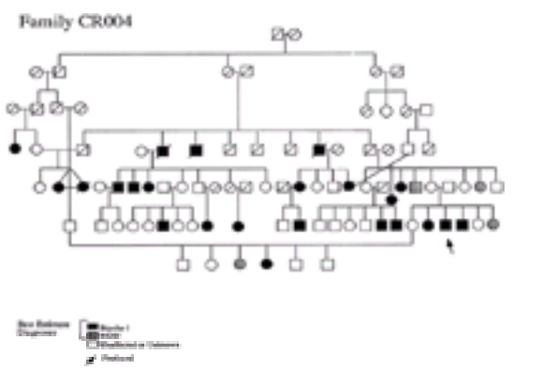

FIGURE 1.18-4 Pedigree of a large Costa Rican family containing multiple members affected with bipolar I disorder and major depressive disorder (MDD). (Reprinted with permission from Freimer NB, Reus VI, Escamilla M, Spesny M, Smith L, Service S, Gallegos A, Meza L, Batki S, Vinogradov S, Leon P, Sandkuijl L: An approach to investigating linkage for bipolar disorder using large Costa Rican pedigrees. Am J Med Genet *67:*258, 1996.)

Because of the continued suggestion of one or more susceptibility loci located on chromosome 18, other groups have also examined this area for evidence of linkage.

Several of these groups have found some evidence for linkage, although weak, at or near 18q23; support for linkage at 18p has been even more uncertain.

The combined evidence of these studies, although somewhat contradictory and confusing, appears to point to two different susceptibility loci on chromosome 18: one on 18p and one on 18q. These loci, if they do indeed represent two independent true areas of linkage, are different in intriguing ways. The 18p finding is perhaps the most difficult to explain because for most studies a single marker explains the majority of the positive findings, and each study points to a different marker. In addition, the evidence for a locus in this area appears to be strongest in individual families—the evidence actually diminishes when families are combined, and it is strongest under a broad phenotype definition that includes not only bipolar I disorder but also major depressive disorder.

In contrast, the 18q finding extends over several markers, and appears to be robust to the addition of new families. Although different markers were tested in the different studies, they all lie within the area of the larger haplotype noted in the Costa Rican families. Finally, this finding appears to be more robust when the phenotype is narrowly defined—the evidence weakens or disappears when the phenotype is expanded to include major depression.

Unlike Alzheimer's disease, where at least part of the genetic story has been successfully elucidated, bipolar I disorder has been resistant to ongoing attempts at clarification. This is in part because of the fact that not only is there likely to be genetic complexity in bipolar I disorder (i.e., locus heterogeneity, incomplete penetrance and so forth), but there is a greater risk for phenotypic complexity as well. There is a great deal of symptom overlap between bipolar I disorder and other mood and psychotic disorders, and currently, as the different inclusion criteria in the studies implies, there is also a great deal of disagreement about the degree of relationship between these disorders. The difficulty in interpreting these studies points to the importance of carefully following up isolated positive results by examining flanking markers, by adding new families or affected individuals, and by attempting replication of significant or near-significant results in an independent sample. Nothwithstanding the uncertainties and contradictions, these studies indicate several promising areas of the genome that warrant further examination. Specifically, the areas of 4p, 18p, and 18q, which either show significant LOD scores or nonparametric results in a single sample or ongoing suggestive evidence in a number of samples, are promising. In addition, new approaches to the study of bipolar I disorder, such as population-based studies and large-scale sib-pair analyses, may allow for the implementation of strategies such as stricter phenotype definition without a concomitant loss of power. These strategies in turn may increase the likelihood of finding loci that either have a small gene effect or are present in only a small proportion of affected individuals.

SCHIZOPHRENIA

Schizophrenia is another psychiatric disorder that has for a variety of reasons defied most attempts at genetic mapping. Perhaps the most significant problem that has been encountered in genetic studies of schizophrenia is the difficulty in phenotypic characterization. The phenotype for schizophrenia is broad, and the cardinal symptoms, delusions and hallucinations, are also found in a number of other psychiatric disorders. More specific characteristics of schizophrenia such as so-called negative symptoms (e.g., flat or inappropriate affect, social isolation, and poverty of thought) and a progressive downhill course, can be difficult to recognize or quantify. Schizophrenia is thought by some investigators to represent the extreme end of a spectrum of psychotic disorders ranging from schizoid personality disorder, schizotypal personality disorder, and paranoid personality disorder to schizoaffective disorder. The diagnosis of schizophrenia is further complicated by the fact that the definition of the disorder has varied dramatically, both across years and between psychiatric centers, leading to significant problems in constructing and interpreting epidemiological studies. However, epidemiological studies done using relatively recent, widely accepted operationalized criteria have indicated that there is likely to be a genetic component for the susceptibility to schizophrenia. Relative risk studies have shown a 10-fold increase in the risk of developing schizophrenia among relatives of affected individuals as compared with relatives of controls, and twin studies show a concordance rate of 40 to 50 percent for monozygotic twins and about 10 percent for dizygotic twins. These studies indicate that although schizophrenia is at least in part genetic, it is not likely to be caused by a single major gene but rather by several genes acting in concert with each other and the environment. Research also indicates that the genetic contribution to schizophrenia is likely to be weaker than that for bipolar I disorder, potentially making it a much more difficult disease to study. Attempts to use measures that are thought to be related to schizophrenia, such as abnormalities in smooth-pursuit eye movements, have also been unsuccessful. Although for the most part linkage and association studies of schizophrenia have been unsuccessful, several recent studies have provided evidence that one or more susceptibility genes for this disorder may soon be within reach.

Early Studies Early studies of schizophrenia were, like those of Alzheimer's disease, based on observed cytogenetic abnormalities in individuals with schizophrenia-like symptoms. In the late 1980s a report of a chromosomal translocation on chromosome 5 in an uncle-nephew pair with schizophrenia prompted several linkage studies in the area of 5q11-q13. Using varying diagnostic models ranging from narrow (including schizophrenia, schizophreniform disorders, and unspecified functional psychosis) to very broad (including all psychiatric disorders seen in the sample) and various genetic models, investigators obtained maximum LOD scores of 2.45 to 6.49 in a group of seven large pedigrees. The highest LOD scores (4.33 to 6.49) were obtained using an extremely broad definition of affected status that included essentially all psychiatric disorders; LOD scores for the narrower phenotypic categories were lower (between 3.22 and 4.33). Although these LOD scores are significant, the fact that they are lower in the narrow than in the broad phenotypic categories suggests that this area of potential linkage may not be specific to schizophrenia, and thus may be difficult to replicate or confirm. Subsequent groups have failed to find evidence of linkage to the 5q11-q13 are or have excluded linkage to this region in their study families; association studies have also produced negative results. In addition, there has been no follow-up to this finding in the form of extension or fine mapping studies in the original population, indicating that it is likely to represent a false positive.

The next area of the genome that gave evidence for a possible susceptibility locus was on chromosome 22. An initial partial genome screen using 240 markers in a subset of families with multiple cases of schizophrenia or schizoaffective disorder, using an autosomal dominant model, identified an area of interest on 22q13. Although the LOD scores were fairly low (three contiguous markers gave LOD scores between 0.94 and 1.54), they are of interest because velo-cardio-facial syndrome (VCFS), a disorder in which affected individuals have been described as having schizophrenia-like symptoms beginning in adolescence or early adulthood, is known to be caused by microdeletions in 22q11, near the area identified in the genome screen for schizophrenia. However, attempts to replicate these linkage results using an additional 217 families from multiple sites and the same parameters as the original study have provided no further evidence for linkage.

Genome Screens Although earlier linkage studies of schizophrenia have pointed to some potentially interesting areas, as is true for bipolar I disorder, the most promising evidence of linkage for a susceptibility gene for schizophrenia has come from complete genome screens. At least two independent genome screens of families with schizophrenia have pointed to one area in particular that is suggestive for linkage—the short arm of chromosome 6. These studies have been supported by follow-up replication and extension studies. Following up on positive LOD scores on 6p25-p24 obtained in an initial genome screen, one group of investigators obtained a maximum LOD score of 3.51 in this area under the assumption of 50 percent heterogeneity (i.e., under the assumption that only 50 percent of the study families were likely to be linked to the locus). Sib-pair analysis provided additional support for linkage in the study families, although the overall results were weaker. Again, all the results were strongest for broad diagnostic categories; a narrow phenotype definition gave nonsignificant LOD scores. In addition, although suggestive for linkage in the region of 6p24-22, this study provided little information about the likely mode of inheritance; for a given diagnostic category, the LOD scores for the codominant, dominant, and recessive models were often similar.

A follow-up study that attempted to replicate the finding of linkage in the 6p area using a sib-pair analysis and a narrow diagnostic phenotype (schizophrenia and schizoaffective disorder only) found excess allele sharing in affected sib pairs at one of the markers that originally showed linkage and at several additional markers in this region, with a maximum LOD score of 2.2. These results provide support for linkage to schizophrenia on chromosome 6, although they do not provide clear confirmation of the original finding; although the regions of interest overlapped in the two studies, they were not identical. Further support for a susceptibility locus on 6p came from a second complete genome screen. Investigators in this study found preliminary evidence of linkage on 6p in five Icelandic pedigrees using a nonparametric method called weighted-rank pairwise correlation. Follow-up of this finding in an additional 65 families also pointed to the 6p25-p24 region; when the two samples were combined, a slight increase in the probability of linkage in this area was obtained but did not meet stringent criteria for significant linkage. Because of the previous work on chromosome 6 and these positive findings, however, 6p25-p24 was examined in a third sample using association methods; in this sample evidence of linkage disequilibrium on 6p was obtained. These data were once again combined with the data from the original study, and gave significant evidence of linkage ($p = 0.00004$) at one marker. However, attempts at replication in a fourth sample were unsuccessful, and a separate replication study in a sample of 57 pedigrees gave only mildly positive evidence of linkage (maximum LOD score of 1.17, sib-pair analysis p value <0.004). Another study that focused on the short arm of chromosome 6 took a slightly different approach. After traditional pedigree and sib-pair analysis produced no significant evidence for linkage on 6p in 10 large Canadian families with schizophrenia, this group used a quantitative trait approach to examine the hypothesis that their study families carried a susceptibility locus specific to the positive symptoms of schizophrenia, including disorganized thinking, hallucinations, and delusions. Using this approach they found significant evidence for linkage (nominal $p = 1.2 \times 10^{-5}$ and 5.4×10^{-6}, and empirical $p = 0.34$ and 0.0085, respectively) in two markers in the 6p11 to 6p21 region, slightly more centromeric than the area implicated in the other studies, but adjoining it.

These studies all point to a possible susceptibility locus on chromosome 6p in or near the area of 6p25-p24, although the evidence is not conclusive. In addition, at least two studies provided no evidence for a susceptibility locus for schizophrenia on 6p using several of the original markers and the same genetic models and parameters used in the first study. Interpretation of the results of these studies is complicated, and there is as yet no clear consensus. Although it is possible that these results represent a false positive, it is also possible that they represent the presence of genetic heterogeneity, that is, that a susceptibility locus for

schizophrenia does indeed exist on 6p, and possibly on 22q, but that these loci are relevant in only a proportion of affected families or individuals. Because the study of the genetics of schizophrenia necessarily involves many complicating factors, a logical next step would be to perform association studies in an appropriate population or to attempt large-scale sib-pair studies. These approaches allow for careful phenotype definition and selection of appropriate study subjects, as well as increasing the number of possible subjects, thereby increasing the chances of finding linkage or association in the presence of complicating factors such as genetic heterogeneity or incomplete penetrance.

TOURETTE'S DISORDER

Although the data is confusing at best and contradictory at worst, there currently appears to be evidence for at least one susceptibility locus for schizophrenia, perhaps more. In contrast, there have been no reports of positive linkage findings to Tourette's disorder from several ongoing genetic studies. Tourette's disorder is a neuropsychiatric disorder with onset in childhood that is characterized by chronic intermittent motor and vocal tics. Twin studies have shown it to have a monozygotic concordance rate of 50 to 70 percent, as compared to a dizygotic concordance rate of 8 percent, indicating that there is a strong genetic component. As with other neuropsychiatric disorders, phenotype definition has been a critical part of the genetic study of Tourette's disorder. Because of the strong phenotypic similarities between it and other tic disorders such as chronic motor tic disorder, many investigators have suggested that these disorders lie along a contiuum, with transient tic disorders at one extreme and Tourette's disorder at the other. Segregation analyses have supported this theory to some extent, indicating that chronic motor tic disorder and obsessive-compulsive disorder, which has been noted to cosegregate in families with Tourette's disorder, may actually be phenotypic variants of it. Although the spectrum approach is not universally accepted and brings with it the problem of potential phenocopies, because of the difficulty of obtaining families with sufficient numbers of affected individuals most studies done to date have included individuals with chronic motor tic disorder and obsessive-compulsive disorder in addition to those with Tourette's disorder.

As noted previously, however, linkage studies have been unsuccessful despite these efforts to increase the power of the study by expanding the phenotype. Early suggestions that susceptibility loci might be located on chromosome 18 or chromosome 9 based on observed cytogenetic abnormalities in a few individuals with Tourette's disorder were not supported by linkage studies in these areas. In addition, although early segregation analysis indicated that the inheritance pattern of the disorder was most likely to be a single major gene transmitted in an autosomal dominant fashion with incomplete penetrance, complete genome screening efforts have also failed to find evidence of linkage. An ongoing collaborative genome screen for Tourette's disorder, which currently encompasses more than 600 markers, has so far indicated exclusion of linkage in up to 95 percent of the genome. Another, more recent study has reported preliminary LOD scores of 1.57 and 2.21 at two individual markers (one on chromosome 8 and one on chromosome 17) in a few families; further work in these areas using additional markers and additional families is currently under way. Candidate gene studies examining the dopamine type 1 (D_1) type 2 (D_2), type 3 (D_3), type 4 (D_4), and type 5 (D_5) receptors, the dopamine transporter protein, prodynorphin, proopiomelanocortin, gastrin-releasing peptide, tyrosine hydroxylase, and dopamine hydroxylase have also been negative. Because of the lack of success with linkage and candidate gene studies despite evidence of a strong genetic contribution to Tourette's disorder, investigators are currently reexamining their assumptions about the disorder in an attempt to identify methods of investigation that are likely to be more successful than the traditional approaches have been.

Segregation Analyses Early segregation analyses indicated that the mode of inheritance of Tourette's disorder was most likely to be autosomal dominant with incomplete penetrance (with a lower penetrance for females than for males) and variable expression of phenotype that included chronic motor tic disorder and obsessive-compulsive disorder. Because linkage analysis using this model has consistently failed to uncover any areas suggestive of linkage, however, the data from these studies have been recently reanalyzed and the underlying assumptions closely examined.

In the first such study, a single large pedigree was reanalyzed under an assumption of assortative mating when it was noticed that a higher-than-expected number of married-in spouses were also affected (36 percent). Some clinical studies have suggested that families in which both parents are affected with tic disorders or Tourette's disorder have children with more severe symptoms than those in which only one parent has a tic disorder. Reanalysis of this pedigree indicated that the correlation resulting from assortative mating was significant; the results also suggested an additive model of inheritance in which heterozygotes (who carry one copy of the disease allele) have a lower risk of developing Tourette's disorder than do homozygotes (who carry two copies of the disease allele), and in which nongene carries have no risk of developing the disorder. A second group also suggested an additive rather than dominant or recessive model of inheritance as a result of their segregation analysis of several families with the disorder; this study additionally provided evidence for the presence of a strong multifactorial background. Extrapolating from the results of their study, the investigators hypothesized that under this model all individuals homozygous for Tourette's disorder allele would be affected, but only 2.2 percent of males and 0.3 percent of females heterozygous for the allele were likely to be affected.

At the same time as some investigators were reevaluating the assumptions underlying the presumed genetic models of Tourette's disorder, others were reevaluating the assumptions underlying the presumed phenotype. The assumption that chronic motor tic disorder or obsessive-compulsive disorder are variant phenotypes of Tourette's disorder for the purpose of genetic studies, although supported by early segregation analyses, ignores the possibility that they may also result from different genetic or nongenetic forms in some or all cases. For this reason, the question of appropriate phenotype specification was examined in a series of simulations using two different phenotypic approaches. The first approach was designed to minimize the risk of obtaining false positives by including only the most severe phenotypes (i.e., individuals with severe Tourette's disorder only); it has the potential drawback of a much smaller sample size, leading to unacceptable loss of power. The second approach was designed to effectively expand the pool of available subjects by doing multiple linkage tests using gradually broadened disease phenotypes; this strategy potentially increases the rate of false-positive results, particularly if corrections for multiple testing are not made. These strategies were compared using simulations in which the true linkage in the population was hypothesized to be for either Tourette's disorder only, for Tourette's disorder chronic motor tic disorder, or for Tourette's disorder, chronic motor tic disorder, and obsessive-compulsive disorder. Like the earlier studies, an autosomal dominant model with incomplete penetrance and a low population gene frequency was assumed. Using the first approach an LOD score of greater than 3 was found for only one family (from a total of 32); in contrast, the LOD score was greater than 3 for four families using the second approach, indicating that the power of detection of linkage was greater for the broader models. When the simulations were repeated using an incorrect model (i.e., assuming a broad phenotype when in fact the true phenotype was narrow or vice versa), the results indicated that if several diagnostic models were tested, the chances of finding linkage were always >70 percent, whereas if only the narrower phenotype was used, the likelihood of finding linkage was high only if chronic motortic disorder and obsessive-compulsive disorder were not in reality variant forms of Tourette's disorder; if they were variant phenotypic expressions, the first approach was much less likely to detect linkage. These results suggest that doing linkage studies using a hierarchical system of phenotype definitions ranging from narrow to broad (with appropriate corrections for multiple testing) could substantially increase the chances of finding linkage to Tourette's disorder.

Unlike Alzheimer's disease, bipolar I disorder, and schizophrenia, there are currently no significant or even suggestive linkage findings for Tourette's disorder. Segregation analyses continue to suggest a strong genetic component, and to support the hypothesis of a single major locus effect, perhaps with an additional environmental component. Given this, and despite evidence that the available family data should be sufficiently informative for linkage studies, the continued difficulty in finding linkage using traditional methods is surprising. Thus, attention has turned to other ways of elucidating the genetic etiology of this disorder. One such strategy is to assume that Tourette's disorder is a heterogeneous disorder and that those with the most severe symptoms are the most likely to have a clear genetic component. Because of the potential loss of power associated with restricting the phenotype to only severely affected cases of the disorder, thereby decreasing the pool of potential subjects, attention is shifting to population-based studies, such as linkage disequilibrium and sib-pair analyses, where larger samples sizes can be collected than are possible in family studies. At least two such studies are currently under way. If they are successful, they will have a significant impact on the way the study of complex diseases is approached.

AGGRESSION

The genetics of aggression is difficult to study because it is poorly defined as a phenotype. Rather than being a syndrome of collected symptoms with a generally agreed-upon definition, aggression is a behavior, with a phenotype that is open to interpretation. Some scientists studying aggression consider only acts of violence against others in their definition of the phenotype; others add acts of violence against oneself, such as suicide attempts, self-mutilatory behavior, and violent thoughts. One definition that is in widespread use and can be applied to both animals and to humans states that aggression is behavior that involves an intent to harm someone else. The key to this definition is in the concept of *intent*, which can be difficult to define in both humans and in animals but provides a way of differentiating aggression from accidental injury. A somewhat narrower definition that applies to humans exclusively is that of violence; *violence* is commonly accepted to mean aggressive behavior by humans towards humans. Measures of aggression vary widely, and range from self-reports to family reports to observations of behavior. Most assessment instruments measure aggression as a relatively permanent personality trait (i.e., as a propensity towards violent behavior) rather than measuring the behavior itself, although newer instruments are beginning to measure this too. These instruments commonly measure either feelings such as anger, resentment, and suspicion; behaviors; or a combination of the two.

Despite these difficulties, several investigators have attempted to measure a genetic contribution to aggressive behavior. A meta-analysis of data from 24 genetic epidemiological studies, mainly twin and adoption studies, suggested that up to 50 percent of the variance in aggressive behavior results from a genetic effect, even

after controlling for the effects of common environments. The results of the individual studies in this set were quite variable, ranging from no evidence of a genetic effect, to a concordance for aggression between identical twin pairs of up to 0.85. The meta-analysis also examined the differences between studies that used self or family report measures of aggression and those that used observational ratings and found that the use of observational ratings greatly reduced the effect of genetic factors and greatly increased the effect of environmental factors. The results of the meta-analysis also showed that both genetics and common environment were equally important in determining aggressive behavior in youths, whereas the impact of common environment decreased and the effect of genetics increased in adults, suggesting that if there is a genetic component to aggression, its impact may change over time.

To date there has only been one study reporting convincing linkage for aspects of aggression in humans. This study examined a large Dutch kindred in which male family members had borderline mental retardation and abnormal behavior, including impulsive aggression, attempted rape, arson, and exibitionism. A genetic defect was identified in p11-p21 of the X chromosome, in the region near the monoamine oxidase type A (MAO_A) and type B (MAO_B) genes, with an LOD score of 3.55. Subsequent mutation analysis revealed a mutation (changing a glutamine to a termination codon) that was present in all affected individuals and in the two obligate carries studied, but was not seen in the unaffected members of the family. Functional studies, in which fibroblast cells were grown in the presence of tryptamine and then exposed to dexamethasone (which produces a 6-fold to 14-fold increase in MAO_A production in normal cells), noted a significant decrease of MAO_A activity in affected individuals and a normal level of MAO_A activity in unaffected individuals.

As a result of this study, and because of reports indicating that aggressive behavior is correlated with lowered concentrations of 5-hydroxyindoleacetic acid (5-HIAA), a serotonin metabolite, in the cerebrospinal fluid of monkeys and humans, several mouse knockout models have been made to examine the relation between genes involved in the serotonin and MAO pathways and aggression. Mice in whom the gene that codes for MAO_A was knocked out were found to have behavioral abnormalities as pups, and increased aggressiveness as adults; these mice showed increased levels of serotonin and norepinephrine and decreased levels of 5-HIAA as pups. Interestingly, the levels of both serotonin and its metabolite returned to normal in the adults. Both pups and adult mice showed persistent changes in the somatosensory cortex on histological examination. Similarly, mice lacking serotonin (5-hydroxytryptamine [5-HT] subtype 1B (5- HT_{1B}) receptor (the homologue of the $5\text{-}HT_{1DB}$ receptor in humans) showed an increase in aggressive behavior when compared to wild-type mice. A third knockout mouse model, deficient in a-calmodulin-dependent protein kinase II (CaMK II), also showed an increase in aggressive behavior, although in this instance the abnormality was seen only in those mice heterozygous for the mutation. The homozygous mutant mice, although not aggressive, showed a large number of other behavioral abnormalities. CaMK-II–deficient mice also showed decreased serotonin release. CaMK-II–mediated phosphorylation is required for the activation of tryptophan hydroxylase, the rate-limiting enzyme in the synthesis of serotonin. The results of these studies appear to be somewhat contradictory at first; the MAO_A knockout mice, which showed an increase in central serotonin concentrations, had increased aggressiveness, as did the $5\text{-}HT_{1B}$ and CaMK-II knockout mice, who showed a decrease in serotonin availability. One explanation that has been put forward is that in order to produce a change in behavior such as an increase in aggression, the genetic defect must affect the developmental process of the animal; thus, it is not the measurable concentrations of available serotonin in adult animals that is important, but the effects of altered concentrations on early development. Although not entirely satisfactory, this hypothesis is particularly appealing in light of the observation that serotonin concentrations, although abnormal in the genetically altered mouse pups, returned to normal in adult mice, and may explain why some genetic mutations associated with increased aggression in adults cause lowered serotonin concentrations whereas others cause increased serotonin concentrations.

At least two other genetic abnormalities, not known to be associated with the serotonin pathways, have also been found to be associated with increased aggression in mice. These abnormalities are in the nitric oxide synthase *(NOS)* gene and in the adenosine receptor a_{2a}. These mice were similar to the other knockout mice discussed in that the males showed increased aggression under testing circumstances when compared to wildtype mice. In addition, the mice with defects in the *NOS* gene showed an abnormal increase in the amount of sexual behavior with nonreceptive females, and the mice with defects in the adenosine receptor showed less exploratory behavior as well as having prominent hypoalgesia. The mechanisms behind these behavioral abnormalities are currently unknown.

The results of these human and mouse studies suggest that aggression is likely to have a complex causation including multiple, perhaps additive, genetic effects. Currently, only a single small kindred with multiple other behavioral and cognitive abnormalities provides evidence for a specific genetic contribution to aggression in humans. Although it is a promising start, this finding by no means explains the etiology of aggression.

The field of genetics has developed a great deal in the last several years, and continues to grow at a rapid pace. For many diseases of interest, it is no longer possible to rely exclusively on traditional linkage studies assuming Mendelian inheritance. New approaches and methodologies that address or circumvent the problems inherent in the study of complex disorders, such as genetic heterogeneity, unknown genetic parameters, uncertain inheritance patterns, and variable phenotypes, have previously led to the identification of genetic defects for such complex disorders such as breast cancer and diabetes. These methods are also successfully being applied to the genetic study of neuropsychiatric disorders, such as Alzheimer's disease, bipolar I disorder, schizophrenia, and Tourette's disorder. Neuropsychiatric disorders have not only provided the impetus but have also served as models for the development and use of new genetic approaches such as complete genome screens using linkage disequilibrium and sib-pair analyses, as well as emphasizing the importance of epidemiological studies, phenotype definition, and careful selection of the study sample. In particular, the genetic studies of Alzheimer's disease have clearly illustrated the value of careful phenotype definition and the use of a variety of methodological approaches, as well as the importance of incorporating all available information, such as epidemiological studies and molecular and genetics databases, into the study. In the next several years the use of these tools will help to elucidate the genetic bases for a number of other neuropsychiatric diseases, including those discussed here.

SUGGESTED CROSS-REFERENCES

Section 1.10 on basic molecular neurobiology and section 1.17 on population genetics provide basic information on the mechanisms of cell division and genetic recombination as well as the required elements of genetic study. Chapter 9 describes the classification of mental disorders, including the use of diagnostic schemas and research instruments. Chapter 12 describes the clinical diagnosis and epidemiology of schizophrenia, Chapter 14 describes the clinical diagnosis and epidemiology of mood disorders, Chapter 42 describes the clinical diagnosis and epidemiology of tic disorders, and section 51.3e and Chapter 10 describe the clinical diagnosis and epidemiology of Alzheimer's disease.

1.19 BASIC SCIENCE OF SLEEP

J. CHRISTIAN GILLIN, M.D., ERICH SEIFRITZ, M.D., REBECCA ZOLTOSKI, PH.D., AND RAFAEL J. SALIN-PASCUAL, M.D., PH.D.

Sleep disturbances are particularly pertinent to psychiatrists and other mental health professionals because these complaints are frequently associated with depression, anxiety, substance abuse, obsessive-compulsive disorders, psychosis, acute and chronic stress, and many other disorders. The neuroscience of sleep regulation, in addition, is important to understand the pathophysiology of psychiatric disorders and the mechanism of action of psychoactive drugs. New insights into the regulation of sleep and wakefulness emerging from molecular biology, genetics, and neuroimaging techniques promise exciting progress in the field of sleep physiology research in particular, and in the pathophysiology of psychiatric disorders in general. The association between sleep and mood disorders is, for instance, intriguing if one considers the powerful antidepressant effect of one night of sleep deprivation, and the recurrence of depressive symptoms after one night of recovery sleep. Furthermore, the sleep electroencephalogram (EEG) has some value as a predictor for treatment outcome as well because it may be used as a biological variable to follow patients during treatment. In addition, exciting new findings on the association between memory function and sleep also emphasize the importance of sleep in neuroscience and in psychiatry.

PHENOMENOLOGY OF SLEEP AND WAKEFULNESS IN NORMAL HUMANS

Sleep Stages and Their Normal Organization Most mammals have two major phases of sleep: *rapid eye movement (REM) sleep* and *non-rapid eye movement (NREM) sleep*. REM sleep is sometimes called *dreaming* or *D sleep* because it is associated with dreaming, or *paradoxical sleep*, because the electroencephalogram EEG becomes activated during this state of sleep. NREM sleep, on the other hand, conforms to traditional concepts of sleep as a time of decreased physiological and psychological activity; it is therefore sometimes called *orthodox sleep* or *slow wave sleep* (SWS), *EEG synchronized sleep*, or *S sleep*.

NREM sleep is further divided into four sleep stages on the basis of visually scored EEG patterns (Table 1.19-1, Fig. 1.19-1).

Table 1.19-1 Technical Terms Commonly Used in Characterizing Sleep

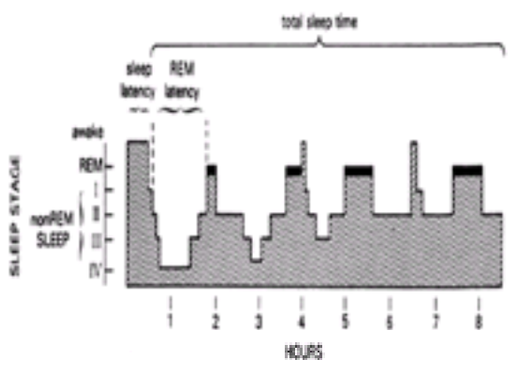

FIGURE 1.19-1 Sleep pattern in a young healthy subject with power spectral analysis of low-frequency band across the night.

Sleep normally begins with *stage 1*, a brief transitional phase, before progressing successively into stages 2 through 4. *Stage 2 sleep* is defined by the presence of sleep spindles and K-complexes in the EEG. *Stage 3* and *Stage 4 sleep*, or *delta sleep* are defined by the presence of delta waves in the EEG, a moderate (20 to 50 percent) and large (>50 percent) proportion of an epoch (usually 30 seconds long) of sleep, respectively.

REM sleep is characterized by an activated EEG, loss of tone in the major antigravity muscles, and periodic bursts of rapid eye movements. The REM latency is usually about 70 to 100 minutes in normal subjects but may be significantly shortened in some patients with depressive disorder, eating disorders, borderline personality disorder, schizophrenia, alcohol use disorder, or other psychiatric disorders. Thereafter, NREM and REM sleep oscillate with a cycle length of roughly 90 to 100 minutes. When it does occur, delta sleep is highest in the first NREM period of the night and declines with each successive NREM period. Most of the delta sleep occurs in the first half of the night and most of the REM sleep occurs in the last half of the night.

REM sleep and NREM sleep differ from each other in many psychological and physiological domains (Table 1.19-2). On a psychological level, REM sleep is associated with dreaming mentation, while NREM sleep is more likely to be associated with abstract thinking. Autonomic functioning is often highly variable during REM sleep; it is usually slow and steady in NREM sleep.

	NREM Sleep	REM Sleep
EEG	Spindles, K complexes, delta waves, synchronized	Low-voltage, mixed frequency, sawtooth waves, activated
EOG	Quiescent or slow movements	Bursts of fast movements
EMG	Partial relaxation	Atonia of antigravity muscles
Intercostal muscles	Partial relaxation	Atonia
Genioglossus	Partial relaxation	Hypotonic
Blood pressure	Decreased, steady	Variable
Heart rate	Decreased, steady	Variable
Cardiac output	Decreased	Decreased
Cerebral glucose metabolism	Decreased	Unchanged or increased
Brain temperature	Decreased	Increased
Respiratory rate	Decreased	Variable
Ventilatory response to CO_2	Intact	Partially impaired
Genitalia	Infrequent tumescence	Tumescence
Mentation	Conceptual, abstract; infrequent dreaming	Perceptual, frequent dreaming
Pathology	Night terrors, somnambulism, panic attacks	Nightmares, REM sleep behavior disorder

Table 1.19-2 Comparison of NREM and REM Sleep

Commonly Used Terms in Sleep Laboratory Studies Many different measurements may be made of sleep, sleepiness, wakefulness, physiology, or performance in a sleep laboratory, depending on the purpose of evaluation. In order to measure the stages of sleep, the subject is usually monitored by electrodes that are attached to the scalp for recording EEG, near the eyes to measure eye movements *(electrooculogram* [EOG]), and on the chin (submental) muscles to record muscle tone *(electromyogram* [EMG]). In the clinical evaluation of a patient suspected of having specific clinical sleep disorder, recordings may be made of nasal and oral air flow by means of thermistors, respiratory movements of the chest and abdomen, electrocardiogram, oxygen saturation, core body temperature (often via the rectal route or the tympanic membrane), muscle twitches of the legs (usually the anterior tibial muscles), penile erections, or esophageal pH (Table 1.19-1).

Although most sleep laboratories around the world use a common set of definitions for sleep stages as defined by Allan Rechtschaffen and Anthony Kales, no commonly accepted definitions exist for some specific measures. For example, depending on the laboratory, sleep onset is defined as the first epoch of stage 1, of stage 2, of REM sleep, or of persistent sleep (e.g., 9 minutes of sleep within a 10-minute period). Likewise, the first REM period may be defined as either the first epoch of REM sleep or the first period of persistent REM sleep (i.e., 3 minutes). REM latency may either include or exclude wakefulness between sleep onset and the first REM period. These variations in definitions do not usually make an appreciable difference, but clinicians and researchers need to be aware of these distinctions when comparing results and reports from different laboratories.

Computer-Assisted Analysis of Sleep Records Although visual scoring is still the standard for the identification of specific sleep stages, considerable progress has been made with computer scoring of sleep stages. Some commercial companies now market hardware and software designed to replace or assist the sleep technician, and further progress can be expected in the coming years. However, there is no generally accepted algorithm of automatic scoring reliable enough to replace visual scoring.

For research purposes, two methods of quantitative EEG wave form analysis have received particular attention: *spectral analysis* and *period-amplitude analysis*. Power spectral analysis uses fast Fourier transformation to compute cumulative or average power (uV^2) of specific frequency bands (Fig. 1.19-1). Period-amplitude analysis computes the peak amplitude of each EEG wave and the time interval between zero (baseline) crossings. It is particularly useful in estimating the amplitude and temporal distribution of transient phenomena in the EEG, such as delta waves, K complexes, and sleep spindles, but it may miss frequency components of the EEG that fail to produce zero crossing; these may be estimated by the calculation of derivatives. Both methods measure slow-wave activity well. Power spectral analysis has also been used to map the topographical distribution of specific frequency bands throughout the progression of sleep. It has, for example been shown that the spatial distribution of sleep spindles and delta waves changes from the beginning to the end of the night.

Measures of Daytime Sleepiness Excessive sleepiness is a common complaint in clinical practice and may be a sign of treatable conditions, such as chronic partial sleep deprivation, certain sleep disorders (sleep apnea, narcolepsy, frequently interrupted sleep, sleep drunkenness), circadian rhythm disorders (phase advance and phase delay syndromes, or a consequence of shift work), certain medical conditions, and the effect of sedating medications. It should be distinguished from fatigue, which often is experienced as a tiredness and a desire to sleep but does not usually lead to sleep. The typical patient with insomnia, for example, complains about fatigue but has difficulty initiating and maintaining sleep. In contrast, the patient with true excessive daytime sleepiness readily and unwillingly falls asleep quickly at inopportune times and places, such as when driving, working, or meeting with friends. Persistent pathological sleepiness is clinically serious and may be associated with significant morbidity and mortality, including poor work performance, accidents, poor judgment, and medico-legal problems for clinicians, patients, and employers who fail to deal with these difficulties appropriately.

Daytime sleepiness can be assessed by either subjective or objective criteria. During the routine review of symptoms, clinicians should inquire about pathological daytime sleepiness, both from the patient and others who have had an opportunity to observe the patient's levels of alertness and sleepiness. For a more detailed evaluation across the day, clinicians can give the patient the Stanford Sleepiness Scale, a seven-point subjective scale ranging from 1 (maximum alertness) to 7 (fighting to stay awake); it can be filled out by the patient, for example, each hour during the day to estimate subjective sleepiness and alertness. Alternatively, for an estimate of average sleep propensity, the Epworth Sleepiness Scale is frequently used.

Of the objective laboratory-based methods for measuring daytime sleepiness, the Multiple Sleep Latency Test (MSLT) is the best known. Mean MSLT is about 11 to 15 minutes for most healthy adults and about 2 to 4 minutes in patients with sleep apnea or narcolepsy. A second objective method for assessing alertness is the Maintenance of Wakefulness Test (MWT), in which the subject is asked to maintain wakefulness during 4 or 5 periods while lying in bed in the dark. Again, the latency to sleep is measured. Normal subjects can usually maintain wakefulness for about 18 minutes before falling asleep. Based on the findings that power in the theta and alpha range of the waking EEG increases progressively during sustained wakefulness, this measure has been proposed as an objective estimate of sleepiness. However, the clinical merit of theta and alpha power assessment needs to be evaluated further.

Circadian and Homeostatic Processes The daily sleep-wake cycle is an example of a *circadian rhythm* (from the Latin *circa*, meaning “about,” and *dies*, meaning “day”). Circadian rhythms are endogenously regulated by a biological clock located in the suprachiasmatic nuclei of the anterior hypothalamus, which in turn is synchronized with the environment by visual or other, nonphotic time clues (*Zeitgebers*, meaning “time givers”). For example, if humans and animals are kept in an environment devoid of time clues, the period length of the sleep-wake cycle and other biological rhythms, such as core body temperature or cortisol, increases from about 24 hours to about 24.2 hours; this condition is called free-running. If, however, a 24-hour light-dark cycle of sufficient amplitude is imposed on this environment, subjects revert to a 24-hour sleep-wake cycle, that is, the subjects and their rhythms are entrained to the 24-hour day.

Sleep and wakefulness are strongly influenced by two separate processes: (1) an endogenous biological clock, which drives the circadian rhythm of the propensity for sleep and the characteristics of sleep across the 24-hour day; and (2) a homeostatic process that increases sleep propensity the longer the period of wakefulness prior to sleep. There is evidence that the duration of wakefulness prior to sleep onset is directly related to the amount of delta activity during NREM sleep, and that this homeostatic process during wakefulness increases in a monotonic function and decays in a negative exponential function when sleep is initiated. It is postulated that the amount of delta activity during NREM sleep is a measure of the sleep pressure accumulated during prior wakefulness, and this dissipates during sleep. The interaction between the circadian process C and the homeostatic process S have been formalized by Alexander Borbely and colleagues in the *two-process-model* of sleep regulation. Because these two processes constantly interact, it is difficult to study the contribution of each of these factors to sleep separately. An elegant method to disentangle the influence of process C and S is the *forced desynchrony* protocol. Thus, if subjects are subjected to a 28-hour light-dark cycle, the sleep-wake period is too long to synchronize with the internal clock, which has a cycle length of about 24.2 hours. This experimental situation leads to a desynchronization of circadian and homeostatic factors, and permits the study of sleep and wakefulness at different circadian phases. Such studies have supported the hypothesis that slow-wave activity is mainly driven through homeostatic processes whereas REM sleep as well as sleep spindles are driven by the circadian system. Humans appear to have two peaks of daytime sleepiness. The first, and obvious one, is at night in the normally entrained individual; the second is in midafternoon (“siesta hour”). Not surprisingly, automobile accidents, in which the driver falls asleep at the wheel, peak during the last half of the night and in the midafternoon. If the circadian temperature curve is used to index the phase position of the circadian pacemaker, it is seen that the major period of sleepiness occurs near the nadir of temperature, that is, at about 3 to 5 AM in normal circumstances. Both the duration of sleep and the type of sleep are strongly influenced by the phase position of sleep onset. People tend to awaken on the rising limb of the temperature curve; thus, sleep tends to be longest when it starts near the peak of the temperature curve. Furthermore, REM sleep is most likely to occur near the temperature nadir; thus, REM latency is shorter and REM time higher during morning naps compared with afternoon or evening naps.

The 24-hour sleep-wake rhythm is driven by the suprachiasmatic nuclei synchronized to the environmental light-dark cycle by Zeitgebers. Lesions of the

suprachiasmatic nuclei in animals result in arrhythmic rest-activity patterns, which no longer follow a circadian rhythm but are distributed in numerous short bouts of sleep and wakefulness during the 24-hour period. Despite the dramatic alteration of the temporal organization of sleep and wakefulness, the total amount of sleep and wakefulness in 24 hours remains fairly constant in the suprachiasmatic nuclei-lesioned animal. Indeed, a suprachiasmatic nuclei-lesioned animal deprived of sleep shows the normal compensatory increase in sleep during the recovery period, thereby demonstrating that the homeostatic and circadian processes can be separated. Although the major circadian pacemaker in mammals is the suprachiasmatic nuclei, a second circadian clock may be located in the retina. Cultured retina cells from wild-type golden hamsters exhibit a circadian 24-hour rhythm of melatonin synthesis, and the rhythm of melatonin production by retina cells of *tau*-mutant hamsters, which have a 20-hour rhythm, has a period of 20 hours. This suggests that the period of the circadian pacemakers is genetically determined.

A number of sleep disorders specifically involve disturbances of the circadian sleep-wake system: jet lag, shift-work schedules, phase-advanced sleep (in which the patient is an extreme lark), phase-delayed sleep (in which the patient appears to be an extreme night owl), and non–24-hour syndrome (in which the patient appears to free-run, with a period length of about 25 hours between each sleep onset). A subjective scale for estimating morningness and eveningness is available for clinical and research purposes.

Because the endogenous period in humans is slightly longer than 24 hours, it is easier to shift sleep-wake rhythms to later rather than earlier. For example, most individuals cope with jet lag more easily when traveling west than when traveling east. It usually takes about one day to accommodate for each time zone traveled when moving in an easterly direction, somewhat faster in a westerly direction. In addition, shift workers seem to feel better and perform better when going from a day to an evening to a night shift *(forward shifting)* than from a day to a night to an evening shift *(backward shifting)*. Appropriate administration of bright light and darkness may ameliorate jet lag and shift-work problems by hastening the resynchronization of the endogenous clock modulating sleep-wakefulness, and controlling temperature and other psychobiological rhythms. For example, exposure to bright light in the evening and darkness in the morning may help with jet lag when traveling westward or shifting from an evening to a night schedule of work. In addition, the administration of exogenous melatonin may shift the phase position of the clock and offers hope for treating jet lag, shift work, and other circadian sleep-wake disorders in which rapid resynchronization of the internal clock with the sleep-wake cycle is required. At this time, however, neither the efficacy nor the safety of melatonin administration for more than very short-term use has been demonstrated.

Free-running in the natural environment has been implicated in two clinical sleep disorders. First, in certain blind persons the circadian system free-runs even though the individual tries to remain on a synchronized sleep-wake pattern. The drifting phase position of the circadian system is shown by the free-running pattern of melatonin secretion (i.e., the onset of melatonin appears approximately 45 minutes later each subjective day). As would be expected, these patients have a cyclic pattern of sleep disturbance with a period of about 3 to 4 weeks as the circadian system goes in and out of synchronization with the environment. Second, patients with the non–24 hour-day syndrome typically go to bed and arise about 30 to 45 minutes later each day (i.e., they are free-running with a sleep-wake cycle length of about 24.5 to 24.75 hours even though they live in the natural environment).

The flexibility of the circadian system appears to diminish with age in most persons. Thus, the elderly usually suffer more from jet lag and shift-work schedules than do the young. In addition, the endogenous circadian pacemaker tends to be phase advanced and of lower amplitude in the elderly compared with the young. For example, teenagers typically like to go to bed around 2 AM and may sleep solidly until noon whereas grandparents retire by 9 PM, arise around 6 AM after a night of shallow sleep, and nap in the midafternoon.

The cellular mechanisms eventually yielding clockwise oscillations in the suprachiasmatic nuclei are currently under intensive investigation. Modern molecular genetic techniques identified genetic loci that modulate the internal pacemaker. In the fruit fly *(Drosophila)*, the genes *period (per)* and *timeless (tim)*, appear to be critical for circadian rhythm generation. The interaction of their products PER and TIM appears to be essential for a 24 hours cycle. Perhaps coupled together, TIM and PER in the cytoplasma are involved in an negative autoregulatory feedback loop with their own genes. High levels turn the genes off; with low levels messenger ribonucleic acid (mRNA) is produced again. In the morning, *tim* and *per* are turned on and mRNA is produced. In the evening, on the other hand, high levels of TIM and PER shut off *tim* and *per*. This autoregulatory feedback loop is an important part of the circadian machinery, and lends new and exciting insight into the way light may reset the clock. For instance, TIM is degraded by light: if light exposure occurs during the early part of the night (i.e., during the production phase of TIM and PER), the level of these proteins is decreased and the phase of the cycle is delayed. On the other hand, if light exposure occurs later in the night (i.e., when TIM and PER levels are falling), these natural processes are accelerated and the clock is advance phased. These interactions are pertinent if one considers that light is the major external clue for resetting the clock, mediated through the *circadian visual system* involving projections from the retina to the suprachiasmatic nuclei via the retinohypothalamic tract, and indirectly to the intergeniculate leaflet and via the geniculohypothalamic tract to the suprachiasmatic nuclei. In mammals, mutant mice are important tools to study the internal clockwork; the golden hamster has a single-gene *(tau)* mutation leading to a reduced period (t) of 20 hours. Other genes that affect period are *clock* and *wheels*, which are located on chromosome 5 and 4, respectively.

PHYLOGENY AND ONTOGENY OF SLEEP

Phylogeny Nearly all animals, even single-cell organisms and plants, have a rest-activity cycle, but circadian timing, amount, and type of sleep varies dramatically between species. A few species, such as the sloth, sleep as much as 20 hours per day; others, such as the shrew, may not sleep at all. Some animals, including humans, are diurnal and sleep predominantly at night. Other animals, such as the laboratory rat, are nocturnal and sleep predominantly in the light. Still other species, such as the cat, are crepuscular and are active predominantly at dawn and dusk.

Among the higher animals, slow-wave sleep is present in birds, mammals, and some reptiles, suggesting an obligatory role for this sleep state. REM sleep occurs in all marsupials and birds as well as in some placental mammals and reptiles, but it may be absent in the monotreme echidna, a primitive egg-laying mammal. Thus, NREM sleep may have evolved earlier than REM sleep, the former in association with homeothermy, the latter with viviparity (live bearing). Recent data, however, indicating the occurrence of REM sleep also in the monotreme platypus suggests that REM sleep was present also in the earliest mammals.

Sleep patterns have evolved as surviving species adapted to their environments. For instance, predators that have secure environments (such as lions) sleep more deeply than do prey that sleep in insecure environments (such as rabbits). Marine mammals, which must breathe as they spend their lives in the water, have evolved interesting ways of sleeping. The blind Incus dolphin, which lives in turbid water, has to maintain almost continual activity; therefore, it apparently sleeps in numerous short periods, each averaging about 90 seconds. Some other dolphin species exhibit unihemispheric sleep: while one hemisphere has slow-wave sleep, the other is awake with low-voltage and fast-frequency EEG waves. If one hemisphere is experimentally deprived of NREM sleep, it shows the expected increases in total sleep and delta sleep, which accompany recovery from sleep deprivation of the whole brain. Similarly, some species of seals have also evolved hemispheric sleep so that one side of the body maneuvers the head near the water surface in order to permit the animal to breathe occasionally as the other half of the brain sleeps. Further understanding of the anatomy and chemistry of these and other species will provide insight into the mechanisms and functions of sleep.

Ontogeny Sleep-wake states change dramatically across the lifespan, not only in the amount of sleep but in its ultradian and circadian timing. The full-term newborn human infant may average about 16 hours of sleep per day, of which about 50 percent is REM sleep. The duration of the REM sleep cycle of the infant is relatively short compared with that of the adult, and the sleep-wakefulness cycle is polyphasic, with numerous short bouts of sleep and wakefulness over the 24-hour period. During the first months of life, sleep-wake cycles gradually change as sleep at night and wakefulness by day become consolidated, although napping may continue into childhood. By age 3 or 4, the percentage of REM sleep falls to adult levels of about 20 to 25 percent and remains in this range for the rest of the individual's life. Nevertheless, REM latency tends to decrease and length of the first REM period tends to increase in later life as stages 3 and 4 sleep decline.

The amount of time spent in delta sleep (stages 3 and 4) each night peaks in early adolescence and gradually falls with age until it nearly disappears at about the age of 60. Young adults typically spend about 15 to 20 percent of total sleep time in delta sleep. By the age of 60 or 70, few individuals have any delta-wave activity during sleep. Interestingly, men tend to lose delta sleep at an earlier age than women. The loss of delta sleep results more from a reduction in amplitude than from fewer slow (0.5-2 Hz) waves. Some researchers have speculated that this might indicate accelerated aging in men.

Sleep in the Elderly After the age of 65, about one third of women and one fifth of men report that they take over 30 minutes to fall asleep. Wake time after sleep onset (WASO) tends to increase with age, perhaps because of the greater incidence of sleep-related breathing disorders (i.e., mild apnea) and nocturnal myoclonus. Using the Apnea Index of £5 apneic episodes per hour as a cut-off criterion, prevalence rates range from 27 to 75 percent for older men and from 0 to 32 percent for older women. In general, the severity of apnea in these older persons is mild compared with that seen in patients with clinical sleep apnea. Periodic limb movements during sleep are also common in the elderly, with prevalence rates ranging from 25 to 60 percent in various studies of the healthy elderly. Individuals with periodic limb movements are reported to sleep about an hour less per night than controls without periodic limb movements. Perhaps as a result, napping also increases with age, although it rarely accounts for a large proportion of total sleep time in healthy individuals.

Average daily total sleep time actually increases slightly after the age of about 65. Greater numbers of elderly individuals fall into either long-sleeping (>9 hours) or short-sleeping (<5 hours) subgroups. It is noteworthy that death rates are higher in both long-sleeping and excessively short-sleeping individuals. The reasons for that are still unknown, although there has been speculation that sleep apnea might contribute to increased mortality in the long-sleeping group.

Although the incidence of insomnia and certain other sleep-wake disorders tends to increase with age, clinicians should not assume that age explains these common complaints. Rather, the clinician must search for underlying conditions that can be treated, such as medical, neurological, psychiatric, situational, pharmacological, or circadian factors.

NEUROBIOLOGICAL BASIS OF SLEEP

Neuroanatomy of Sleep-Wakefulness The neuroanatomy and neurophysiology of sleep and wakefulness remain incompletely understood. Behavioral and cortical EEG activation depend upon the reticular activating system, arising within the brainstem, and more rostral thalamic, hypothalamic, limbic, and cortical systems. Moreover, the isolated brainstem itself can generate components of REM sleep. NREM sleep, on the other hand, is controlled by widespread anatomic areas. In any case, no specific neuroanatomical sleep center has yet been identified with certainty for the entire constellation of REM or NREM sleep.

Reticular Activating System Components of the ascending reticular activating system (ARAS) are critically important for the generation and maintenance of waking states or arousal (Fig. 1.19-2). They reside in the oral pontine and mesencephalic tegmentum, including both noradrenergic cell bodies, such as the locus ceruleus, and cholinergic cell bodies, such as the pedunculopontine tegmental and lateral dorsal tegmental nuclei. The locus ceruleus neurons project rostrally through the mesencephalic tegmentum directly and diffusely to cortical areas and subcortical way stations; in addition, noradrenergic neurons project caudally into the brainstem and spinal cord. The pedunculopontine tegmental and lateral dorsal tegmental form the largest collection of cholinergic cells in the pontine tegmentum. They innervate the thalamus, hippocampus, hypothalamus, and cingulate cortex. In addition, histaminergic neurons in posterior hypothalamus project to the cortex and maintain arousal. Glutaminergic neurons in subcortical and cortical structures may also play an important role in wakefulness and arousal.

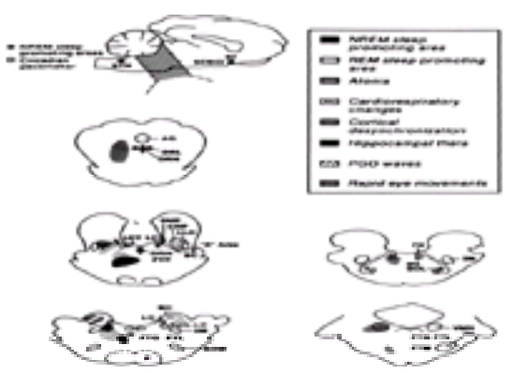

FIGURE 1.19-2 Localization of NREM and REM sleep promoting areas in the brain.

Anatomical Control of REM Sleep At least five anatomical sites have been implicated in the generation of NREM sleep: the basal forebrain area, thalamus, hypothalamus, dorsal raphe nucleus, and nucleus tractus solitarius of the medulla. For example, lesions of the preoptic basal forebrain area produce hyposomnia lasting 4 to 6 weeks in rats and cats whereas electrical stimulation and local warming of this region elicits both EEG and behavioral signs of sleep. In addition, some noncholinergic neurons in the basal forebrain discharge selectively during NREM sleep. The thalamus in general and the reticular nucleus of the thalamus in particular appear to play an important role in the generation of cortical sleep spindles (12 to 14 Hz) and delta waves (0.5-3 Hz, 75 μV or greater in humans) during NREM sleep. Recently Mircea Steriade and colleagues hypothesized that thalamocortical cells are hyperpolarized by corticothalamic cells and are depolarized by cholinergic input from basal forebrain and the lateral dorsal tegmental and pedunculopontine tegmental, as well as through noradrenergic, serotonergic, and excitatory amino-acid input. The thalamocortical cells, which drive and synchronize the ensembles of cortical cells to produce the major EEG rhythms, change their rhythms from spindle frequencies to delta frequencies as they hyperpolarize. This theory also explains the fact that immediately prior to and during REM sleep, when cholinergic activity in the lateral dorsal tegmental and pedunculopontine tegmental is high, the EEG becomes gradually desynchronized. While histaminergic cells in posterior hypothalamus maintain arousal, ventrolateral preoptic neurons in the anterior hypothalamus may be involved in the induction of slow-wave sleep. The dorsal tegmental, the origin of the serotonergic projections of the brain, may be involved in the induction of sleep, at least insofar as either selective lesions or depletion of serotonin induce a dramatic insomnia lasting several days. Finally, the nucleus tractus solitarius was implicated by experiments in which medullary anesthesia or cooling of the fourth ventricular floor caused EEG activation. Low-frequency stimulation of this region produced EEG synchronization and behavioral sleep while cells in this region increase their discharge rate during NREM sleep. These regions all appear to facilitate sleep; however, none have been found to be essential.

In terms of pathophysiological concepts of mood disorders and the proposed mechanisms of action of antidepressant treatment it is pertinent to emphasize the role of serotonin on sleep regulation. Monosynaptic projections from the dorsal raphe nucleus to the cholinergic-cholinoceptive lateral dorsal tegmental and pendunculopontine tegmental produce a hyperpolarization of these so-called REM-on cells through serotonin (5-hydroxytryptamine [5-HT]) subtype 1A (5-HT $_{1A}$) receptors and finally inhibit REM sleep. On the other hand, activation of the self-inhibitory 5-HT $_{1A}$ autoreceptors in the dorsal raphe nucleus lead to a disinhibition of REM sleep. While the 5-HT$_{1A}$ agonist ipsapirone inhibits REM sleep and enhances NREM sleep EEG power in the lower frequencies, pindolol (Visken), a b-adrenergic receptor antagonist with 5-HT$_{1A}$ antagonistic properties produces a reduction of both REM sleep and of EEG power in the lower EEG frequencies. In combination these findings suggest that pindolol preferentially blocks 5-HT $_{1A}$ presynaptic, rather than 5-HT$_{1A}$ postsynaptic receptors, which is particularly pertinent for the proposed mechanism of action of how pindolol augmentation of a selective serotonin reuptake inhibitor (SSRI) might work.

Neurological lesions associated with pathological somnolence, stupor, or coma have been noted in midbrain and diencephalon, the oral pontine and midbrain tegmentum, and the posterior hypothalamus and subthalamus. A recently described syndrome of “fatal insomnia” is associated with degeneration of the thalamus, although it is doubtful that the insomnia resulted directly from degeneration of the thalamus. Data in the prion knock-out mice suggest that the sleep abnormalities in fatal familial insomnia are related to the function of this membrane surface protein. Genetic factors also account for narcolepsy; there is evidence of an involvement of human lymphocyte antigen (HLA) DQA1*0102 and DQB1*0602 in narcolepsy as candidate susceptibility genes in the HLA class II region. Much effort has been made to identify endogenously produced “sleep substances” that induce or promote sleep. Generally, brain extracts from sleep-deprived animals have been screened for such substances. Although none of the candidates have satisfied the criteria required for such a factor, a recently described membrane lipid (cerebrodiene) that accumulates during wakefulness may be involved in the induction and maintenance of sleep. Another interesting somnogenic candidate is adenosine, which may increase in brain tissue with increasing duration of wakefulness; infusion of adenosine into basal forebrain promotes delta sleep.

Anatomic Sites for Control of REM Sleep Transection and lesion studies suggest that the midpons is necessary for REM sleep. Transection at the midpontine level produces a preparation with local signs of REM sleep (rapid eye movements, muscle atonia) caudal to the transection, whereas transection at the pontomedullary junction produces a preparation that does not show REM sleep signs in the medulla, but does show signs in the forebrain. Electrolytic and kainic acid lesions of the oral and caudal pontine tegmentum, including the lateral dorsal tegmental and pendunculopontine tegmental, eliminate or markedly reduce the amount of REM sleep. After suffering a shrapnel wound with a sliver lodging in the pontine mesencephalic region, a soldier apparently ceased to have REM sleep. Despite the documented loss of REM sleep over a period of several years, the individual has no specific problems related to the loss of REM sleep.

As proposed in the reciprocal interaction model of REM sleep, cholinergic REM-on neurons in lateral dorsal tegmental and pendunculopontine tegmental orchestrate the various events of REM sleep. They are inhibited by REM-off neurons within locus ceruleus and DRN. The REM-off cells decrease their discharge activity preceding a REM sleep episode and are at a very low level of activity or are silent during REM sleep, thus disinhibiting the spontaneously active cholinergic neurons in lateral dorsal tegmental and pendunculopontine tegmental. Serotonergic terminals, acting on 5-HT $_{1A}$ receptors on cholinergic cells, apparently hyperpolarize cholinergic burst cells, which may be responsible for pontine-geniculate-occipital spikes, large monophasic electrical waves appearing just before and during REM sleep in cats and, presumably, in many other species. Those data are consistent with the hypothesis that serotonergic neurons within DRN inhibit pontine-geniculate-occipital spikes. For example, they cease firing just before the appearance of pontine-geniculate-occipital spikes. Noradrenergic neurons within locus ceruleus may also inhibit REM sleep: not only are there REM-off cells within locus, but administration of metyrosine (Demser), an inhibitor of tyrosine

hydroxylase, the rate-limiting enzymatic step in the synthesis of catecholamines, shortens REM latency and increases REM sleep time in humans and animals. Consistently, in 1988 it has been shown that a depleting serotonin from the brain by using the rapid tryptophan depletion challenge (i.e., a short-term) diet with high loading of amino acids, but without the essential amino acid tryptophan) leads to a disinhibition of REM sleep. This finding might be particularly pertinent for the association of depression with short REM latency and increased REM sleep.

Muscle Atonia of REM Sleep The muscle atonia of REM sleep is abolished by bilateral lesions of the pontine reticular region, just lateral to the locus ceruleus (peri-locus ceruleus a-region), and its descending pathway to the bulbar reticular formation. Animals can ambulate during REM sleep and may show oneiric behavior, including locomotion, attack, and flywatching, as if the animal were acting out a dream. Thus, the muscle atonia of REM sleep is apparently mediated through nonmonoaminergic neurons of the peri-locus ceruleus a-region, which project via tegmentoreticular tract projections to the bulbar magnocellular field and excite neurons in the reticular zone. This area in turn, via projections in the ventrolateral reticulospinal tract, may induce muscle atonia by hyperpolarizing spinal motoneurons. Those mechanisms for atonia may be clinically relevant to two conditions characterized by abnormalities of muscle atonia: (1) *narcolepsy*, in which patients experience sudden brief episodes of *cataplexy*, or loss of muscle tone while awake; and (2) *REM sleep behavior disorder*, in which human subjects maintain muscle tone during REM sleep and may act out their dreams.

Biochemistry of Sleep and Wakefulness The biochemistry of sleep also remains incompletely understood, although dramatic progress has been made in recent years (Table 1.19-3).

Substance	Possible Roles in Regulation of Sleep-Wakefulness
Serotonin	L-tryptophan has hypnotic effects, increases delta sleep. Serotonergic neurons in DRN cease firing in REM sleep and may inhibit cholinergic neurons in LDT-PPT. PGO waves, and REM sleep
Norepinephrine	Noradrenergic neurons in LC cease firing in REM sleep and may inhibit REM sleep. Arousal
Acetylcholine	Cholinergic neurons in dorsal tegmentum orchestrate REM sleep, and together with basal forebrain inhibit cortical EEG synchronization through influence on thalamus
Dopamine	Mediates alerting effects of amphetamine and cocaine and sedating effects of antipsychotics. Sleepiness of narcolepsy may be related to decreased dopamine turnover
γ-aminobutyric acid (GABA)	Hypnotic and other effects of benzodiazepines may be mediated through enhancement of GABA
Adenosine	Appears to promote sleep. Alerting effects of caffeine may be mediated by blockade of adenosine receptors
Interleukins and other immune modulators	Interleukin promote slow-wave sleep in animals, and immune modulators may be increased in plasma at sleep onset in normal controls. NREM sleep measures may correlate with natural killer cell activity in humans
Prostaglandins	PGD_2 and PGE_2 increase sleep and wakefulness, respectively, in animals
Endogenous sleep factors	Putative hypnotoxins include delta-sleep-inducing substances—peptide (DSIP), uridine, arginine vasotocin, muramyl peptides, and others

Table 1.19-3 Neurotransmitters and Neuromodulators That May Regulate Sleep-Wake States

Cortical and behavioral arousal mechanisms involve dopaminergic, noradrenergic, histaminergic, glutaminergic, and cholinergic neurons. Data implicating the latter systems have been briefly mentioned already. In addition, antihistamines and b-adrenergic receptor antagonists, and, to some extent, anticholinergic agents have sedative effects. Neurotransmitter regulation of NREM sleep and REM sleep is complex.

Consistent with the concept that cholinergic neurons mediate cortical arousal and REM sleep, administration of carbachol, neostigmine, and other cholinergic agonists within the medial pontine reticular formation induce REM sleep in cats. Recently, a “hot spot” within the peribrachial region of the cat has been described where a single injection of a cholinergic agonist will, after the delay of a day, significantly increase pontine-geniculate-occipital activity and REM sleep for over 10 days.

Although there is a large database on how aminergic projections from the DRN and the locus ceruleus turn off REM sleep by hyperpolarization of cholinergic REM-on cells, how the REM-off neurons are inhibited is just beginning to be understood. It appears, that GABAergic, glycinergic, and nicotinic neurons and receptors within these monoaminergic nuclei play an important role.

It is of particular interest to mental health professionals that REM sleep can be promoted in humans by cholinergic agonists, such as physostigmine, arecoline, pilocarpine, and RS 86 (an experimental muscarinic agonist). Physostigmine-induced REM periods appear to be completely normal in their EEG, EOG, and EMG patterns, and, moreover, are associated with dreams that appear to be indistinguishable from those collected by arousing subjects from spontaneous REM periods. Furthermore, cholinergic agonists appear to substantially affect NREM sleep, even causing a decrease in EEG power in the delta frequencies.

How is it that a few molecules of a cholinergic agonist can induce or release the fascinating process we know of as dreaming? If these turn on the stage lights of the theater of the mind, who or what determines which play will be enacted? It is possible that neuroimaging studies during sleep and, particularly during REM sleep, might reveal new insights into the neuronal basis of dreaming. Based on emission tomography (PET) studies it has been suggested that the amygdala cingulate gyrus and other areas associated with emotions are activated during REM sleep.

Brain Metabolism Consistent with the popular hypothesis that sleep is a time of rest and restoration, whole body and brain metabolic rates decrease during NREM sleep compared with wakeful states and during REM sleep. However, metabolic rate is about the same or slightly increased during REM sleep as compared with wakefulness. Local cerebral metabolism has been studied in humans utilizing the ^{18}F-fluoro-deoxyglucose method with PET or by measuring cerebral blood flow. No specific sleep center has yet been identified by those techniques.

The relationships between environmental and core body temperature, metabolism, and sleep have been investigated. Some investigators hypothesize that sleep and wakefulness have homeostatic effects on body and brain temperature. For example, it is known that the onset of NREM sleep tends to depress metabolic rate in both the brain and the body, which may explain why delta sleep is increased after subjects are warmed in a hot tub or sleep in a moderately warm environment. Increased wakefulness in relatively cold environments may be explained by the body's efforts to warm itself. That the nocturnal core body temperature of depressed patients drops below that of normal controls is a related finding.

Neuroendocrinology and Neuroimmunology Some hormones and immune modulators are affected by the sleep-wake cycle in that the time course of their plasma levels may be either circadian or sleep related. For example, plasma thyroid-stimulating hormone (TSH) rises during the evening hours and is inhibited by sleep onset. Growth hormone, on the other hand, is stimulated by sleep onset, particularly in association with delta sleep, whereas prolactin levels are increased throughout most of the sleep period. In adolescents, luteinizing hormone is also increased during sleep. While cortisol secretion increases towards the end of the sleep period, this increase is primarily driven by an endogenous circadian rhythm whether or not sleep occurs. In contrast, sleep onset actually reduces secretion of adrenocorticotropic hormone (ACTH) and cortisol. Melatonin is released at night in the dark in entrained subjects, but its release also occurs independently of sleep and wakefulness. In depression, the composition of hormonal secretion during nocturnal sleep appears to be altered, including an increased level of cortisol and a blunted sleep–onset-associated peak of growth hormone and prolactin concentrations.

In keeping with traditional advice to “get a lot of sleep when you are sick,” sleep and the immune system apparently have positive effects on each other. Certain immune modulators such as interleukins and tumor necrosis factor may promote sleep. Sleep deprivation may depress immune measures in man and animals. The interrelationships between the brain and the immune system are exciting areas of research; particularly interesting is the finding that sleep architecture and continuity changes are possibly among the first biological signs to change after seroconversion in human immunodeficiency virus (HIV)-infected subjects.

DREAMING AND OTHER PSYCHOLOGICAL EXPERIENCES DURING SLEEP

Dreams are reported about 70 to 80 percent of the time when subjects are awakened from REM sleep. Nevertheless, dreaming is not confined to REM sleep only; it is reported during awakenings from NREM sleep about 10 to 20 percent of the time, and is reported especially frequently after a few minutes of stage 1 sleep at sleep onset. Some type of mental activity appears to occur much of the time throughout sleep. Indeed, it may be the inability to “turn off the mind” during sleep that leaves many ruminative insomniac patients feeling as if they never slept at all.

By most definitions, dreams involve a visual experience with a plot that evolves over time. Dreams are experienced, if not always remembered, in full color and appear to take place in real time. Nevertheless, about one third of dreams often involve rapid shifts in time and place from one scene to the next; about 30 percent of dreams entail normally impossible acts such as flying or talking with animals. Despite the often bizarre experiences of dreaming, most dreamers seem to accept these

experiences uncritically as real. Some persons, however, so-called “lucid dreamers” are consciously aware that they are dreaming and can change the “script” of their dream as it takes place.

Although averaging about 10 hours of REM sleep a week, most people spontaneously remember only about one or two dreams during that time, and the variation in dream recall between people is impressive. Many people say they rarely if ever dream; others say they dream nearly every night. Why such variation exists is not known. Dream recall does not appear to be related to the amount of REM sleep, but may be correlated with the number or duration of waking episodes during the night. The memory for dreams is evidently increased if subjects are awakened directly from REM sleep and have an opportunity to think consciously about their dreams. The memory for dreams is strangely fleeting: nearly everyone has had the experience of awakening from a dream, thinking about it, and then later failing to recall the content despite remembering having had a dream. While it is plausible to invoke psychological defenses—repression, suppression, and denial—for forgetting dreams, such explanations seem forced for dreams that are inherently interesting, bizarre, exciting, or psychologically benign.

The classic nightmare occurs during REM sleep, but frightening experiences may also arise out of NREM sleep. The night terror or incubus, for example, typically occurs during delta sleep in the first or second NREM period. This disorder is characterized by a sudden attack of fear, screaming, shortness of breath, and tachycardia; it may last for several minutes and may be unresponsive to attempts to console the victim. In contrast to a nightmare, the patient rarely recalls specific content or visual images when awakened from a night terror and often has total amnesia for the entire episode the next day.

Nearly half of all patients with panic disorder experience classic panic attacks during sleep, typically in NREM sleep during transitions between stages 2 and 3. While patients with posttraumatic stress disorder often experience terrifying nightmares and flashbacks, some of these events apparently occur during NREM sleep and are not typical REM sleep nightmares. This may explain why monoamine oxidase inhibitors, which can totally eliminate REM sleep, have had only modest success in treating these patients.

Interesting new approaches, based on functional brain imaging, the emerging neurophysiology of sleep, and cognitive neuroscience are now available to study the phenomenology and neuroscientific basis of dreaming. Functional imaging is certainly an approach that has the potential to provide more insight into brain areas activated during sleep, and in particular, during dreaming and REM sleep. So far, PET studies have yielded the most precise neuroanatomical information. Future research will certainly profit from the improved temporal and spatial resolution of functional magnetic resonance imaging (fMRI) techniques. Unfortunately, it has not been possible yet to coregister EEG and fMRI because of mutual interference.

SLEEP DEPRIVATION

Historical evidence suggests that the general population of the United States sleeps less now than it did at the beginning of this century. With the invention of the electric light bulb and central heating, the move from rural to suburban and urban life styles, and the growth of international commerce and communication, periods of work and play have expanded to fill the last temporal frontier, nighttime. Does this mean that the general population, or at least large segments of it, is chronically sleep deprived? There is no doubt that many individuals are pathologically sleepy, either acutely or chronically because of partial sleep deprivation or because of clinical disorders. Excessive sleepiness is an important public health issue because it is responsible for many car and occupational accidents, and impaired performance, for example, by sleep-deprived physicians. Although the subjective report of insomnia should not be equated with objective sleep loss, prospective epidemiological studies have shown that persistent complaints of insomnia predict the later onset of depressive disorders.

Partial and selective deprivation of sleep and its different stages has been used to investigate the functions of sleep. Unfortunately, this strategy has not forced sleep to reveal all its secrets. For example, volunteers have been kept awake for as long as 12 days. As one might expect, total or partial sleep deprivation makes one very sleepy, but it has not provoked either insanity or physical illness. The major effects were found to be psychobiological, primarily reduced alertness, attention, information processing, motivation, and performance, especially for sustained, boring tasks or for highly complex tasks. Many antidepressant drugs and benzodiazepines selectively reduce REM sleep and delta sleep, respectively, but without harmful effects that are directly attributable to the loss of REM or delta sleep.

In humans, interruption of sleep continuity may be more disturbing than loss of total sleep time. Frequent short breaks in sleep, for example, for as short as 15 seconds every 10 minutes, produces significant daytime sleepiness and dysphoria even though total sleep time is preserved. Such interference occurs in patients with bad coughs, painful arthritis, sleep apnea, or nocturnal myoclonus. Since many patients do not remember these frequent short interruptions, it is useful for the clinician to talk with a bedpartner who can comment on sleep continuity.

In keeping with the homeostatic function of sleep, a rebound in total sleep time or specific sleep stages usually follows deprivation of sleep, or of a specific stage of sleep. After total and partial sleep deprivation, recovery sleep is characterized by short sleep latency and increased sleep efficiency, delta sleep, and total sleep time. Objective and subjective measures of daytime sleepiness are also increased. Similarly, following REM sleep deprivation, REM rebound occurs, including shortening of REM latency and increase of REM sleep time for a few nights. In general, however, recovery from sleep deprivation does not require minute-by-minute compensation for lost sleep.

Overnight sleep deprivation depresses cerebral glucose metabolic rates within specific subcortical areas in human brain during wakefulness, particularly the white matter areas of the thalamus and midbrain. This observation suggests that sleep deprivation depresses general arousal systems. However, selected areas of the brain may be spared when they are engaged in specific tasks at the time of the study, for example, visual areas when the subject has to perform a visual continuous performance task. In other words, sleep deprivation apparently reduces the number of parallel processing operations the brain can carry on simultaneously. This model is consistent with the general observation that sleep-deprived subjects can usually perform relatively well on focused tasks for short periods of time if they are motivated sufficiently. Less important activities or competing duties, however, may be neglected.

In contrast to the previously described effects of relatively short-term sleep deprivation in humans, prolonged sleep deprivation in rats results in death, requiring about 3 weeks of total sleep deprivation or about 5 weeks of selective REM deprivation. In these studies experimental animals were awakened whenever they entered sleep or REM sleep respectively, by turning a disc on which they lived; control animals who lived on the other half of the same disc, however, did not die. The cause of death was apparently related to a significant increase in overall metabolism in the face of falling body temperature and increased food intake; the exact mechanisms remain unknown.

Whether the results of those rat studies are applicable to humans is unknown. For instance, a 72-year-old woman who claimed to have slept only an hour a day since her late teens has been studied. Another case was reported of a man who apparently stopped sleeping altogether for months and responded to treatment with serotonin precursors. Subjects with either brainstem lesions or those taking monoamine oxidase inhibitors (MAOIs), and who had no REM sleep over a period of years have also been studied without apparent difficulties related to the loss of REM sleep.

Thus, several questions about sleep remains unanswered: Why do we sleep? What functions does sleep serve? Various theories have stressed the themes of rest, recovery, or restoration, energy conservation and metabolic modulation, ecological and ethological processes that favor the survival of the species, instinctive behaviors, and enhancement of cognition and memory. Nevertheless, scientific support for these theories is still unavailable.

IMPLICATIONS FOR PSYCHIATRIC DISORDERS

Psychiatrists have long had a strong interest in sleep and dreaming, especially in whether sleep disturbances cause mental disorders or vice versa? In the last century, the famous English neurologist Hughlings Jackson said “Find out about dreams and you will find out about psychosis.” Later, Freud made dream interpretation one of the key elements of psychoanalytic theory and practice. Following the discovery of REM sleep in the early 1950s, psychiatrists and sleep researchers studied the sleep patterns of schizophrenic and depressed patients, testing the hypothesis that hallucinations might represent waking dreams or some derangement of REM sleep, and determining whether or not deprivation of REM sleep or sleep in general would be psychologically deleterious or beneficial.

The new neurobiology of sleep has important implications for depression, some types of alcoholism and schizophrenia, eating disorders, borderline personality disorder, and other clinical conditions associated with short REM latency, increased REM sleep, increased REM sleep density, and loss of stages 3 and 4 sleep.

The emerging concepts of sleep neurophysiology are consistent with the cholinergic-aminergic imbalance hypothesis of mood disorders, which proposes that depression is associated with an increased ratio of central cholinergic to aminergic neurotransmission. The characteristic sleep abnormalities of depression may reflect a relative predominance of cholinergic activity, originating within the lateral dorsal tegmental and pendunculopontine tegmental, in relationship to noradrenergic and serotonergic activity, originating within the locus ceruleus, and the DRN, respectively. Cholinergic projections from dorsal tegmentum or basal forebrain to

thalamus may also suppress delta sleep. Consistent with the role of cholinergic mechanisms, depressed patients are significantly more sensitive, compared with normal controls, to the REM-sleep–inducing effects of muscarinic agonists, such as arecoline or RS 86, but (not of pilocarpine, another selective muscarinic agonist). On the other hand, central depletion of either serotonin or catecholamines shortens REM latency and increases REM sleep. Antidepressant medications presumably reduce REM sleep by either their anticholinergic properties or by enhancing aminergic neurotransmission. Intense and prolonged dreams often accompany abrupt withdrawal from antidepressant drugs, a reflection of a REM rebound following drug-induced REM deprivation.

Short REM latency has been found in some patients with schizophrenia, obsessive-compulsive disorder, alcoholism, eating disorders, narcolepsy, and borderline personality disorder. Both short REM latency and decreased delta sleep appear to be state and trait characteristics of depression. Short REM latency may also be a genetic marker for depressive disorders within families, and an indicator of a poor prognosis in recovered depressed and alcoholic patients. For example, among the unaffected relatives of depressed patients with short REM latency, the presence of short REM latency and deficits of slow wave sleep may be risk factors for the later development of a mood disorder. However, although none of the sleep parameters are specific for mood disorders as has been proposed for a long time, it appears that “multivariate” clusters of sleep changes might be more specific for particular disorders.

Although the morbidity associated with sleep deprivation has been emphasized, the paradoxical finding that total sleep deprivation, partial sleep deprivation (especially in the last half of the night), and selective REM sleep deprivation have antidepressant effects in depressed patients and must not be overlooked; unfortunately, the beneficial effect of total and partial sleep deprivation only lasts until the next sleep period, after which the patient typically awakens depressed again. Hence, sleep may be depressogenic in some patients. There is some evidence suggesting that selective REM sleep deprivation repeated over about 2 weeks, or a continued sleep-phase advance protocol after total sleep deprivation, might result in a sustained antidepressant effect. However, so far the latter treatment modes have scientific rather than practical implications because these protocols are extremely costly and time-consuming.

Many of the following observations suggest that some depressed patients are overaroused, at least in some areas of the brain: the antidepressant effects of sleep deprivation, loss of delta sleep and sleep continuity, and increased core body temperature during sleep. Moreover, a preliminary PET study showed that cerebral glucose metabolism during the first NREM period was significantly elevated in depressed patients compared with normal controls and that depressed patients had some of the abnormalities during sleep that had previously been reported in other patients while awake, such as decreased relative metabolic activity in the anterior cingulate and ventral-medial prefrontal cortex. Consistent with the overarousal hypothesis, depressed patients who responded to sleep deprivation showed significantly elevated metabolic rates within the anterior cingulate gyrus before sleep deprivation as compared with nonresponders and normal controls. After clinical improvement, metabolic activity normalized in responders, but did not change in the two other groups.

If the clinical applications of sleep deprivation therapy in depression remain limited, the experimental and theoretical implications of sleep deprivation in depression are fascinating. In what other ways can depression be “turned” off and on so quickly and predictably as sleep deprivation and recovery sleep?

On a more practical clinical level, as understanding of the basic mechanisms of arousal and sedation, increases the clinician will manage better not only symptoms of insomnia and hypersomnia associated with psychiatric illness but iatrogenic sleep problems often associated with medications. For example, many patients complain of insomnia during treatment with SSRIs. Interestingly, depletion of brain serotonin, with the tryptophan free amino acid drink challenge, actually reverses the poor sleep efficiency in euthymic patients treated with SSRIs. These observations suggest that serotonin has an arousing effect under some circumstances. This arousing effect of serotonin may be mediated by the 5-HT_2 receptor, because SSRIs that antagonize this receptor tend to increase sleep efficiency and sleep quality more than SSRIs without this property.

The clinical wisdom of the centuries, linking sleep to psychiatric disorders, has been reinforced by the revelations of modern neurobiology. Sleep remains one of the “royal roads” to understanding psychiatric disorder, and treating the patients who suffer from them.

SUGGESTED CROSS-REFERENCES

Section 1.13 is devoted to the related issue of chronobiology. Chapter 21 discusses sleep disorders. Section 31.33 includes a discussion of sleep deprivation and sleep delay therapies. Section 51.3b focuses on sleep disorders in the elderly.

1.20 APPETITE

NORI GEARY, PH.D., AND GERARD P. SMITH, M.D.

Recent methodological innovations in the behavioral, physiological, biochemical, and genetic sciences have led to fundamental changes in the understanding of the controls of eating. The traditional view, which held that food intake was tightly controlled by hypothalamic neural centers reacting to the state of energy balance, has been replaced by a more complex concept of control by a distributed neural network in the brain that integrates oropharyngeal food stimuli (including those giving rise to hedonic perceptions), gastrointestinal signals, hormonal and metabolic signals, and environmental and experiential contingencies.

An important part of this change in perspective has been to focus on the individual meal as the functional unit of analysis for the investigation of eating rather than on measures of food intake over extended periods (e.g., kcal/day). This change is based on the realization that understanding the controls of individual meals is necessary for understanding disordered as well as normal patterns of eating: abnormally large meal sizes are the crucial behavioral change in binge eating, and abnormally small meals are the crucial behavioral change in restricted eating and anorexia nervosa. Therefore, this chapter reviews the basic science of eating from the perspective of the normal and disordered controls of individual meals.

MEALS

Meal as the Unit of Analysis The meal is the biological and functional unit of eating. It is the biological unit because in the vast majority of animal species and in humans, ingestive behavior is organized as discrete bouts, or meals, separated by intervals of noneating. Furthermore, this basic pattern is maintained despite great variations in food availability, food quality, opportunities or pressures to engage in nonfeeding behaviors, and the presence of physiological challenges, such as infection. The meal is the functional unit of eating because the timing, size, and content of meals provides a complete description of the basic nutritional functions of food, namely what to eat and how much to eat. The same may be said of other functions of food, for example, the psychological function of maximizing the pleasures of eating.

The phases of the meal that require analysis are the initiation of eating, the maintenance of eating during the meal, and the termination of eating (Fig. 1.20-1A). The intermeal interval is bounded by the end of one meal and the beginning of the next. Ingestion of food during the meal stimulates positive feedback signals from the mouth that contribute to the maintenance of eating and negative feedback signals from the mouth, stomach, and small intestine that ultimately terminate eating (Fig. 1.20-1B).

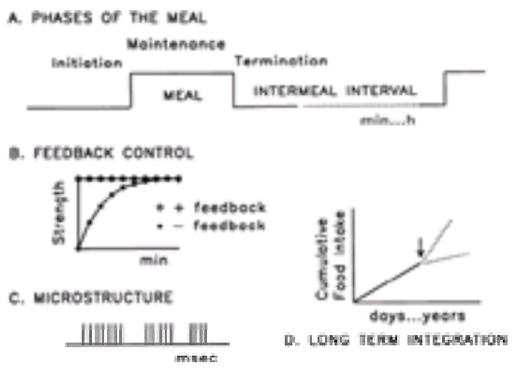

FIGURE 1.20-1 A, The meal is the functional unit of eating. Direct and indirect controls of the initiation, maintenance, and termination of eating determine the size of meals and the duration of intermeal intervals. **B**, Meal size is a function of positive and negative feedbacks elicited by preabsorptive food stimuli arising during meals. Positive feedback, shown in hypothetical units, begins as soon as eating begins and is thought not to decay significantly during the meal. Negative feedback increases in strength gradually as eating continues. When the strength of negative feedback equals that of positive feedback, eating stops and the meal ends. **C**, Microstructural analyses are based on the patterns of the individual movements of eating, for example, the temporal organization of individual licks of liquid foods on an event recorder. **D**, Amount eaten in the long term is simply the sum of the sizes of many individual meals. This schematic demonstrates the typically constant increase in cumulative intake evident on a macroscopic scale (e.g., kcal/d). This rate is increased or decreased if energetic demands are increased or decreased, for example, by changing physical activity, as shown to the right of the arrow.

Microstructure Eating employs a variety of movements. Food is licked, sucked, bitten, or masticated prior to being moved by lingual and palatal movements to the oropharynx and swallowed. These are all largely automatic rhythmic movements organized by central pattern generators in the hindbrain. Therefore, it is not surprising that the hindbrain also contains sufficient neural machinery to initiate and terminate eating movements in response to various afferent stimuli.

The temporal organization of eating movements is the microstructure of eating (Fig. 1.20-1C). The chief advantage of the analysis of microstructure is its potential to track behavior back through the motor neurons producing it. This analysis has produced very promising results in highly restricted experimental situations. It is not yet possible, however, to link individual licks and bites with the controls of meal timing, size, and content.

Meal and the Scale Controls of meals are sometimes considered short-term mechanisms and are supposed to be under fundamentally different constraints than the “long-term” mechanisms presumed to be related to more biological variables. For this reason, long-term studies of eating often do not involve any direct measure of behavior, but rely on indirect measures, such as amounts eaten per day or week. This strategy can provide a net accounting of long-term changes of eating within the larger control system of energy balance (Fig. 1.20-1D), but it has serious disadvantages. Most importantly, the lack of a behavior makes it a dead end for the brain sciences. The brain cannot be understood without an understanding of its behavioral output. In contrast, meal analysis not only provides behaviors to track back into physiology, but also connects to all long-term controls because the amount eaten over any period of time is completely determined by the number and size of meals. Therefore, all influences on eating must affect the timing or size of meals. Thus, the meal is also the appropriate unit of analysis for studying the contribution of eating to the regulation of energy balance.

Subjective Experience of Eating The subjective experiences associated with meals are scientifically accessible in humans, and analysis of them has produced many important insights into normal and disordered eating. This work has been most productive when it has been based on operationally defined categories of subjective experience. Theoretical categorizations of subjective experience, in contrast, have been less useful. For example, the traditional distinction between appetite as an urge to eat elicited by anticipation of the pleasures of eating, and hunger as an urge to eat elicited by the vegetative consequences of nutrient depletion has not been illuminating.

CONTROLS OF MEAL FREQUENCY

Because the frequency of eating is a determinant of intake, it is important to identify the adequate stimuli and mechanisms of the controls of the initiation of eating.

The adequate stimuli are numerous and diverse. They include olfactory, visual, auditory, temporal, circadian, metabolic, cognitive, and social stimuli. Most of these are conditioned on the basis of prior eating experience. Despite conventional wisdom, gastric contractions are not adequate stimuli for meal initiation. Stimuli resulting from inhibition of glucose utilization in the brain or liver and the inhibition of fatty acid oxidation in the liver may be unconditioned stimuli for meal initiation, but they probably do not operate when food is readily available.

A new physiological stimulus for the initiation of eating related to metabolism is a transient decline in plasma glucose that has been recorded prior to spontaneous meals in rats and humans (Fig. 1.20-2). The decline is too small to influence cellular glucose availability; rather, its pattern appears crucial: pharmacologically stimulated declines that are too small or too large do not stimulate feeding. The relative importance of this stimulus in controlling meal initiation under normal environmental conditions remains to be determined. The mechanisms of how these arious stimuli initiate eating are unknown. The lone exception is that hepatic vagal afferents are necessary for the initiation of eating by inhibition of metabolism in the liver.

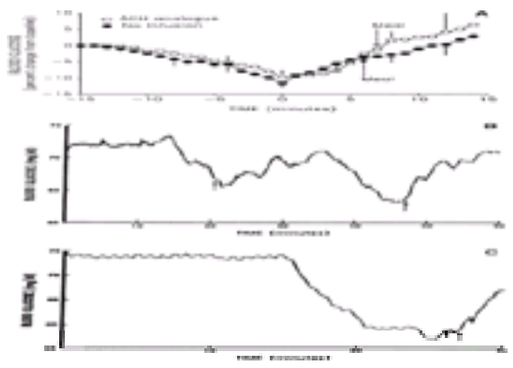

FIGURE 1.20-2 The premeal transient decline in blood glucose in rats and humans. **A**, Filled circles, percent deviations from baseline blood glucose during undisturbed spontaneous feeding in rats. Note that meals begin several minutes after the nadir. Open circles, intravenous infusions of an insulin secretogogue that produced similar declines also elicited meal initiation. (Reprinted with permission from Campfield LA, Smith FJ: Meal initiation occurs after experimental induction of transient declines in blood glucose. Am J Physiol *265:*R1423, 1993.) **B, C**. Blood glucose changes preceding requests for morning meals (arrows) in two normal weight volunteers spending the night in a metabolism laboratory. (Reprinted with permission from Campfield LA, Smith FJ, Rosenbaum M, Hirsch J: Human eating: Evidence for a physiological basis using a modified paradigm. Neurosci Biobehav Rev *20:*133, 1996.)

CONTROLS OF MEAL SIZE

Direct Controls The most experimentally accessible, and consequently the best understood, controls of eating are the direct controls of meal size. These have two defining characteristics. First, these signals originate from the action of ingested food acting on preabsorptive receptors during the meal. The critical receptors are localized in the oropharynx, stomach, and upper small intestine. The preabsorptive location and defined temporal domain of their action make these signals very accessible, and probably also accounts for their prepotency in the physiological control of eating. These receptors transduce food stimuli into changes in peripheral neural activity and changes in local or systemic levels of chemical signals. Information encoded in these ways functions as feedback controls that affect meal size by influencing either the maintenance of eating during the meal or the termination of eating at the end of the meal.

The second defining characteristic of direct controls of meal size is that their afferent signals are initially processed in the hindbrain. Local interneuronal networks in the hindbrain consist of neurons that receive afferent stimuli from the gut, interneurons that integrate these stimuli, and premotor and motor neurons that produce the rhythmic oral movements of eating. These hindbrain networks provide the basic physiological control of eating. Their function has been elegantly demonstrated in decerebrate rats, in which supracollicular transections of the brainstem disconnect the hindbrain from the diencephalon and telencephalon (Fig. 1.20-3). Decerebrate rats do not search for food, but when liquid food is delivered into the mouth, they eat and swallow discrete meals that are terminated by passive rejection of delivered food. Furthermore, meal size is normally responsive to many of the same direct controls of meal size that operate in the intact rat (Fig. 1.20-4).

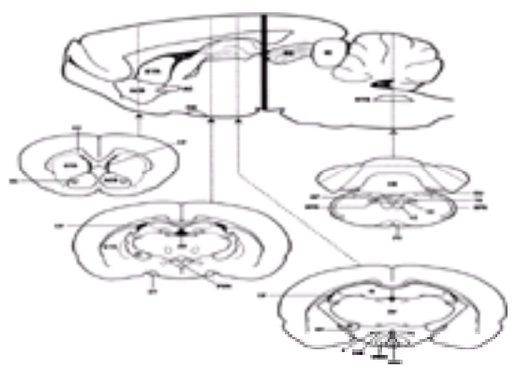

FIGURE 1.20-3 Schematic drawing of sagittal and coronal sections of the rat brain indicating several structures implicated in the central control of eating. The dotted lines indicate the planes of section of the coronal sections. The thick vertical line in the sagittal section indicates the level of the cerebral disconnection used in the studies of the chronic decerebrate rat discussed in the text. FIGURE 1.20-4 Intakes of various concentrations of sucrose by intact and chronic decerebrate (cd) rats. Sucrose was delivered by intraoral catheters until rejected by the animal. Intake is an increasing function of sucrose concentration in cd rats that feed normally (closed condition). The gain of this function is dramatically increased in sham feeding rats in which postingestive controls of meal size are minimized by opening a gastric cannula (opened condition). Note the close correspondence of both the stimulatory effect of increasing sucrose concentration and the interaction of this effect with the inhibitory effect of normal postingestive food stimuli in intact and cd rats. (Reprinted with permission from Grill HJ, Kaplan JM: Sham feeding in intact and chronic decerebrate rats. Am J Physiol *262:*R1070, 1992.)

Indirect Controls Indirect controls of meal size are formally distinguished from direct controls in that they do not arise from the preabsorptive action of food during meals. They also appear to be distinct from direct controls in several other ways. For example, they tend to act for longer periods than the durations of individual meals and intermeal intervals. Second, the neural mechanisms of indirect controls are localized predominantly in the forebrain. Forebrain networks mediate the higher functions of eating, including the appetitive behaviors involved in food search and selection as well as the subjective experience of eating. Forebrain systems receive ascending hindbrain afferents and forebrain sensory inputs, and are interconnected with each other and with the hindbrain systems in complex but poorly understood distributed eural networks. These neurological facts mean that forebrain systems control eating by modulating the direct controls of eating. Thus, although forebrain systems are necessary for many controls of eating, they are not sufficient for any of them.

Table 1.20-1 lists several indirect controls of eating. Given their variety, it is not surprising that the experimental analysis of indirect controls of eating has proceeded at an uneven pace. For example, identification of any normal metabolic controls of eating has been surprisingly difficult. Indeed, whether energy metabolism exerts any physiological control over meal size except after long periods of food deprivation is controversial. Similarly, until 1994, little was known about the mechanism by which adiposity influenced eating.

Type*	Examples
Metabolic	Changes in availability of substrates, changes in adipose tissue mass
Cyclic	Circadian and ovarian hormonal rhythms
Immune system	Neoplasms, infections
Conditioned	Learned preferences, aversions, and satieties

*Types are neither mutually exclusive nor exhaustive. Note that conditioned controls are produced by physiological contingencies, such as illness; by social or ecological contingencies, such as group sizes or the relative densities of food sources or predators; and, in humans, by cultural and esthetic contingencies.

Table 1.20-1 Indirect Controls of Meal Size

In contrast to the difficulty in identifying a specific metabolic control of eating, learned controls of eating are prominent and pervasive. With the exception of a few unconditioned gustatory preferences and aversions (such as for sweet and bitter taste), all food selection appears to be learned. Controls of meal initiation and meal size are also readily conditionable in animals and humans. Flavor provides the *conditioned stimuli* for these learned controls. The *unconditioned stimuli* for many learned controls, such as satiety conditioned by the nutrient density of a food, are postingestive consequences of eating. Other controls may involve higher-order conditioning. For example, cultural socialization may result in a preference for the flavor of capsaicin (chili), which all infants avoid.

Some forms of learned controls of eating are special forms of conditioning. Flavor aversions conditioned by upper gastrointestinal food poisoning, for example, can be learned after only one *conditioned stimuli-unconditioned stimuli* pairing despite extraordinarily long *conditioned stimuli-unconditioned stimuli* delays (hours), and are extremely resistant to extinction. Carefully designed tests are required to reveal learned controls of meals, and much remains to be done on this problem. But this work should be a high priority in the investigation of disordered eating because the number of unconditioned hindbrain mechanisms through which all learned controls of meal size operate is small enough to make it possible to achieve control of them in humans. Furthermore, behavior therapy programs should increase the accessibility of conditioned physiological controls of eating because they are highly structured and can present specific food stimuli.

SIGNALS AND PERIPHERAL MECHANISMS FOR CONTROL OF MEAL SIZE

The size of an individual meal is controlled by the central neural integration of positive and negative feedback signals that affect the maintenance or termination of eating (Fig. 1.20-1B). Thus, increases in meal size result if there is an increase in positive feedback signals, a decrease in negative feedback signals, or both, and decreases in meal size result if there is a decrease in positive feedback signals, an increase in negative feedback signals, or both (Table 1.20-2). This simple syllogism has provided a powerful strategy in the analysis of normal eating, and should be equally useful in the analysis of disordered eating.

	Signal Type*	
Change of Meal Size	Positive	Negative
Increase	↑	—
Increase	—	↓
Increase	↑	↓
Decrease	↓	—
Decrease	—	↑
Decrease	↓	↑

*Signals are the hypothetical neural representations of the direct controls of meal size that originate from preabsorptive actions of food stimuli during meals. Positive signals tend to increase meal size and negative signals tend to decrease meal size. Changes in their strength can result from changes in afferent activity or changes in the central neural processing of that afferent information, for example as the result of influence of indirect controls. ↑ indicates increased strength, ↓ indicates decreased strength, and — indicates no change.

Table 1.20-2 Changes in Positive and Negative Feedback Signals that Lead to Changes in Meal Size

Direct Controls of Meal Size

Maintenance of Eating Flavors are the only known signals facilitating eating once it has begun. These positive feedback controls of meal size arising from oropharyngeal food stimuli reach the brain through the olfactory (via retronasal stimulation), trigeminal, facial, glossopharyngeal, and vagus nerves. This afferent information (except for the olfactory stimuli) is initially processed in the hindbrain. For example, sweet tastes elicit smiles and ingestive responses in normal and mesencephalic human infants, whereas bitter tastes elicit grimaces and rejection. Similarly, test meal size is a graded function of sucrose concentration in the chronic decerebrate rat. The identity of this function in intact and decerebrate rats (Fig. 1.20-4) demonstrates that hindbrain processing of this signal is sufficient for this control of meal size without any contribution from forebrain neural networks involved in the perception of sweetness.

If inhibitory postingestive signals are eliminated by use of the sham feeding technique, the gain of the intake function increases dramatically (Fig. 1.20-4). Indeed, as originally observed by Ivan Pavlov, after a day of food deprivation, animals sham feed nearly continuously for hours.

Termination of Eating Signals contributing to the normal termination of meals are referred to as *satiety signals*. Oropharyngeal food stimuli, gastric, and intestinal food stimuli all give rise to satiety signals. The oropharyngeal signals are presumably neural and are not well understood; some may involve the cephalic phase release of gut peptides.

Control of meal size by gastric volume has been demonstrated in rats with pyloric cuffs that prevent ingested food from passing into the small intestine. The mechanoreceptors initiating this control apparently activate vagal and splanchnic visceral afferents, possibly through the release of gastrin-releasing peptide or neuromedin B.

Food stimuli arising from the intestinal phase of digestion activate chemoreceptors that initiate a number of potent satiety signals. Many of these signals reach the hindbrain via vagal afferents, which are stimulated directly by small intestinal luminal contents or indirectly by gut peptides that are released by the preabsorptive actions of food. Intestinal infusions of various food stimuli that match the normal rates of emptying from the stomach have convincingly demonstrated the physiological

role of intestinal satiety signals in animals and humans.

A simple method to study postingestive satiety mechanisms is the administration of preloads. Oral preloads, sometimes administered in ways that minimize oropharyngeal stimuli, have been used extensively in animals and humans to determine the contributions of a food's metabolic energy content, nutrient composition, colligative and osmotic properties, and weight, to its satiating potency. This work suggests that there is no general quantitative relation among these variables, although some interesting points have emerged. When mixed nutrient preloads are used, the decrease in eating is usually proportional to the preload's metabolizable energy content, although the compensation is often incomplete. When the preload's macronutrient composition is varied, protein preloads are typically more satiating than isoenergetic loads of carbohydrate or fat. Finally, liquid foods, especially soups, are typically relatively more satiating than foods in other physical forms, especially for women.

The relative contribution of satiating food stimuli that activate receptors in different loci in animals can be isolated experimentally by techniques such as the chronic gastric cannula and the inflatable pyloric cuff. Alternative strategies are required in humans. One is to vary the time between preloads and test meals. Such studies indicate that preloads are more satiating when eating begins sooner after loading (£ 30 min) than when eating begins later (£ 60 min), suggesting that preabsorptive signals are more important than postabsorptive signals in mediating the satiating effects of preloads. Another strategy to identify the site of action of food stimuli is to compare the effects of infusions made into successive functional compartments. This method has also produced strong evidence for the primacy of intestinal over postabsorptive signals in satiety. For example, a recent study compared the satiating effects of intraduodenal glucose infusions and intravenous glucose infusions that produced identical increases in systemic glucose levels. Intraduodenal, glucose decreased premeal hunger ratings and decreased meal size; intravenous glucose did not.

GUT PEPTIDES Gut peptides appear to be an especially important class of direct satiety signals elicited by food stimuli in the small intestine (Table 1.20-3). One of these, cholecystokinin (CCK), is now proven to be a physiological control of meal size, based on fulfillment of five criteria: (1) CCK is released during meals; (2) administration of CCK in amounts that reproduce prandial levels is sufficient to inhibit meal size; (3) CCK reduces meal size in the absence of abnormal or adverse behavioral, physiological, or subjective effects; (4) administration of antagonists of the type A CCK (CCK $_A$) receptor before meals increases meal size; and (5) CCK$_A$ receptor antagonists block the satiating effect of food stimuli that release endogenous CCK. All these criteria have been met in rats; further work is required to establish the last two criteria in humans.

Physiological Status	In Animals	In Humans
Cholecystokinin (CCK)	Y	+
Pancreatic glucagon	Y	+
Insulin	+	?
Gastrin-releasing peptide	?	?
Neuromedin B	?	?
Amylin	+	?
Somatostatin	?	?
Neurotensin	?	?
Apolipoprotein A-IV	?	?
Enterostatin	?	?

*Each peptide listed is directly or reflexively released during meals and each has been implicated in the mechanism of satiation in animals. Physiological status in animals and humans is rated as proven (Y), probable (+), or unclear (?), based on comparisons of prandial levels with threshold doses of exogenous peptide for inhibition of meal size and on tests of antagonism of endogenous peptide.

Table 1.20-3 Peripheral Peptides Hypothesized to Signal Satiety*

Pancreatic glucagon has also fulfilled these criteria in rats. Figure 1.20-5 shows an example of the specific satiating actions of CCK and glucagon in young men of normal weight.

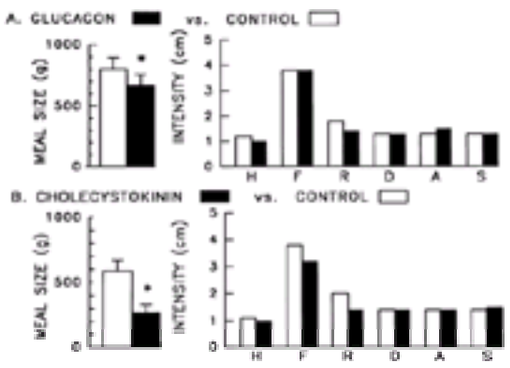

FIGURE 1.20-5 Cholecystokinin and pancreatic glucagon are released during meals in response to preabsorptive food stimuli. Intravenous infusion of either peptide during meals in normal human volunteers reduces meal size without physical or subjective side effects. **A**, Effects of intravenous infusion of pancreatic glucagon (3 ng/kg^{-1}/min^{-1}) on the size of macaroni and beef lunches and postprandial subjective ratings in 12 normal weight men. **B**, Effects of similar infusions of cholecystokinin octapeptide (CCK-8, 2 ng kg^{-1} min^{-1}) in 8 of the same men. Psychophysical ratings were made with 15-cm visual analog scales (0 cm, “not at all”; 15 cm, “most possible”) of “hungry” (H), “stomach full” (F), “restless” (R), “dizzy” (D), “stomach ache” (A), and stomach sick (S). Scales were completed just after the meal. Both peptides significantly decreased meal size (*) without changing the normal pattern of postprandial subjective reports. (Reprinted with permission from Geary N, Kissileff HR, Pi-Sunyer FX, Hinton V: Individual, but not simultaneous, glucagon and cholecystokinin infusions inhibit feeding in men. Am J Physiol *62:*R975, 1992.)

SYNERGY Many of the direct controls of meal size appear to interact in a functionally synergistic fashion, that is, their actions combine in a supra-additive manner. For example, the satiating potency of exogenous CCK is increased by small gastric preloads, even of substances that are not CCK secretagogues. Because such synergistic interactions present the possibility for maximal changes in meal size by minimal manipulations, they are an especially attractive avenue for development of therapeutic controls of meal size.

Indirect Controls of Meal Size Conditioning modulates both meal timing and meal size; other indirect controls appear to act mainly on meal size. For example, increased eating in cold environments, during lactation, after ovariectomy, or after body weight loss caused by food deprivation as well as the decreased eating after forced weight gain are mediated primarily by changes in meal size.

Fat Mass, Insulin, and OB Protein Since the classic experiments by G. C. Kennedy in the early 1950s, it has been known that the mass of fat in the body is correlated inversely with meal size and food intake. Recent work has demonstrated that this lipostatic control is mediated in rodents by actions in the brain of circulating insulin and OB protein (also called leptin), the product of the *oB* gene.

Insulin is a negative-feedback signal of lipostatic control because: (1) basal concentrations of plasma insulin are positively correlated with adipose mass; (2) plasma insulin is actively transported into the brain by a vascular receptor transport mechanism; and (3) intracerebral infusion of insulin in amounts too small to have peripheral effects by diffusion into the blood decreases meal size and food intake. It is clear that obesity involves some dysfunction of lipostatic control because it is characterized by hyperinsulinimia. Resistance to the inhibitory effect of insulin on eating has been demonstrated directly after central administration of insulin in genetically obese *(fa/fa)* rats.

OB protein is a secretory product of the adipose tissue discovered in 1994. It is a negative-feedback signal of lipostatic control because plasma concentration of OB protein is a linear function of fat mass, and peripheral or central administration of OB protein decreases meal size in a potent, dose-related manner. Receptors for OB protein are widespread in the periphery and the brain, and the physiology of these systems is under intense investigation in animals and humans. It is already clear

that increased meal size accounts for the hyperphagia of genetically obese rodents that fail to produce biologically active OB protein (*ob*/*ob* mouse) or lack functional OB receptors (*db*/*db* mouse and *fa*/*fa* and *cp*/*cp* rats) and that decreased meal size accounts for the hypophagia of normal animals treated with OB protein. A report that infusion of specific antibodies to the OB protein into the lateral ventricle of rats increased food intake suggests that OB protein may exert a tonic indirect inhibitory control of meal size. As a rule, the concentration of circulating OB protein is positively correlated with adiposity in humans, suggesting that decreased sensitivity may contribute to obesity. This hypothesis is supported by a demonstration that mice made obese by feeding a very high-fat diet were less hypophagic than control mice following OB protein administration. Isolated instances of human obesity may arise from mutations in the genes expressing OB protein or its receptor. Three such families have been identified, two with mutations resulting in deficiencies of functional OB protein and one with a deficiency in functional OB protein receptors.

Estradiol Estradiol exerts phasic and tonic inhibitory effects on eating. The phasic effect is a cyclical decrease in food intake that occurs during the periovulatory period. The tonic effect is revealed by ovariectomy, which in animals elicits a dramatic increase in the basal level of feeding and abolishes the cyclical feeding rhythm. These changes are best correlated with hanges in circulating estradiol, and estradiol is the only hormone of the hypothalamic-pituitary-ovarian axis that normalizes eating and body weight in ovariectomized animals. All these effects are accounted for by changes in meal size. One of the mechanisms by which estradiol decreases meal size is by increasing the potency of cholecystokinin. Estradiol's potential role in the increased vulnerability of women to eating disorders has not been established. It is possible that estradiol's inhibitory influence on eating may be part of the reason that anorexia nervosa often develops near menarche.

Learning Gastric and intestinal satiety signals, the major direct negative-feedback controls of meal size, also provide important unconditioned stimuli for indirect, conditioned controls of meal size. The importance of conditioned controls can be demonstrated by experimental manipulations that prevent the normal actions of the postingestive controls of meal size and lead to their gradual extinction (Fig. 1.20-6). This has been modeled in the sham feeding rat and probably occurs in patients who vomit or purge after binge-eating.

FIGURE 1.20-6 The potency of learned controls of meal size based on postingestive food stimuli is revealed by the progressive increase in test meal size during repeated sham feeding trials. During sham feeding liquid food drains from open gastric cannulas without significant accumulation in the stomach or small intestine, so that learned controls based on gastrointestinal food stimuli extinguish. In this experiment rats were offered a sweet liquid diet once daily, after 3 hours of deprivation of their maintenance diet. During week 1, rats fed normally (real feeding, RF); during weeks 2 to 7, sham feeding (SF) tests were alternated with real feeding tests, and during weeks 8 to 11, rats only sham fed. The figure shows the average real and sham meal sizes in each week. During the first sham feeding test, rats still ate well-defined meals terminated by behavioral signs of normal satiety, indicating that after this short period of food deprivation, pregastric food stimuli can elicit satiety. Meal size, however, nearly doubled during this test, because of the absence of direct, unconditioned gastric and postgastric controls of eating. Sham meal size doubled during weeks 3 to 7, when sham and real feeding tests were alternated, whereas real meal size increased only a small amount, and sham meal size almost doubled a third time during weeks 8 to 11, when there were no real feeding tests. These increases reflect the extinction of conditioned satiety. Subsequent studies indicate that this conditioned satiety is based on both gastric and intestinal food stimuli.

CENTRAL MECHANISMS OF THE CONTROL OF MEAL SIZE

Hypothalamic Centers and a Distributed Network Experimental manipulations of the hypothalamus produce large effects on eating. Lateral hypothalamic damage produces hypophagia; electrical stimulation in this area elicits eating. Lesion and stimulation of the ventromedial hypothalamus have the opposite results. Originally presented as explanations of how eating was organized neurologically into a lateral hunger center reciprocally connected with a medial satiety center, these hypothalamic effects are now seen as problems to be solved in terms of hypothalamic functions in the distributed neural network that controls eating. Figure 1.20-3 indicates several sites that are functional nodes in this network in animals. Direct knowledge of the network that controls human eating is extremely limited, but increased progress in this area may be expected as evolving techniques in brain imaging reinvigorate functional neuroanatomy.

Neuropharmacology, Neurotransmitters, and Neuromodulator Neuropharmacological methods have largely replaced classical lesion and stimulation techniques in the study of eating. In a few instances it is now possible to link particular direct controls of meal size with the specific central neurochemical systems that are necessary for their normal processing.

In addition, a number of amines and peptides reliably increase or decrease eating (Table 1.20-4). Although it is reasonable to assume that the stimulants of eating enhance the orosensory positive-feedback effect of the test diets and that inhibitors of eating enhance the postingestive negative-feedback effects of the test diets, further work is required to demonstrate this and to eliminate the alternative possibilities (Table 1.20-2). Those endogenous substances for which there is the most evidence of function under physiological conditions (Table 1.20-4) are discussed. Again, this progress results mainly from work in animals, in which it is now possible to manipulate and measure brain neurochemicals at the sites of their biological action during meals. In contrast, only very indirect methods, such as measurements of the concentrations of neurotransmitters or metabolites in the cerebral spinal fluid, are possible in humans and these cannot usually be done in the context of eating.

Increase Eating		Decrease Eating	
Chemical	Physiological Status	Chemical	Physiological Status
Dopamine	Y	Serotonin	Y
Neuropeptide Y	Y	Corticotropin-releasing factor	Y
Norepinephrine	Y	Gastrin-releasing peptide	Y
Endogenous opioids	Y	Glucagon-like peptide 1	+
Galanin	+	Oxytocin	+
Growth-hormone-releasing factor	+	Neuromedin B	?
Melanin-concentrating hormone	+	Enterostatin	?
Orexins A and B (hypocretins 1 and 2)	+	α-melanocyte-stimulating hormone	+

Each neurochemical listed occurs in the brain and has been implicated in the central physiology of eating in animals. Endogenous opioids include beta-endorphin and dynorphin. Physiological status in animals is rated as present (Y), probable (+), or unclear (?), based on tests of agonists and antagonists of the endogenous components.

Table 1.20-4 Central Neurotransmitters and Neuromodulators Implicated in the Control of Eating

Stimulants of Eating

DOPAMINE Dopamine is thought to play an important role in mediating the rewarding effects of food that maintain eating, produce pleasure, and reinforce learning about food. In animals, dopamine antagonists markedly decrease the appetitive and consummatory responses maintained by food. For example, dopamine antagonists selectively reduce the orosensory positive-feedback effect of sucrose solutions that stimulate ingestion without altering the sensory intensity of the sucrose or its postingestive satiating potency, and without impairing oromotor movements, the animals' motor capacity, or creating an aversion. Dopamine is released in several brain areas that are thought to mediate reward functions, including the nucleus accumbens, medial hypothalamic areas, and the amygdala.

Dopamine may also be involved in the central processing of the satiating effect of peripheral CCK, and dopamine inhibits intake when injected into perifornical sites in the hypothalamus. This is a good example of how the effect of a transmitter on eating is determined by the site and functional contingencies of the network it acts in.

NOREPINEPHRINE Noradrenergic neurons in the locus ceruleus of the hindbrain project to the hypothalamus and many other brain sites. Numerous studies support a role for norepinephrine in the control of feeding. Administration of norepinephrine into the paraventricular nucleus and perifornical hypothalamus increases meal size and preferentially stimulates carbohydrate intake via an a_2-adrenergic receptor mechanism. Corticosterone also upregulates these receptors. Furthermore, spontaneous feeding increases paraventricular nucleus norepinephrine release and also upregulates a_2-adrenergic receptors. The effect of norepinephrine infusion into the paraventricular nucleus shows rapid tolerance, however, so that chronic infusions do not affect body weight.

NEUROPEPTIDE Y Neuropeptide Y is the most potent known centrally acting orexigen. Short-term central administration of neuropeptide Y increases feeding in numerous animal species, although it had no effect in the single test in primates, done in baboons. Long-term central administration of neuropeptide Y leads to sustained hyperphagia and increased body weight in rats. The paraventricular nucleus and adjacent perifornical hypothalamus, which receive projections from neuropeptide Y cells in the hindbrain and in the arcuate nucleus of the hypothalamus, are considered the most likely sites for a physiological action of neuropeptide Y. Concentrations of neuropeptide Y in this area change during meals, and administration of neuropeptide Y antibodies or antisense neuropeptide Y deoxynucleotides here decreased feeding. Several lines of evidence suggest that both insulin and OB protein may inhibit feeding in part by down-regulating neuropeptide Y.

OPIOIDS Administration of opioid antagonists such as naloxone (Narcan) reduce meal size under a variety of conditions. This inhibitory effect appears to be relatively selective for preferred foods, such as sweet or high-fat foods, suggesting that opioids are particularly relevant to the maintenance of eating by preferred foods. Ligands for the μ-, k-, and d-opioid receptor subtypes have all been reported to stimulate feeding, and several brain areas, including the ventral tegmentum, various hypothalamic nuclei, the amygdala, and the nucleus accumbens, have been implicated in opioid-induced feeding. Endogenous opioids are also necessary for the orexic effect of neuropeptide Y. The most important site of this opioid mediation is the nucleus tractus solitarius of the hindbrain. This is a clear demonstration of the dependence of forebrain effects on eating on hindbrain mechanisms proximal to the final motor neurons that control eating.

Inhibitors of Eating

SEROTONIN The prototypical serotonin agonist dexfenfluramine (withdrawn from the U.S. market), which releases synaptic serotonin and blocks serotonin reuptake, inhibits eating in animals and humans. The inhibitory effect in rodents can be blocked by antagonism of two serotonin receptor subtypes, serotonin (5-hydroxytryptamine [5-HT]) subtype 2C (5-HT_{2C}) are 5-HT_{1B}; 5-HT_{1B} is the homologue of the 5-HT_{1D} subtype in other mammals. Complementary work with serotonin agonists indicates that 5-HT_{1B} receptors primarily affect meal size and 5-HT_{2C} receptors affect eating rate. Endogenous serotonin appears to have a physiological role in satiety because both intraventricular injection of 5-HT_{2C} receptor antagonists and direct injection of 5-HT_{1A} receptor antagonists in the brainstem raphe, where they stimulate autoreceptors on serotonin perikarya, increase meal ize. Additionally, mutant mice without 5-HT_{2C} receptors are overweight and unresponsive to serotonin agonists. There is also evidence that part of CCK's satiating action is mediated by central 5-HT_{2C} receptors. Serotonin may be also be involved in the stimulatory effect of sweet taste on eating. The hypothalamic paraventricular nucleus appears to be an important site of serotonin effects on eating in animals but it is not the only one.

CORTICOTROPIN-RELEASING FACTOR This peptide is synthesized by neurons in many brain areas, including the medial parvocellular subnucleus of the paraventricular nucleus, which is the source of the projection to the median eminence, the medial preoptic area, the nucleus tractus solitarius, and the amygdala. Administration of CRF into the cerebral ventricles or into the paraventricular nucleus has a potent anorectic effect, and CRF appears to be involved in many circumstances in which eating is inhibited. Interestingly, there appears to be a reciprocal relationship between many controls of CRF and neuropeptide Y activity, for example, has opposite effects OB protein on neuropeptide Y and CRF. Furthermore, the two peptides have opposite effects on sympathetic nervous activity related to metabolism as well as on eating.

DISORDERED CONTROLS OF MEAL SIZE IN BULIMIA NERVOSA

The quantitative approach to the controls of meal size that has fueled the recent progress in the basic science of eating has begun to be applied to patients with eating disorders. The most significant results have come from studies in patients with bulimia nervosa when it was discovered that patients ate much larger meals under laboratory conditions. This difference can be obtained in individual test meals of a single test diet or in residential laboratory settings in which patients have access to a variety of foods for 1 or more days. An important aspect of the results in the latter condition is that patients with bulimia nervosa did not necessarily eat more meals than controls, but dramatically increased the size of about one quarter of their meals.

There is considerable evidence that the postingestive negative-feedback effects of food are less satiating in patients with bulimia nervosa. Equivalent preloads of food decrease intake less in patients with bulimia nervosa than in controls, particularly when the patients are eating large meals. Furthermore, patients with bulimia eat a larger amount of food to produce equivalent self-reports of fullness during a meal. This suggests that ingested food has a less satiating effect because the peripheral, preabsorptive, negative-feedback mechanisms are decreased or that the central processing of this negative-feedback information reduces the potency of the negative feedback; there is growing evidence to support both these possibilities.

Two peripheral, negative-feedback signals are decreased in bulimia patients. First, volume distention of the stomach produces a decreased perceptual and mechanical response, presumably because the stomachs are larger than normal as the result of accommodation to the frequent ingestion of large meals. Second, food-stimulated release of CCK is less in patients with than bulimia nervosa than in controls (Fig. 1.20-7).

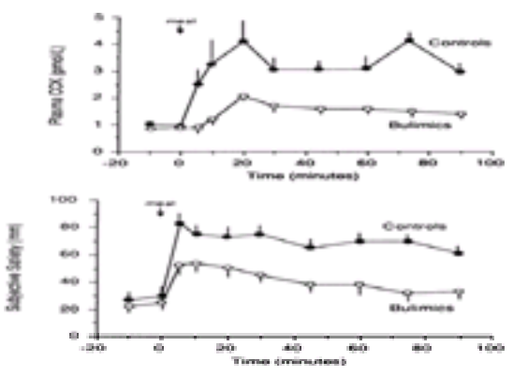

FIGURE 1.20-7 Prandial concentrations of cholecystokinin (CCK; **A**) and the subjective experience of satiety (**B**) are reduced in patients with bulimia nervosa. Fourteen patients and 10 control women matched for age and weight were offered a 400-ml liquid meal after an overnight fast (arrows) and ate it in 1 to 2 minutes. Plasma CCK was measured with a selective bioassay. Satiety was measured by a 100-mm visual analog scale (0 = empty, 100 = full). Both the peak CCK concentration and the integrated CCK response (area under the curve) were significantly reduced in patients with bulimia and this correlated with reports of significantly less satiety beginning 5 minutes after meal onset. (Reprinted with permission from Geracioti TD Jr, Liddle RA: Impaired cholecystokinin secretion in bulimia nervosa. N Engl J Med *319:*683, 1988.)

In addition to the diminished negative-feedback potency of these direct controls, there is evidence in support of abnormal indirect control and central processing. The most significant abnormality of the indirect controls is cognitive. This is demonstrated by the much larger meals eaten by bulimia patients when they are instructed to binge compared to when they are instructed not to binge. Thus, the instructions decrease the potency of the defective, negative-feedback direct controls. It is possible that instructions also enhance positive feedback directly (Table 1.20-2), but there is no evidence for this. The conditioning process resulting in this abnormal cognitive control is unknown.

The abnormal central processing of the negative-feedback information may result from a decrease in central serotonergic function that has been demonstrated under

a variety of conditions. If central serotonin function is decreased in bulimia patients, they should be more vulnerable than controls to a further decrease in serotonin function produced by serotonin depletion. This prediction has been confirmed: acute tryptophan depletion that probably decreased central serotonin activity increased meal size in patients with bulimia, but not in controls. Because abnormally large meals are characteristic of obesity as well as bulimia nervosa, it is interesting to note that facilitation of serotonin synaptic activity is the primary action of the most efficacious antiobesity drugs, including fenfluramine, dexfenfluramine (withdrawn from the U.S. market), and sibutramine (Meridia).

Finally the defects in central serotonin, gastric distention, and peripheral CCK associated with bulimia may be synergistic, (i.e., they may produce supraadditive effects). This is because in animals the satiating potency of CCK is synergistic with gastric distention and is reduced by decreased central serotonergic function.

SUGGESTED CROSS-REFERENCES

Section 1.4 contains further information of the physiology of monoamine neurotransmitters, and Section 1.6 contains similar information about neuropeptides. Basic learning theory is presented in Section 3.3. Eating and feeding disorders are reviewed in Chapter 20 and Chapter 41; Section 25.3 includes background information on obesity.

1.21 FUTURE DIRECTIONS IN NEUROSCIENCE AND PSYCHIATRY

SOLOMON H. SNYDER, M.D.

The rapid advances in molecular neurosciences over the past two decades are continuing to accelerate as the tools provided by the field of molecular biology become ever more powerful. These tools will enable the development of more selective therapeutic agents with fewer adverse effects. More tantalizing and less certain is the possibility that the abnormal genes that play a role in major mental illness will be deciphered. The major genes involved in schizophrenia and mood disorders will be pinned down well before the end of 2010. However, this does not mean that the "cause" of these diseases will be fully elucidated; most investigators suspect that there will be as many different causes of the major psychotic disorders as there are of pneumonia.

ABNORMAL GENES

The technique of *reverse genetics* in which deoxyribonucleic acid (DNA) sequences and blood cells of extended families are analyzed to look for correlations with the disease process, has achieved great success recently. Specific molecular genetic abnormalities have been detected for cystic fibrosis, Duchenne's muscular dystrophy, and several other conditions. Numerous groups have been employing reverse genetic techniques to seek specific abnormalities in patients with mood disorders and schizophrenia. There have been reports of "clues," some of which have been replicated in independent investigations. Unique patterns on chromosome 18 have been detected by several researchers into mood disorders and there are more preliminary hints of abnormalities in schizophrenia. Advances in Alzheimer's disease have been substantial and may bolster efforts to pin down the molecular genetics of the principal psychiatric disorders. The presence of amyloid plaques has long been known to be a hallmark of Alzheimer's disease. However, amyloid deposits occur in numerous diseases and seem to represent a form of "scar" following neuronal damage. Hence, one school of thought has argued that amyloid deposition is merely secondary to some other primary event. With the first elucidation of specific abnormal genes in certain hereditary forms of Alzheimer's disease came the "Eureka" discovery that some of these mutations involved steps in processing the amyloid precursor protein. Although these abnormalities account for only a small percentage of the total population of Alzheimer's disease patients, amyloid is increasingly believed to be causally involved in a major portion of the disease. Because the specific lesion need not be in the amyloid protein precursor itself, the most prevalent aberration discovered in Alzheimer's disease occurs in the presenilins, membrane-associated proteins whose normal biological role is unknown and may not relate directly to amyloid. However, presenilin mutations lead to disordered amyloid processing. Analogously, some cases of depression may derive from abnormalities in serotonin metabolism whereas others could involve distinct systems whose malfunction secondarily disrupts serotonin mechanisms.

Similar reasoning might be applied to the dopamine hypothesis of schizophrenia. The major antipsychotic drugs act by blocking dopamine receptors, and drugs such as amphetamines that release dopamine can exacerbate psychotic symptoms. Based on these findings, researchers have looked for specific dopamine abnormalities in schizophrenia, and there have been reports of increased levels of certain forms of dopamine receptors in drug-free patients with schizophrenia. However, the fact that dopamine-related drugs modulate symptoms in no way directly implicates dopamine in causation. Nonetheless, like amyloid in Alzheimer's disease the impressive body of circumstantial evidence on dopamine might turn out to be of fundamental importance.

Even if the specific abnormality in a disease is found understanding of causation or any tools to treat patients may remain elusive. In 1983 restriction fragment length polymorphism studies pointed toward the abnormal gene in Huntington's disease, and after a decade-long search, this gene was identified and was found to code for a large protein designated *huntingtin*. Unfortunately, nothing about huntingtin has explained the pathophysiology of Huntington's disease. The caudate nucleus of patients with Huntington's disease shrivels selectively. However, huntingtin concentrations are uniform throughout the brain and the protein occurs in high densities all over the body. There are now some valuable clues that might contribute to our understanding of psychiatric disorders. The molecular disturbance in Huntington's disease involves increased numbers of glutamine molecules occurring in repeats of up to 80 or more in huntingtin, whereas normal subjects have only a few of these repeats. Researchers have speculated that the glutamine repeats cause huntingtin to bind to other proteins that are the real neurotoxic culprits. One protein that binds selectively to huntingtin, especially forms of huntingtin that have larger numbers of glutamine repeats, is designated *huntingtin-associated protein* (HAP). In contrast to the ubiquitous distribution of huntingtin, HAP occurs only in the brain and displays discrete regional localizations similar to those of neuronal nitric oxide synthase, which has been implicated in neurotoxicity. The glutamine repeats in huntingtin also bind to glyceraldehyde-3-phosphate dehydrogenase. This enzyme is usually thought of only as a housekeeping enzyme of the glycolytic pathway, but it also appears to be a messenger protein that interacts with numerous other macromolecules in the cell, including serving as a transcription factor in the nucleus. Thus HAP, glyceraldehyde-3-phosphate dehydrogenase, or another protein may be the ultimate mediators of damage, and nitric oxide synthase may also play a role. Such a chain of functionally and physically associated proteins may help to explain seemingly conflicting findings in various diseases.

Identifying protein-protein interactions has become increasingly important in all aspects of biology. Various proteins, such as actin and myosin, are known to bind to each other, but the extent of large multiprotein complexes has not been adequately appreciated. The yeast-two hybrid system is an extremely powerful tool that enables scientists to identify novel protein-protein interactions by evaluating the ability of the proteins synthesized from the complementary deoxyribonucleic acid (cDNA) of a known protein to interact with a large universe of proteins synthesized from a cDNA library of any chosen tissue such as the brain; HAP was discovered by the yeast-two hybrid approach.

Investigating the neuropathology of mental illness was long regarded as a dead-end enterprise but newer imaging techniques have revealed specific abnormalities; for example, increased lateral ventricular size has been observed repeatedly in chronic schizophrenia and specific abnormalities have been observed in portions of the temporal lobe as well as in the more primitive areas of the frontal lobes. The patterns of disturbance suggest an aberration of development rather than a neurodegenerative process, which fits with the contrast between schizophrenia and Huntington's disease, the latter being a classic neurodegenerative condition. Patients with Huntington's disease seem to be completely normal until degeneration sets in; by contrast, children destined to develop schizophrenia appear to be "not quite right" from earliest childhood. One might speculate that abnormal genes in schizophrenia could influence neural development of the temporal lobe

MAKING NERVES GROW

Given the likelihood that major mental illnesses are neurodegenerative or neurodevelopmental, can anything be done therapeutically for such disturbances? Although drugs can improve symptoms in neurodegenerative disease (such as cholinesterase-inhibiting drugs in Alzheimer's disease), the present generation of drugs is probably incapable of restoring disordered neuronal patterns. In the ideal situation nerves that never developed properly or those that degenerated would grow; this concept may no longer be pure fantasy.

Research on neurotrophic factors has burgeoned in recent years. Nerve growth factor (NGF) was the first to be discovered, followed by brain-derived neurotrophic factor (BDNF), neurotrophin 3 and 4 (NT3 and NT4), and, more recently, glial-derived neurotrophic factor (GDNF). Receptors for these factors have been characterized at a molecular level as deriving from the family of genes designated *trk*, which are related to growth-stimulating oncogenes.

These neurotrophic factors cannot readily be employed as therapeutic agents, because they do not penetrate blood-brain barrier and are extensively metabolized in the body. However, recombinant techniques make possible the synthesis of large amounts of these proteins, which are now in advanced clinical trials (e.g., the insulin-like growth factor [IGF-1, myotrophin] for amyotrophic lateral sclerosis). An initial clinical trial of NGF administered subcutaneously has revealed its therapeutic efficacy in diabetic neuropathy. In the brain NGF selectively stimulates the growth of cholinergic neurons. Loss of the cholinergic pathway to the cerebral cortex whose cell bodies are in the basal nuclei of the forebrain accounts for much of the memory deficit in patients with Alzheimer's disease. Lesions of this pathway produce memory losses in animals. Injection of NGF into the cerebral ventricles stimulates the regrowth of the cholinergic neurons selectively and alleviates the memory deficit. Clinical trials of NGF administered by an in-dwelling cannula into the brains of Alzheimer's patients are anticipated.

Neurotrophic actions of small-molecule drugs that pass the blood-brain barrier and are orally available have been observed recently in the course of research on the immunophilins. Immunophilins are the protein receptors for classic immunosuppressant drugs such as cyclosporin-A and FK506. Immunosuppression derives from the

binding of the drug-immunophilin complex to the calcium-activated phosphatase calcineurin, inhibiting its ability to remove phosphate groups from certain proteins. One of these proteins, *nuclear factor of activated T cells* (NFAT), is a transcription factor that can only enter the nucleus when it is dephosphorylated. By blocking calcineurin, phosphatase activity, treatment with the immunosuppressant drugs increases phosphorylated levels of NFAT; the latter cannot enter the nucleus to stimulate formation of the cytokine interleukin-2, which normally initiates the immune response of T cells.

Immunophilin levels are up to fifty times higher in the brain than in tissues of the immune system and are especially enriched in the growth cones of regenerating neurons. These findings led to experiments revealing the very potent neurotrophic actions of immunosuppressant drugs in stimulating the growth of various neuronal systems such as dorsal root ganglia. The drugs stimulate the growth of all types of damaged neurons, including the sciatic and facial nerves and dopamine and serotonin neurons in the brain. The neurotrophic actions also occur with drug derivatives whose complexes with the immunophilin do not bind to calcineurin so that the drugs are not immunosuppressant. Although these drugs show promise in animal models of damaged neurons, clinical trials have not yet been conducted to assess their therapeutic relevance.

CHAPTER 2. NEUROPSYCHIATRY AND BEHAVIORAL NEUROLOGY

2.1 NEUROPSYCHIATRY: CLINICAL ASSESSMENT AND APPROACH TO DIAGNOSIS

TIFFANY W. CHOW, M.D., AND JEFFREY L. CUMMINGS, M.D.

Neuropsychiatry is the clinical discipline devoted to understanding and treating brain-based behavioral disturbances. It encompasses human behavior, emotion, cognition, and their physical bases. The traditions of biological psychiatry gave rise to neurology when clinicians observed abnormal human behaviors and searched for causes based on neuroanatomy. The neuropsychiatrist must master psychopharmacology and neuroscience in order to understand the physical basis of behavior and to benefit patients with behavioral disturbances produced by central nervous system disorders. This scientific pursuit combines research, education, and clinical patient care. Neurologists must heed the behavioral aspects of neurological disorders whereas psychiatrists cannot expect to fully comprehend behavior without appreciating its physical underpinnings; all effective therapeutic interventions for abnormal behavior must eventually be translated into neurological events. Contemporary neuropsychiatry investigates not only the neurological basis of psychiatric disorders such as schizophrenia, bipolar illness, depression, anxiety, and obsessions and compulsions but also explores the behavioral alterations exhibited by patients with overt brain disorders such as stroke, epilepsy, and multiple sclerosis. This introductory section reviews behavioral aspects of neurological disorders and presents a comprehensive approach to neuropsychiatric assessment.

MENTAL STATUS EXAMINATION

The key to accurate neuropsychiatric diagnosis is a comprehensive mental status examination. Mental status testing, augmented by the clinical history, will lead to a specific diagnosis or to the generation of diagnostic hypotheses. The neurological examination, selected laboratory studies, the success of treatment interventions, and repeated evaluation over time will eventually complete the diagnostic process. Effective management demands accurate diagnosis. The neuropsychiatrist must make an accurate behavioral assessment in order to identify and manage the underlying brain disorder.

The elements of a comprehensive mental status examination include observation of the dress and spontaneous demeanor of the patient, evaluation of mood, assessment of thought form (including formal thought disorder, obsessional thinking, perseveration, and others) and thought content (delusions, hallucinations, preoccupations, and others). This is followed by a more structured probing of cognitive domains that include attention, language, memory, visuospatial and constructional abilities, calculation, abstraction and judgment, and frontal-systems skills. Interview schedules and rating scales may be used to standardize and quantify the observations. Referral to a neuropsychologist or speech pathologist may be indicated for further testing of neuropsychological and communicative abilities. Table 2.1-1 provides an outline of a thorough mental status examination.

Table 2.1-1 Neuropsychiatric Comprehensive Mental Status Evaluation

In neuropsychiatric assessment, behavioral phenomena are explored and cognitive functions probed as a means of investigating brain function. Although complex behavior is a product of integrated brain activity, individual brain regions make specialized contributions to each human capacity and may produce recognizable syndromes when injured. Structured neuropsychiatric assessment of the major brain regions synthesizes the information into a comprehensive behavioral and etiological formulation. Cortical or subcortical, right hemisphere or left hemisphere, and anterior or posterior hemispheric location and emotional and cognitive dimensions are systematically evaluated.

Observational Assessment Even a casual interaction with the patient provides an opportunity for neuropsychiatric data collection. Patients with dementia, delirium, or frontal lobe syndromes may appear disheveled and unkempt whereas patients with schizophrenia-like illnesses or secondary mania may be eccentric or flamboyant. Patients with unilateral neglect following lateralized brain injury may ignore objects or people in one hemi-universe and fail to dress or groom one half of the body. Signs of incontinence may be evident in patients with frontal lobe syndromes or dementia. The patient's spontaneous demeanor may evidence anxiety (e.g., hyperthyroidism), impulsivity (e.g., orbitofrontal syndromes), or apathy (e.g., medial frontal lobe syndromes). Social interactions are revealing: patients with delusional disorders may be suspicious and establish poor rapport, patients with orbitofrontal dysfunction may be unduly familiar with the examiner, and patients with delirium or frontal lobe disorders may be disinhibited and distractible. Observing the patients' interactions with their spouses is critical: patients with dementias such as dementia of the Alzheimer's type (also called Alzheimer's disease) become increasingly dependent on their spouse for information and automatically turn to them for answers during the examination. Observation of the patient's affect may provide additional information. A variety of context-incongruent affects may be manifested by patients with brain dysfunction including jocularity, sadness, irritability, anger, affective lability, and perplexity. Each of these affective abnormalities may have diagnostic or localizing significance. Verbal output including speech (the mechanical aspects of communication) and language (the propositional content of communication) also provides diagnostic information. Abnormalities of speech include mutism, dysarthria, increased or decreased voice volume, stuttering, abnormal rate of speech, and disturbed speech prosody (loss of melody or inflection). Language disturbances in neuropsychiatric syndromes include aphasia (fluent or nonfluent), echolalia (echoing what the examiner says), and palilalia (repeating oneself). Patients with Tourette's disorder will have involuntary vocalizations ranging from subtle sighs, sniffs, grunts, and barks to shouting and coprolalia (swearing). A wide variety of diagnostically important motor behaviors may be evident during the examination, including movement disorders (tremor, chorea, parkinsonism, tics, myoclonus, tremor, gait abnormalities), compulsions, stereotypies, hyperactivity, or absence spells. Alterations of the patient's posture may also be diagnostically meaningful. Patients with Parkinson's disease have a flexed, stooped posture whereas patients with progressive supranuclear palsy have an extended, upright posture. Finally, the patient's psychomotor speed should be noted. Response latencies may be prolonged or the patient may interrupt the examiner impulsively, anticipating the question. Speech and movement may be slowed or executed with abnormal rapidity. Slowing of central processing is typical of subcortical neurological disorders, medial frontal syndromes, and depression. Patients with secondary mania or disinhibited orbitofrontal syndromes may have accelerated speech and increased motor activity.

Neuropsychiatric Interview The neuropsychiatric interview includes a more formal evaluation of the patient's mood and affect as well as thought form and thought content. The interview is conducted in the same way as a conventional psychiatric assessment, but a wider variety of phenomena may be observed in neuropsychiatry patients because of the expression of abnormalities resulting from the concomitant delirium, dementia, aphasia, or amnesia.

Disturbances of Mood *Mood* refers to an internally experienced pervasive emotion; *affect* is the outward emotional display. Mood disturbances commonly occur in the course of neurological disease. Depression is the most frequent mood disturbance, attending stroke, Parkinson's disease and other movement disorders, epilepsy, and multiple sclerosis. Patients often evidence depressive symptoms of sadness and feelings of hopelessness, helplessness, worthlessness, and guilt. Loss

of interest in work, hobbies, or recreational activities may be marked; patients may acknowledge loss of energy and fatigue. Associated disorders include insomnia (difficulty falling asleep, frequent nocturnal awakenings, early-morning awakening), alterations in appetite, loss of libido, and motor behavior changes (agitation, slowed movement and speech, reduced voice volume). Suicidal ideation may range from passive wishes for death to directed suicidal activities. Among neuropsychiatric illnesses, Huntington's disease and complex partial epilepsy have substantially increased suicide rates. Typical changes of affect accompanying depressed mood include tearfulness and sobbing, but the overall range of mood and affect may be reduced.

Euphoria, hypomania, or mania may also occur in neuropsychiatric disorders. Euphoria is most common with frontal lobe dysfunction (trauma, frontal lobe tumors, frontal lobe degenerative diseases, frontal infections) and with secondary mania. The patient with mania or hypomania may exhibit an elevated mood, undue optimism, inflated self-esteem, grandiosity, exaggerated confidence, and motoric hyperactivity. Distractibility, flight of ideas, racing thoughts, and pressured speech may be evident. Insomnia, increased appetite, and exaggerated libido may also occur.

Anxiety occurs in a variety of neuropsychiatric conditions including metabolic encephalopathies (e.g., hyperthyroidism, anoxia), toxic disorders (e.g., lidocaine toxicity), and degenerative disorders (e.g., Alzheimer's disease, frontotemporal dementia, Parkinson's disease). The patient exhibits excessive worry and apprehension, undue pessimism, and feelings of impending death or disaster. Somatic symptoms including palpitations, tachycardia, shortness of breath, lightheadedness, fleeting pains, dry mouth, nausea, diarrhea, and perspiration are often prominent. The patient may appear tense with furrowed brow and worried expression; tremor, tachypnea, pupillary dilatation, and restless fidgeting may be observed.

Mood lability is a disorder of mood regulation observed in neuropsychiatric syndromes. Patients may shift rapidly from sadness to jocularity. Typically, patients with marked lability are irritable and alternate among anger, apathy, and euphoria. The emotional outbursts are usually shortlived. Lability is common in patients with frontal lobe dysfunction or mental retardation. In the mood lability syndromes, mood and affect are congruent (i.e., the patient both feels anger and appears angry). On the other hand, the affective instability of pseudobulbar palsy is marked by incongruent mood and affect, as described below.

Mood and affect may be dissociated in neuropsychiatric disorders. Pseudobulbar palsy is a disorder of affect in which the patient's emotional expression is a gross exaggeration of or completely at variance with the patient's mood. The patient may weep in minimally sad situations or in the absence of an appropriate stimulus. Alternatively, the patient may laugh when sad or when no humorous event has occurred. The abnormal pseudobulbar affect is accompanied by the loss of other bulbar functions normally under supranuclear control and manifested by dysarthria, increased gag response, increased jaw jerk and facial muscle stretch reflexes, and facial weakness with hypomimia. Congruence between mood and affect should be explored in patients with neuropsychiatric illness, and the associated neurological signs of pseudobulbar palsy must be sought during the physical examination. In most cases patients with pseudobulbar palsy have bilateral lesions of the descending corticobulbar tracts. Common causes are cerebrovascular disease, multiple sclerosis, amyotrophic lateral sclerosis, traumatic brain injury, and brainstem or skull base tumors.

Disorders of Thought Form Formal thought disorders are less common than delusions as psychotic manifestations of neuropsychiatric diseases, but classic thought disorders have been observed in the schizophrenia-like illnesses accompanying epilepsy, Huntington's disease, and idiopathic basal ganglia calcification. Tangentiality, circumstantiality, loose associations, illogicality, derailment, and thought blocking may be observed. Flight of ideas occurs in secondary mania; circumstantiality is evident in some patients with temporal lobe epilepsy or alcohol-induced persisting dementia.

The thought form disorders common to neuropsychiatric conditions are perseveration, intrusions, and incoherence. *Perseveration* refers to the inappropriate continuation of an act or thought after its proper context has passed. *Intrusions* are late recurrences of words or thoughts from an earlier context. Perseverations and intrusions are seen in aphasias, frontal lobe syndromes, and dementing illnesses. *Incoherence* occurs when there is no logical association between words or ideas. Incoherence occurs in extreme cases of psychosis but is more common in delirium and cortical dementia such as dementia of the Alzheimer's type.

Disorders of Thought Content Many disorders of thought content may be observed in neuropsychiatric diseases. Delusions are the principal manifestation of psychosis in neurological disorders. A delusion is a false belief based on incorrect inference about external reality, and the delusion is firmly held in spite of evidence to the contrary. The most common types of delusions are persecutory beliefs involving the conviction of personal endangerment, theft of personal property, spousal infidelity, or entry by unwelcome strangers into one's home. Content-specific delusions such as *Capgras's syndrome* may also be observed in neurological illnesses, however, and the type of delusion is not helpful in distinguishing schizophrenia or other idiopathic psychotic illnesses from the delusions of neurological disease. Table 2.1-2 lists and defines the content-specific delusions that have been reported in neuromedical disorders with delusions.

Delusion	Content
Capgras's syndrome	A significant other (usually a family member) has been replaced by an identical-appearing imposter
Erotomanic (de Clerambault's syndrome)	The individual is secretly loved by another, usually someone of higher social or economic status
Dorian Gray	Others are aging while the individual appears to remain the same age
Persecutory (Fregoli's phenomenon)	A persecutor is able to assume the appearance of others
Doppelganger	The individual has a twin or second self
Delusional incubus or succubus	Demon or phantom sits on top of or has sex with the individual during sleep
Intermetamorphosis	Familiar persons takes on the appearance of tormentors
Lycanthropy (werewolfism)	The individual periodically turns into an animal (werewolf)
Jealous (Othello syndrome)	The individual's spouse is unfaithful
Parasitosis	The individual is infested with insects, worms, lice, vermin
Delusional phantom boarder	Unwelcome guests are living in the individual's home

Table 2.1-2 Content Specific Delusions Observed in Neuropsychiatric Disorders

Schneiderian first-rank symptoms are delusional experiences that include hearing one's thoughts spoken aloud, hearing voices arguing about oneself, hearing voices commenting on one's actions, having bodily sensations imposed from outside, attributing one's feelings to external sources, experiencing one's drive and actions as controlled from the outside, having one's thoughts inserted or withdrawn from the mind, broadcasting one's thoughts, and attributing special delusional significance to one's perceptions. Although most common in schizophrenia, first-rank symptoms have been reported in a number of neurological illnesses with schizophrenia/like manifestations including epilepsy, Huntington's disease, and idiopathic basal ganglia calcification.

Hallucinations are common manifestations of neuropsychiatric illness. They are sensory perceptions occurring without appropriate external stimulation of the relevant sensory organ. Hallucinations and delusions may occur together as elements of a psychotic process, or hallucinations may be recognized by the nondelusional patient as unreal. Hallucinations by themselves are neither necessary nor sufficient evidence of psychosis. Hallucinations may occur in any sensory modality, including visual, auditory, tactile (formication), gustatory, and olfactory. Somatic hallucinations are sensory experiences involving the patient's body and internal organs. Hallucinations may be formed, well-defined and recognizable sensations (e.g., visual hallucinations of people or animals; auditory hallucinations of voices) or unformed, elementary sensations (visual hallucinations of flashing light or colors; auditory hallucinations of unrecognizable noises).

Obsessions are another type of anomalous thought content. The patient experiences recurrent, intrusive thoughts, images, or impulses that are ego-dystonic and involuntary. The obsessional thoughts typically involve violent, sexual, or visceral-eliminative themes. Patients with obsessions frequently also have compulsions—repetitive, stereotyped behaviors that are recognized as senseless but cannot be resisted. Washing and checking compulsions are the most common, although nearly any action can be ritualized and become the object of compulsive repetition.

Depersonalization and *derealization* also are examples of altered thought content that refer to dissociative experiences. In derealization the patient may feel as if in a dream. Depersonalization is a state of altered experience in which the feeling of one's own reality is temporarily lost. There may be a loss of ability to experience emotion and a disturbed perception of time. Neuropsychiatric disorders to be considered in the differential diagnosis of depersonalization include epilepsy, migraine, encephalitis, and systemic metabolic disorders.

Mental Status Examination Systematic probing of the patient's mental state is a crucial part of neuropsychiatric assessment. Diagnostic hypotheses generated while taking the history and conducting the neuropsychiatric interview are further refined by mental status testing. The examination should be conducted methodically and should comprehensively assess the major domains of neuropsychological function (Table 2.1-1). Where possible, the examination should be quantified to facilitate

comparisons among patients and documentation of changes in the patient's function over time. The patient's age, handedness, educational level, primary language, and sociocultural background may all influence the mental status examination and should be determined prior to initiating the evaluation.

Alertness and Attention The patient's level of arousal and attention are evaluated by observation and testing. Levels of hypoarousal descend from drowsiness to obtundation, stupor, and then coma. The *drowsy* patient is fatigued and falls asleep when unstimulated. *Obtundation* is a state of moderately reduced alertness with slow responses and diminished interest in the environment. *Stupor* is the next most severe level of impaired consciousness. Stuporous patients must be vigorously stimulated to be aroused and engaged in conversation. Stupor returns when stimulation ceases. *Coma* is state of unarousable unresponsiveness. Comatose patients have no psychological response to external stimulation or internal needs. Impaired arousal occurs in toxic-metabolic encephalopathies, increased intracranial pressure, large strokes, encephalitis, and traumatic brain injury. Alternately, *hyperarousal* with anxiety, autonomic hyperactivity (tachycardia, tachypnea, hyperthermia), and exaggerated startle responses may occur in metabolic disorders, particularly during withdrawal from alcohol, opiates, or sedative-hypnotic agents.

Stupor must be distinguished from akinetic mutism, locked-in syndrome, and catatonic unresponsiveness. *Akinetic mutism* is a state of silent, alert-appearing immobility. The patient's eyes are open and may follow environmental events; there are regular sleep-wake cycles. The patient may be completely inert or may have occasional brief movements to adjust posture spontaneously or in response to vigorous stimulation. The disorder has occurred with large frontal lobe injuries, bilateral cingulate gyrus damage, and midbrain pathology. *Locked-in syndrome* occurs with bilateral pontine lesions that render the patient mute and paralyzed. Intellectual function, however, is not impaired and the patients can communicate by eye movements or eye blinks (e.g., blinking once for “yes” and twice for “no”). In *catatonic stupor* the patient is mute and motionless. A psychological pillow and waxy flexibility may be elicited. Brief impulsive acts may punctuate the catatonic period. Catatonia occurs in a wide variety of neurological, toxic-metabolic, and psychiatric disorders including frontal lobe syndromes, hypoglycemia, schizophrenia, and depressive disorders.

Attention is impaired in disorders of arousal but may also be abnormal in patients who are fully alert. Delirium and acute confusional states are characterized by abnormal attention in alert patients. Two types of tests are particularly useful in detecting compromised attention: *forward digit span* and *continuous performance tests.* In testing digit span, the patient must repeat increasingly long series of numbers spoken aloud by the examiner. The numbers are given at a rate of one per second in a monotone voice. A normal forward digit span is seven digits long; fewer than five is abnormal and indicates impaired attention. Sustained attention is evaluated by a continuous performance test such as the “A” test, in which the clinician says a series of random letters at a rate of one per second. The patient is asked to signal each time the letter “A” occurs. The test continues for 1 minute and assesses the patient's ability to sustain concentration over time. Distractible patients make errors of omission, failing to detect one or more of the *A*s. Individuals with normal attention perform the test perfectly. Acute confusional states and impaired attention are usually indicative of a toxic or metabolic disorder but also occur with increased intracranial pressure, frontal lobe disorders, or focal lesions of the posterior right hemisphere.

Mental control tests are tasks that require intact attention but also depend on other intellectual resources. Serial subtractions, spelling words backwards, reverse digit span, and reciting the days of the week or months of the year in reverse order are examples of tests used to investigate mental control; both the accuracy and the speed of performance are observed. Attention, language, frontal lobe functions, and calculation skills contribute to mental control abilities. When instrumental functions (language, calculations) are intact, impaired mental control is usually indicative of a frontal systems disorder.

Impaired attention conditions all aspects of behavior and intellectual function. Patients who are drowsy or in acute confusional states will perform badly on comprehension, repetition, drawing, and calculation tests because of the inability to sustain attention. In general, conclusions regarding a potential underlying dementia or memory disturbance cannot be drawn while the patient is in a confusional episode. Management efforts are directed to controlling the associated disorder and restoring attention; reexamination will then reveal the baseline mental condition.

Memory Aspects of memory to be assessed in the course of mental status examination include learning, recall, recognition, and memory for remote information. Learning, recall, and recognition can be assessed in both verbal and nonverbal domains.

Inquiring about personal orientation is one means of assessing recent memory. Temporal and spatial orientation must be continuously updated and patients with memory abnormalities may fail to establish the current day, date, or place. Orientation to self is rarely lost and has little value as a memory test.

Word-list memory tests are a common means of assessing learning, recall, and recognition. The patient is given three words to remember and then is asked to recall them 3 minutes later. The examiner notes how much difficulty the patient has in learning the three words initially and how many times the words must be presented before the patient can repeat all three. A few minutes later, the patient is asked to remember the three words. If he or she can do so, the performance is normal. If the words cannot be remembered, the patient is given clues (e.g., the category of items to which the word belongs or a multiple-choice list of words containing the target and several foils) to distinguish between storage and recall deficits. Patients with encoding or registration deficits (e.g., amnesia) will not find prompting and clues helpful; patients with intact storage but impaired retrieval (e.g., patients with frontal-subcortical circuit disturbances) are aided by these maneuvers. Memory performance patterns are often more rigorously elicited with a ten-word list rather than a three-word list.

Nonverbal memory can also be tested to distinguish between encoding and access impairments. Patients are asked to copy several figures (usually as part of the constructional task described below); a few minutes later the patients must reproduce the drawings from memory; if they cannot spontaneously remember the drawings, the patients may choose from a group of figures containing the targets and several foils. Patients who cannot recognize the original drawings have a nonverbal encoding disturbance as part of an amnestic disorder; patients who cannot recall the drawings but are able to recognize them within a group of stimuli and foils have a nonverbal memory access abnormality resulting from a frontal-subcortical circuit disorder.

Remote memory testing evaluates the patient's ability to remember events and individuals of the remote past. This aspect of memory function may be gauged while taking a history of the patient's illness, by inquiring about the patient's significant life events (e.g., dates of marriage, birth dates of children), and by asking about political leaders and important historical events. Although remote information is not stored in specific focal brain areas and recall failures do not provide localizing information, the temporal profile of remote memory may be diagnostically revealing. Amnestic disorders are characterized by a period of anterograde amnesia following the onset of the disorder (this may continue indefinitely if the patient fails to recover or time-limited if memory function returns), a period of retrograde amnesia extending backwards in time for a few seconds to a few years from the time of onset of the amnesia, and intact remote recall for material beyond the period of the retrograde amnesia. Patients with dissociative amnesia usually complain of profound retrograde but not anterograde amnesia. Patients with Alzheimer's disease demonstrate a temporal gradient, progressively losing the episodic memories from more recent to more remote.

Language Language assessment includes observing the patient's spontaneous speech and testing language comprehension, repetition, naming, reading, and writing. Abnormalities of language must be distinguished from disorders of speech *(dysarthria)*, abnormalities of inflection and melody *(aprosodia)*, and absence of linguistic output *(mutism).* Language-related abilities that may be evaluated include speech prosody, automatic speech, singing, and right-left orientation. Language disturbances are usually observed in the course of taking the history and conducting the neuropsychiatric interview, and these patients will require the most detailed testing. When the verbal exchange has been unremarkable, testing of a few difficult items of the major linguistic categories is adequate to establish normal language function.

Spontaneous speech reveals abnormalities of thought and language and the two types of abnormalities must be carefully distinguished. Disorders of thought form and content have been discussed above. Aphasic disturbances of spontaneous verbalization are characterized as fluent or nonfluent. *Fluent aphasias* feature normal or excessive amounts of speech, normal phrase length with complex sentence structures, preserved speech melody, no dysarthria, a paucity of information content with excessive dependence on words of indefinite reference such as “thing” and “it,” and paraphasic errors. Paraphasias may involve the substitution of one phoneme for another (e.g., “nook” for “book”) in phonemic (literal) paraphasias; the replacement of one word with another in verbal (semantic) paraphasias; or the construction of new words in neologistic paraphasias. *Nonfluent aphasias* exhibit essentially the opposite features of fluent aphasias. The patients have reduced verbal output, shortened phrase lengths or one-word replies, agrammatism with a tendency to omit the syntactic functor words (e.g., “and,” “but,” “the”), increased articulatory effort and impaired speech initiation, reduced speech melody, and dysarthria. There are few or no paraphasias and information content is relatively normal. Inflection of the remaining limited verbal output may be preserved. The individual aphasia syndromes are described below.

Language comprehension is tested by asking the patient to follow verbal commands, respond to “yes” and “no” questions, or decipher complex linguistic constructions. The easiest commands are one-step orders involving whole body responses such as “stand up” and “turn around.” Next in order of difficulty are single-step commands involving midline body parts such as “open your mouth,” “close your eyes,” and “stick out your tongue.” Pointing to room objects and body parts assesses the next level of comprehension. Patients are asked to point to one, two, or three objects visible in the examination room (e.g., “point to the ceiling, then to the floor, then to the desk”) or to one, two, or three body parts (e.g., “point to your nose, then to your shoulder, then to your knee”). Pointing to objects in an array of items laid in front of the patient presents a igher level of difficulty for most patients than sequential pointing to room objects or body parts. An array such as a comb,

pen, coin, and keys is provided, and the patient is asked to point to several of the items in turn (e.g., “point to the keys, then to the comb, then to the pen”). Each time the test is repeated, the item order is changed. Pointing tasks may be made more difficult by asking the patient to point to an item that is described rather than named (e.g., “point to the entrance to the room” or “point to the source of illumination”). Pointing is impossible for some patients because of paralysis or apraxia, and “yes” and “no” questions may be used to minimize the motor demands of the task. These may range from easy (e.g., “are the lights on in this room?”) to modestly difficult (e.g., “do you put our shoes on before your socks?”). Finally, complex questions such as “Is my wife's brother a man or a woman?” or “if a lion is killed by a tiger, which animal is dead?” allow the examiner to determine if the patient can follow complex linguistic formulations. Impaired comprehension usually implies dysfunction of posterior structures of the dominant or left hemisphere. Comprehension is abnormal in many aphasic syndromes, dementia, and delirium.

Repetition is assessed by asking the patient to repeat increasingly long phrases or sentences beginning with a single word and progressing to sentences eight to ten words in length (e.g., “the quick brown fox jumped over the lazy dog”). Abnormalities include omissions and paraphasic substitutions. The repetition span will typically be one or two words longer than the digit span, and patients with shortened digit spans will be able to repeat only brief phrases. Conversely, the digit span is a repetition test, and patients with repetition disturbances (e.g., several of the aphasias) will have abnormal digit spans.

Assessment of naming involves asking the patient to name objects and parts of objects, body parts, pictures or drawings of objects, and colors. Naming is compromised systematically with impairment of rarely used low-frequency words impaired prior to commonly used high-frequency words. Thus, a thorough language examination must include naming of low- and high-frequency words. As a rule of thumb, objects are of higher frequency than the parts of the objects (e.g., “wristwatch” is a more common word than “watchband” or “crystal,” and “glasses” is a higher-frequency word than “lens” or “frame”). Error types include failure to respond, production of paraphasic errors, and circumlocutory responses where the patient describes the object or its use but does not name it. Anomia occurs in aphasias, dementias, and deliria. Adequate vision must be ensured before errors are ascribed to naming deficits.

Evaluation of reading entails assessment of the patient's ability to read aloud and to comprehend what is read. These two aspects of reading may be impaired independently. The most elementary assessment of reading involves asking the patient to read aloud and point to an object the name of which has been written (e.g., “nose” or “door”). Comprehension of more complex written material is evaluated by asking the patient to read and follow written commands (e.g., “raise your right hand”) or to read and fill in the blanks in incomplete written sentences (e.g., “a man who repairs cars and trucks is known as a _____”). Again, adequate vision must be demonstrated before failures are ascribed to an alexia. Abnormalities of spontaneous speech are usually recapitulated in reading aloud, and deficits in reading comprehension typically co-occur with disturbances of comprehension of spoken language. In some cases—alexia with agraphia, alexia without agraphia, and simultanagnosia—reading abnormalities occur in patients without aphasic disturbances.

Writing may be disturbed on a mechanical or aphasic basis. Mechanical agraphias occur in patients with limb paresis, limb apraxia, or movement disorders such as tremor and chorea. Micrographia is a characteristic aspect of parkinsonism in which the script becomes progressively smaller as the patient writes a sentence or extended series of numbers or letters. Aphasic agraphias accompany aphasic syndromes and the same types of errors noted in verbal output are reproduced in written form. For example, patients with Broca's aphasia have impoverished agrammatic output, whereas those with Wernicke's aphasia have fluent paraphasic writing. Agraphia occurs without aphasia in Gerstmann's syndrome (agraphia without alexia, acalculia, right-left disorientation, finger agnosia), alexia with agraphia, and callosal agraphia (left-handed agraphia in patients with injury of the corpus callosum). Agraphia also occurs in dementia and is a sensitive index of the attentional deficit in delirium.

Word-list Generation Word-list generation tasks involve asking the patient to think of as many members of a specific category (category fluency) or as many words beginning with a specific letter (semantic fluency) as possible in 1 minute. Typically, the patient is asked to produce as many animals names as possible in 1 minute or is asked to think of as many words beginning with the letter “F” as possible in 1 minute (excluding numbers, proper names like France or Frank, and repetitions of words with the same core such as *fix, fixed, fixing*, and *fixation*). Normal individuals produce between 12 and 24 animals names in 1 minute (mean: 18, less than 12 is abnormal) and between 10 and 20 words beginning with the letter “F” (mean: 15;less than 10 is abnormal). Word-list generation is sensitive to anomia and word-finding disturbances, lexical search abnormalities associated with frontal-subcortical systems dysfunction, and psychomotor retardation.

Visuospatial Skills There are a number of visuospatial abilities including spatial attention, perception, construction, visuospatial problem solving, and visuospatial memory. Constructional tasks are the most widely used screening tests of visuospatial ability. Clock drawing and copying figures of increasing complexity are useful assessment techniques. In the clock drawing test, the patient is asked to draw a clock and fill in the clock numbers; when that task is complete, the patient is asked to draw in the clock hands to indicate that the time is 10 minutes after 11 o'clock. Patients with poor planning skills will draw a clock face that is too small to conveniently contain the required numbers or may space the numbers inappropriately. Patients with unilateral neglect will ignore half of the clock face. Patients with frontal lobe disorders may have stimulus boundedness and will place one hand on the 10 and one on the 11 when attempting to set the clock for 10 minutes after 11:00.

Tests of copying begin by having the patient reproduce an elementary shape such as a circle; then the patient is asked to copy two or three more challenging figures (e.g., intersecting circle and triangle, overlapping pentagons, cube). Abnormalities include distortions of size, failure to reproduce the shapes accurately, absence of perspective, perseveration on individual elements, drawing over the stimulus figure, or unilateral neglect. Hemi-neglect is a valid indicator of contralateral brain injury, but other types of constructional abnormalities do not have precise localizing value. Injury of the posterior aspect of the right hemisphere produces the most severe and most enduring visuospatial deficits, but dysfunction of frontal, occipital, or parietal lobes of either hemisphere (cortical or subcortical) can adversely affect drawing abilities. Preliminary evidence suggests that the two hemispheres have complementary roles in constructional abilities—the right hemisphere mediates the external configuration whereas the left hemisphere mediates the internal details (Fig. 2.1-1). Drawing disturbances are common with focal brain damage, degenerative disorders, and toxic and metabolic encephalopathies. The term “drawing apraxia” is avoided here; *apraxia* is applied to disorders characterized by an inability to do on command tasks that can be performed spontaneously. Using this definition, drawing disturbances are not apraxias.

FIGURE 2.1-1 Hemineglect. A patient with a right middle cerebral artery infarct was asked to draw a flower. The placement of all features of the flower on the right side demonstrates left hemineglect.

Calculation Calculation skills tested on mental status examination include addition, multiplication, subtraction, and division. Higher-order mathematical skills are not assessed except in specific circumstances where premorbid mathematical abilities are well documented and the examiner is mathematically sophisticated. Patients are asked to perform one- and two-digit tasks (e.g., 16 + 32, 15 × 3) mentally or to address more demanding problems with the aid of pencil and paper. Calculation abilities are determined by the individual's education and occupational history. Acalculias occur in aphasic syndromes where aphasic substitutions of one digit for another lead to inaccurate answers, visuospatial disorders leading to incorrect alignment of columns of numbers, and primary anarithmetias where basic mathematical processes are disrupted. Anarithmetias occur with damage to the posterior aspect of the left hemisphere.

Abstraction Abstracting skills refer to the patient's ability to derive a general principle from a specific example. Similarities, differences, idioms, and proverbs are used to assess abstracting capacity. Similarities require the patient to identify the class or category of which two items are members (e.g., rose and tulip, bicycle and train, watch and ruler). Differences require the patient to identify the salient distinguishing feature between two similar items (e.g., child and midget, canal and river, lie and mistake). Idioms are metaphorical statements or aphorisms that require the patient to generalize to a larger meaning (e.g., “seeing eye to eye,” “level headed,” and “eyes peeled”). Proverbs are usually double metaphors that require the patient to ignore the immediate meaning and derive a lesson or maxim (e.g., “don't cry over spilled milk,” “people who live in glass houses shouldn't throw stones,” “the tongue is the enemy of the neck”). Success on abstraction tasks depends on the individual's level of education. In addition, these tests are culturally biased and proverbs from the individual's own culture must be used to make a valid assessment of

abstraction abilities. Abstraction is sensitive to many types of brain dysfunction and task failure is a nonspecific indicator of cerebral dysfunction. Abstraction deficits are particularly common with frontal systems disorders.

Judgment and Insight Assessing judgment is an important aspect of mental status testing. It should be done so as to yield ecologically valid results that meaningfully relate to the individual's everyday decisions. Questions regarding the patients' insight into their own conditions, their plans for the future, and their understanding of their own limitations best demonstrate their insight and judgment. Questions such as “What would you do if you were walking beside a lake and saw a 2-year-old child playing alone at the end of a pier?” also help to explore the patient's interpersonal and social judgment. Judgment is impaired in many neurological conditions. Orbitofrontal damage produces particularly marked alterations in social judgment.

Frontal-Subcortical Systems Tasks Frontal-subcortical systems tests assess the integrity of a complex circuitry involving the frontal cortex, caudate and thalamic nuclei, and the connecting white matter tracts. Frontal-subcortical functions are among the most difficult to examine either with bedside techniques or formal neuropsychological measures. Some areas of the frontal lobe such as the orbitofrontal cortex produce few identifiable cognitive changes when injured but have major behavioral ramifications with obvious disinhibition and impulsiveness. The principal abnormalities that are observed in patients with frontal-subcortical systems dysfunction include perseveration, motor programming deficits, apathy, poor word list generation, impaired set maintenance, abnormal recall with preserved recognition memory, stimulus boundedness, concrete interpretation of proverbs, imitation of actions of the examiner, and impulsive responses to environmental events.

Motor programming tasks sensitive to injury to the convexities of the frontal lobe and related subcortical structures include alternating programs (Fig. 2.1-2) (e.g., alternating shapes or Ms and Ns in series are copied from a sample provided by the examiner and then extended across a page of paper), reciprocal programs (e.g., the patient holds the right hand in a fist close to his or her own face and extends the left, making a ring with the thumb and first finger, then the positions are repeatedly reversed), and the go-no go test (e.g., when the examiner taps under the table once, the patient taps twice; when the examiner taps twice, the patient makes no response). Another task, copying multiple loop figures, often elicits perseveration (Fig. 2.1-3). Execution of serial hand sequences frequently is disrupted in patients with frontal-subcortical systems abnormalities. In this task, the examiner demonstrates a sequence of three hand positions (e.g., fist, slap, side of hand) and the patient is asked to learn and perform the sequence. If the patient fails, the patient is then asked to say aloud “fist, slap, side.” If the patient fails to guide the hand sequence correctly despite learning the verbal progression, verbal-motor dissociation and hence frontal-subcortical dysfunction is implicated.

FIGURE 2.1-2 Alternating programs. The examiner's model is above, the patient's attempt to duplicate the pattern is below. Failure to alternate between the two shapes is evident.

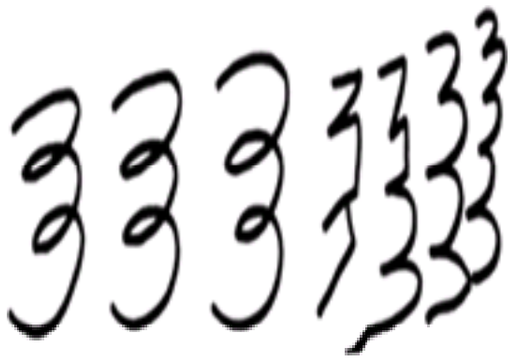

FIGURE 2.1-3 Multiple loops. The three figures on the left were drawn by the examiner. When the patient attempts to copy the figures, perseveration with production of additional loops is demonstrated.

Difficulty maintaining a mental set and limitations in appropriately shifting between tasks also is typical of patients with frontal-subcortical systems dysfunction. Tests to elicit these deficits include trail-making tests (e.g., asking the patient to sequentially alternate between numbers and letters—1-A-2-B-3-C, and so on) and card sorting tests (e.g., the Wisconsin Card Sorting Test) where the patient sorts cards according to a series of criteria designated by the examiner such as color, shape, or number. The patient must discover and apply the sorting criteria through trial-and-error observations. These tests are typically administered and interpreted by neuropsychologists.

Environmental dependency and poor response inhibition can be demonstrated in patients by creating situations with competing demands. One such neuropsychological test (e.g., the Stroop Test) involves writing the name of a color in a different color (e.g., writing the word “blue” in the color red) and asking the patient to ignore the color name and read the color of the print. Patients with frontal-subcortical systems deficits often cannot inhibit the tendency to read the word rather than state the color.

In addition to these more specific frontal systems tests, poor abstracting abilities, stimulus boundedness on clock drawing tests, poor word-list generation, and adopting poor strategies when drawing complex figures (Fig. 2.1-4) aid the examiner in recognizing a frontal-subcortical systems disturbance. These deficits are common in patients with head trauma, frontal lobe degenerations, frontal lobe neoplasms, chronic multiple sclerosis, Huntington's disease and other basal ganglia disorders, multiple subcortical infarctions, and some brain infections such as syphilis.

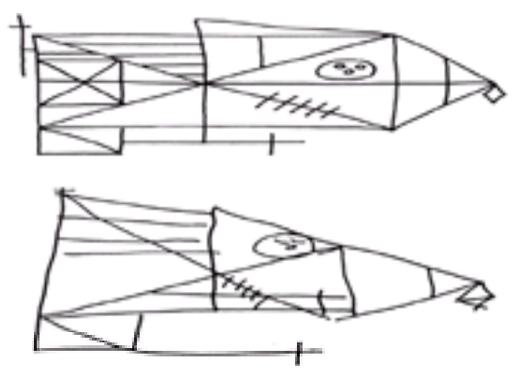

FIGURE 2.1-4 Rey-Osterreith Figure. The figure above was drawn by the examiner; the figure below is an attempt to copy the modal by a patient with frontal lobe

dysfunction.

Miscellaneous Tests A variety of miscellaneous tests may aid diagnosis or localization when added to the mental status examination in specific circumstances. Testing of praxis, prosody, right-left orientation, finger identification, singing, automatic speech, and visual recognition are among these specialized tasks. *Ideomotor apraxias* are abnormalities of learned motor behavior that occur in the absence of motor, sensory, or comprehension deficits and involve motor tasks that the patient can perform spontaneously but cannot execute on command. Apraxis of limbs and buccofacial structures may be detected. Limb commands include performing an action that ordinarily requires no object (e.g., thumb a ride, wave goodbye) or may involve pantomiming the use of an object (e.g., throw a ball, hammer a nail). Typical oral-lingual commands include pretending to blow out the flame of a burning match, coughing, licking the lips, and pretending to sniff a flower. Failures may involve substituting the limb for the imaginary object (e.g., using the hand for the hammer instead of pretending to hold the hammer) or, in more severe cases, simply failing to perform the act adequately. Ideomotor apraxias of the type described here occur with lesions of the left hemisphere or corpus callosum.

Aprosodias are disorders of speech melody and inflection. They assume particular importance in neuropsychiatry because prosody is the means by which emotion is communicated and any disruption of this mechanism impairs the patient's ability to relay his emotional state. Executive aspects of prosody are tested by having the patient inflect a neutral sentence (e.g., “I'm going to the store”) to provide a variety of different meanings such as anger, happiness, and surprise. Prosodic comprehension is assessed by having the patient guess the emotion when the same or a similar neutral test phrase is differentially inflected by the examiner. Executive prosody is disrupted by lesions of the right premotor cortex or the basal ganglia, receptive prosody is impaired by lesions of the posterior superior right temporal lobe (equivalent of Wernicke's area in the right hemisphere).

Disturbances of *right-left orientation* and *finger identification* occur in conjunction with agraphia and acalculia as part of *Gerstmann's syndrome.* Right-left orientation is assessed by asking the patients to point to their own body parts using various combinations of right and left (e.g., “Point to your right shoulder”; “With your right hand, touch your left knee”). If they perform these less demanding tasks accurately, they are asked to point to specific parts of the examiner who is seated facing the patient. The patient is thus required to perform a mental reversal to correctly respond to the commands (e.g., “Which is my right hand?” “Where is my left shoulder?”). The examiner may make the task more difficult by crossing his own hands, thus requiring another reversal by the patient. Finger identification is also tested with a hierarchy of increasingly complex tests. At the most elementary level, the patients are asked to name each finger (e.g., thumb, forefinger, middle finger, ring finger, pinkie or little finger). If the patients are able to perform, they are asked to point to the equivalent finger of one hand while the examiner touches a finger of the other hand held out of sight above the patient's head. Another taxing test of finger identification involves having the patients close their eyes and then state how many fingers are between the fingers of one hand touched by the examiner (e.g., if the examiner touches the thumb and pinkie, there are three fingers between). Gerstmann's syndrome occurs with lesions of the left angular gyrus. All four components must be present for the syndrome to have localizing significance.

Singing and *automatic speech* may be useful adjuncts in language assessment, particularly in the patient with very limited verbal output. In some cases, patients who are mute and incapable of propositional speech nevertheless are able to sing. This occurs in extrapyramidal syndromes such as advanced Parkinson's disease and in patients with nonfluent aphasias. Automatic speech refers to recitation of overlearned sequences such as the alphabet, days of the week, months of the year, nursery rhymes, or prayers. Automatic speech, like singing, may be preserved when little other verbal output can be demonstrated. Preserved automatic speech despite severely impaired spontaneous verbal output is characteristic of *isolation aphasia* (also known as *mixed transcortical aphasia*) and may also be demonstrable in patients with mental retardation syndromes and advanced dementias.

Visual recognition skills may be compromised by specific lesions of the nervous system. Visual perception is intact and naming skills are normal but the patient cannot recognize the object, place, or person. When there are visual complaints, recognition of objects, places, and faces should be tested. *Visual object agnosia* occurs with bilateral lesions of the inferior longitudinal fasciculi or adjacent cortex of the medial occipito-temporal regions. The patients can see the objects, have intact language skills, and can accurately identify the objects by palpation but cannot identify them visually. *Prosopagnosia* refers to impaired recognition of familiar faces. The patient can tell that faces are not identical but cannot recognize familiar individuals such as friends, family members, and celebrities. Auditory recognition skills are intact and the patient will recognize familiar individuals by their voices. Prosopagnosia can occur with lesions limited to the right posterior hemisphere, but many patients have bilateral posterior hemispheric injuries. *Environmental agnosia*, the inability to recognize familiar places such as the patient's own home, may accompany prosopagnosia. *Phonagnosia* refers to the inability to recognize familiar voices, and *auditory agnosia* involves the loss of recognition of all sounds. Stroke is the most common cause of all types of agnosia.

NEUROLOGICAL AND PHYSICAL EXAMINATION

The neurological examination consists of assessment of cranial nerves, motor systems, sensory abilities, muscle stretch reflexes, and primitive reflexes. The findings of the neurological examination are augmented by selected aspects of a general physical examination. The details of the neurological and physical examinations are well described elsewhere and will not be recapitulated here, but the observations most useful in neuropsychiatric assessment are reviewed.

Cranial Nerve Examination Function of the *cranial nerve I (olfaction)* is tested by asking the patient to identify a variety of distinctive odors (e.g., perfume, coffee, chocolate, soap, spices). Requiring patients to close their eyes during the testing will help to ensure that olfaction *per se* is being assessed. The olfactory nerves, bulbs, and tracts are located on the inferior service of the frontal lobe where they are vulnerable to damage by contusions in the course of close head trauma and compression by subfrontal tumors. Olfaction may also be compromised by smoking, sinusitis with rhinitis, and nasal trauma.

Examination of *cranial nerve II (optic)* includes visual inspection of the nerve head, assessment of visual acuity, and mapping of the visual fields. The optic nerve is the only nerve directly accessible to visual inspection by the examiner. By means of ophthalmoscopy, the clinician can detect optic atrophy (a pale disc), papilledema reflecting increased intracranial pressure, or papillitis associated with optic nerve ischemia or inflammation. Macular degeneration, pigmentary retinopathy, retinal infarction, narrowing of retinal vessels, and retinal hemorrhages or exudates may be seen. Visual acuity is tested with a Snellen chart held 18 inches from the face: each eye is tested separately with glasses or pin hole to minimize visual disturbances produced by abnormalities of the shape of the optic globe (astigmatism). Acuity should be correctable to 20/20 if optic nerve function is normal. Impaired acuity after correction implies the presence of prechiasmatic optic nerve dysfunction such as ischemic optic neuritis or inflammation associated with multiple sclerosis or other inflammatory disorder. Papilledema creates an enlarged blind spot but does not impair visual acuity in the remaining visual fields. Visual field defects are identified by covering one of the patient's eyes and comparing the patient's visual field to that of the clinician's by determining when the patient detects a stimulus (moving finger or small stimulus item) entering the visual field from the periphery. The shape of the visual field is determined by repeating this maneuver in all quadrants. Homonymous visual field defects do not disturb visual acuity. Bilateral double simultaneous visual stimulation allows detection of visual neglect: if the patient has full visual fields with monocular testing but extinguishes stimuli in one hemi-field during double simultaneous stimulation, then a neglect syndrome is present. Damage to the optic nerve will produce a monocular visual field defect of the ipsilateral eye. Postchiasmatic injury between the optic chiasm and the occipital lobe usually produces a homonymous visual field defect. Occipital injuries produce highly congruent field defects of similar size and shape in both fields, whereas more anterior lesions (e.g., damage to the geniculocalcarine radiation in the temporal lobe) produce incongruent field defects. Midline tumors in the region of the optic chiasm such as craniopharyngiomas or chromophobe adenomas may compress the chiasm medially, producing a bitemporal visual field defect. Impaired vision of any cause may be associated with release hallucinations (formed or unformed visual hallucinations occurring in the blind field). Visual neglect occurs most often with lesions of the parietal cortex but has also been reported with frontal lobe and subcortical lesions.

Ocular motility, pupillary responses, and eyelid position are mediated by *cranial nerves III, IV, and VI* (*oculomotor, trochlear, and abducens*, respectively). The rectus externus moves the eye laterally and is mediated by the abducens nerve; the superior oblique moves the eye downward when the globe is in the adducted position and is mediated by the trochlear nerve; all the remaining ocular movements, the pupillary responses, and position of the eyelid are determined by oculomotor nerve function. Pursuit movements are tested by having the patient follow the examiner's finger through seven positions (adduction, adducted and up, abducted and up, abducted, abducted and down, adducted and down, convergence). The patient's saccades (volitional movements) are then tested by asking the patient to look to the right, left, up, and down without following a visual target. Conjugate gaze is mediated by gaze centers in the pons (lateral movements) and the midbrain (vertical movements). Brainstem lesions, extrapyramidal movement disorders (e.g., Parkinson's disease and Huntington's disease), and bilateral upper motor neuron lesions may produce supranuclear gaze palsies manifested by incomplete ocular movements, hypometric (abnormally small) saccades, and irregular pursuit movements. Pupillary changes occur in response to light stimulation and in conjunction with convergence (constriction of the pupil with near vision). Cranial nerve III is responsible for pupillary constriction through its parasympathetic branches whereas pupillary dilatation is a function of the sympathetic nervous system. Lid position is determined by the balanced input from the third nerve responsible for volitional eye opening, the seventh cranial nerve mediating lid closure, and sympathetic input that also participates in keeping the lid open. Pupillary abnormalities occur with brainstem lesions, syphilis (*Argyll-Robertson pupil*, in which the reaction to light is lost while the convergence-accommodation mechanism is intact), diabetes, and compression by aneurysms or other mass lesions. Third-nerve palsy results in ptosis, a nonreactive

pupil, and an inability to adduct, elevate, or depress the eye. Lid retraction may occur with lesions of the collicular plate or in parkinsonian syndromes. Horner's syndrome includes ptosis, pupillary constriction, and diminished sweating on the ipsilateral side of the face. It results from sympathetic paralysis caused by lateral medullary infarcts, cervical cord lesions, pulmonary apical or mediastinal lesions, or neck trauma.

The *cranial nerve V (trigeminal)* innervates the muscles of mastication and is responsible for facial and corneal sensation. The fifth cranial nerve is involved in tic doloreux and other facial pain syndromes.

Cranial nerve VII (facial) supplies the facial musculature including the platysma muscles of the anterior neck, orbicularis oris and buccinator muscles, orbicularis oculi, and the frontalis. In addition, its branches innervate the lacrimal and salivary glands, muscles of the stapedius, and taste fibers of the anterior two thirds of the tongue. Fibers supplying the upper facial muscles receive supranuclear input from ipsilateral and contralateral motor cortex, whereas fibers innervating the lower facial muscles receive only contralateral input. Thus, peripheral nerve lesions result in ipsilateral paralysis of upper and lower face whereas upper motor neuron lesions above the level of the seventh nerve nucleus produce only contralateral lower facial paresis. All human faces are asymmetrical and facial asymmetry by itself should not be regarded as evidence of paresis; asymmetries, however, can result from weakness and their detection should lead to careful testing for evidence of muscle paresis. The facial nerve receives input from both descending pyramidal neurons mediating volitional movements and nonpyramidal limbic system connections mediating emotional responses. This dual innervation results in the preservation of emotional responses in spite of paralysis of volitional facial movements in patients with pyramidal tract lesions (most evident in the syndrome of pseudobulbar palsy) and a lack of emotional facial responses with intact volitional movements in patients with lesions of the limbic system. The latter has been observed, for example, in patients with seizure foci arising from lesions of the temporal lobes. The facial musculature is involved in generalized movement disorders (e.g., chorea, tics, parkinsonism), which are discussed below.

The *cranial nerve VIII* is responsible for hearing (*auditory branch*) and balance (*vestibular branch*). Auditory compromise is associated with deafness and can produce auditory hallucinations. Vestibular end organ or nerve lesions produce nystagmus and vertigo and, when acute, may be associated with the experience of sudden shifts in the environment (e.g., vertical inversion). Vestibular nystagmus is horizontal or combined horizontal-rotatory and is typically accompanied by vertigo and nausea. Lesions disrupting vestibular connections in the central nervous system can produce nystagmus in any direction and are usually not associated with vertiginous or nauseous sensations. Vestibular nystagmus should be distinguished from gaze-paretic nystagmus resulting from inadequate ocular deviation and occurring with paresis of cranial nerves III, IV, or VI. The quick or jerk phase of gaze-paretic nystagmus occurs in the direction of the weakened muscle. Nystagmus also occurs with a variety of medications, particularly anticonvulsant and sedative-hypnotic drugs. Table 2.1-3 presents the differential diagnosis of nystagmus and related disorders of ocular movement.

Table 2.1-3 Types of Nystagmus and Related Ocular Movements

Cranial nerves IX and X (*glossopharyngeal and vagus*, respectively) control pharyngeal and laryngeal function, taste, and the gag reflex. The glossopharyngeal nerve conveys sensory information (including taste sensation from the posterior third of the tongue) and the vagus nerve is primarily responsible for the motor aspects of these structures. Dysfunction of the vagus nerve results in a hoarse voice or aphonia and dysphagia. Supranuclear lesions in the syndrome of pseudobulbar palsy produce an exaggerated gag reflex.

Cranial nerve XI (*spinal accessory*) innervates the upper half of the trapezius muscle and the sternocleidomastoid muscle. *Cranial nerve XII* (*hypoglossal*) innervates the tongue; tongue weakness is common in pseudobulbar palsy.

Motor System Examination Motor system examination includes assessment of muscle bulk, strength, and tone as well as tests of coordination and identification of movement disorders. Normal motor function depends on the functional integrity of the pyramidal motor system, extrapyramidal nuclei, cerebellum, spinal cord, peripheral nerve, myoneural junction, and muscle. Assessment of the motor system is particularly important in neuropsychiatry; psychiatric disturbances frequently produce associated motor system manifestations, movement disorders are often accompanied by neuropsychiatric abnormalities, and many of the agents used to treat psychiatric diseases adversely affect motor system function.

Muscle *bulk* is examined by visual inspection and palpation and occasionally by measurement. The dominant limbs, particularly the upper extremity, have slightly greater bulk than the nondominant extremity. Muscle wasting may occur with volitional disuse, muscle disease, nerve or spinal cord disease, and in generalized weight loss secondary to malnutrition, systemic illness, or advanced brain diseases.

Muscle *strength* is tested by asking the patient to exert maximal power of specified muscle groups. Strength is graded as 0—no evidence of muscle contraction, 1—muscle contraction without movement of the limb, 2—limb movement after gravity eliminated, 3—limb movement against gravity, 4—limb movement against partial resistance, 5—normal strength. Upper and lower limbs and both proximal and distal musculature should be assessed. Distal weakness is characteristic of peripheral neuropathies; proximal weakness is a manifestation of primary muscle disease. Weakness below a specific level of innervation occurs with spinal cord disease (*paraparesis* or *quadriparesis*), and fatigability is most characteristic of muscle and myoneural junction disorders (e.g., myasthenia gravis). Lateralized weakness (*hemiparesis*) is a manifestation of lesions of the contralateral brainstem or above. Pyramidal tract pathology produces a “predilection” pattern of weakness affecting the extensor muscles of the upper limbs and the flexor muscles of the lower limbs; this is known as a *decorticate posture* and imitates the antigravity posture of the biped. Pyramidal lesions of the pons result in flexor weakness of all limbs and consequent extensor posturing; extension of all limbs is known as the decerebrate posture and recapitulates the antigravity posture of the quadruped.

Muscle *tone* is evaluated by passively manipulating the limbs or neck while the patient relaxes. Additional information can be garnered by asking the patient to perform motor activities with the contralateral limb while tone in the ipsilateral limb is determined (e.g., the patient is asked to draw a large square in the air with one arm while the examiner is testing the tone of the other). Activation of tone by this maneuver (*Froment's sign*) is characteristic of parkinsonianism. *Hypotonia* is relatively unusual in neuropsychiatric disorders. Muscle tone is decreased in muscle and peripheral nerve disease, cerebellar syndromes, early in the course of many choreiform disorders, and in the short term following an upper motor neuron lesion. Episodic hypotonia occurs in narcoleptic patients and accounts for their cataplectic attacks. Increased muscle tone (*rigidity*) is encountered in a variety of neuropsychiatric conditions. *Spasticity* is a form of rigidity in which the muscle is flaccid at rest and reacts with increasing tone to slow passive stretch. In many cases, the tone abruptly decreases after reaching a certain magnitude resulting in a sudden loss of resistance (the clasp-knife phenomenon). Spasticity results from upper motor neuron lesions that result in disinhibition and hyperexcitability of alpha and gamma motor neurons of the spinal cord. Muscle stretch reflexes are mediated through the same mechanism as spasticity and are exaggerated in spastic disorders. Parkinsonian extrapyramidal syndromes produce *plastic rigidity* (also known as “*lead pipe” rigidity*) characterized by an increased resistance to passive movement that is independent of the velocity of limb movement. The rigidity is produced by dysfunction of the nigrostriatal projection or the globus pallidus. Plastic rigidity may involve primarily the appendicular musculature (in Parkinson's disease) or may be more pronounced in the axial structures such as the neck and trunk (in progressive supranuclear palsy). *Cogwheel rigidity* observed in some extrapyramidal disorders results from the occurrence of tremor that is palpated as intermittent resistance when manipulating the limbs; it may occur with or without plastic rigidity. “ *Gegenhalten*” (also known as *paratonia*) refers to the resistance to movement encountered in patients with advanced brain diseases. It is characterized by active resistance to passive limb movements in all directions and at any velocity. It may result from release of primitive protective or position holding mechanisms similar to the released motor programs responsible for grasp and suck reflexes. *Waxy flexibility* is classically associated with catatonia. The patient's limb has moderate resistance to passive movement and maintains the end position of the movement (like candle wax). Catatonia occurs in a variety of psychiatric, frontal lobe, extrapyramidal, and toxic-metabolic disorders.

Coordination may be disrupted by many types of motor and sensory abnormalities but is primarily dependent on intact cerebellar function. Disturbances of coordination must be interpreted with caution to avoid ascribing the effects of weakness, spasticity, or sensory loss to cerebellar disease. Tests of coordination used in the standard neurological examination include rapid alternating movements (alternating supination and pronation movements of the hand), fine finger movements (repeated apposition of the thumb and first finger), finger-to-nose movements (the patient alternates between touching his own nose and the examiner's finger), heel-knee-shin maneuvers (the patient touches the knee of one leg with the heel of the other and then gently slides the heel down the shin), and rebound check tests (the clinician suddenly releases as the patient is pushing his extended arms upward against the examiner; the clinician observes whether the patient can quickly arrest the upward movement after release of the limbs). Gait, eye movement, and tremor-related observations aid in identifying a cerebellar disorder. Dysdiadochokinesia (abnormal rapid alternating movements), ataxia, loss of rebound check, and intention tremor are characteristic cerebellar disturbances.

Gait and posture are examples of motor acts dependent on successful motor and sensory integration. Systematic gait observations should assess step initiation, stride length, step height, base width, step symmetry, path deviation, trunk stability, speed, turning, and adventitious movements. *Festination of gait* refers to increasingly fast forward movement with an inability to stop. Asking the patient to perform tandem toe-to-heel walking makes cerebellar, sensory, and vestibular disturbances of gait and balance more evident. Table 2.1-4 summarizes the principal types of gait abnormalities.

Observation	Abnormality	Cause
Step initiation	Start hesitation	Parkinsonism
Stride length	Shortened	Parkinsonism
Step height	Decreased	Parkinsonism
	Increased	Sensory abnormality
Base width	Increased	Cerebellar ataxia, chorea, sensory abnormalities
Step symmetry	Asymmetric	Pain with unilateral avoidance
Path course	Deviation	Cerebellar or vestibular ataxia
Trunk stability	Unsteady	Cerebellar or vestibular disorders
Speed	Slowed	Parkinsonism
Turning	En bloc	Parkinsonism
Adventitious movements	Present	Chorea, athetosis, dyskinesia, tics, tremor, myoclonus, dystonia

Table 2.1-4 Abnormalities of Gait

Posture may be extended or flexed. In addition, sensory abnormalities, cerebellar disorders, and extrapyramidal disturbances may contribute to postural instability. Decorticate (flexed upper limbs, extended lower limbs) and decerebrate postures (all limbs extended) have already been described. Parkinson's disease and many parkinsonian syndromes produce a tendency to flexion of all limbs; progressive supranuclear palsy causes a characteristic extended posture. Postural stability is tested by asking the patient to stand with legs comfortably apart and eyes open; the examiner then stands behind the patient and pulls backward on the patient's shoulders with a short rapid jerk. Patients with extrapyramidal disorders fall backwards or must take a compensatory backward step. Sensory input to postural mechanisms can be tested by asking the patient to stand with feet together and eyes closed. Patients with sensory abnormalities from peripheral neuropathy disorders or the spinal cord affecting its posterior columns can stand with eyes open but not with eyes closed (*Romberg's sign*); patients with cerebellar ataxia cannot stand with feet together whether the eyes are open or closed.

Soft signs are minor motor and sensory abnormalities that are normal in the course of early development but abnormal when present beyond childhood. They have been reported with increased frequency in a variety of psychiatric disorders including schizophrenia and sociopathy. Soft signs lack definitive localizing significance but are indicative of subtle brain dysfunction. Table 2.1-5 lists the main soft signs elicited in the course of the neurological examination.

Test	Soft Sign
Articulation	Mild dysarthria
Finger tapping	Slow, clumsy, irregular
Foot tapping	Slow, clumsy, irregular
Rapid alternating movements	Slow, clumsy, irregular
Eye closure	Cannot maintain on command
Tongue extrusion	Cannot maintain on command
Arms extended	Minor choreiform movements
Finger-to-nose	Jerky, clumsy
Heel-to-shin	Jerky, clumsy
Heel walking	Unsteady, posturing of upper limbs
Toe walking	Unsteady, posturing of upper limbs
Standing on one foot	Cannot balance
Hopping on one foot	Unsteady
Tandem walking	Unsteady
Tandem walking backwards	Unsteady
Face-hand test	Distal stimulus extinguished when distal and proximal stimulus delivered simultaneously
Two-point discrimination	Perceives two separate points only when more widely separated than normal
Graphesthesia	Errors in recognizing numbers written on fingertips by the examiner
Romberg sign	Patient feels unstable when standing with feet together, eyes closed

Table 2.1-5 Neurological Soft Signs

A wide variety of *movement disorders* may be observed in the course of the neuropsychiatric examination. Four general classes of movement disorders can be distinguished—parkinsonism, dystonia, hyperkinesias, and tremor. The first three are irregular disorders, and tremor is a regular hyperkinesia. Parkinsonian syndromes are characterized by rigidity and bradykinesia. Dystonic disorders produce sustained postural deviations. Hyperkinesias include chorea, dyskinesias, athetosis, tics, and myoclonus. Tremors are regularly alternating movements. Several different types of movement disorders (e.g., parkinsonism, dystonia, and tremor) can occur simultaneously.

Parkinsonism may be produced by degenerative disorders (Parkinson's disease, progressive supranuclear palsy), multiple small strokes (lacunar state), metabolic disorders (hypothyroidism, hypoparathyroidism), head trauma, CNS infections (Creutzfeldt-Jakob disease, HIV encephalopathy), CNS tumors, hydrocephalus, and drug treatment. Medications most likely to induce parkinsonism include dopamine receptor antagonists, such as phenothiazines and butyrophenones. Table 2.1-6 summarizes the differential diagnosis of parkinsonism. The parkinsonian syndrome features bradykinesia and plastic rigidity with or without a rest tremor. Manifestations of bradykinesia include a masked face, reduced spontaneous blinking, diminished spontaneous swallowing with sialorrhea, start hesitation when initiating movement, shuffling gait (combination of reduced stride length and decreased step height), decreased arm swing when walking, en bloc turns, slowed movement, and reduced spontaneous gesturing.

Degenerative disorders
Parkinson's disease
Progressive supranuclear palsy
Cortico-basal ganglionic degeneration
Idiopathic basal ganglia calcification
Dementia with Lewy bodies
Rapid Huntington's disease (Westphal variant)
Parkinsonism-dementia amyotrophic lateral sclerosis complex of Guam
Wilson's disease
Hallervorden-Spatz disease
Azorean disease (Machado-Joseph disease)
Striatonigral degeneration
Olivopontocerebellar atrophy
Shy-Drager syndrome
Pallidal atrophies
Vascular disorders
Binswanger's disease
Lacunar state
Metabolic conditions
Hypoparathyroidism
Hypothyroidism
Drugs and toxins
Antipsychotics
Lithium carbonate
Reserpine
Methyl-phenyl-tetrahydropyridine (MPTP)
Manganese
Reserpine
Trauma
Dementia pugilistica
Postconcussive encephalopathy
Infections
Encephalitis lethargica
HIV encephalopathy
Creutzfeldt-Jakob disease
Syphilis
Miscellaneous
Carbon monoxide intoxication
Carroll-Hallervorden (Wolf's disease)
Dyke-Lee syndrome
Hydrocephalus
Meningioma
Neoplastic metastasis/carcinomatosis

Table 2.1-6 Causes of Parkinsonism

Hyperkinetic movement disorders include athetosis (observed primarily in cerebral palsy), chorea (Huntington's disease, Sydenham's chorea, neuroacanthocytosis), tardive dyskinesia, myoclonic disorders (Creutzfeldt-Jakob disease, myoclonic epilepsy, hereditary myoclonus, drug-induced myoclonus), ballismus (usually occurring as hemiballismus following infarction of the subthalamic nucleus), and tic disorders (Gilles de la Tourette syndrome, simple tic syndromes). *Hemiballismus* is a dramatic disorder in which the patient manifests large-amplitude flinging movements of the arm and leg contralateral to a lesion of the subthalamic nucleus; with time, the movement may evolve into hemichorea. *Chorea* is an irregular hyperkinesia intermediate in speed between the slower athetosis and the faster myoclonus. The choreic movements resemble normal movements and may be incorporated into semipurposeful gestures to partially obscure their occurrence. Electromyographic recordings, however, reveal that antagonistic muscles are active at inappropriate times. In Sydenham's postinfectious chorea the movements involve the distal musculature more than the proximal; in Huntington's disease the proximal musculature is more affected. *Dyskinetic movements* observed in tardive dyskinesia are a special instance of chorea. *Myoclonus* refers to random asynchronous brief muscle jerks large enough to move a limb. *Tics* are similar to myoclonus in amplitude and duration but are stereotyped, repetitively involving the same muscles, and they are subject to partial temporary volitional suppression. Table 2.1-7 summarizes the principal hyperkinetic movement disorders. *Athetosis* is a slow, writhing hyperkinesia.

Table 2.1-7 Differential Diagnosis of the Principal Hyperkinetic Disorders

Dystonia is a movement disorder in which there is tonic contraction of antagonistic muscle groups leading to sustained postural abnormalities. Initially, the muscle contractions may be intermittent, giving rise to an irregular tremor-like disorder. Dystonia may be (1) focal: involving a single body part (e.g., torticollis), (2) segmental: involving adjacent body parts (e.g., torticollis plus involvement of one shoulder), or (3) generalized. Table 2.1-8 provides the differential diagnosis of dystonia. Idiopathic dystonias appear to have few neuropsychiatric associations; secondary dystonias occur in conjunction with many of the other hyperkinesias (including Huntington's disease and Parkinson's disease); and dystonia is a frequent adverse effect of treatment with neuroleptic agents (e.g., dopamine receptor antagonists). Drug-induced dystonias may be acute (neuroleptic-induced acute dystonia) occuring within a few hours of initiating treatment or increasing the drug dosage, or they may be manifestations of tardive dyskinesia.

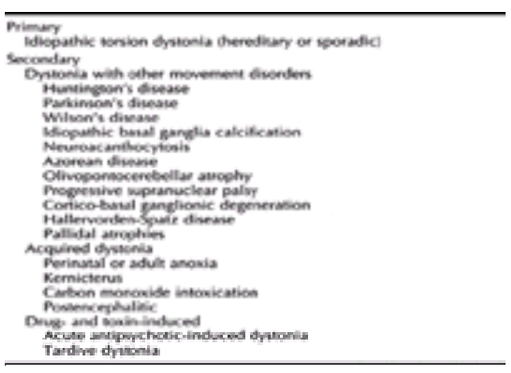

Table 2.1-8 Differential Diagnosis of Dystonia

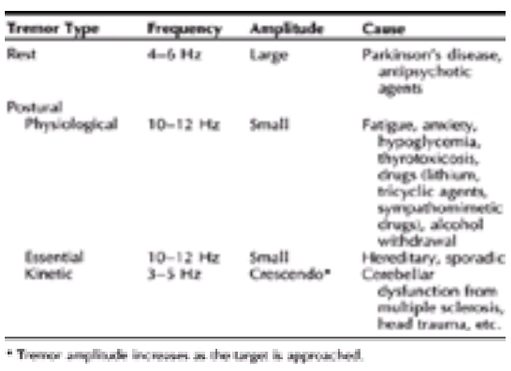
Tremor is an involuntary, regular oscillation of a body part around a fixed point. Table 2.1-9 presents a classification of tremors including rest tremors, postural tremors, and kinetic tremors. *Rest tremors* include the typical large-amplitude, low-frequency (approximately 4–6 Hz) tremor of Parkinson's disease and other parkinsonian states. This tremor disappears with sleep and is better characterized as a tremor of alert repose, occurring when the patient is alert but inactive. Rest tremor is suppressed by volitional movement. The principal *postural tremors* include exaggerated physiological tremors and essential tremors. These are small-amplitude, high-frequency (10–2 Hz) tremors that are absent at rest and occur during postural maintenance activities (holding the arms outstretched in front of the body, writing and so on). Exaggerated physiological tremors occur with fatigue, excitement, hypoglycemia, and thyrotoxicosis as well as in metabolic encephalopathies and drug-induced toxic states (caused by lithium, tricyclic agents, sympathomimetics, and so on). Essential tremors are usually inherited but may occur sporadically. Kinetic tremors are those that worsen with movement. Cerebellar intention tremors are the classic example of kinetic tremors and are observed frequently in patients with multiple sclerosis.



Tremor Type	Frequency	Amplitude	Cause
Rest	4–6 Hz	Large	Parkinson's disease, antipsychotic agents
Postural			
Physiological	10–12 Hz	Small	Fatigue, anxiety, hypoglycemia, thyrotoxicosis, drugs (lithium, tricyclic agents, sympathomimetic drugs), alcohol withdrawal
Essential	10–12 Hz	Small	Hereditary, sporadic
Kinetic	3–5 Hz	Crescendo*	Cerebellar dysfunction from multiple sclerosis, head trauma, etc.

* Tremor amplitude increases as the target is approached.

Table 2.1-9 Classification of Tremor

Sensory Examination Examination of sensory function includes assessment of primary sensory modalities mediated at the thalamic level as well as secondary or cortical sensation. Sensory information is projected from peripheral receptors to the post-Rolandic sensory cortex via peripheral nerves, spinal cord, brainstem, and thalamus; damage at any of these levels may produce a sensory deficit. Primary modalities include light touch, pain (tested by examining the patient's ability to distinguish a sharp pin from a dull object), temperature, and vibration. Vibration should be tested with a 128-Hz tuning fork. Cortical sensory modalities include joint position sense, two-point discrimination (ability to discriminate two closely spaced areas of stimulation from a single stimulation), graphesthesia (ability to identify numbers “written” on the tips of the fingers), and stereognosis (ability to recognize by touch objects placed in the hand). Tactile double simultaneous stimulation is a sensitive and valuable means of detecting unilateral neglect. The patient is told that they will be touched in one or two areas including the face, dorsum of the hands, or front of the lower legs. The patient's ability to perceive bilateral simultaneous stimuli is then systematically assessed. Patients with neglect will fail to perceive

stimuli on one side of the body when they are simultaneously stimulated on the other side. Primary sensory abilities (e.g., light touch) must be intact to perform the test. Patients with unilateral neglect may manifest the related behavioral disorder of *anosognosia* (denial of illness).

Muscle Stretch Reflexes Muscle stretch reflexes are monosynaptic spinal cord reflexes that are modulated by descending connections. Muscle stretch reflexes are decreased in muscle, peripheral nerve, and nerve root disorders and increased in the presence of upper motor neuron lesions. Every muscle has an associated muscle stretch reflex and the examiner chooses a small number that can routinely be obtained in the screening evaluation and selects more specific reflexes to explore hypotheses generated in the course of the examination. A reasonable screening examination would include the following muscle stretch reflexes: biceps, brachioradialis, triceps, finger flexors, knee jerks, and ankle jerks. Reflexes are graded as 0—absent or unobtainable, 1—decreased, 2—normal, 3—brisk with spread of the contraction response to adjacent muscles, or 4—clonus. *Clonus* refers to the series of rhythmic reflex contractions observed when a muscle is abruptly subjected to sustained stretch. Clonus is most easily elicited at the ankles but may be observed in the knees, wrists, and jaw. Lateralized increased reflexes in conjunction with weakness, spasticity, and the Babinski sign comprise the upper motor neuron syndrome indicative of a contralateral lesion of the descending pyramidal system. Reflexes are diminished in the acute phase of an upper motor neuron lesion but gradually increase during the first few weeks following the injury.

Pathological and Primitive Reflexes *Babinski's sign* is the most important pathological reflex sought in the neurological examination. It is typically elicited by stroking the lateral aspect of the plantar surface of the foot from back to front with a semi-sharp object (Figure 2.1-5). A normal response consists of plantar flexion of the great toe; an abnormal response (Babinski's sign) is comprised of dorsiflexion of the great toe with or without fanning of the other toes. It is produced by upper motor neuron lesions and is a fragment of a protective flexion reflex. In its completely developed form (observed in infants and in some patients with severe spinal cord injuries), there is a flexor synergy with flexion of hip, knee, and toe removing the foot from the noxious stimulus. Thus, Babinski's sign like other primitive reflexes represents the release of more primitive motor programs from suprasegmental control. There is no equivalent reflex in the upper extremity, but *Hoffman's sign* (thumb flexion elicited by briskly flexing the distal phalanx of the middle finger while holding the digits in a dorsiflexed position) may be used to assess hyperreflexia in the upper extremities and is frequently present in patients with upper motor neuron lesions and Babinksi signs in the lower limbs.

FIGURE 2.1-5 Babinski reflex. (Reprinted with permission from Major RH, Delp MH: *Physical Diagnosis*, ed 5. Saunders, Philadelphia, 1956.)

The *glabella tap reflex (Myerson's sign)* is often mistakenly considered a primitive reflex similar to grasp and suck responses, but it is best considered a sign of extrapyramidal dysfunction. Continued blinking with tapping of the glabellar region is associated with movement disorders and is seen in Parkinson's disease and medication-induced parkinsonism. To be abnormal the blinking must continue to occur after four or more glabella taps.

The *grasp reflex* refers to involuntary gripping of objects in or near the patient's hand. Four types of grasp response have been described: (1) the simple grasp response occurs when the patient's thenar eminence is stimulated; (2) the hooking response occurs when the patient's flexed fingers are gently extended; (3) if the hooking response is marked, there is loss of voluntary relaxation and the patient grips steadily as the examiner withdraws his hand (traction grasp); and (4) in patients with advanced disease, the sight of the examiner's hand or light touch of the hand causes the patient to move his hand to grasp the examiner's hand (groping response or magnetic grasp). Grasp reflexes occur in patients with advanced brain disease and with more restricted lesions limited to the medial frontal lobes. Grasp responses can be elicited in the feet as well as in the hands.

The *sucking reflex* is comprised of sucking movements of the lips, tongue, and jaw elicited by gentle stimulation of the lips. Like the grasp reflex, these are primitive motor programs that occur normally in infants and reappear as age-inappropriate signs in patients with frontal lobe and diffuse brain dysfunction.

The *palmomental reflex* features ipsilateral contraction of the mentalis muscle in response to stroking of the thenar eminence of the hand. This reflex can be seen in a range of ages in individuals and may be regarded as pathological when it is unilateral or when it does not fatigue with repeated stimulation.

Physical Examination Selected aspects of the general physical examination are particularly important in neuropsychiatric assessment. Dysmorphological features are important in the recognition of congenital and chromosomal syndromes. The manifestations of fetal alcohol syndrome, for example, may be evident in adults and include microcephaly, short palpebral fissures, maxillary hypoplasia, short nose, smooth philtrum with thin and smooth upper lip, small distal phalanges, and small fifth fingernails.

Examination of the head and neck is essential. Patients may have enlarged heads from compensated hydrocephalus (adult males should have a head circumference less than 58.4 cm and adults females less than 57.5 cm) or small heads from inadequate brain development. Palpation of the head may reveal evidence of a previous craniotomy not revealed or recalled by the patient. A short neck is characteristic of platybasia associated with congenital deformities of the posterior fossa *(Arnold-Chiari malformation)* and of basilar impression (occurring, for example, with Paget's disease of the skull) that may give rise to hydrocephalus.

The neuro-ophthalmological examination may contribute essential information in the neuropsychiatric examination. Examination of the optic nerve, visual fields, extraocular movements, lid position, and pupillary responses have already been discussed. In addition, inspection of the eyes may reveal a Kayser-Fleischer ring at the corneal limbus in Wilson's disease. Retinal inspection may show macular degeneration (associated with blindness and visual hallucinations), and retinal degenerations (occurring with phenothiazines, particularly thioridazine, and some hereditary CNS disorders). Cataracts may be present in diabetes, hypoparathyroidism, and Wilson's disease and after treatment with chlorpromazine (Thorazine) and corticosteroids.

Cardiovascular assessment is of obvious interest in neuropsychiatry. Cardiac and carotid auscultation as well as blood pressure measurement are necessary in most examinations. Abdominal palpation may occasionally reveal organomegaly in neuropsychiatric illnesses including hepatomegaly in alcoholism. Skin changes in neuropsychiatric disorders include pigment deposition after long-term treatment with chlorpromazine, small pigmented papules (angiokeratoma corporis diffusum) in Fabry's disease, and a variety of anomalies in the phakomatoses such as tuberous sclerosis and von Recklinghausen's disease.

NEUROBEHAVIORAL SYNDROMES

Behavioral disturbances associated with neurological disorders will be divided arbitrarily into neurobehavioral syndromes and neuropsychiatric syndromes. Neurobehavioral syndromes include deficit disorders such as aphasia, amnesia, frontal lobe disorders, and anosognosia. Neuropsychiatric syndromes include productive disorders such as delusions, hallucinations, depression, mania, anxiety, personality changes, obsessive-compulsive disorders, and paraphilias.

Aphasia *Aphasia* refers to the loss of language abilities produced by brain dysfunction. The most common cause of isolated aphasia is stroke, but it may also occur with brain tumors, infections, trauma, and in the course of degenerative diseases such as Alzheimer's disease.

There are eight major aphasia syndromes, each identifiable by a distinctive combination of changes of fluency, comprehension, and repetition (Table 2.1-10). *Wernicke's aphasia* has a fluent output with poor comprehension and impaired repetition. Naming is abnormal, reading comprehension is impaired, reading aloud is compromised, and writing contains errors similar to the fluent paraphasic output. *Broca's aphasia* is characterized by a terse nonfluent output, intact comprehension, and poor repetition. Reading comprehension is preserved and reading aloud has the same nonfluent characteristics as spoken language; naming and writing are impaired. *Global aphasia* is the most severe aphasic syndrome: spontaneous output is nonfluent and often severely limited, comprehension is abnormal, and

repetition is disturbed. Naming, reading comprehension, reading aloud, and writing are all abnormal. *Anomic aphasia* is a mild aphasic syndrome with fluent output, preserved comprehension, and intact repetition. The principal disturbances are a word-finding deficit and abnormalities of naming. Reading aloud and writing contain the same abnormalities noted in spontaneous speech. *Conduction aphasia* resembles Wernicke's aphasia in having fluent output and impaired repetition, but comprehension is preserved. Conduction aphasia patients read with comprehension but cannot read aloud. Writing contains paraphasic errors. The typical paraphasias of conduction aphasia are phonemic substitutions, whereas patients with Wernicke's aphasia have verbal and neologistic paraphasias. *Transcortical sensory aphasia* is similar to Wernicke's aphasia (fluent output, poor comprehension) with intact repetition. Reading aloud, reading comprehension, and writing are compromised. *Transcortical motor aphasia* has features similar to Broca's aphasia (nonfluent output, intact comprehension) with normal repetition. Reading comprehension is intact; reading aloud and writing are abnormal. *Mixed transcortical aphasia* resembles global aphasia (nonfluent, poor comprehension) but repetition is intact.

Aphasia Type	Fluency	Comprehension	Repetition	Naming	Reading Comprehension	Reading Aloud	Writing
Wernicke's	F	Impr	Impr	Impr	Impr	Impr	Impr
Anomic	F	Normal	Normal	Impr	Normal	Impr	Impr
Conduction	F	Normal	Impr	Impr	Normal	Impr	Impr
Transcortical sensory	F	Impr	Normal	Impr	Impr	Normal	Impr
Broca's	NF	Normal	Impr	Impr	Normal	Impr	Impr
Transcortical motor	NF	Normal	Normal	Impr	Normal	Impr	Impr
Mixed transcortical	NF	Impr	Normal	Impr	Impr	Impr	Impr
Global	NF	Impr	Impr	Impr	Impr	Impr	Impr

F, fluent; NF, nonfluent; Impr, impaired.

Table 2.1-10 Characteristics of the Major Aphasia Syndromes

Each of the aphasic syndromes is associated with a different region of erebral cortical dysfunction. Wernicke's aphasia is produced by a lesion of the posterior superior left temporal gyrus (Wernicke's area). Broca's aphasia reflects pathology of the middle third of the left inferior frontal gyrus (Broca's area). Global aphasia is associated with a large left-hemisphere lesion involving the anterior and posterior lateral convexity. Global aphasia is occasionally produced by a combination of two lesions, one involving Wernicke's area and another affecting Broca's area. Anomic aphasia occurs with lesions of the posterior inferior left temporal gyrus, left angular gyrus, or left temporal pole. Conduction aphasia is seen with disruption of the arcuate fasciculus traversing from Wernicke's area to Broca's area. Transcortical sensory aphasia is caused by lesions of the posterior inferior parietal region. Transcortical motor aphasia may occur with lesions of the left medial frontal lobe or the convexity area superior to Broca's area. Mixed transcortical aphasia is produced by lesions combining the syndromes of transcortical motor and transcortical sensory aphasia or by large lesions of the anterior and posterior medial left hemisphere.

Localizing principles regarding lesion location in aphasic patients can be derived from these observations. Syndromes with impaired repetition all have lesions bordering directly on the Sylvian fissure of the left hemisphere (Wernicke's, Broca's, and conduction aphasias), whereas those with intact repetition (transcortical aphasias) have lesions that spare the immediate peri-Sylvian structures. Disorders with impaired comprehension have lesions affecting posterior hemispheric structures (behind the Rolandic fissure), whereas aphasic syndromes with intact comprehension typically have lesions limited to anterior hemispheric structures. These localization rules apply only to right-handed adults. Children often exhibit nonfluent aphasias regardless of the lesion localization in the left hemisphere, and left-handed individuals may have mixed cerebral dominance resulting in atypical aphasia syndromes following localized left hemisphere injury.

Etiological diagnosis is aided by aphasia syndrome identification. Wernicke's aphasia and conduction aphasia are most often caused by emboli, usually arising from the heart. Transcortical aphasias arise from lesions of the vascular border zone regions and are typically seen with large-vessel disease involving the extracranial carotid arteries. Transcortical sensory aphasia is commonly observed in the middle phases of Alzheimer's disease. Global aphasia usually occurs with thromboembolic occlusion of the left middle cerebral artery.

Amnestic and Memory Disorders *Amnesia* refers to an inability to learn new information despite normal attention, language, and other intellectual abilities. Amnestic disorder is typically characterized by a period of *retrograde amnesia* extending back from the time of onset of the amnesia and encompassing a few seconds to a few years of the patient's life. Retrograde amnesia does not include all of the patient's past life and personal identity is not forgotten. Persons with amnesia who claim to have forgotten all personal history are usually found to be malingering or are suffering from an idiopathic psychiatric disorder. Amnestic disorders also have an *anterograde amnesia* that extends forward from the time of onset of the memory disorder. Anterograde amnesia may be temporary, lasting until memory functions recover, or it may be permanent. In patients exhibiting recovery of memory function, there may a concomitant shrinking of retrograde amnesia as the anterograde amnesia resolves. The memory dysfunction in amnesia is an inability to store new information for later recall. Memory for newly learned information is not aided by clues or prompting strategies. *Confabulation* refers to untrue responses to questions that are formulated by amnestic patients without a deliberate attempt to mislead. The confabulated responses are often drawn from the patient's actual experiences but are produced out of context. For example, when asked about their occupation, the patient may produce a detailed but untrue description, the details of which were taken from a job they had 10 or 20 years previously. Confabulation is common in the acute phases of amnesia but is rare in chronically amnestic patients.

Amnestic disorder is associated with a restricted set of lesions involving limbic structures of the medial aspect of the cerebral hemispheres. The damage that produces amnesia affects the hippocampus, fornix, mammillary bodies, or medial thalamic nuclei. Severe amnesia usually reflects bilateral damage, whereas unilateral injury results in relatively modest and hemisphere-specific deficits with left-sided lesions producing verbal amnesia and right-sided lesions causing deficits in learning nonverbal and visuospatial information.

The differential diagnosis of amnesia includes pathological processes that predominantly affect the medial hemispheric limbic areas. Table 2.1-11 lists the most common causes of amnesia and the site of the associated lesion. Hippocampal injury occurs with closed head trauma, occlusion of the basilar or posterior cerebral artery, anoxia, hypoglycemia, tumors, and herpes simplex encephalitis. The hippocampus is involved early in the course of Alzheimer's disease, and an amnestic disorder is occasionally the presenting manifestation of this degenerative disorder. The fornix can be involved by surgery, brain tumors, and rupture of anterior cerebral artery aneurysms. Mammillary bodies are affected in the Wernicke-Korsakoff syndrome and by brain tumors. The medial thalamic nuclei are involved in Wernicke-Korsakoff syndrome, brain tumors, and some strokes (occlusion of thalamoperforant branches of the posterior communicating and posterior cerebral arteries).

Syndrome	Anatomical Site of Pathology
Wernicke-Korsakoff syndrome	Mammillary bodies, medial dorsal nucleus of thalamus
Head trauma	Hippocampus
Stroke (posterior cerebral artery)	Hippocampus
Subarachnoid hemorrhage (rupture of aneurysm of anterior cerebral artery)	Fornix
Anoxia	Hippocampus
Hypoglycemia	Hippocampus
Herpes simplex encephalitis	Hippocampus
Alzheimer's disease	Hippocampus
Neoplasms	Temporal lobe, fornix, hypothalamus, thalamus
Surgery (lobectomy)	Temporal lobe
Transient global amnesia	Hippocampal ischemia (in some cases)
Electroconvulsive therapy	Uncertain

Table 2.1-11 Differential Diagnosis of Amnesia and the Associated Site of the Lesion

A few clinical signs help to distinguish among the amnestic disorders. The Wernicke-Korsakoff syndrome classically evolves through an acute phase of Wernicke's

encephalopathy characterized by ophthalmoplegia, ataxia, and delirium. If the responsible thiamine deficiency is not reversed, the patient will progress into the Wernicke-Korsakoff syndrome that includes persistent amnesia, nystagmus, and ataxia. A peripheral neuropathy is usually present and a history of alcohol abuse is common, although any cause of thiamine deficiency (i.e., starvation, prolonged vomiting, gastric carcinoma) can produce the Wernicke-Korsakoff syndrome. Lesions of the hippocampus (e.g., posterior cerebral artery occlusion, brain tumors, trauma) commonly impinge on the adjacent fibers of the optic radiation and cause a superior quadrantanopsia or homonymous hemianopsia. Frontal–lobe-type behavioral disturbances commonly accompany posttraumatic amnesias because of orbitofrontal injury occurring in conjunction with the temporal lobe damage.

Amnesia must be distinguished from several other types of memory abnormalities. *Age-cognitive decline* (also known as *benign senescent forgetfulness*) occurs in the course of normal aging. It is characterized by impaired spontaneous recall, retained recognition skills, an absence of deficits in other neuropsychological domains, and an acute awareness of the loss of timely recall. Age-associated cognitive decline is not the harbinger of a dementing illness. The characteristic memory disturbance of *Alzheimer's disease* features both difficulty in learning new information and impaired remote recall. Throughout most of the course of the illness there is an inability to remember remote as well as newly learned material. The memory abnormality of the frontal lobe syndromes and *subcortical dementias* such as Huntington's disease and Parkinson's disease is a retrieval deficit with poor recall and intact recognition. Patients learn and retain information but have difficulty spontaneously accessing it. Unlike patients with amnesia, they are aided by clues, prompting strategies, and encoding enhancement techniques such as embedding the to-be-remembered material in a story.

Frontal Lobe Disorders Frontal lobe disorders are among the most important syndromes in neuropsychiatry. Frontal lobe dysfunction is present in many idiopathic psychiatric diseases (depression, schizophrenia, obsessive-compulsive disorder), and frontal lobe lesions produce profound behavioral alterations. Lesions of the deep subcortical as well as the superficial cortical structures of the frontal lobe produce behavioral disorders and “frontal systems” dysfunction more accurately reflects the anatomy of the conditions with frontal-lobe–type behaviors.

Three behavioral complexes are currently recognized with frontal systems dysfunction: an orbitofrontal disinhibition syndrome, a medial frontal apathetic-akinetic syndrome, and a frontal convexity neuropsychological deficit and motor programming disorder (Table 2.1-12). Combinations of symptoms are the rule rather than the exception in most patients with frontal lobe disorders.

Behavioral Syndrome	Location of Major Abnormality	Features
Disinhibition	Orbitofrontal	Impulsiveness, loss of tact, may be facetious
Apathetic	Medial frontal	Limited motivation and initiative
Motor programming deficits	Frontal convexity	Perseveration, impersistence, impaired serial-order behavior
Depression	Frontal polar and subcortical (caudate nucleus)	Major depressive symptoms

Table 2.1-12 Principal Frontal Lobe Syndromes

The *orbitofrontal syndrome* is the most well known and flamboyant of the frontal lobe behavioral disorders. The patients are disinhibited, making tactless remarks and acting on impulse. They are coarsened, lack empathy, and show little concern for the feelings of others. They fail to plan ahead and exhibit little concern about their illness or future. Mood is typically irritable and labile with a fatuous euphoria. Inappropriate jocularity with an insensitive humor (*witzelsucht*) may be observed. There is a lack of social restraint and an undue familiarity with strangers. Despite the marked behavioral alterations, these patients may have few or no neuropsychological deficits and exhibit intact language, memory, and visuospatial skills. The orbitofrontal syndrome occurs with posttraumatic encephalopathy, frontal brain tumors (particularly inferior frontal meningiomas), anterior cerebral artery stroke or aneurysm rupture, multiple sclerosis, and degenerative frontal lobe diseases such as Pick's disease. Deficits in olfaction commonly accompany the syndrome because of the proximity of the olfactory nerves, bulbs, and tracts to the orbital surface. This syndrome has been observed with inferior caudate lesions as well as disturbances of the orbitofrontal cortex.

The *medial frontal lobe syndrome* is also a striking behavioral disorder. The severity of the syndrome extends from *akinetic mutism* at the most severe end of the spectrum to a mild lack of motivation on the other. Akinetic mutism occurs with bilateral medial frontal lesions and is characterized by mutism and very limited spontaneous movement. The patients, however, appear alert, have their eyes open, exhibit ocular following movements of environmental events, will eat when fed, and may move with persistent stimulation or pain. The syndrome has been reported with bilateral anterior cerebral artery occlusions, trauma, hydrocephalus, bilateral thalamic infarction, and midline tumors of the thalamus, third ventricle, hypothalamus, and pituitary. Partial amelioration of the syndrome by dopaminergic agents (levodopa [Larodopa], bromocriptine [Parlodel]) suggests that interruption of ascending dopaminergic fibers may play a role in the pathophysiology of the disorder. An attenuated form of this syndrome occurs with unilateral medial frontal lobe lesions. Loss of initiative, poor motivation, limited gesturing, and apathy characterize the spontaneous behavior of patients with medial frontal lesions. A variety of neurobehavioral and neuropsychological abnormalities may accompany the neuropsychiatric disorders. Patients with left-sided lesions manifest transcortical motor aphasia with little speech initiation, nonfluent output, intact comprehension, and preserved repetition. With lesions of either hemisphere, a callosal apraxia with inability to perform learned motor acts on command with the left hand may also be present. If the lesion extends posteriorly to the medial central gyrus, paresis of the contralateral leg and foot will be evident.

Frontal convexity lesions produce abnormalities of sequential behavior including perseveration (abnormal continuation of behavior), impersistence (abnormal early termination of behavior), deficits in set shifting, and disturbances of programming sequential motor acts such as alternating programs, reciprocal programs, multiple loops, and serial hand sequences (Fig. 2.1-1 and Fig. 2.1-2). Patients also have difficulty developing strategies that will facilitate copying complex figures (Fig. 2.1-3), exhibit poor judgment, and are concrete on tests of abstraction. There may be no elementary neurological abnormalities. Tumors, stroke, trauma, and frontal degenerations account for most cases of the frontal convexity syndromes. The condition has been observed with dorsal caudate lesions as well as frontal convexity lesions.

Neglect and Anosognosia Unilateral *neglect* refers to a hemi-inattention disorder in which the patient fails to attend to or act on stimuli in one hemi-universe. Visual neglect is most striking and easily demonstrable, but in its fully developed form hemi-sensory neglect includes all sensory modalities (e.g., hearing, touch). Hemi-motor neglect may also occur, with the patient failing to act in one hemi-space. The patient with neglect fails to draw or copy one half of objects (Fig. 2.1-1), may not dress or groom one half of the body, will not see or hear individuals and events occurring on one side of the body, and will extinguish (fail to perceive) stimuli on the side contralateral to the lesion when both sides of the body or visual field are stimulated. Hemi-sensory neglect is more common and more enduring with lesions of the right parietal lobe or right thalamus than with left-sided lesions, but it occurs with injury to either hemisphere. Motor neglect occurs with frontal or subcortical damage.

Anosognosia refers to the denial of hemiparesis that occurs in some patients with unilateral neglect. In some usages, the term has been extended to encompass all forms of denial of illness. A variety of anosognosic phenomena has also been described, enlarging the syndrome to include all types of abnormal regard for the affected limbs. *Hemiasomatognosia* refers to neglect of one side of the body when there is no hemiparesis, and *somatophrenia* is the term for denial of ownership of one's paretic limbs. When limb weakness is acknowledged but minimized, the term *anosodiaphoria* is used; hatred of a weak limb is called *misoplegia.* Preoccupation and personification (e.g., naming the limb, etc) are two other variants of anosognosia.

NEUROPSYCHIATRIC SYNDROMES

Delusions Delusions, false beliefs held despite evidence to the contrary, occur in a variety of neurological disorders. They are most common in Alzheimer's disease, vascular dementia, Huntington's disease, temporal lobe epilepsy, and multiple sclerosis. They also occur in posttraumatic encephalopathy, Wilson's disease and other degenerative extrapyramidal disorders, and brain tumors, but they are not common in these conditions. Delusions are rare in Parkinson's disease, except as a manifestation of dopamine or anticholinergic toxicity. Delusions are frequent in delirium. When delusions occur with focal lesions, the injury is usually in the left or right temporal-parietal region. With left-sided lesions, delusions occur in conjunction with Wernicke's aphasia; with right-sided lesions, prominent visual hallucinations

commonly accompany the delusional disorder. Together, these clinical observations indicate that delusions are most common in diseases affecting the temporal lobe cortex or the basal ganglia, particularly the caudate nucleus. Delusions are more frequent in disorders with bilateral than unilateral damage.

Several principles have evolved that aid in characterizing and understanding delusions in neurological diseases. First, delusions are not reactions to declining intellectual function; the more intact the delusional patient's cognition, the more complex the delusions tend to be. Patients with dementing illnesses have simple delusions, whereas patients with single strokes or other limited lesions exhibit complex, well structured, and firmly held delusional beliefs. The intellect is in the service of the delusional process. Second, no specific neuropsychological correlates of delusions (e.g., deficits in memory, language, visuospatial functions, frontal lobe abilities) have been consistently identified. Cognitive abnormalities indicative of frontal lobe or temporal lobe dysfunction are common in delusional patients. Third, there is no delusional content that distinguishes neurological illnesses from idiopathic psychotic processes such as schizophrenia. Most delusions in neurological illness tend to be persecutory beliefs, but any type of delusional content can be observed (Table 2.1-2). Fourth, visual hallucinations are more common in conjunction with delusions in neurological illness than with idiopathic psychoses. Auditory hallucinations occur with delusions in both neurological and idiopathic psychiatric disorders. Fifth, delusions are most common in diseases affecting both hemispheres such as the degenerative disorders and vascular dementia. Sixth, when delusions follow unilateral lesions, the laterality of the damage may influence the delusion content. Schneiderian first-rank symptoms are more common with left-sided lesions, and delusions of substitution and misidentification syndromes such as the Capgras's symptom are more common with right-hemisphere lesions. Seventh, delusions are not invariably linked to lesions in specific anatomical structures in the same way that a hemiparesis predictably follows a pyramidal tract lesion, and other nonanatomical factors (e.g., biochemical changes, developmental factors, environmental conditions) must participate in determining the occurrence of delusions. Eighth, it is common for the onset of delusions to be delayed for considerable periods after the occurrence of a brain insult. In temporal lobe epilepsy, for example, several years may elapse between the occurrence of the brain injury with the onset of the seizures and the first appearance of delusions. Ninth, the approach to treatment of delusions in neurological illness involves addressing both the delusions and the underlying illness. Delusions may respond to neuroleptic agents and rarely improve with anticonvulsants or other nonneuroleptic medications.

Hallucinations Hallucinations are sensory perceptions occurring without the appropriate stimulation of the corresponding sensory organ. Visual hallucinations are common in neurological illness. The differential diagnosis of visual hallucinations is presented in Table 2.1-13. Ocular diseases that produce total or partial blindness—enucleation, cataracts, macular degeneration, retinal diseases, or vitreous traction—are common causes of hallucinations. Vitreous traction produces unformed flashes of light; the other processes may produce formed or unformed hallucinations. Inflammation of the optic nerves from ischemic optic neuritis or optic nerve demyelination can cause phosphenes or unformed flashes of light.

Condition/Lesion Location	Cause
Ocular abnormality	Enucleation Cataracts Macular degeneration Vitreous traction
Optic nerve abnormality	Optic neuritis (ischemic, demyelinating, glaucoma)
Brainstem abnormality	Peduncular hallucinosis (infarction, tumor)
Cerebral hemispheric lesions	Geniculocalcarine lesions (infarction, tumor) Epilepsy
Neurological illnesses	Migraine Narcolepsy
Medical illnesses	Delirium
Toxic disorders	Delirium Withdrawal Hallucinogens
Psychiatric disorders	Schizophrenia Mania Depression
"Normal" conditions	Hypnagogic hallucinations Imaginary companions of childhood Sensory deprivation Sleep deprivation

Table 2.1-13 Differential Diagnosis of Visual Hallucinations

Lesions of the midbrain produce the syndrome of *peduncular hallucinosis* characterized by visual hallucinations typically of a formed type occurring in the evening and associated with a benign affect. A sleep disturbance is usually present. The condition rarely lasts more than a few days. Peduncular hallucinosis has been produced by midbrain strokes and brainstem tumors.

Lesions of the geniculocalcarine radiations produce a visual field defect. Hallucinations within the field abnormality are common in the early period soon after the injury occurs. Known as *release hallucinations*, these are usually formed, are not necessarily stereotyped from episode to episode, last from minutes to hours at a time, and may be modified by moving or closing the eyes.

Focal seizures may produce visual hallucinations. Occipital foci tend to produce unformed hallucinations while parietal and temporal foci produce formed hallucinations. *Ictal hallucinations* are brief and stereotyped. They may be associated with other seizure phenomena (e.g., interruption of consciousness, head or eye deviation) and are generally not lateralized in the visual field. *Micropsia* (things look small and far away), *macropsia* (things look large and close), and *metamorphopsia* (distortions) may also occur in the course of seizures.

Hallucinations in *migraine* vary from simple light flashes, to scintillating scotomata, to fully formed complex visions. The classical hallucination of migraine is a fortification spectra that looks like the jagged top of the wall of a fort or castle. Hallucinations precede the headache and may be the dominant aspect of the migrainous attack. Micropsia and macropsia may occur in migraine where they are termed the “Alice in Wonderland syndrome.”

Narcolepsy is associated with the tetrad of sleep attacks, visual hallucinations, cataplexy (loss of muscle tone with subsequent falling), and sleep paralysis (momentary inability to move or speak on awakening from sleep). The hallucinations occur on falling asleep (hypnagogic) or on awakening (hypnopompic) and are usually terrifying in nature. Documentation of sleep-onset rapid eye movement (REM) sleep with multiple sleep latency polysomnography confirms the diagnosis.

Visual hallucinations are common in delirium associated with toxic or metabolic encephalopathies, in alcohol or sedative-hypnotic withdrawal, and with ingestion of hallucinogens such as lysergic acid diethylamide (LSD), psylocibin, and mescaline, and dissociative agents such as phencyclidine (PCP). Visual hallucinations occur in up to 30 percent of patients with Parkinson's disease treated with dopaminergic agents (e.g., levodopa bromocriptine pergolide [Permax]). Dementia is a common predisposing factor in Parkinson's disease patients with hallucinations.

Visual hallucinations occur in idiopathic psychoses including schizophrenia, depression, and mania. They are rarely the dominant type of hallucination in these circumstances. Normal individuals may experience visual hallucinations on falling asleep or in the course of sensory or sleep deprivation. The imaginary companions of childhood often have a visual aspect.

Hallucinations in other sensory modalities are less common than visual hallucinations in neurological illnesses. *Auditory hallucinations* occur in conjunction with persecutory delusions in the delusional disorders described earlier. They may also occur with deafness, brainstem lesions, and epilepsy. *Tactile hallucinations* are reported in delirium, withdrawal (particularly opiate withdrawal), and in association with delusions of infestation. *Gustatory* and *olfactory hallucinations* occur in psychoses and epilepsy.

Depression Depressive symptoms are common in neurological diseases. In some cases, the mood changes represent grief for lost function, altered role and status, and increased dependence. In many, however, the depression is more severe than anticipated for the functional disability and greater than experienced by patients with nonneurological disabling diseases. In these conditions the depression is a behavioral manifestation of the brain dysfunction. Neurological diseases in which depression has been identified as a prominent abnormality include Alzheimer's disease, Parkinson's disease, Huntington's disease, Wilson's disease, idiopathic basal ganglia calcification, stroke and vascular dementia, multiple sclerosis, and epilepsy. Endocrine disorders, systemic illnesses, and a wide variety of medications are also capable of inducing a depressive disorder.

The diagnosis of mood disorders in patients with neurological illness presents a difficult challenge. Many neurological diseases without mood changes produce symptoms that are characteristic of depressive episodes—diminished pleasure and interest, weight loss, insomnia, agitation, retardation, fatigue, impaired concentration—and may lead to the misdiagnosis of depression. Other neurological illnesses, such as the parkinsonian disorders, produce psychomotor slowing, stooped posture, fatigue, and impaired concentration resembling depression; depression in these disorders can be overlooked or overdiagnosed. Experiential manifestations of depression including feelings of sadness, worthlessness, hopelessness, and recurrent thoughts of death or suicide are the most dependable

indicators of a depressive syndrome and should be carefully sought. Dementia patients, however, may be unable to describe these subjective symptoms and depression must be inferred from the associated symptoms.

A few observations pertain to most neurological disorders manifesting depression as part of their symptom complex. First, the entire spectrum of depression severity may be observed, with some patients manifesting few mood symptoms and others meeting all criteria for a major depressive episode. In some disorders such as Alzheimer's disease, major depressive disorder is rare while depressive symptoms are common. Second, frontal-subcortical systems structures are the sites most often implicated in the depression syndromes. Depression may occur with lesions elsewhere in the nervous system, but they are less common and less severe. Third, there is preliminary evidence that depressive symptoms may differ subtly in different neurological disorders. Suicide is common in Huntington's disease and epilepsy, but rare in Parkinson's disease; psychosis is common in depressed patients with epilepsy and rare in Parkinson's disease; the depression of Parkinson's disease is characterized by more anxiety and less guilt than primary depressive disorders; psychomotor retardation is more extreme in post-stroke depression than in other depression syndromes. Fourth, depression in neurological diseases usually responds to treatment with psychopharmacological agents or electroconvulsive therapy.

Mania Mania is much less common than depression in the course of neurological illness. Maniform symptoms have been observed in Huntington's disease, Wilson's disease, idiopathic basal ganglia calcification, stroke, trauma, multiple sclerosis, general paresis, viral encephalitis and postencephalitic syndromes, frontal degenerative disorders, and following thalamotomy. A variety of medications have also been reported to produce manic behavior including steroids, triazolobenzodiazepines, dopaminergic agents, thyroid preparations, sympathomimetics, and stimulants. Antidepressant agents may precipitate manic episodes in depressed patients.

Structural lesions producing mania usually involve the basotemporal region, parathalamic structures, or the inferior medial frontal lobe. When lateralized, the lesions have had a marked right-sided predominance. A family history of psychiatric illness is more common in patients with secondary mania than in normal controls or in patients with secondary depression, and genetic vulnerability may facilitate the appearance of mania in the setting of brain dysfunction. The natural history of secondary mania is variable, patients may experience a single manic episode, recurrent mania, or alternating periods of depression and mania. The optimal treatment of secondary mania has not been determined. Tranquilization may be necessary in the acute phases of the manic episode; lithium (Eskalith), carbamazepine (Tegretol), clonazepam (Klonopin), and valproate (Depakene) may be used in the treatment of secondary mania; these agents may also be used prophylactically in patients who require treatment with agents that have previously precipitated manic behavior.

Personality Alterations *Personality* refers to stable patterns of behavior that include the way one relates to, perceives, and thinks about the environment and oneself. This is the least explored area of neuropsychiatry. Personality changes have been difficult to quantify for study, and personality alterations may be difficult to distinguish from the delusional and mood disorders that also occur in neurological illness. Table 2.1-14 summarizes the personality alterations observed in specific neurological diseases and conditions.

Neurological Disease	Personality Alteration
Alzheimer's disease	Disengagement, indifference
Frontal lobe degenerations	Disinhibition or apathy
Huntington's disease	Irritability, impulsiveness
Human immunodeficiency virus (HIV) encephalopathy	Apathy
Focal lesions	
Orbitofrontal	Irritability, impulsiveness, "pseudopsychopathic"
Medial frontal	Apathy, loss of motivation and initiative
Right hemisphere (childhood)	Schizoid
Right hemisphere (adult)	Alexithymia
Left hemisphere (Wernicke's area)	Suspiciousness, irritability
Bilateral temporal lobe	Placidity (component of the Kluver-Bucy syndrome)
Ventromedial hypothalamus	Rage
Temporal lobe epilepsy	Suspiciousness, Geschwind's syndrome (hyperreligiosity, circumstantiality, hypergraphia, viscosity, hyposexuality)

Table 2.1-14 Personality Alterations Described in Neurological Illnesses

Alzheimer's disease has a profound impact on personality and the behavioral changes may predate the neuropsychological deficits. Early in the illness, patients become disengaged and indifferent, showing little concern about their own disease or insight into the feelings of family members. Late in the course, impulsiveness and aggression are often exhibited. Patients with other dementia syndromes exhibit contrasting personality alterations. Frontotemporal dementias such as Pick's disease usually produce disinhibition, impulsiveness, and facetiousness characteristic of orbitofrontal dysfunction or apathy suggestive of medial frontal pathology. Huntington's disease combines marked irritability with impulsiveness sometimes leading to aggression, violence, and suicide. Many subcortical dementias (e.g., Parkinson's disease, progressive supranuclear palsy, HIV encephalopathy) cause apathy and indifference.

Focal lesions also may be associated with personality alterations. The marked personality alterations following orbitofrontal and medial frontal lesions have already been described. Patients with Wernicke's aphasia are often suspicious, demanding, aggressive, and irritable. Preliminary studies of adults with right hemisphere lesions suggest that they may exhibit alexithymia with reserved expression of emotions and a tendency to forego symbolic thought. Right hemisphere damage sustained in childhood may result in a schizoid type of behavioral pattern, perhaps because the inability to perceive or execute emotional cues limits the child's ability to engage in interpersonal relationships.

Limbic system lesions have profound effects on personality. Ventromedial hypothalamic lesions produce a syndrome of dementia, hyperphagia, and rage. Bilateral medial temporal lobe lesions produce the Kluver-Bucy syndrome of placidity, hypersexuality and altered sexual behavior, visual agnosia, hypermetamorphosis (compulsive exploration of environmental stimuli), and hyperorality.

A controversial area of research in neuropsychiatry concerns personality changes in epilepsy. Personality inventories reveal that the most common type of personality change in epilepsy patients is increased suspiciousness and paranoia. An uncommon syndrome (known as the *temporal lobe epilepsy personality* or *Geschwind's syndrome*) occurring in patients with partial complex seizures consists of hypergraphia, circumstantiality, interpersonal viscosity, hyperreligiosity, and hyposexuality. This personality style is not unique to epilepsy but occurs with increased frequency in patients with epilepsy and can be the presenting manifestation of the limbic seizure disorder.

Anxiety Anxiety is a state of apprehension, tension, or uneasiness that occurs in anticipation of internal or external danger. The anxiety syndrome includes motor tension, autonomic hyperactivity, apprehensive expectation, and heightened vigilance. Anxiety occurs in a variety of neurological and medical disorders and can be precipitated by drugs. Neurological diseases causing anxiety include brain tumors (particularly in the regions of the temporal lobe or third ventricle), trauma, stroke, migraine, encephalitis, multiple sclerosis, epilepsy, Alzheimer's disease, Parkinson's disease, Huntington's disease, and Wilson's disease. The principal medical conditions associated with anxiety include hypoxia, hypoglycemia, hyperthyroidism, Cushing's disease, and mitral valve prolapse. Medications capable of causing anxiety are cocaine, sympathomimetics (e.g., amphetamines), caffeine, organophosphate toxicity, lidocaine, and procaine penicillin. Alcohol and sedative-hypnotic withdrawal are frequently accompanied by anxiety. When anxiety is associated with focal brain lesions, the pathology usually involves the right temporal lobe.

Treatment of anxiety in neurological disorders requires attention to the underlying condition as well as the anxiety symptoms. When pharmacological agents are indicated, conventional anxiolytics and b-adrenergic receptor antagonists are useful.

Obsessive-Compulsive Disorder *Obsessions* are recurrent, intrusive, senseless ideas, thoughts, and images that are ego-dystonic and involuntary. *Compulsions* are repetitive activities carried out in response to an obsession or executed in a stereotyped and ritualized fashion. Lesions in basal ganglia are associated with obsessive-compulsive behavior (Table 2.1-15). Conditions affecting the basal ganglia and producing obsessive-compulsive disorder include Parkinson's disease, postencephalitic Parkinsonism, Huntington's disease, progressive supranuclear palsy, Tourette's disorder, neuroacanthocytosis, Sydenham's chorea, carbon monoxide poisoning, neonatal hypoxia, bilateral caudate infarctions, cardiopulmonary arrest, and manganese poisoning. Obsessional thinking has also been observed in conjunction with neuroleptic-induced and postencephalitic oculogyric crises. Treatment of obsessions and compulsions in neurological disorders entails treatment of the underlying disease and symptomatic relief of the obsessive-compulsive disorder.

Acute dystonia with oculogyric crises
Anoxia with bilateral globus pallidus lesions
Anoxic injury to caudate and putamen
Bilateral caudate nucleus infarctions
Carbon monoxide intoxication with bilateral globus pallidus injury
Carbon monoxide poisoning with bilateral caudate nucleus lesions
Huntington's disease
Manganese intoxication
Neuroacanthocytosis
Parkinsonism with compulsions during "on" period in patients experiencing on-off swings
Postencephalitic parkinsonism
Progressive supranuclear palsy
Sydenham's chorea
Tourette's disorder

Table 2.1-15 Neurological Disorders Associated With Obsessive-Compulsive Disorder

Paraphilias and Altered Sexual Drive Neurological disorders can produce paraphilic behavior and alterations in sexual drive. Markedly diminished sexual interest occurs with temporal lobe epilepsy, hypothalamic lesions, and right hemisphere brain injuries. Heightened sexual drive occurs in secondary mania, postictally (i.e., after a seizure), following markedly improved seizure control in patients with epilepsy (e.g., after temporal lobectomy or with improved anticonvulsant control of seizures), with introduction of levodopa or other dopaminergic agents in Parkinson's disease, with diencephalic or frontal lobe lesions, after septal injury, and in the Kluver-Bucy syndrome. Hypersexuality has also been induced by amphetamines, cocaine, hyperthyroidism, hypercortisolism, and androgen administration.

Paraphilias are characterized by intense sexual urges and sexually arousing fantasies usually involving nonhuman objects or animals, the suffering or humiliation of oneself or one's partner, or children or other nonconsenting persons. Examples of paraphilias include exhibitionism, fetishism, frotteurism, pedophilia, sexual masochism, sexual sadism, transvestitism, voyeurism, bestiality (zoophilia), and telephone scatologia. Paraphilic behavior has been described in association with temporal lobe epilepsy, postencephalitic states, Tourette's disorder, frontal lobe disorders, Huntington's disease, brainstem tumors, bilateral temporal injury, septal injury, and multiple sclerosis. Paraphilic behavior has occasionally occurred with dopaminergic therapy of Parkinson's disease.

Ganser's Syndrome Ganser's syndrome is a syndrome of approximate answers that may be a manifestation of malingering, confusional state, or disinhibition syndromes. Patients with Ganser's syndrome will respond to items on mental status examinations in such an approximately correct fashion as to raise suspicion of duplicity (e.g., “five quarters in a dollar, 13 months in one year.”

Table 2.1-16 lists acquired neuropsychiatric syndromes that have lateralized origins, arising from left, right, or bilateral hemisphere damage.

Left Hemisphere	Right Hemisphere	Bilateral
Aphasia	Delusions with Schneiderian first-rank symptoms	Gerstmann's syndrome (acalculia, finger agnosia, right/left disorientation, agraphia without alexia)
Ideomotor apraxia	Primary progressive aphasia	Verbal amnesia
Depression (LR)	Alexithymia Aprosodia Capgras syndrome Mania Nonverbal amnesia Social impropriety Visuospatial abnormalities (RL)	Abulia Kluver-Bucy syndrome (placidity, altered sexual behavior, visual agnosia, hypermetamorphosis, hyperorality) Severe amnesia

Table 2.1-16 Etiological Lateralization of Neuropsychiatric Syndromes

PRINCIPLES OF NEUROPSYCHIATRY

This summary of neuropsychiatric syndromes leads to several generalizations that are applicable to clinical practice. First, essentially all types of behavior observed in idiopathic psychiatric syndromes can occur in association with a neurological disorder and neurological diseases are an important part of the differential diagnosis of behavioral disturbances. Second, the phenotypic identity of psychiatric and neurological disorder does not necessarily imply pathogenetic identity, but shared pathophysiological mechanisms in similar disorders is likely and provides a framework for treatment and research. Third, diagnosis informs therapy and a thorough diagnostic evaluation should be a part of every psychiatric assessment. Fourth, deficit syndromes frequently accompany productive symptoms and a probing mental status examination aids in the identification and characterization of neuropsychiatric syndromes. Fifth, laboratory tests and neuroimaging play an important role in confirming clinical diagnoses. Sixth, late-onset disorders are more likely to be related to brain diseases, but neuropsychiatric disorders are not limited to the elderly. Seventh, patients with neuropsychiatric illnesses usually lack the premorbid psychiatric or personality alterations that occur in many idiopathic psychiatric disorders. Eighth, the presence of neuromedical illness in a patient with a behavior disturbance should lead the clinician to explore potential relationships between the two. Ninth, patients with neuropsychiatric illness often lack the family history of psychiatric disability common in many with idiopathic psychiatric disorders; however, hereditary neuropsychiatric illnesses such as Huntington's disease are exceptions to this rule. Tenth, pharmacotherapy relies on intervention in brain processes and is applicable in neuropsychiatric as well as idiopathic psychiatric disorders. Neuropsychiatric syndromes are more common in patients who are older or who have sustained brain injuries and drug dosages will usually have to be adjusted downward to avoid pharmacotoxicity.

SUGGESTED CROSS-REFERENCES

2.2 NEUROPSYCHIATRIC ASPECTS OF CEREBROVASCULAR DISORDERS

ROBERT G. ROBINSON, M.D., AND SERGIO E. STARKSTEIN, M.D., FH.D.

Cerebrovascular disease represents one of the major health problems in the United States, with an estimated annual incidence for thromboembolic stroke between 300,000 and 400,000. Since the late 1970s, however, there has been a steady decline in the incidence of stroke, presumably related to the improved control of hypertension. Nevertheless, among adults over age 50, stroke remains the third leading cause (after heart disease and cancer) of mortality and morbidity in the United States.

Although virtually any psychiatric disorder may occur in patients with cerebrovascular disease, the only disorder listed in the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) that is specific to cerebrovascular disease is vascular dementia (Table 2.2-1). Other disorders that may be related to cerebral infarction or hemorrhage are shown in Table 2.2-1. These diagnoses require that “there is evidence from the history, physical examination, or laboratory findings that the disturbance is the direct physiological consequence of the cerebrovascular disorder.”

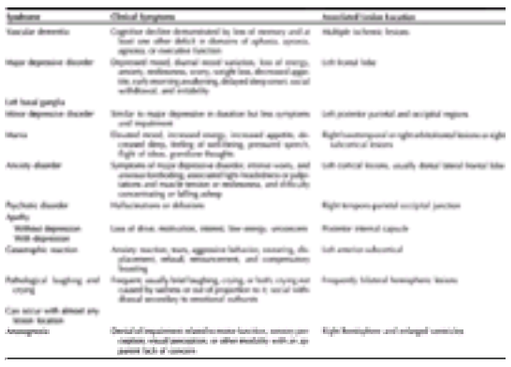

Table 2.2-1 Clinical Syndromes Associated With Cerebrovascular Disease

HISTORY

The first reports of emotional reactions following brain damage (usually caused by cerebrovascular disease) were made by neurologists and psychiatrists in case descriptions. For example, Adolf Meyer proposed that insanities following brain injury may be related to specific locations and causes of brain injury although he believed that most of these disorders resulted from a combination of psychological, social, and biological factors. Joseph Babinski noted that patients with right hemisphere disease frequently displayed the symptoms of anosognosia, euphoria, and indifference. Eugen Bleuler recognized that “melancholic moods following stroke may last for months and sometimes longer.” Emil Kraepelin stated that cerebrovascular disorder may either accompany manic depressive disease (bipolar I disorder) or may itself engender states of depression.

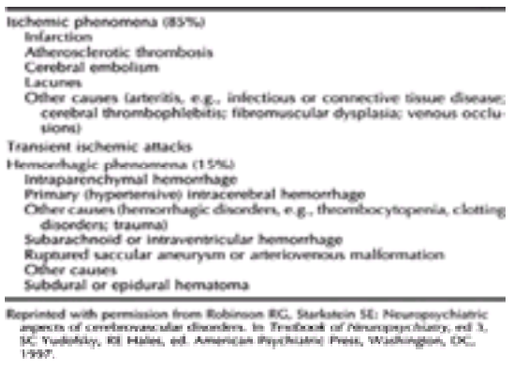
Kurt Goldstein was the first to describe an emotional disorder that he termed *catastrophic reaction* thought to be uniquely associated with brain disease. Catastrophic reaction is an emotional outburst involving various degrees of anger, frustration, depression, tearfulness, refusal, shouting, swearing, and sometimes aggression. Goldstein ascribed this reaction to the organism's inability to cope when faced with a serious defect in its physical or cognitive functions.

A second emotional abnormality, also thought to be characteristic of brain injury, was the *indifference reaction* described by Derek Denny-Brown. Associated with right hemisphere lesions, this reaction consists of symptoms of indifference toward failure, lack of interest in family and friends, enjoyment of foolish jokes, and minimization of physical difficulties. In the late nineteenth century, Leonore Welt first described euphoria and loquaciousness associated with orbital frontal injury. Hermann Oppenheim used the term *Witzelsucht* to refer to the inappropriate sense of humor in these patients and Karl Kleist distinguished the orbital frontal cortex as the center of emotional life and the dorsal lateral frontal cortex as the source of psychomotor and intellectual activity.

A third emotional disorder that has been historically associated with brain injury such as cerebral infarction is pathological laughter or crying in which patients' emotional displays are characteristically unrelated to their inner emotional state. For example, crying might occur spontaneously or after some seemingly minor provocation.

COMPARATIVE NOSOLOGY

The most pragmatic way to classify cerebrovascular disease is to examine the means by which parenchymal changes occur in the brain. The first of these, ischemia, may occur either with or without infarction of parenchyma, and includes transient ischemic attacks, atherosclerotic thrombosis, cerebral embolism, and hemorrhage (Table 2.2-2). Hemorrhage may cause either direct parenchymal damage by extravasation of blood into the surrounding brain tissue, as in intracerebral hemorrhage, or indirect damage by hemorrhage into the ventricles, subarachnoid space, extradural area, or subdural area (Fig. 2.2-1). These changes result in a common mode of expression: a sudden, convulsive, focal neurological deficit or stroke.



Ischemic phenomena (85%)
- Infarction
- Atherosclerotic thrombosis
- Cerebral embolism
- Lacunes
- Other causes (arteritis, e.g., infectious or connective tissue disease; cerebral thrombophlebitis; fibromuscular dysplasia; venous occlusions)

Transient ischemic attacks

Hemorrhagic phenomena (15%)
- Intraparenchymal hemorrhage
- Primary (hypertensive) intracerebral hemorrhage
- Other causes (hemorrhagic disorders, e.g., thrombocytopenia, clotting disorders; trauma)
- Subarachnoid or intraventricular hemorrhage
- Ruptured saccular aneurysm or arteriovenous malformation
- Other causes
- Subdural or epidural hematoma

Reprinted with permission from Robinson RG, Starkstein SE: Neuropsychiatric aspects of cerebrovascular disorders. In Textbook of Neuropsychiatry, ed 3. SC Yudofsky, RE Hales, ed. American Psychiatric Press, Washington, DC, 1997.

Table 2.2-2 Classification of Cerebrovascular Disease

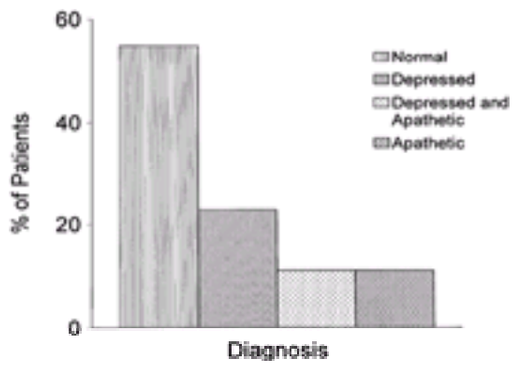


FIGURE 2.2-1 The percentage of patients with apathy, depression, or both following acute stroke among 80 consecutive patients. About half of the patients with apathy had an accompanying depressive disorder. (Data from Starkstein SE, Fedoroff JP, Price TR, Leiguarda R, Robinson RG: Apathy following cerebrovascular lesions. Stroke *24:* 1625, 1993.)

There are four major categories of cerebrovascular disease (Table 2.2-1): atherosclerotic thrombosis, cerebral embolism, lacunae, and intracranial hemorrhage. In various studies of the incidence of cerebrovascular disease, the ratio of infarcts to hemorrhages has been shown to be about 5 to 1. Atherosclerotic thrombosis and cerebral embolism each account for approximately one third of all strokes. There are many other less common causes of cerebrovascular disease.

EPIDEMIOLOGY

Vascular Dementia In a review of population-based studies the European Community for Concerted Action on Epidemiology and Prevention of Dementia found a consistent increase in the lifetime prevalence of vascular dementia with advancing age. Prevalence rates ranged from 1.5 per 100 for women ages 75 to 79 years in the United States to 16.3 per 100 for men older than age 80 in Italy. In most age groups men had a higher prevalence of vascular dementia than did women. Vascular dementia is the most common type of dementia in Japan, representing up to 50 percent of all clinical cases and from 54 to 65 percent of all autopsy-confirmed cases of dementia (Table 2.2-3).

Disorder	Prevalence rate	Studies
Vascular dementia	1.5/100; women 75–79 yrs; USA	Rocca et al. (1991)
	16.3/100 men >80 yrs; Italy	Rocca et al. (1991)
Major depressive disorder	10/100 dementia cases in USA	Kaszniel et al. (1988)
	15/100 strokes in community	Burvill et al. (1995)
	28/100 strokes in acute-care hospital	Robinson & Starkstein (1987)
Mania	<1/100 strokes in acute-care hospital	Robinson & Starkstein (1987)
Anxiety	6/100 strokes in acute-care hospital	Castillo et al. (1993)
	27/100 anxiety + acute depression	Castillo et al. (1993)
	28/100 anxiety ± acute depression	Astrom et al. (1993)
	3.5/100 anxiety neurosis in community	House et al. (1992)
Psychosis	<1/100 strokes in acute-care hospital	Robinson & Starkstein (1987)
Apathy	11/100 apathy only–acute-care hospital	Starkstein et al. (1992a)
	11/100 apathy ± depression in acute-care hospital	Starkstein et al. (1992a)
Catastrophic reaction	19/100 strokes in acute-care hospital	Starkstein et al. (1992b)
Pathological emotions	15/100 acute stroke in community	House et al. (1991)
	21/100 6-month poststroke	House et al. (1991)
	12/100 1-year poststroke	House et al. (1991)
	18/100 rehabilitation hospital	Robinson & Starkstein (1987)
Anosognosia	24/100 strokes in acute-care hospital	Starkstein et al. (1992)

Table 2.2-3 Prevalence Studies of Psychiatric Disorders After Stroke

In two autopsy series, stroke accounted for approximately 20 to 25 percent of all dementia cases, and 10 to 15 percent of cases were thought to be the result of a combination of vascular disease and dementia of the Alzheimer's type. In a clinical series using in vivo imaging, the proportion of dementia that was directly attributable to stroke was 10 to 15 percent.

Depression Depressive disorders are probably the most common emotional disorder associated with cerebrovascular disease. The prevalence depends upon whether community-based samples or hospitalized patients are studied or whether patients with acute stroke or those with chronic stroke are evaluated. Approximately 15 to 25 percent of community-based samples of acute stroke patients and 30 to 40 percent of patients hospitalized with acute stroke have a clinically diagnosable major or minor depressive disorder (Table 2.2-3).

Mania Mania occurs much less frequently than depression following stroke (only 3 cases were identified among a consecutive series of more than 300 acute stroke patients including 143 patients with longitudinal assessment). Although numerous case reports and empirical studies document that stroke is associated with mania, there are no epidemiological studies that document the incidence or prevalence of this condition.

Anxiety In a consecutive series of 309 patients with first-episode acute stroke lesions, only 6 percent met the criteria for generalized anxiety disorder in the absence of any other mood disorder. On the other hand, 27 percent of the 309 met the criteria of the revised third edition of DSM (DSM-III-R) for generalized anxiety disorder (excluding the 6-month duration criteria). The majority of patients with generalized anxiety disorder also had major or minor depression (i.e., 21 percent of the 27 percent with generalized anxiety disorder). A Swedish study also found that 28 percent of 80 patients with acute stroke had this disorder; 55 percent also had major depression (Table 2.2-3). A community-based study reported that 3.5 percent of 89 patients with stroke met of the ninth revision of *International Statistical Classification of Diseases* (ICD-9) criteria for anxiety neurosis at 1 month poststroke. Thus, anxiety disorder following stroke is usually comorbid with a depressive disorder but a small number of patients will have anxiety alone.

Psychosis Although it is rare, case reports and empirical studies have documented that psychosis may occur after stroke. No epidemiological study has documented the incidence or prevalence of psychosis following stroke.

Apathy Apathy is the absence or lack of feeling, emotion, interest, concern, or motivation and has been reported frequently among patients with brain injury. Using an apathy scale, of 80 consecutive patients with single stroke lesions, 9 (11 percent) showed apathy as their only psychiatric disorder whereas another 11 percent had both apathy and depression (Fig. 2.2-1; Table 2.2-3).

Catastrophic Reaction *Catastrophic reaction* is a term coined by Kurt Goldstein to describe anxiety, tears, aggressive behavior, swearing, displacement, refusal, renouncement, and compensatory boasting that he attributed to an “inability of the organism to cope when faced with physical or cognitive deficits.” Using a Catastrophic Reaction Scale (CRS) developed to assess the existence and severity of the catastrophic reaction, 12 of 62 consecutive patients (19 percent) with acute stroke lesions were found to have catastrophic reactions (Table 2.2-3).

Pathological Emotions *Pathological emotions* are characterized by episodes of laughing, or crying or both, that are not appropriate to the context. These episodes may appear spontaneously or may be elicited by nonemotional events and do not correspond to underlying emotional feelings (Table 2.2-2). This condition was found in 13 of 89 patients (15 percent) seen at 1 month poststroke, in 21 percent at 6 months, and in 12 percent at 1 year (Table 2.2-3). Other studies have reported frequencies of 18 percent in patients at a rehabilitation hospital and of 14 percent in patients in a community-based study.

Anosognosia The term *anosognosia* was first used by Joseph Babinski in 1914 to indicate the lack of awareness of hemiplegia. It has also been used to refer to unawareness of other poststroke deficits such as cortical blindness, hemianopia, and amnesia. Among 80 acute stroke patients, 24 percent had moderate or severe anosognosia (Table 2.2-3).

ETIOLOGY

Poststroke Depression Although the cause of poststroke depression is unknown, a number of studies have suggested that location of brain injury may play an important role. The first study to report a significant role for lesion location in poststroke depression examined 29 patients with left-hemisphere brain injury secondary to stroke (*N* = 18) or traumatic brain injury (*N* = 11) and found a significant inverse correlation between the severity of depression and the distance of the anterior border of the lesion from the frontal pole (Fig. 2.2-2). This surprising finding led to a number of subsequent examinations of this phenomenon in other populations; all these studies found a significant correlation between severity of depression and proximity of the lesion to the frontal pole.

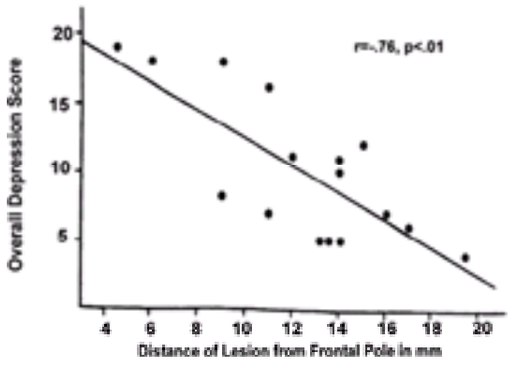

FIGURE 2.2-2 Scatter plot of the relationship between severity of depression in patients with stroke or traumatic brain injury and distance of the anterior border of the lesion from the frontal pole as measured on CT scan. For both stroke and trauma lesions, depression increased with proximity of the lesion to the frontal pole. (Reprinted with permission from Robinson RG, Szetela B: Mood change following left hemispheric brain injury. Ann Neurol *9:*447, 1981.)

Other studies of patients with acute stroke have also found that hemispheric lesion location plays an important role in poststroke depression. For example, a study of 45 patients with single lesions restricted to either cortical or subcortical structures in the left or right hemisphere found that significantly more (44 percent) patients with left cortical lesions or left subcortical lesions (39 percent) were depressed compared to patients with right cortical lesions (11 percent) or patients with right subcortical lesions (14 percent) (Fig. 2.2-3). Although some studies have not replicated this finding, most of the studies with negative findings examined patients who were beyond the acute stroke period. Other studies of patients within the first few weeks poststroke have found lateralized effects of infarction on major depressive disorder.

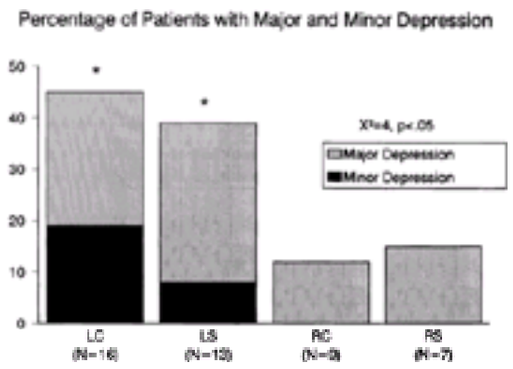

FIGURE 2.2-3 The frequency of depression in patients with acute first-ever stroke lesions restricted to cortical or subcortical brain regions. Both cortical and subcortical lesions of the left hemisphere were associated with greater frequency of depression than patients with right hemisphere lesions. (Data from Starkstein SE, Robinson RG, Price TR: Comparison of cortical and subcortical lesions in the production of poststroke mood disorders. Brain *110:*1045, 1987.)

Although significantly more patients with left anterior lesions developed poststroke depression compared with other lesion locations, not every patient with a left anterior lesion developed a depressive disorder. That raised the question of why some but not all patients with lesions in these locations develop depression. Thirteen patients with major poststroke depression were compared to 13 stroke patients without depression who were matched for lesion size and location. Patients with major depressive disorder, however, had significantly more subcortical atrophy as measured both by the ratio of third ventricle to brain (i.e., the area of the third ventricle divided by the area of the brain at the same level), and the ratio of lateral ventricle to brain (i.e., the area of the lateral ventricle contralateral to the brain lesion divided by the brain area at the same level) (Fig. 2.2-4). It is likely that the subcortical atrophy preceded the stroke because it was visible within a few days after the stroke and was found on the side of the brain opposite the lesion.

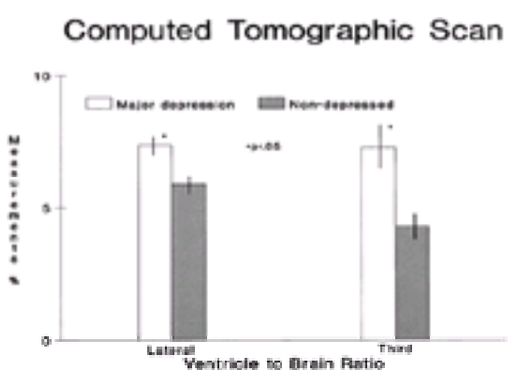

FIGURE 2.2-4 Ventricular to brain ratios in patients with and without major depression who were matched for lesion size and location. Patients with depression had larger ventricles, suggesting a mild degree of subcortical atrophy perhaps occurring prior to stroke, making them more vulnerable to developing depression. (Data from Starkstein SE, Robinson RG, Price TR: Comparison of patients with and without poststroke major depression matched for size and location of lesion. Arch Gen Psychiatry *45:*247, 1988.)

Several studies have reported that patients with depression were more likely than patients without depression to have either a previous personal history or a family history of psychiatric disorders. In addition, a low but significant correlation has been found between depression and functional physical impairment (i.e., activities of daily living); this association, however, was not found by all investigators. Thus, the severity of physical impairment does not appear to be a major determinant of depression. Several studies have found that depression may adversely affect physical recovery from stroke. One study examined a consecutive series of 63 stroke patients with subsequent major or minor depressive disorder compared to nondepressed stroke patients during a 2-year follow-up. Although both groups had similar impairments in activities of daily living during the time they were in the hospital, the depressed patients had significantly less improvement by 2 years follow-up than the nondepressed patients (Fig. 2.2-5). This finding held true after controlling for important variables such as the type and extent of in-hospital and rehabilitation treatment, the size and location of the lesion, the patient's demographic characteristics, the nature of the stroke, the occurrence of another stroke during the follow-up

period, and medical history.

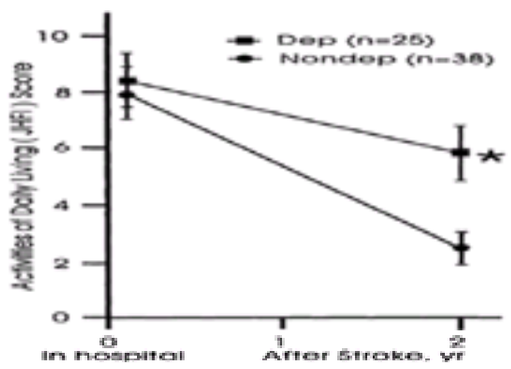

FIGURE 2.2-5 Change in activities of daily living scores (as measured by JHFI) for in-hospital depressed patients (either major or minor depression) and in-hospital nondepressed patients. At the time of the in-hospital evaluation, cognitive impairment associated with major depression and left hemisphere stroke lasted for about 1 year. (Reprinted with permission from Parikh RM, Robinson RG, Lipsey JR, Starkstein SE, Fedoroff JP, Price TR: The impact of post-stroke depression on recovery in activities of daily living over two-year follow-up. Arch Neurol *47:*785, 1990.)

Depression has also been found to be more common in nonfluent aphasic patients as compared to fluent aphasic patients. Although it may be that the higher frequency of depression among nonfluent aphasic patients is related to their greater awareness of their impairment, aphasia and depression do not appear to be causally related. The association between nonfluent aphasia and poststroke depression may be explained by the fact that the lesion location that produces nonfluent language may also produce depression.

It has been suggested that poststroke depression may be the consequence of severe depletions of norepinephrine or serotonin produced by frontal or basal ganglia lesions. In support of this hypothesis, a positron emission tomography (PET) study found that patients with left hemisphere stroke showed a significant inverse correlation between the amount of *N*-methylspiperone binding (presumably serotonin [5-hydroxytryptamine (5-HT)] type 2 [5-HT $_2$] receptor binding) in the left temporal cortex and severity of depression (i.e., higher depression rating scale scores were associated with lower serotonin receptor binding). Patients with right hemisphere lesions on the other hand had an increase in 5-HT $_2$ receptor binding in the temporal and parietal cortex. Thus, a greater depletion of biogenic amines in patients with right hemisphere lesions as compared with those with left hemisphere lesions could have led to a compensatory upregulation of receptors that might protect against depression. Also, patients with left hemisphere lesions may have had moderate depletions of biogenic amines but without a compensatory upregulation of serotonin receptors, therefore having a dysfunction of biogenic amine systems in the left hemisphere. This dysfunction ultimately may have led to the clinical manifestations of depression.

Mania A study of 17 patients with secondary mania (mood disorder due to stroke, with manic features) found that most had right hemisphere lesions. The frequency of right hemisphere lesions was significantly higher among 28 patients with major depressive disorder, who tended to have left frontal or basal ganglia lesions (Fig. 2.2-6). These findings were replicated in other patients with secondary mania. Lesions associated with mania were either cortical (basotemporal cortex or orbitofrontal cortex) or subcortical (frontal white matter, basal ganglia, or thalamus). A PET study with fluorine-18 deoxyglucose (FDG) showed a focal hypometabolic deficiency in the right basotemporal cortex in 3 patients with right subcortical lesions.

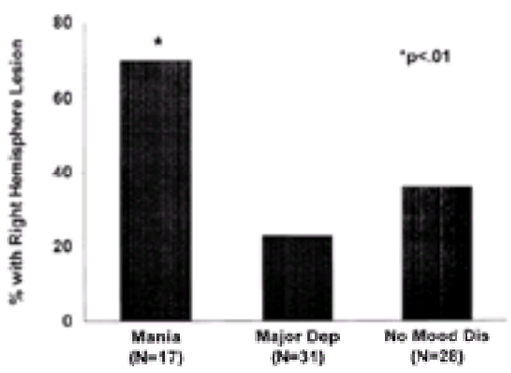

FIGURE 2.2-6 The percent of patients with mania, major depressive disorder, or no mood disorder following brain injury divided by lesion location as visualized on CT scan. Mania was strongly associated with right hemisphere lesions and major depressive disorder with left hemisphere injury. (Data from Robinson RG, Boston JD, Starkstein SE, Price TR: Comparison of mania with depression following brain injury: Causal factors. Am J Psychiatry *145:*172, 1988.)

Thus, right hemisphere lesions that lead to mania appear to be in specific right hemisphere structures that have connections to the limbic system. The right basotemporal cortex may be particularly important because direct lesions as well as distant hypometabolic effects (diaschisis) of this cortical region were frequently associated with secondary mania.

Not every patient with a lesion in limbic areas of the right hemisphere develops secondary mania, which suggests that risk factors must exist for this disorder. One study found that patients with secondary mania had a significantly higher frequency of positive family history of mood disorders than did depressed patients or patients with no mood disturbance. Another study compared patients with secondary mania to patients with no mood disturbance who were matched for size, location, and etiology of brain lesion. Patients with secondary mania had significantly greater degree of subcortical atrophy than no mood disturbance patients, as measured by bifrontal and third ventricular to brain ratio. Of the patients who developed secondary mania, those who had a positive family history of psychiatric disorders had significantly less atrophy than those without such a family history, suggesting that genetic predisposition to mood disorders and brain atrophy may be independent risk factors for poststroke mania.

Although the mechanism of secondary mania remains unknown, lesion studies as well as metabolic studies have suggested that the right basotemporal cortex may play an important role. A combination of biogenic amine system dysfunction and release of tonic inhibitory input into the basotemporal cortex and lateral limbic system may lead to mania.

Poststroke Psychosis Information about the mechanism of poststroke psychosis (psychotic disorder due to stroke) is derived from anecdotal or small case series. One study of 5 patients with psychosis following stroke found that all patients had right hemisphere lesions, primarily involving frontoparietal regions. When compared with 5 patients matched for age, education, and lesion size and location but no psychosis, patients with secondary psychosis had significantly greater subcortical atrophy, as manifested by larger areas of both the frontal horn of the lateral ventricle and the body of the lateral ventricle (measured on the side contralateral to the brain lesion). Several investigators have also reported a high frequency of seizures among patients with secondary psychosis. These seizures usually started after the brain lesion but before the onset of psychosis. Three of 5 control subjects matched for psychosis and lesion were found to have seizure disorder, as compared to 0 of 5 poststroke nonpsychiatric control subjects.

It has been hypothesized that three factors may be important in the mechanism of organic hallucinations, namely a right hemisphere lesion involving the temporoparietal cortex, the presence of seizures, and subcortical brain atrophy.

Apathy A study of 80 patients with single stroke lesions found that patients with apathy showed a significantly higher frequency of lesions involving the posterior limb of the internal capsule as compared to patients with no apathy. Lesions in the internal globus pallidus and the posterior limb of the internal capsule have been

reported to produce behavioral changes, such as motor neglect, psychic akinesia, and akinetic mutism. The ansa lenticularis is one of the main internal pallidal outputs, and it ends in the pedunculopontine nucleus after going through the posterior limb of the internal capsule. In rodents, this pathway has a prominent role in goal-oriented behavior and dysfunction of this system may explain the presence of apathy in patients with lesions of the posterior limb of the internal capsule.

Catastrophic Reaction In a study of 62 patients with acute stroke, those demonstrating catastrophic reactions had a significantly higher frequency of lesions involving the basal ganglia compared to acute stroke controls. When 10 depressed patients with a catastrophic reaction were compared to 10 depressed patients without a catastrophic reaction, the group with catastrophic reaction had significantly more anterior lesions, mostly located primarily in subcortical regions (i.e., 8 of 9 depressed patients with catastrophic reaction had subcortical lesions; 3 of 9 depressed patients without catastrophic reaction had subcortical lesions).

Based on these findings, the catastrophic reaction may result from neurophysiological dysfunction rather than realization of intellectual impairment. Catastrophic reaction occurred predominantly in patients with major depressive disorder associated with anterior subcortical lesions. Subcortical damage has also been hypothesized to underlie the “release” of emotional display by removing inhibitory input to limbic areas of the cortex.

Pathological Emotions Pathological emotions have classically been explained as secondary to the bilateral interruption of descending neocortical upper motor neuron innervation of bulbar motor nuclei. Some patients with pathological emotions have bilateral lesions and pseudobulbar palsy but others do not. One study found that patients with frontal or temporal lesions in either hemisphere had a significantly increased frequency of pathological emotions. Examination of lesion size and location in 12 patients with pathological crying found that the patients with the most frequent crying episodes had relatively large bilateral pontine lesions; the intermediate group had large bilateral lesions. The least affected patients had relatively large unilateral subcortical lesions. It was hypothesized that pathological emotions may arise from partial destruction of raphe serotonergic neurons or their projections.

DIAGNOSIS AND CLINICAL FEATURES

Vascular Dementia Dementia is a syndrome that includes deterioration of intellectual ability as well as alterations in the patient's emotional and personality functions. Multi-infarct dementia is characterized by an abrupt onset, by stepwise deterioration of intellectual function, and gradual accumulation of neuropsychological deficits in which some cognitive functions are more impaired than others; it results from ischemic injury in multiple brain regions. To make the diagnosis, these deficits must not be limited to a period of depression or delirium and must be of sufficient degree to impair work, usual social activities, or interpersonal relations. Finally, there must be evidence of organic factors related to these disturbances.

For the diagnosis of vascular dementia using DSM-IV criteria, cognitive decline should be demonstrated by loss of memory and at least one other deficit, including aphasia, apraxia, agnosia, or deterioration of executive function. Multifocal deficits are expected, and single defects in cognition, such as amnestic states, aphasia, and apraxias, do not fulfill the criteria. Single lesions may produce vascular dementia if they lead to loss of memory as well as some other cognitive function, deficits that are severe enough to produce impairment in daily living.

Diagnosing vascular dementia can be difficult. A particularly difficult differential diagnosis occurs in patients with cerebral infarction but without prominent (focal) neurological symptoms. This is frequently the case with thalamic or parietal lobe infarctions that present with confusion and drowsiness as the only clinical manifestations. Diagnostic problems may also occur when nonvascular diseases, intracranial neoplasms, or subdural hematoma present with focal neurological deficits of acute onset.

Poststroke Depression A comparison of depressive symptoms among patients with acute stroke with and without depression was undertaken to determine whether depression or acute physical illness was the cause of depressive symptoms. A consecutive series of 85 stroke patients who acknowledged the presence of a depressed mood (no other symptom was required) were compared with 120 stroke patients without a depressed mood. The study found that, except for early morning awakening, all the affective and autonomic symptoms of depression were significantly more frequent among patients with a depressed mood than among patients without a depressed mood ($p < .01$; (Fig. 2.2-7). Moreover, the presence of nonspecific symptoms of depression (i.e., the frequency of depressive symptoms in the nondepressed group) may have led to false-positive diagnoses in only 3 percent of patients, and only 5 percent of patients had all the symptoms necessary for a diagnosis of major depressive disorder except for feelings of sadness (i.e., possible false-negative cases). Therefore, the use of DSM-IV criteria in an acutely medically ill population does not appear to produce significant numbers of false-positive or false-negative cases.

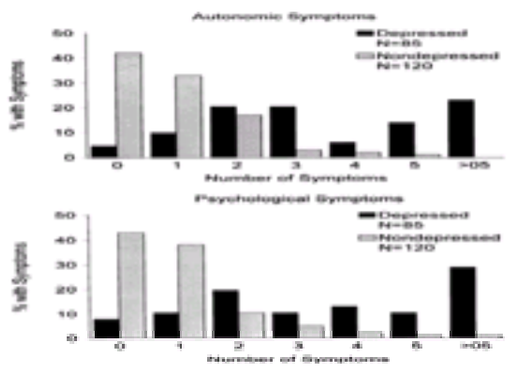

FIGURE 2.2-7 Autonomic and psychological symptoms of depression among patients with depressed mood after stroke. (Reprinted with permission from Fedoroff JP, Starkstein SE, Parikh RM, Price TR, Robinson RG: Are depressive symptoms non-specific in patients with acute stroke? Am J Psychiatry *148:*1172, 1991.)

Mania The symptoms of mania examined were in a series of 12 consecutive patients who met third edition of DSM (DSM-III) criteria for an organic affective syndrome, manic type. These patients, who developed mania after a stroke, traumatic brain injury, or tumors, were compared to patients with primary mania (i.e., no known neuropathology). Both groups of patients showed similar frequencies of elation, pressured speech, flight of ideas, grandiose thoughts, insomnia, hallucinations, and paranoid delusions. Thus, the symptoms of mania that occurred after brain damage (secondary mania) appeared to be the same as those found in mania without brain damage (primary mania).

Anxiety The diagnosis of generalized anxiety disorder based on DSM-IV criteria is termed “anxiety disorder due to stroke with generalized anxiety.” It requires the presence of anxiety and worry the majority of the time for 6 or more months with three or more of the following symptoms: restlessness or being keyed up, early fatigue, difficulty concentrating, irritability, muscle tension, or sleep disturbance. Generalized anxiety disorder was associated with a prior history of alcohol abuse significantly more frequently among patients with acute stroke lesions than among depressed or control patients. A subsequent in-hospital study found that patients with generalized anxiety disorder and major depressive disorder were significantly more impaired in their activities of daily living and social functioning at 1 to 2 years follow-up than patients with major depressive disorder alone. Hospitalized patients with generalized anxiety disorder, however, were not more impaired in their activities of daily living or social functioning than patients without this disorder. These findings suggest that impairment does not cause the disorder but the disorder impacts on physical and social recovery from stroke.

Apathy In a study of 9 patients with poststroke apathy compared to 71 stroke patients without apathy, the only demographic correlate of apathy was age. Apathetic patients (with or without depression) were significantly older than nonapathetic patients. Also, apathetic patients showed significantly more severe deficits in activities of daily living (ADL) and there was a significant interaction between depression and apathy on scale scores, with the greatest impairment found in patients who were both apathetic and depressed.

Catastrophic Reaction Catastrophic reactions occurred in 12 of 62 patients (19 percent) admitted to the hospital with stroke. Patients with catastrophic reactions were found to have a significantly higher frequency of familial and personal history of psychiatric disorders (mostly depressive disorder) than patients without catastrophic reactions. Catastrophic reactions, however, were not significantly more frequent among aphasic compared with nonaphasic patients. This finding did not support the contention that catastrophic reactions represent an understandable psychological response of “frustrated” aphasic patients. Furthermore, 9 of the 12 patients with catastrophic reaction also had after their strokes major depressive disorder, 2 had minor depressive disorder and only 1 was not depressed. Thus,

catastrophic reaction was significantly associated with major depressive disorder.

Pathological Emotions A study of the clinical correlates and treatment of emotional lability (including pathological laughter and crying) was conducted in 28 patients with either acute or chronic stroke. A Pathological Laughter and Crying Scale (PLACS) was developed to assess the existence and severity of emotional lability. There are no generally accepted criteria for the diagnosis of pathological emotions. Patients with this condition, however, acknowledged an inability to control their crying or laughter, an increased frequency of emotional display, and a recognition that the emotional display was inconsistent with or excessive in terms of their underlying emotional feelings.

PATHOLOGY AND LABORATORY EXAMINATION

Vascular Dementia The clinical identification of vascular dementia requires a medical history, neurological examination, psychiatric interview, and psychometric testing using a dementia rating scale. Structural imaging studies using computed tomography (CT) or magnetic resonance imaging (MRI) scans should document the existence of one or more cerebral infarctions (Fig. 2.2-2). Laboratory data that can be helpful are blood chemistries (including B_{12}, folate, thyroid function), cerebrospinal fluid analysis, an electroencephalogram (EEG), and an EEG with evoked responses, CT, MRI, and, in certain cases, cerebral angiography. Data from these laboratory studies will usually identify cases of potentially treatable forms of dementias caused by tumor, vascular malformation, cerebral hematoma, normal-pressure hydrocephalus, infections, and metabolic, toxic, and drug-induced encephalopathy, as well as dementia due to vitamin or endocrine deficiencies.

Poststroke Depression The dexamethasone (Decadron) suppression test (DST) has been investigated as a possible biological marker for major depressive disorder with melancholic features. Several studies have demonstrated a statistical association between major poststroke depression (mood disorder due to stroke with major depressive-like feature) and failure to suppress serum cortisol in response to administration of dexamethasone. The specificity of the test, however, has generally been insufficient to allow it to be diagnostically useful. In a study of 65 patients whose acute strokes had occurred within the preceding year, 67 percent of the patients with major poststroke depression failed to suppress serum cortisol, compared to 25 percent of patients with minor depressive disorder, and 32 percent of nondepressed patients. The sensitivity of the DST for major depression was 67 percent but the specificity was only 70 percent. False-positive tests, found in 30 percent of patients, seemed to be related to large lesion volumes.

A study of growth hormone response to desipramine found that growth hormone responses were significantly blunted in patients with poststroke depression, suggesting that diminished a_2 adrenergic receptor function may be an important marker for poststroke depression. The sensitivity of the test was 100 percent and the specificity was 75 percent. Future studies may further examine the validity of the endocrine response as a marker of poststroke depression.

Other Disorders The utility of laboratory examinations in the diagnosis or prognosis of mania, anxiety disorder, psychosis, apathy, catastrophic reactions, or anosognosia have not been established except as discussed in the section on etiology.

COURSE AND PROGNOSIS

Vascular Dementia The course of vascular dementia is characterized by current stroke with associated deterioration of cognitive function. The probability of recurrent stroke is about 7 percent per year. The course and prognosis, however, can be influenced by prevention. A longitudinal study of 173 patients examined the frequency of risk factors for stroke and cerebral atherosclerosis among patients with vascular dementia. Although hypertension was the single most potent risk factor for cerebral atherosclerosis and stroke, hypotension, present in 66 percent of cases, was by far the most common risk factor for vascular dementia in this sample. Heart disease of the atherosclerotic type, with or without cardiac arrhythmia, was also represented in the majority of cases of vascular dementia. Cardiac disease may provide a source of cerebral emboli leading to vascular dementia. Smoking of one or more packs of cigarettes per day was a risk factor in 21 percent of the patients. Hyperlipidemia of the type 4 form (hypertriglyceridemia) was present in 29 percent of cases. Diabetes mellitus of sufficient clinical severity to require medical treatment was found in 20 percent of the cases, and symptomatic peripheral vascular disease with ischemic symptoms referable to the lower extremities was present in 6 percent of the cases. The association with limited education suggested that education-induced factors (perhaps neurobiological or social factors) place patients at greater risk for developing dementia from a vascular cause. Thus, the course and prognosis of vascular dementia is dependent upon factors that place patients at risk for vascular dementia.

Depression In a 2-year longitudinal study, a consecutive series of 103 acute stroke patients were examined for depression at 3, 6, 12, and 24 months follow-up. At the time of the initial in-hospital evaluation, 26 percent of the patients had the symptom cluster of major depressive disorder whereas 20 percent had the symptom cluster of minor depressive disorder (Fig. 2.2-8). Although both major and minor depressive disorders were still present in 86 percent of patients at 6 months follow-up, only 1 of 5 patients with in-hospital major depression continued to have the condition at 1 year follow-up (2 cases had minor depression). Patients with minor depression, however, had a less favorable prognosis, with only 40 percent having no depression at 1 year and 30 percent having no depression at 2 years follow-up. In addition, about 30 percent of patients who were not depressed in the hospital became depressed after discharge. Thus the natural course of major depression appeared to be between 6 months and 1 year whereas the duration of minor depression was more variable and in many cases the patients appeared to be chronically depressed.

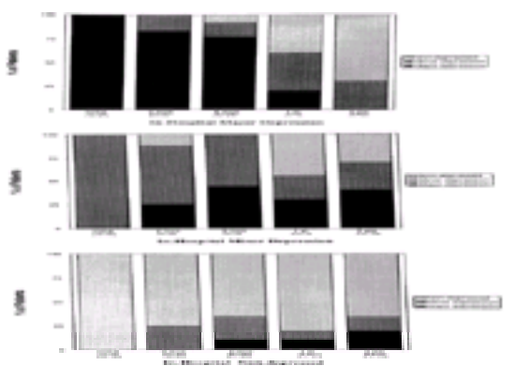

FIGURE 2.2-8 Diagnostic outcome in patients with acute stroke. The upper panel shows the diagnoses at 3, 6, 12, and 24 months follow-up for patients with an in-hospital diagnosis of major depressive disorder. The middle and lower panels show similar data for patients with in-hospital minor depressive disorder or no depression. Patients with in-hospital minor depressive disorder had a greater frequency of depressive disorders at 2 years than patients with major depressive disorder or nondepressed patients. (Data taken from Robinson RG, Bolduc P, Price TR: A two-year longitudinal study of poststroke depression: Diagnosis and outcome at one- and two-year follow-up. Stroke *18:*837, 1987.)

Other studies have also found that major depression had a duration of less than 1 year in the majority of cases, but a minority may develop chronic depression. A 10-year follow-up of patients with major or minor depression in the hospital found that depressed patients had a fourfold higher likelihood of dying than patients without depression. This finding held up even when other factors related to prognosis such as concurrent medical illness were controlled.

The nature of poststroke mood disorders is exemplified by the following case history.

CENTER>

A 52-year-old married man suffered a heart attack while playing basketball. Two nights later he had a thromboembolism that produced a large right middle cerebral artery infarct with left hemiparesis and sensory deficit. Within a couple of months he developed depression that lasted for several months. After a course of antidepressant medication, he became manic with grandiose ideas, pressured speech, decreased sleep, and increased energy. Those symptoms were effectively treated with lithium (Eskalith), but depression ensued, with prominent suicidal thoughts and delusional beliefs. This was treated effectively with electroconvulsive therapy and the patient remained euthymic on lithium and nortriptyline (Pamelor).

Mania The course of mania following stroke has not been systematically examined. Anecdotal cases have been reported that recurrent episodes of mania or

depression may occur in these patients. The response to medication and the course of disorder for individual patients with single or recurrent episodes of mania are shown in Figure 2.2-9.

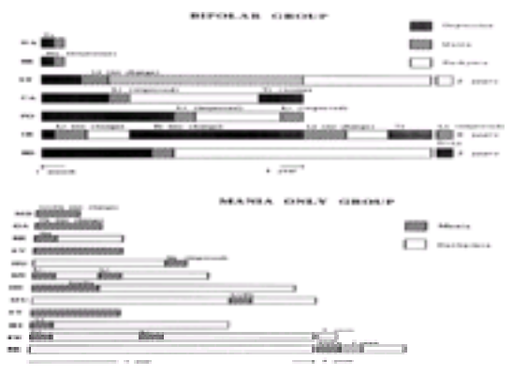

FIGURE 2.2-9 A, Longitudinal evolution of mood disorder for individual patients with bipolar I disorder. **B**, Longitudinal evolution of mood disorder for individual patients with unipolar mania (mania without depression). Tr, tricyclic antidepressant; Ne, nortryptyline; Li, lithium; Ca, carbamazepine. (Reprinted with permission from Robinson RG, Starkstein SE: Neuropsychiatric aspects of cerebrovascular disorders. In *Textbook of Neuropsychiatry*, ed 3, SC Yudofsky, RE Hales, editors. American Psychiatric Press, Washington, DC, 1997.)

Anxiety A 2-year follow-up of 142 patients with acute stroke found that 23 percent of patients developed anxiety disorder due to stroke with generalized anxiety after the initial in-hospital evaluation (i.e., between 3 and 24 months poststroke). Early-onset but not late-onset was associated with prior history of psychiatric disorder, including alcohol abuse. Early-onset anxiety disorder had a mean duration of 1.5 months whereas the delayed-onset form of the disorder had a mean duration of 3 months. In addition, the existence of anxiety disorder also influenced the duration of depression. Patients with generalized anxiety and major depressive disorder had a mean duration of depression that was significantly longer than the duration of depression without anxiety disorder.

Other Disorders The course and prognosis of patients with psychosis, apathy, catastrophic reaction, pathological emotion, and anosognosia have not been systematically studied.

TREATMENT

Vascular Dementia Some of the risk factors for stroke can be effectively treated, which raises the hope that the natural progression or even pathogenesis of vascular dementia might be effectively treated. Stroke of cardioembolic origin is responsible for about 15 percent of all ischemic strokes; this percentage is even higher among younger patients. Following cardioembolic stroke, anticoagulation is an effective treatment to reduce the risk of recurrence.

Since the late 1980s, treatment with antiplatelet aggregate drugs has reduced the number of repeated ischemic vascular episodes in patients with transient ischemic attacks. The efficacy of these drugs suggests that aspirin treatment might also modify the course of vascular dementia. Aspirin combined with other antiplatelet drugs has been shown to be effective in secondary prevention of stroke. The United Kingdom-Transient Ischemic Attack (UK-TIA) Aspirin Trial, with 2435 patients using two different dosages of aspirin, found a 21.7 percent and 25.1 percent reduction (depending on dosage) in the risk of nonfatal strokes, myocardial infarction, or death compared with placebo treatment.

Other therapeutic measures that may be helpful in vascular dementia include smoking cessation, prevention or careful management of diabetes mellitus, potassium supplementation (because of its vascular protective effect), estrogen replacement (in postmenopausal women), antihypertensive medications (angiotensin-converting enzyme inhibitors and calcium channel inhibitors), lipid-lowering agents, anticoagulants (for patients in whom emboli are likely), and aspirin. For patients who are in a “predementia” stage (i.e., those who have a history of transient ischemic attacks, stroke, previous cognitive impairment, or silent cerebral infarctions, but without global cognitive impairment), prevention may include carotid endarterectomy (when carotid stenosis is from 70 to and 99 percent), anticoagulants, aspirin, ticlopidine (Ticlid), agents that interfere with amyloid depositions in vessels (in the case of stroke secondary to lupus), and calcium channel inhibitors (pretreatment to attenuate the effect of infarcts). Finally, for patients in the dementia stage (i.e., patients with atherosclerosis of the extracranial arteries, cardiac embolism, and intracranial small vessel disease who have already shown evidence of cognitive decline in several areas of intellectual functioning), treatment measures may include antidepressant drugs, antihypertensive agents, cholinergic agonists, nerve growth factor, aspirin, or ticlopidine.

Depression Several randomized double-blind treatment studies have been published on the efficacy of antidepressant treatment of poststroke depression. The first study examined 14 patients treated with nortriptyline and 20 patients given a placebo. The 11 patients treated with nortriptyline who completed the 6-week study showed significantly greater improvement in their scores on the Hamilton Rating Scale for Depression (HAM-D) than did the 15 placebo-treated patients ($p < .01$; Fig. 2.2-10). Successfully treated patients had serum nortriptyline levels between 50 and 150 ng/mL. Three patients experienced adverse effects (including delirium, confusion, drowsiness, and agitation) that were severe enough to require the discontinuation of nortriptyline. A recent double-blind controlled trial using the selective serotonin reuptake inhibitor (SSRI) citalopram (Celexa) found that HAM-D scores were significantly more improved over 6 weeks in patients receiving active ($N = 27$) compared with placebo ($N = 32$) treatment. At both 3 and 6 weeks, the active group had significantly lower HAM-D than the placebo group. This study was the first to establish the efficacy of SSRIs in the treatment of poststroke depression.

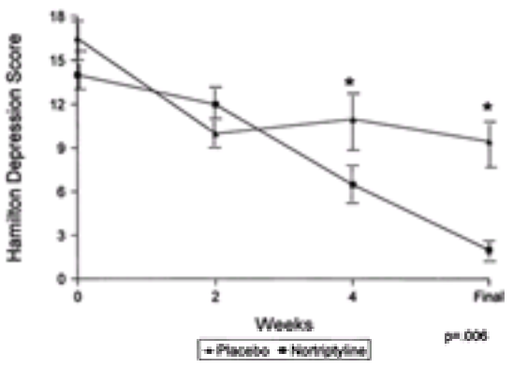

FIGURE 2.2-10 Hamilton depression scores during 6 weeks of double-blind treatment of poststroke depression with nortriptyline or placebo. Repeated measures analysis showed significant treatment effects with nortriptyline being superior to placebo at 4 and 6 weeks of treatment. (Reprinted with permission from Lipsey JR, Robinson RG, Pearlson GD, Rao K, Price TR: Nortriptyline treatment of poststroke depression: A double-blind treatment trial. Lancet *i*:297, 1984.)

Electroconvulsive therapy has also been reported to be effective for treating poststroke depression; it causes few adverse effects and no neurological deterioration. Finally, psychological treatment, including group and family therapy, has also been reported to be useful. However, controlled studies have not been conducted for these treatment modalities.

Anxiety Disorders There have been no systematic studies of the treatment of anxiety disorders following stroke. For guidance, the clinician must look to studies performed on patients with anxiety disorders not associated with brain injury. Benzodiazepines are the most commonly used medications in generalized anxiety disorders. Short-acting benzodiazepines are a prudent choice because longer-acting agents may place the patient at a greater risk for adverse effects, such as sedation, ataxias, disinhibition, and confusion. As with tricyclic drugs, very conservative dosage and careful monitoring must be employed.

In light of the comorbidity of anxiety and depression, antidepressants (tricyclics or SSRIs) may also be of benefit for the poststroke patient with generalized anxiety disorder. Tricyclic drugs may be efficacious in the treatment of generalized anxiety disorder even in the absence of depression; however, the specific needs of the poststroke patient have not been investigated. In one multicenter trial that excluded patients with comorbid depression, both chlordiazepoxide (Librium) and imipramine (Tofranil) were found to be superior to placebo in treatment of this disorder over an 8-week period. Finally, buspirone (BuSpar) may be useful in reducing anxiety without many of the adverse effects such as sedation and without the risk of development of tolerance.

Psychosis There are no controlled treatment trials among patients with delusions or hallucinations following stroke. Anecdotal reports have suggested two basic approaches to treatment, one utilizing anticonvulsant medications and the other antipsychotic agents. The use of anticonvulsants has its rationale in the frequent coexistence of seizures with psychotic disorders following stroke.

Apathy There have been no controlled trials of treatment of apathy following stroke. Patients have been treated with nortriptyline, apomorphine, and amphetamines with some success. Since this is a relatively common consequence of stroke, treatment trials are urgently needed to address a problem that can be devastating to the resumption of physical and social activities following stroke.

Pathological Emotions The treatment of pathological laughter and crying in patients with stroke has been assessed in two double-blind placebo-controlled trials. Using a standardized Pathological Laughter and Crying Scale (PLACS), a double-blind drug trial of nortriptyline versus placebo was conducted. The dosage of nortriptyline was titrated from 20 mg on week 1, to 50 mg on weeks 2 and 3, to 70 mg on week 4, to 100 mg on weeks 5 and 6. Twenty-eight patients completed the 6-week protocol (4 patients dropped out). Patients on nortriptyline showed significantly greater improvement in PLACS scores compared with placebo-treated controls (Fig. 2.2-11). These group differences were statistically significant at weeks 4 and 6. Although a significant improvement in depression scores was also observed, improvements in PLACS scores were significant for both depressed and nondepressed patients who displayed pathological emotion. This indicates that treatment response was not simply related to treatment of depression.

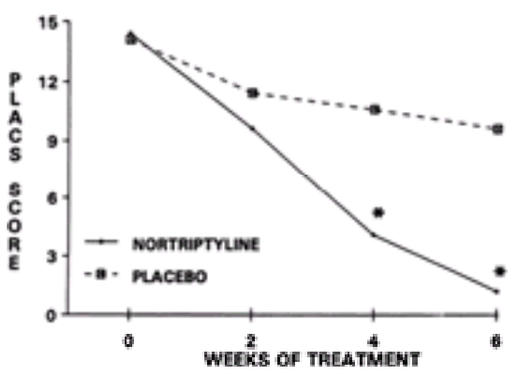

FIGURE 2.2-11 Pathological laughter and crying scale (PLACS) scores during 6 weeks of double-blind treatment of poststroke pathological emotions with nortriptyline or placebo. Repeated measures analysis showed significant treatment effects with nortriptyline being superior to placebo at 4 and 6 weeks of treatment. (Reprinted with permission from Robinson RG, Parikh RM, Lipsey JR, Storkstein SE, Price TR: Pathological laughing and crying following stroke: Validation of measurement scale and double-blind treatment study. Am J Psychiatry *150:* 286, 1993.)

Citalopram has also been evaluated in the treatment of pathological emotion following stroke. In a double-blind placebo-controlled crossover study, 16 patients were evaluated and treatment was given for 3 weeks after a week of washout. All of the citalopram-treated patients reported a greater than 50 percent reduction in the number of crying episodes. Eight patients responded within 24 hours of taking citalopram (20 mg), 3 patients responded within 3 days, and only 4 patients took more than a week to respond. None of the patients had major depressive disorder, but HAM-D scores dropped significantly during treatment with citalopram.

Thus, citalopram as well as nortriptyline appears to be an effective method of treatment for pathological crying following stroke. In addition, poststroke depression and pathological laughing and crying appear to be independent phenomena, although they may coexist. Both depression and pathological laughing and crying, however, are amenable to treatment.

A 64-year-old right-handed, married woman with no history of stroke suffered a thrombotic right hemisphere stroke with a hemiparesis but no sensory deficit. Beginning within a few days after the stroke, the patient had uncontrollable crying episodes that occurred 5 to 10 times per day and lasted for about 1 to 2 minutes. She and her husband were retired and had an active social life. In addition to the crying episodes, the patient had major depressive disorders with a HAM-D score of 19. She stated that she felt sad but the crying was greatly in excess of her sadness at the time and she had no sense of being able to control the crying. Her PLACS score was 24, which was severe. She showed no improvement over 6 weeks of treatment with placebo but improved greatly after a course of nortriptyline. The pathological emotions were more troublesome to her than the depression. She stopped seeing any friends or even leaving the house for fear of being embarrassed socially by these crying episodes.

Other Disorders Effective treatments have not been established for catastrophic reactions or anosognosia.

2.3 NEUROPSYCHIATRIC ASPECTS OF BRAIN TUMORS

FACUNDO F. MANES, M.D., AND ROBERT G. ROBINSON, M.D.

Brain tumors can be divided into primary tumors (those arising from the brain and its coverings) and metastatic tumors (those arising elsewhere in the body). Table 2.3-1 lists the most clinically important tumors. In children, astrocytomas and medulloblastomas are the most common tumors; in adults, the most common are metastatic tumors, astroglial neoplasms (including glioblastoma multiforme), meningiomas, and pituitary adenomas.

TABLE cellSpacing=0 cellPadding=0 align=left border=0 hspace="10" vspace="5">

Histologically benign
Meningioma
Pituitary adenomas
Acoustic neuromas
Craniopharyngiomas

Lymphomas
Medulloblastomas
Primitive neuroectodermal tumors
Germ cell tumors
Pineal cell tumors
Chordomas
Choroid plexus carcinomas
Metastatic brain tumors
Single or multiple metastases
Meningeal carcinomatosis

Table 2.3-1 Most Frequent Brain Tumors

Patients with brain neoplasms characteristically have focal neurological disturbances. However, primary and metastatic intracranial tumors produce direct and indirect effects on brain functions that could result in behavioral alterations. Before neuroimaging and modern neurosurgical techniques became available it was well recognized that some patients with tumors would first present with neurobehavioral or psychiatric manifestations. The current knowledge on neuropsychiatric aspects of brain tumors is scanty and based on clinical case reports and large, uncontrolled case studies from the older literature.

Intracranial tumors have a high incidence of mental symptoms, consisting of personality changes, emotional disturbances, and intellectual defects. One study found that the prevalence of mental symptoms in patients with tumors of the temporal lobes was 94 percent, with neoplasms of the frontal lobes it was 90 percent, and with infratentorial tumors it was 47 percent. Another study found neuropsychiatric symptoms in 51 percent of patients with brain tumors, and yet another showed that in 18 percent of patients, behavioral changes were the first clinical manifestation of a brain tumor. The significant advances that have occurred in the diagnosis and surgical management of brain tumors, however, have decreased the frequency of mental symptoms presenting as the first manifestation of a brain tumor.

The frequency of intracranial tumors at autopsies conducted in psychiatry hospitals is reported to be about 3.5 percent. Based on two studies, the frequency of intracranial tumors in general hospital autopsies is between 3.7 and 5 percent, similar to that in chronic psychiatric hospitals.

PRINCIPAL INTRACRANIAL TUMORS

Gliomas Gliomas include astroglial neoplasms (which are thought to have astrocytic precursors), oligodendrogliomas arising from oligodendrocytes, and ependymomas apparently derived from ependymal cells. Mixed types also occur. The glioblastoma multiforme is a primitive and highly malignant form of glioma whose cell of origin is uncertain. Gangliomas are tumors with both neoplastic glia and neoplastic neurons. The pathological distinction between subtypes of gliomas is usually made on descriptive grounds. These distinctions are helped by the presence of glial fibrillary acidic protein in astroglial tumors, myelin basic protein in oligodendrogliomas, and ciliary bodies in ependymomas.

Glioblastoma Multiforme and Anaplastic Astrocytoma (Malignant Astrocytoma) Glioblastoma multiforme and anaplastic astrocytoma account for about 20 percent of all intracranial tumors, about 55 percent of all tumors of the glioma group, and more than 90 percent of gliomas of the cerebral hemispheres in adults. Although predominantly cerebral, these tumors may be observed in the brainstem, cerebellum, or spinal cord. The peak incidence is in middle adult life, but no age group is exempt. Glioblastoma multiforme (Fig. 2.3-1) and anaplastic astrocytoma differ in age of onset and response to treatment. The mean age of patients with glioblastoma is 56 years and of those with anaplastic astrocytoma, 46 years. Postoperative survival is higher in patients with anaplastic astrocytoma.

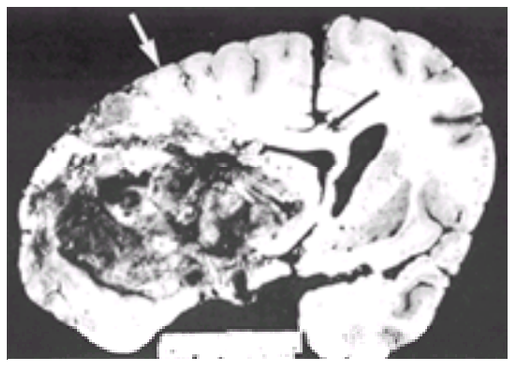

FIGURE 2.3-1 Glioblastoma multiforme. This large necrotic, hemorrhagic neoplasm has infiltrated the temporal and frontal lobes, basal ganglia, and internal capsule. Note the marked enlargement of the right hemisphere and the right cingulate gyrus herniation (*black arrow*). Just superior to the neoplasm is an area of infarction (*white arrow*) caused by compression of the middle cerebral artery by the neoplasm. (Reprinted with permission from Golden A, Powell DE, Jennings CD: *Pathology: Understanding Human Disease*, ed 2. Williams & Wilkins, Baltimore, 1985.)

Clinically, diffuse cerebral symptoms and seizures usually give way in a few weeks or months to a more definite frontal, temporal, parietooccipital, or callosal syndrome. The treatment of these tumors is complex and includes surgery, radiation, chemotherapy, and immunotherapy.

Astrocytoma (Low-Grade Astroglial Neoplasms) Grades 1 and 2 astrocytomas (Fig. 2.3-2), which constitute between 25 and 30 percent of cerebral gliomas, may

occur anywhere in the brain or spinal cord. In children the tumors are usually in the cerebellum. By far the most common presenting symptom is an epileptic seizure. Excision of part of the cerebral astrocytoma may allow survival in a functional state for many years. The role of radiation in patients with low-grade astroglial neoplasms is controversial, and chemotherapy has no proven benefit in the treatment of patients with low-grade astrocytomas.

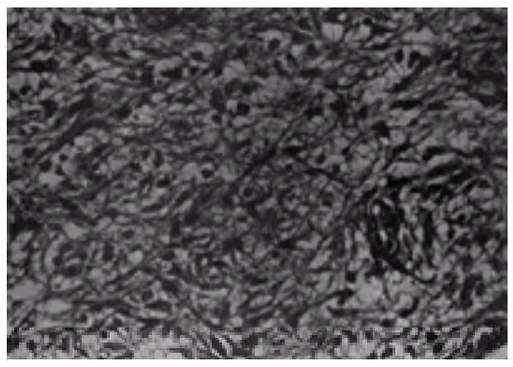

FIGURE 2.3-2 Astrocytoma. These fibrillary astrocytes form an irregular meshwork. Hematoxylin-phloxin-saffron, ×350. (From Robertson DM, Dinsdale HB: *The Nervous System.* Williams & Wilkins, Baltimore, 1972.)

Oligodendrogliomas Oligodendrogliomas (Fig. 2.3-3) represent the third most common glioma, following glioblastoma and astrocytoma. They occur most frequently within the cerebral hemispheres, often in a frontal location. Surgical resection is the most common treatment.

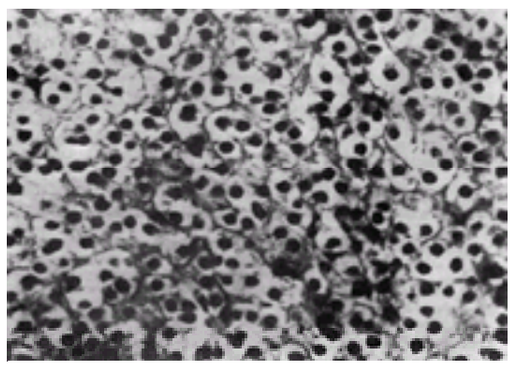

FIGURE 2.3-3 Oligodendroglioma. The prominent nuclei are surrounded by unstained cytoplasm. Hematoxylin and eosin stain (Reprinted with permission from Hirano A: *A Guide to Neuropathology.* Igaku-Shoin, New York, 1981.)

Meningiomas Meningiomas are usually benign growths that rarely invade the substance of the brain, thus presenting the potential for curative surgery. Meningiomas represent approximately 15 percent of all brain tumors. There is some evidence of a hormonal component in their growth: they may enlarge during pregnancy, they occur twice as often in women as in men, and they are more common in patients with breast carcinoma. Of all intracranial meningiomas, 85 to 90 percent are located supratentorially. Children show an increased incidence of intraventricular and posterior fossa meningiomas, as well as meningiomas without dural attachment. Radiation may provide important adjunctive therapy for surgically unresectable meningiomas (Fig. 2.3-4).

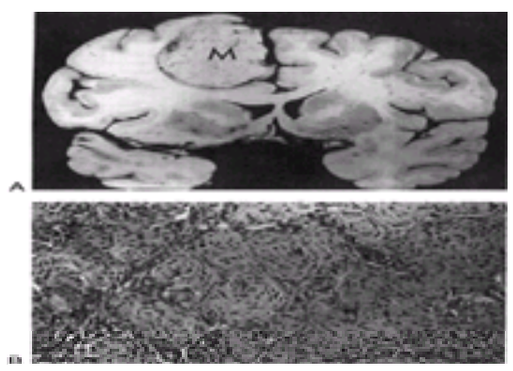

FIGURE 2.3-4 A, Parasagittal meningioma. This well-circumscribed, globoid, discrete meningioma (*M*) is attached to the dura and falx. It compresses rather than invades the underlying superior frontal gyrus. **B**, Meningioma. The tumor cells appear uniform and are arranged in whorls. (Reprinted with permission from Golden A, Powell DE, Jennings CD: *Pathology: Understanding Human Disease*, ed 2. Williams & Wilkins, Baltimore, 1985.)

Metastatic Brain Tumors Brain metastasis is a common complication of systemic cancer and an important cause of morbidity and mortality in cancer patients. It is the most common type of intracranial tumor, and its incidence may be rising. The frequency of metastasis to the brain varies dramatically from one type of cancer to another. Clinical presentations of metastatic disease include progressive neurological deficit, seizure, and hemorrhage. Intracerebral hemorrhage is especially likely to be the presenting event for melanomas, renal cell carcinomas, and choriocarcinomas. Surgery is the best treatment for single metastatic lesions.

Meningeal Carcinomatosis Cancer metastatic to the cerebral meninges represents approximately 5 percent of metastatic tumors; breast, lung (Fig. 2.3-5), and melanoma are the most common primary tumors. Multiple deficits of cranial nerves and spinal nerve roots are common presenting syndromes and are sometimes difficult to distinguish from paraneoplastic states.

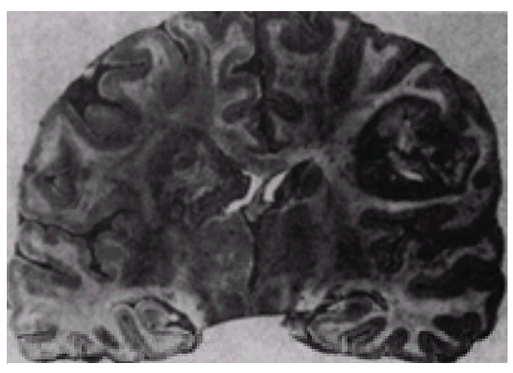

FIGURE 2.3-5 Metastatic carcinoma (from the lung). The well-circumscribed masses contain necrotic cysts. (Reprinted with permission from Russell DS, Rubenstein

LL: *Pathology of Tumors of the Nervous System*, ed 3. Williams & Wilkins, Baltimore, 1971.)

EPIDEMIOLOGY

New brain tumors develop in approximately 35,000 adult Americans each year. Recent evidence indicates that the incidence of primary tumors among elderly persons is increasing. More adults die each year of primary brain tumors than of Hodgkin's disease or multiple sclerosis.

Primary brain tumors account for about 2 percent of cancer deaths but are responsible for 7 percent of the years of life lost from cancer before the age of 70. They are responsible for 20 percent of malignant tumors diagnosed before the age of 15. About 30 percent of deaths are due to cancer in Western society, and 1 in 5 of those who die of cancer exhibit intracranial metastatic deposits at autopsy.

Among the causes of death from intracranial disease, tumor is exceeded in frequency only by stroke. Primary tumors of the brain represent 22 percent of all childhood neoplasms, second in frequency only to leukemia. In the United States, the annual incidence of all brain tumors is 46 per 100,000, and that of primary tumors is 15 per 100,000.

Given the current early diagnosis and treatment of brain tumors, formal studies of psychiatric symptoms of brain tumors are difficult to carry out, and the prevalence is difficult to estimate.

ETIOLOGY

The production of symptoms by tumor growth is governed by certain principles of physics and physiology. The cranial cavity has a restricted volume, and the three elements contained therein—the brain (about 1400 mL), cerebrospinal fluid (CSF) (140 mL), and blood (150 mL)—are relatively incompressible. According to the Monro-Kellie doctrine, the total bulk of the three elements is constant, and any increase in the volume of one of them must be at the expense of one or both of the others. Tumors growing in one part of the brain compress and destroy brain tissue and displace CSF and blood; once the limit of this accommodation is reached, the intracranial pressure rises. Elevation of the intracranial pressure and perioptic pressure impairs axonal transport in the optic nerve and venous drainage from the optic nerve head and retina, exhibited as papilledema. Once pressure is raised in a particular compartment of the brain, it begins to displace tissue; eventually there tissue at a distance from the tumor is displaced, resulting in false localizing signs.

DIAGNOSIS AND CLINICAL FEATURES

The physician should be aware of the subtlety of presentation of brain tumors in many patients and the need for efficient and expeditious diagnosis. A single seizure, loss of interest in usual activities, or loss of hearing for high frequencies may all signal a tumor, and the physician should have a high index of suspicion in these settings.

Patients with brain tumors typically present with headaches, seizures, nonspecific cognitive or personality changes, or focal neurological signs. As a result of the widespread availability of sensitive imaging techniques such as magnetic resonance imaging (MRI), tumors are being detected at an earlier stage, and patients with subtle clinical signs and symptoms are being diagnosed.

Headaches Headaches are the presenting symptom in approximately 35 percent of patients with brain tumors and develop during the course of the disease in 70 percent. Most of these headaches are intermittent and nonspecific. They are generally dull, nonthrobbing, and often indistinguishable from tension headaches. The headaches are usually on the same side as the tumor. Supratentorial tumors usually produce headaches with a frontal location, because most supratentorial pain-sensitive structures are supplied by the trigeminal nerve. The posterior fossa is innervated by cranial nerves IX and X and upper cervical nerves, which usually produce pain in the occipital region and neck. Certain features of a headache increase the possibility of a tumor. These include headaches that wake the patient at night or are worse on waking and improve over the course of the day; headaches exacerbated by postural change, coughing, or exercise; headaches of recent onset that differ from the patient's usual headaches; and the presence of nausea or vomiting, papilledema, and focal neurological signs.

Seizures Seizures are the presenting symptom in approximately one third of patients with brain tumors and are present at some stage of the illness in 50 to 70 percent of patients. Approximately half of the patients have focal seizures and the other half have generalized seizures. As a rule the seizures respond to standard anticonvulsant medications and may also improve following surgery.

Papilledema Papilledema is an important sign of increased intracranial pressure transmitted through the optic nerve sheath. Advances in neuroimaging have resulted in many patients being diagnosed at an earlier stage, and the frequency of papilledema in patients with brain tumor today is probably much lower than it was in the past.

Vomiting Vomiting appears in a relatively small number of patients with a tumor syndrome and usually accompanies the headache. It is more frequent in tumors involving the posterior fossa.

Altered Mental Status Mental status changes are the initial symptom in 15 to 20 percent of patients with brain tumors. These changes may range from subtle problems with concentration, memory, affect, personality, initiative, and abstract reasoning to severe cognitive problems and confusion. With increasing intracranial pressure, there is also depression of the levels of consciousness, resulting in drowsiness and eventually to stupor and coma if treatment is not given.

Regional Symptoms and Signs Sooner or later, patients with psychomotor asthenia, headaches, and seizures display focal cerebral signs (localized weakness, localized sensory loss, and paresthesias or dysesthesias, ataxia, and incoordination). Some patients may present with such signs. Nearly always, however, the focal signs at first are slight and subtle.

Cranial Nerves Tumors of the base of the skull frequently affect cranial nerves. The pattern of involvement and the presence of accompanying neurological signs depends upon the location of the tumor.

NEUROLOGICAL AND NEUROPSYCHIATRIC SYMPTOMS AND BRAIN TUMOR LOCATION

Brain neoplasms pose some difficulties for examining clinical-anatomical correlations. For example, they may not be confined to discrete areas of the brain, so a precise correlation of lesion location and behavioral change is often not possible. Particulary with infiltrating gliomas, associated edema, mass effect, hydrocephalus, and the progressive growth of the neoplasm can complicate clinical-anatomical relationships. Unlike studies of mood disorders after cerebrovascular lesions, there are relatively few studies of psychiatric disorders associated with brain tumors (Table 2.3-2 and Table 2.3-3).

Table 2.3-3 Case Reports of Psychiatric Changes After Brain Tumors

Frontal Lobe Initially, frontal lobe tumors are often clinically silent. As the tumor enlarges, however, there may be personality changes such as disinhibition, irritability, impaired judgment, and lack of initiative (abulia). In addition, hemiparesis, seizures, aphasia, urinary frequency and urgency, and gait difficulties may occur. Gaze preference and primitive reflexes (e.g., forced grasping and snout) may also be present. Meningiomas of the olfactory groove may produce anosmia.

Manic behaviors may also follow frontal damage (Table 2.3-2). Predisposing factors to secondary mania are either a family history of mood disorders or atrophy in frontal and diencephalic regions, probably existing before the brain tumor. Lesion location seems to be an important factor in secondary mania, because most patients reported in the literature had lesions involving ventral brain areas of the right hemisphere (mainly right orbitofrontal and basotemporal cortices). Dysfunction of these heteromodal ventral brain regions may release archicortex brain regions, resulting in disinhibited behaviors. Conversely, patients with injury to the dorsolateral prefrontal cortex often present with apathy, indifference, and psychomotor retardation. Patients with anterior cingulate lesions may be akinetic, with mutism and inability to respond to commands. Euphoria is more common in patients with right frontal damage; those with left frontal lesions tend to exhibit akinesia, abulia, and depressed affect (Table 2.3-4).

Tumor Type	Lesion Location	Treatment	Authors

Table 2.3-4 Case Reports of Depression After Brain Tumors

Temporal Lobe Temporal lobe tumors frequently cause seizures. These include simple partial seizures characterized by olfactory and gustatory hallucinations, déjà vu, and feeling of fear and pleasure and complex partial seizures characterized by impairment of consciousness, repetitive psychomotor movements, and automatic behavior. Temporal lobe tumors may also cause memory disturbances, visual field defects (superior quadrantanopsia) and, when the dominant temporal lobe is involved, aphasia. Temporolimbic tumors tend to cause psychosis and schizophrenia-like illnesses (Table 2.3-3) perhaps because of disruption of limbic structures, including components of the Papez circuit: the hippocampus, fornix, mammillary bodies, mammillothalamic tract, anterior thalamic nucleus, cingulate gyrus, and parahippocampal gyrus. Mania is also associated with temporal lobe lesions, frequently involving the right side. Irritability, panic disorder, and changes in personality have also been described in patients with brain tumors in the temporal lobe.

Parietal Lobe Parietal lobe tumors are not frequently associated with psychiatric symptoms. Tumors of the parietal lobe can produce contralateral sensory loss, particularly involving joint position sense, two-point discrimination, stereognosis, and graphesthesia as well as other modalities. Lesions in the dominant parietal lobe are associated with aphasia, while lesions in the nondominant parietal lobe may result in neglect of the contralateral side and the loss of ability to acknowledge deficits (anosonognosia). Parietal lobe lesions may also lead to hemiparesis, homonymous visual deficits (or neglect), agnosia, apraxias, sensory seizures, and disturbance of visual spatial ability.

Occipital Lobe Occipital lobe astrocytomas may cause homonymous hemianopsia, visual hallucinations, and (less commonly) visual seizures characterized by lights, colors, and formed geometric patterns. Tumors at the parietooccipital junction may produce visual agnosias such as aprosopagnosia (inability to recognize faces).

Diencephalic Tumors and Third Ventricular Tumors Tumors around the third ventricle may produce symptoms resulting from hypothalamic dysfunction, autonomic dysfunction, and impaired memory. Tumors of the thalamus can produce hemiparesis, hemisensory deficits, visual disturbances, and frank alterations in mood and personality. Lesions in this region interrupt cortical-stratial-pallidal-thalamic-cortical loops, which affect many frontal lobe functions. Hypothalamic tumors can reproduce several symptoms observed in anorexia nervosa.

Corpus Callosum Tumors of the corpus callosum have been reported to produce a variety of psychiatric manifestations. The location of the lesion on the corpus callosum may be important for the production of certain psychotic symptoms. Depressive and cognitive symptoms may be produced by lesions anywhere along the anterior half of the corpus callosum.

Posterior Fossa Tumors Headaches and ataxia are the two most common symptoms. Midline cerebellar lesions may produce truncal ataxia, while lesions in the cerebellar hemispheres may cause appendicular ataxia. No correlation has been established between tumors in the posterior fossa and development of psychiatric symptoms.

Brainstem Tumors Brainstem tumors produce cranial neuropathies, weakness, numbness, ataxia, and occasionally vertigo, nausea, and vomiting. Mania has been reported after brainstem tumor.

Pituitary Tumors Pituitary tumors have been reported to produce a wide variety of neuropsychiatric symptoms from depression and apathy to paranoia. Tumors in this region can produce endocrine alterations, which can cause neuropsychiatric symptoms.

INFLUENCE OF LESION LATERALITY

A frequent observation is that patients with left hemisphere lesions are prone to depressive or catastrophic reactions, whereas patients with right hemisphere lesions

often show undue cheerfulness and indifferent emotional reactions. An emotional valence hypothesis posits that the right hemisphere processes negative emotions and the left hemisphere, positive emotions. Vascular lesions in the left anterior cortex were found to be associated with a significantly higher frequency of major depression than lesions in other locations. Another study found that left-side lesions were commonly associated with akinesia and depression, whereas right side lesions were more often associated with euphoria and underestimation by patients of the seriousness of the illnesses. More studies of tumor location and its effects on mood changes are needed.

IMAGING AND LABORATORY EXAMINATION

The introduction of computed tomography (CT) scanning and, more recently, MRI has revolutionized the diagnosis and management of brain tumors.

Skull X-Rays Plain skull films are rarely necessary today with the widespread availability of CT and MRI. Occasionally they may be useful in demonstrating calcification, bony erosion, or hyperostosis.

Computed Tomography CT scans can detect over 90 percent of brain tumors. Small tumors (<0.5 cm), tumors adjacent to bone (e.g., pituitary adenomas, clival tumors, and acoustic neurinomas), brainstem tumors, and low-grade astrocytomas may be missed and are better detected by the more sensitive MRI. CT scans tend to be better tolerated than MRI because of their shorter scanning time, and they are more sensitive in detecting calcification and bony involvement. Contrast enhancement is indispensable in the evaluation of brain tumors and may help disclose their presence (Fig. 2.3-6).

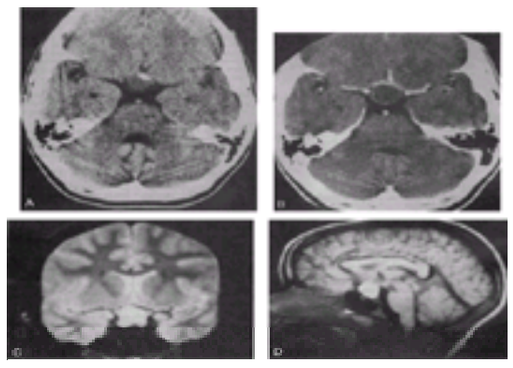

FIGURE 2.3-6 Craniopharyngioma. **A**, Axial CT scanning demonstrates a soft tissue mass in the suprasellar cistern precontrast with calcification. **B**, Rim enhancement noted postcontrast typical of a craniopharyngioma. **C**, A coronal T2-weighted MRI scan demonstrates the cystic nature of the lesion, which elevates the anterior cerebral artery A_1 segments. Note signal void in the vascular structures owing to flow. **D**, A sagittal T1-weighted MRI scan demonstrates the craniopharyngioma; typical hyperintensity on the T1 image is attributed to the cyst contents. (Reprinted with permission from Zimmerman EA, Cohen BH: Congenital tumors. In *Merritt's Textbook of Neurology*, ed 9, LP Rowland, editor. Williams & Wilkins, Baltimore, 1995.)

Magnetic Resonance Imaging MRI provides much greater anatomical detail in multiple planes and is especially useful for visualizing skull base, brainstem, and posterior fossa tumors. MRI is superior to CT scans in detecting hemorrhage and solid and cystic components within tumors and in demonstrating the relationship of the tumors to intracranial vessels. As with CT scans, the use of contrast agent greatly increases the sensitivity of the test. Newer techniques such as magnetic resonance spectroscopy, which allows direct investigation of tumor metabolism, and echoplanar MRI which scans images in less than 100 ms and provides information on tumor perfusion and diffusion, are currently being evaluated for possible use in separating recurrent tumors from radiation change.

Angiography Magnetic resonance angiography provides a noninvasive means of displaying blood vessels in the brain. It is increasingly replacing conventional angiography, although angiography has better resolution and is still necessary in certain situations.

Electroencephalography (EEG) EEG in patients with brain tumors may reveal nonspecific electrical abnormalities. However, the EEG is often normal in patients with brain tumors and thus has limited value as a screening test.

Cerebrospinal Fluid Analysis Examination of the CSF can be useful in the diagnosis of certain brain tumors and in evaluating the extent of leptomeningeal spread. Lumbar puncture holds definite risks for individuals with increased intracranial pressure and should be avoided in these patients.

DIFFERENTIAL DIAGNOSIS

The physician should be aware of the subtlety of presentation of brain tumors. A single seizure, headaches, nausea and vomiting, sensory changes, a loss of interest in usual activities, and other focal neurological signs and symptoms may all be signs of a tumor. In addition, certain situations should make the clinician suspect the presence of a brain tumor. Organic causes should be considered when a patient presents with psychiatric symptoms without previous psychiatry history, without family history of psychiatric disorder, or with atypical features. The evaluation of an intracranial mass lesion involves careful neurological and medical examinations. Neuroimaging such as CT or MRI with contrast is indicated. The differential diagnosis for brain tumors includes subdural hematoma, aneurysm, stroke, infection, demyelinative diseases, degenerative neurological diseases, hydrocephalus, and pseudotumor cerebri.

COURSE PROGNOSIS AND TREATMENT

The course and ultimate prognosis for a patient with an intracranial tumor depend upon the tumor's histological type, rate of growth, invasiveness, and response to treatment. Given the early diagnosis of brain tumors and their surgical treatment, formal treatment studies of mood disorders after brain tumors are difficult to carry out. Most patients with neuropsychiatric symptoms after brain tumors were treated with drugs frequently used among patients with functional psychiatry symptoms, such as neuroleptics, anticonvulsants, antidepressants, and lithium. These drugs should be used with care in patients with brain tumors, because of their adverse effects, such as excessive sedation and lowered seizure threshold. Whether the agents used in the treatment of mood disorders will also be useful for treating mood disorders and other psychiatric disorders associated with brain tumors remains to be empirically established. At the present time, there are no controlled studies of the treatment of psychiatric consequences of brain tumors.

SUGGESTED CROSS-REFERENCES

Functional neuroanatomy is discussed in Section 1.2, neuroimaging in Section 1.15 and Section 1.16, schizophrenia in Chapter 12, and mood disorders in Chapter 14.

2.4 NEUROPSYCHIATRIC ASPECTS OF EPILEPSY

MARIO F. MENDEZ, M.D., FH.D.

Epilepsy is associated with a range of biologically based psychopathology. Studies from communities, epilepsy clinics, and psychiatric hospitals demonstrate an increased prevalence of psychiatric problems among patients with epilepsy as compared to patients without epilepsy. Among the former group, much of the psychopathology results from electrophysiological, structural, or chemical changes in the temporal limbic system and possibly in the frontal lobes.

Although most patients with epilepsy are normal, one quarter or more have schizophreniform psychoses, depression, personality changes, or hyposexuality. These behavioral changes are chronic and present between seizure episodes. Other behaviors are more episodic and directly related to the seizure discharges. Patients may have auras with psychic content, nonconvulsive status epilepticus, prodromal symptoms, postictal confusion, and a periictal psychosis that usually occurs in the postictal period and is distinct from the schizophreniform psychosis of epilepsy.

There are important implications for the management of epilepsy patients who manifest psychopathology. These include maximizing the mood-stabilizing and other psychotropic effects of anticonvulsant drugs such as carbamazepine (Tegretol), valproate (Depakene), and clonazepam (Klonopin). Secondly, psychotropic medications can lower the seizure threshold, an important consideration when choosing a psychotropic drug for a brittle epileptic patient. Finally, the clinician must consider the potential interaction of anticonvulsant and psychotropic medications and monitor their respective drug levels.

DEFINITION

Epileptic *seizures* are sudden, involuntary behavioral events associated with either excessive or hypersynchronous electrical discharges in the brain. The seizure itself is known as the *ictus.* The *interictal period* refers to the period between the postictal abnormalities and the next ictus, and *periictal* refers to the period just before or after the ictus and is applied when there is insufficient information to know where the ictus ends or begins. Epileptic seizures can be primary, secondary to a neurological condition, or reactive to a situational factor such as sleep deprivation or drug withdrawal. *Epilepsy* is the current tendency to seize, and *status epilepticus* is prolonged or repetitive seizures without intervening recovery.

In epilepsy, abnormal electrical discharges are caused by hyperexcitable neurons with sustained postsynaptic depolarization. Proposed mechanisms for this sustained depolarization include changes in ionic conductance, decreased g-aminobutyric acid (GABA) inhibition of cortical excitability, and increased glutamate-mediated cortical excitation. In animals, alumina-induced membrane changes alter the ratio of intracellular-extracellular ionic concentrations and result in abnormal neuronal firing. Anticonvulsants such as phenytoin (Dilantin), carbamazepine, and valproate reduce this repetitive firing through effects on sodium channels. Ethosuximide (Zarontin) works through blockage of calcium currents. Penicillin-induced cortical injury causes seizures through decreased GABA inhibition. Barbiturates and benzodiazepines may reduce seizures by enhancing GABA-receptor current; valproate may reduce seizures through blockage of GABA catabolism. Kainic acid, a glutamate agonist, induces seizures through increased synaptic action at its *N*-methyl-D-aspartate (NMDA) receptors. Much work is under way on potential anticonvulsants that may work through inhibition of this excitatory receptor mechanism.

The electroencephalogram (EEG) is a surface recording of brain wave activity used in the evaluation of seizures. Basic waves include normal waking alpha (8 to 13 Hz), which is most prominent over the occipital region, high-frequency beta (above 13 Hz), and theta (4 to 7.5 Hz) and delta slowing (3.5 Hz or less). Seizures are manifest as multiple spikes of spike and wave discharges on the EEG (Fig. 2.4-1). A spike is a sharp transient with a duration of 20 to 70 msec. Interictally single spikes and other markers of abnormal electrical activity may be seen, often emanating from a temporal lobe.

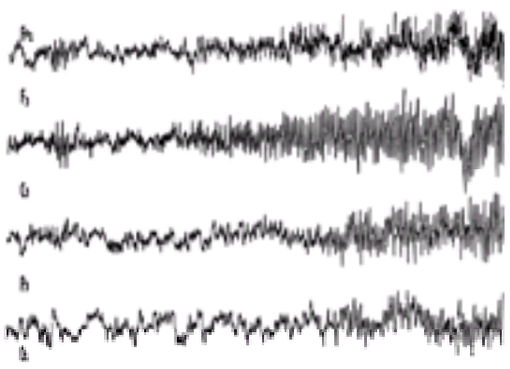

FIGURE 2.4-1 Electroencephalogram demonstrating the focal onset of seizure discharges from the left frontotemporal region consistent with the onset of complex partial seizures.

HISTORY

In his book on epilepsy, *On The Sacred Disease*, Hippocrates (460 to 377 bc) attacked the prevailing belief that those afflicted with epilepsy were possessed by gods or goddesses. He proposed that epilepsy was a brain disease caused by the blockage by phlegm of air-carrying vessels to the brain. Despite this initial view, throughout most of human history epilepsy was believed to indicate demonic possession or the accumulation of bad humors, and attempts at exorcism involved trephination, cautery of the back of the skull, diuretics, emetics, bloodletting, purging, sweating, and even intercourse to release sperm. In the eighteenth century the first scientific treatise on epilepsy since ancient times attributed seizures to masturbation. By happenstance, bromides, which were introduced to diminish libido and masturbation, proved to be the first successful anticonvulsant medication. With the development of effective anticonvulsants and the introduction of EEG, the pendulum has swung back to Hippocrates' belief that epilepsy is rooted in organic brain disease.

The purported association of epilepsy with behavioral disorders also dates to antiquity. The brain was the seat of both the falling sickness and madness and both were believed to be related to phlegm. With demonic possession as a form of punishment, unusual or abnormal behaviors became associated with seizure patients even during their seizure-free periods. At the turn of the nineteenth century the psychiatric writings of Emil Kraepelin emphasized that epilepsy patients underwent personality changes and had a predisposition to psychosis. With the greater understanding of the physical basis of epilepsy, many clinicians sought to protect patients from the demonic stigma of their disease; in their view, psychiatric problems resulted from the psychosocial difficulties associated with having seizures rather than any unique relationship of epilepsy with psychiatric illness. The current age was initiated by the definition of temporal lobe epilepsy and the concept of a physiological disturbance in the limbic or emotional brain.

NOSOLOGY

The International Classification of Epileptic Seizures divides seizures into *generalized* and *partial* (Table 2.4-1). Generalized seizures are those with an initial widespread bihemispheric involvement, and partial seizures are those that emanate from a focus limited to part of one hemisphere. In adults, most generalized seizures are tonic-clonic seizures (*grand mal seizures* or *convulsions*) and characterized by an abrupt loss of consciousness with tonic rigidity followed by a synchronous, clonic release. Partial seizures are either complex partial seizures (*psychomotor* or *temporal lobe epilepsy*) or simple partial seizures, depending on whether or not there is complex symptomatology such as an alteration of consciousness or psychic symptoms (Table 2.4-2). Simple partial seizures produce isolated motor, sensory, autonomic, psychic, or mixed symptoms in a clear sensorium. Simple partial seizures that evolve to complex partial seizures are considered auras. Complex partial seizures are usually characterized by motionless staring combined with simple automatisms (automatic motor activity) and last about 1 minute. Complex partial seizures that evolve to generalized tonic-clonic seizures are "secondarily generalized." Finally, there is a second form of generalized seizures, *absence (petit mal) seizures*, which occur less commonly in adults and are characterized by brief lapses of consciousness. Absence seizures differ from complex partial seizures in being short (10 seconds) and very repetitive; in lacking auras, postictal confusion, or complex automatisms; and in having characteristic 2 to 4 cps spike-and-wave discharges on EEG.

I. Partial (focal, local) seizures
  A. Simple partial seizures
     Motor, somatosensory, autonomic, or psychic symptoms
  B. Complex partial seizures
     1. Begin with symptoms of simple partial seizure but progress to impairment of consciousness
     2. Begin with impairment of consciousness
  C. Partial seizures with secondary generalization
     1. Begin with simple partial seizure
     2. Begin with complex partial seizure (including those with symptoms of simple partial seizures at onset)
II. Generalized seizures (convulsive or nonconvulsive)
  A. Absence (typical and atypical)
  B. Myoclonus
  C. Clonic
  D. Tonic
  E. Tonic-clonic
  F. Atonic/akinetic
III. Unclassified

Table 2.4-1 International Classification of Epileptic Seizures

Type	Symptoms	Probable Source
Dysphasic[1]	Nonfluent Impaired comprehension	Left perisylvian language areas
Dysmnestic	Déjà vu, déjà vécu, déjà pensé, déjà entendu, jamais vu, prescience, illusion of memory	Mesobasal temporal,[2] especially on right
Cognitive	Dreamy state, altered time sense, derealization, depersonalization	Mesobasal temporal and temporal neocortex
	Forced thinking, forced actions, and abstract or obscure thoughts	Frontal association cortex
Affective	Fear, anxiety, apprehension, depression, pleasure, unpleasure	Mesobasal temporal and temporal neocortex
Illusions[3]	Macropsia, micropsia, telopsia, movement, metamorphopsia, increased color intensity, increased stereopsis intensity	Lateral superior temporal neocortex, especially on right for visual illusions
Hallucinations[3]	Structured, hallucinatory remembrances, autoscopy	Mesobasal temporal and temporal neocortex

[1] Does not include speech arrest or simple vocalizations.
[2] Includes hippocampus, amygdala, and the parahippocampal gyrus.
[3] Includes within integrative (eg, emotion, illusion, stereopsis) or experiential (memories of past experience or involvement).

Table 2.4-2 Psychic Auras

EPIDEMIOLOGY

Seizure disorders are common and usually have an early onset. Epilepsy affects 20 to 40 million people worldwide, has a lifetime prevalence of at least 0.63 percent, and an annual incidence of about 0.05 percent. The overall incidence is high in the first year, drops to a minimum in the 30s and 40s, then increases again in later life. More than 75 percent of patients have their first seizure before age 18, and 12 to 20 percent have a familial incidence of seizures. Among adults, the most common seizures are complex partial seizures and generalized tonic-clonic seizures.

Psychopathology Epidemiological studies from communities, psychiatric hospitals, and epilepsy clinics have indicated a higher prevalence of psychiatric problems among epilepsy patients as compared to normal controls. About one quarter of all those with epilepsy and one half of those specifically with complex partial seizures had psychosis, depression, personality disorders, or hyposexuality. These problems are about equally divided between those that occur ictally or periictally and those that occur interictally or are variably related to the ictus. The percentage of epilepsy patients in psychiatric hospitals was also higher than the general prevalence of epilepsy and ranged from 4.7 percent of all inpatients in a British psychiatric hospital to 9.7 percent in a U.S. Veterans Affairs psychiatric facility. Among patients attending epilepsy clinics, about 30 percent had a prior psychiatric hospitalization and 18 percent were on at least one psychotropic drug. Furthermore, epidemiological studies indicate an increased interictal psychopathology among head-injured patients with epilepsy, compared to head-injured patients without epilepsy. Despite criticisms of selection bias, these studies constitute a broad spectrum of sources that indicate greater overall psychopathology in epilepsy patients.

Do epilepsy patients have greater psychopathology than other similarly impaired patients? If this were so, it would suggest that the psychopathology is of biological origin rather than a less specific reaction to chronic disease. Although disputed by some investigators, several studies report more psychopathology among epilepsy patients than among patients with long-term diseases that do not directly affect the brain. Furthermore, the pattern of behavioral changes in patients with seizures appear specific to epilepsy. For example, on the Minnesota Multiphasic Personality Inventory-2 (MMPI-2), despite a lack of difference in overall psychopathology, patients with epilepsy have higher schizophrenia scale and paranoia scale scores than patients with other neurological disabilities.

Many studies found a special relationship to psychopathology in patients whose seizures emanated from mediobasal temporal lesions. Psychiatric disturbances, primarily psychosis and personality disorders, are two to three times more common in patients with complex partial seizures, most of whom have a temporal focus, compared to those with generalized tonic-clonic seizures; other studies have failed to find a difference. Nevertheless, 60 to 76 percent of adults with epilepsy, regardless of seizure type, have a temporal lobe focus, and many generalized tonic-clonic seizures are secondarily generalized from a temporal lobe focus without a preceding complex partial seizure. Therefore, the presence of mediobasal temporal limbic pathology cannot be excluded in comparison groups with generalized tonic-clonic seizures.

Psychosis Psychosis is the specific psychiatric disorder most clearly associated with epilepsy. The lifelong prevalence of all psychotic disorders among epilepsy patients ranges from 7 to 12 percent. In a follow-up of 100 children with complex partial seizures for up to 30 years, of the 87 who survived to adulthood and did not have mental retardation, 9 (10 percent) experienced a psychotic illness. Moreover, in temporal lobectomy studies, where there is surgical removal of an epileptic focus, psychosis occurred in 7 to 8 percent of patients, even long after the seizures were arrested. That represents about a twofold or greater risk of psychosis for patients with epilepsy than for the general population; patients whose epilepsy has a mediobasal temporal focus are especially at risk.

Studies on the laterality of the seizure focus suggest an association of a left-sided focus with psychosis. Although conclusions derived from surface EEG recording are open to criticism, depth recording of presurgical patients show that twice as many patients with left temporal lesions have psychosis. Positron emission tomography (PET) scans and single-photon emission computerized tomography (SPECT) scans may show predominant left temporal hypometabolism in epilepsy patients with psychosis.

Depression The prevalence of depression in various studies varies and may range from 7.5 to 34 percent of patients with epilepsy. Those with complex partial seizures and poor seizure control are more likely to suffer from mood disorder. Psychological studies also suggest a greater incidence of ideational orientation, self-criticism, and depression among epilepsy patients with a left hemisphere focus. In comparison, other studies have not established the proposed association of

right hemisphere foci with mania and other disorders. Patients with complex partial seizures of temporal lobe origin have a higher incidence of depression than do patients with other types of seizure disorders.

Other Behaviors The prevalence of other specific behavioral disorders among patients with epilepsy is less well established. There is convincing evidence, however, that personality disorders, suicidal behavior, and hyposexuality are more prevalent among epilepsy patients than among those without seizure disorders.

ETIOLOGY

Most new-onset epilepsy is idiopathic, but other frequent causes include trauma in the third and fourth decades, neoplasms in the fifth and sixth decade, and cerebrovascular disease in the elderly. Although some complex partial seizures originate from frontal or temporal neocortex and other areas, at least two thirds of complex partial seizures and generalized tonic-clonic seizures originate from the mediobasal temporal limbic structures (hippocampus, amygdala, and parahippocampal gyrus).

Psychopathology The relationship of seizures, psychiatric syndromes, and the mediobasal temporal lobes implies that many behavioral changes are more than psychological reactions to the psychosocial stressors of epilepsy. Stimulation and ablation studies in man and animals link temporal limbic structures to emotional behavior.

For example, temporal limbic stimulation of humans evokes psychic auras and automatisms; amygdalar stimulation and ablation of animals results in either aggression or placidity. Moreover, psychotic behavior in cats occurs when their limbic structures undergo kindling (i.e., the repeated application of epileptic agents in order to induce lasting behavioral changes).

There are several potential organic causes of psychiatric disturbances in epilepsy (Table 2.4-3). First, the pathology itself could be the source of both the seizures and the behavioral changes. Left hemisphere and temporal lobe lesions may be associated with a schizophreniform psychosis, and psychosis in epilepsy may be particularly frequent if there is specific underlying pathology or ventricular enlargement. Second, ictal or subictal epileptiform activity may promote behavioral changes by facilitating distributed neuronal connections, increasing limbic-sensory associations, or changing the overall balance between excitation and inhibition. Third, the absence of function, such as the interictal hypometabolism observed on PET scans (Fig. 2.4-2), may lead to depression or other interictal behavioral changes. Among epilepsy patients with a schizophreniform psychosis, SPECT scans have shown reductions in cerebral blood flow in the left medial temporal region. Fourth, seizures may result in neuroendocrine or neurotransmitter changes such as increased dopaminergic or inhibitory transmitters, decreased prolactin, increased testosterone, or increased endogenous opioids, all of which can affect behavior. Furthermore, neurobiological factors may be potentiated by psychodynamic factors such as feelings of helplessness, learned helplessness, dependency, low self-esteem, and the disruption of reality testing. In sum, the psychiatric manifestations of epilepsy are heterogeneous disorders with a multiplicity of causes.

Common neuropathology, genetics, or developmental disturbance
Ictal or subictal discharges potentiate abnormal behavior
Kindling or facilitation of a distributed neuronal matrix
Changes in spike frequency or inhibitory-excitatory balance
Altered receptor sensitivity (e.g., dopamine receptors)
Secondary epileptogenesis
Absence of function at the seizure focus
Inhibition and hypometabolism surrounding the focus
Release or abnormal activity of remaining neurons
Dysfunction or downregulation of associated areas
Neurochemical
Dopamine and other neurotransmitters
Endorphins
Gonadotrophins and other endocrine hormones
Psychodynamic and psychosocial effects of living with epilepsy
Dependence, learned helplessness, low self-esteem, weak defense mechanisms
Disruption of reality testing
Neurobiological and psychodynamic factors potentiate each other
Sleep disturbance
Anticonvulsant drug-related

Table 2.4-3 Proposed Relations of Psychiatric Disturbances to Epilepsy

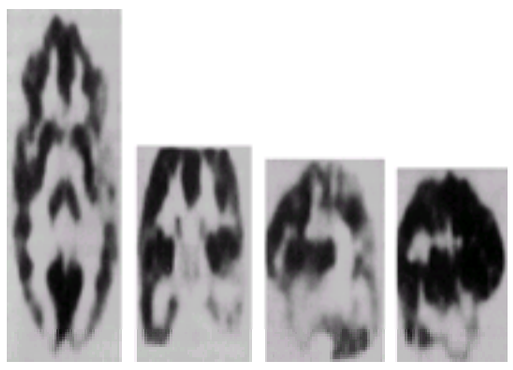

FIGURE 2.4-2 ^{18}Fluorodeoxyglucose positron emission topography (PET) scans demonstrating interictal hypometabolism in the left temporolimbic region. (Reprinted with permission from Engel J Jr: *Seizures and Epilepsy.* FA Davis, Philadelphia, 1989.)

DIAGNOSIS

In epilepsy, psychiatric behaviors can be conceptualized in relation to the ictus or seizure discharges. These behaviors occur as part of the ictus, periictally, or during the interictal period (Table 2.4-4). Moreover, a range of other behaviors appear to have some relation to the ictus but do not clearly fall into one of the former three categories.

I. Ictal
A. Ictal psychic symptoms
B. Nonconvulsive status: simple partial seizures, complex partial seizures, and periodic lateralizing epileptiform discharges
II. Periictal (includes predromal, postictal, and mixed ictal)
A. Prodromal symptoms: irritability, depression, headache
B. Postictal delirium
C. Periictal psychotic symptoms
1. Concomitant with increased seizure frequency
2. Concomitant with decreased seizure frequency
3. The postictal psychoses
III. Interictal
A. The schizophreniform psychosis
B. Personality disorders
C. The Gastaut-Geschwind syndrome
IV. Variably related to ictus
A. Mood disorders (depression and mania)
B. Dissociative states
C. Aggression
D. Hyposexuality
E. Suicide
F. Other behaviors

Table 2.4-4 Behavioral Disorders in Epilepsy

Ictal Seizure discharges can produce semi-purposeful automatisms and psychic auras such as mood changes, derealization and depersonalization, and forced thinking. Ictal fear, which ranges from a vague apprehension to abject fright, has occurred without any other seizure manifestation, and ictal depression has extended

days or longer after the seizure has passed. Some patients have pleasurable auras. Fyodor Dostoyevsky had “ecstatic auras” during which he felt in perfect harmony with the entire universe and “would give 10 years of this life, perhaps all of it, for a few seconds of such bliss.” The experience of epileptic derealization or depersonalization could impair reality testing. Another psychic aura is “forced thinking,” characterized by recurrent intrusive thoughts, ideas, or crowding of thoughts. Forced thinking must be distinguished from obsessional thoughts and compulsive urges. Epilepsy patients with forced thinking experience their thoughts as stereotypical, out-of-context, brief, and irrational, but not necessarily as ego dystonic.

A 36-year-old right-handed man presented with frontal headaches and 5 years of complex partial seizures. His seizures began with 15 seconds of a sense of “impending doom,” speech arrest, and orobuccal movements followed by 30 seconds of altered consciousness. At seizure onset, he felt forced to think the phrase “tell me yes.” The phrase repeated itself several times in his mind without his being able to control it. Concomitantly, his mouth would open, and he would attempt to say the phrase but could utter only unintelligible sounds. The patient interpreted this phrase as a call for help. On examination, he had a mild memory deficit, normal language testing, a right facial droop, and brisk right-sided reflexes with a right Babinski response. Neuroimaging revealed a left frontal mass lesion. EEGs showed amplitude attenuation and polymorphic delta in the left frontal area, and intraoperative electrocorticography disclosed polyspike and spike-wave discharges and impaired language from just below the lesion. The patient underwent subtotal resection of a 4.3 × 3 × 3 cm oligodendroglioma. Postoperatively his forced thinking and seizures resolved, but he had a nonfluent aphasia.

Cognitive disorders follow status epilepticus with simple partial seizures, complex partial seizures, or absence seizures. Recurrent or prolonged simple partial seizures do not result in alteration of consciousness or invariable abnormalities on EEG, and, if manifested by psychic auras, simple partial seizures may be difficult to distinguish from primary psychiatric disturbances. Status epilepticus from complex partial seizures and absence seizures results in prolonged alterations of responsiveness. With the addition of various ictal auras, complex partial status epilepticus can appear psychotic. Occasionally, EEGs and a therapeutic trial of anticonvulsant medications may be the only way to distinguish behavioral disturbances caused by nonconvulsive status epilepticus. Finally, recurrent EEG complexes known as *periodic lateralizing epileptiform discharges* may also be associated with prolonged confusional behavior and focal cognitive changes.

A 68-year-old man had a left temporal-parietal hemorrhagic stroke. An initial fluent aphasia and right hemiparesis completely resolved, but he developed poststroke epilepsy. His seizures began with speech arrest and were followed by secondary generalization to tonic-clonic seizures. The postictal periods lasted for days because of continued left hemisphere periodic lateralizing epileptiform discharges. During these prolonged postictal periods, he was confused, placid, and had a return of his aphasia. One year later, after achieving seizure control, the patient developed mania for the first time in his life. His mania was in a clear sensorium without a change in his neurological examination or epileptiform activity on EEG. He did not sleep, had flight of ideas, and had grandiose ideation including beliefs that he was a three-star general, had killed Hitler, and was now a millionaire. He exposed himself to everyone including his daughter and inserted pencils up his penis because he believed that he needed catheterization. His psychosis lasted for 3 months until he had two generalized tonic-clonic seizures. Postictally, for 10 days he remained placid, confused, and aphasic, with a right beating nystagmus and periodic lateralizing epileptiform discharges maximal in the left temporal region (Fig. 2.4-3). With a new anticonvulsant medication he returned to normal with total resolution of his mania.

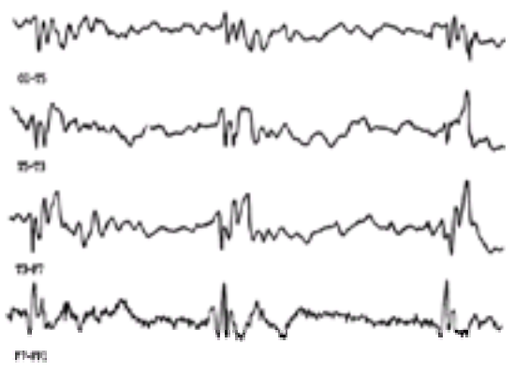

FIGURE 2.4-3 Periodic lateralizing epileptiform discharges (PLEDs).

Periictal Features Psychiatric disturbances can occur before seizures *(prodromal)*, after seizures *(postictal)*, or during intermittent seizure activity. Some patients experience prodromal symptoms that begin at least 30 minutes before seizure onset, last 10 minutes to 3 days, and are continuous, with irritability, depression, headache, confusion, and other symptoms. The postictal period is characterized by a delirium lasting minutes to hours or, occasionally, days. Prolonged postictal confusion may particularly follow right temporal complex partial seizures. Some twilight states result from a protracted period of intermixed ictal and postictal changes.

Periictal psychotic symptoms often worsen with increasing seizure activity. Rarely, psychotic symptoms alternate with seizure activity. In this “alternating psychosis,” when patients are having seizures they are free of psychotic symptoms, but when they are seizure free and their EEG has “forced or paradoxical normalization,” they manifest psychotic symptoms. This alternating pattern is much less common than the increased emergence of psychotic behavior with increasing seizure activity.

An important periictal psychiatric disorder consists of brief psychotic episodes that follow clusters of generalized tonic-clonic seizures, (i.e., postictal psychosis). These psychotic episodes occur in patients who have complex partial seizures with psychic auras, frequent secondary generalization to tonic-clonic seizures, and bilateral interictal discharges. The postictal psychosis of epilepsy emerges after a lucid interval of 2 to 72 hours (mean of 1 day) during which the immediate postictal confusion resolves and the patient appears to return to normal. The postictal psychotic episodes last 16 to 432 hours (mean of 3½ days) and often include grandiose or religious delusions, elevated moods or sudden mood swings, agitation, paranoia, and impulsive behaviors but no perceptual delusions or voices heard. The postictal psychoses remit spontaneously or with the use of low-dose psychotropic medication.

A 33-year-old man with a 15-year history of generalized tonic-clonic seizures and a 4-year history of periictal psychotic episodes had several hospitalizations for recurrent postictal psychosis. The initial flurry of generalized tonic-clonic seizures was followed by a 24- to 48-hour latency period, and, subsequently, 2 to 7 days of delusions, hallucinations, and disordered thought processes. He believed that people could transmit messages and read his thoughts, and voices commanded him to love his neighbor. The patient claimed to be able to predict the future and to communicate with a dead grandfather who voiced dissatisfaction with things on earth. During these episodes, the patient had loose associations, euphoria, agitation, and occasional spike and waves on EEGs. Between psychotic episodes, he was psychiatrically and neurologically normal, and his EEGs showed left temporal interictal spikes. After the postictal psychosis, the patient returned to baseline without residual changes in behavior.

Interictal Features

Schizophreniform Psychosis Most epilepsy patients with a schizophreniform psychosis have a chronic interictal illness without known direct relationship to seizure events or ictal discharges. Many of these patients, however, develop worsening psychotic symptoms concomitant with an increase in seizure frequency or with anticonvulsant withdrawal and a few others have worsening psychotic symptoms on control of the seizures (“alternating psychosis”). The terms *alternating psychosis* and *forced normalization* refer to this demonstrable antagonism between the psychosis and the seizures or EEG discharges. Epilepsy patients with this long-term interictal psychosis often have an 11- to 15-year history of seizures, usually poorly controlled complex partial seizures with secondary generalized tonic-clonic seizures. However, seizure control with anticonvulsants or removal of the seizure focus does not prevent the development of this psychosis, which occasionally emerges for the first time after successful seizure treatment. This disorder sometimes resembles a schizoaffective psychosis with intermixed affective symptoms. In addition, there are prominent paranoid delusions, relative preserved mood, normal premorbid personality, and no family history of schizophrenia. Other reported differences with idiopathic schizophrenia are outlined in Table 2.4-5.

Epilepsy Characteristics:
Complex partial seizures with secondary generalized tonic-clonic seizures
More auras and automatisms than in nonpsychotic epilepsy patients
Epilepsy present for 11 to 15 years before psychosis
Long interval of poorly controlled seizures
Recently diminished seizure frequency, especially generalized tonic-clonic
Left temporal focus
Mediobasal temporal lesions, especially tumors
Psychosis Characteristics:
Atypical paranoid psychosis—parania with sudden onset
Psychosis alternating with seizures
Preserved affective warmth
Failure of personality deterioration
Less social withdrawal than schizophrenia
Less systematized delusions than schizophrenia
More hallucinations and affective symptoms than schizophrenia
More religiosity than schizophrenia
More positive as opposed to negative symptoms
Few Schneiderian first-rank symptoms
Negative family history for psychosis
No family history of schizophrenia

Table 2.4-5 Proposed Predisposing Factors for the Interictal Schizophreniform Psychosis of Epilepsy

A 23-year-old man developed paranoid delusions after his daily complex partial seizures were controlled for the first time. His seizures dated from age 8 and consisted of a rising epigastric sensation and facial flushing followed by a motionless stare and automatisms, often culminating in secondary generalized tonic-clonic seizures. Prior to initiating anticonvulsant therapy, there was no history of paranoid or psychotic behavior. Afterwards, he believed that people were sending energy to him through small concealed batteries. He felt able to work this energy off with his fluorescent watch dial and a one-armed plastic crucifix in his boot. The patient also believed that people were watching him, trying to manipulate him, and threatening him through telephone lines and telephone poles. His examination was remarkable for the degree of emotion when relating his bizarre ideas. He had a lesion in the left anterior temporal area, probably consistent with an old calcified cyst, and left temporal spikes on EEG. His paranoid delusions subsequently abated with antipsychotic therapy.

Personality Disorders Among patients with epilepsy there is a high prevalence of personality disorders including borderline, atypical or mixed, histrionic and dependent disorders. Patients with personality disorders show dependent and avoidant personality traits. The most common personality disorder in epilepsy is a borderline personality disorder. Not surprisingly, patients with epilepsy frequently lack a stable character structure and can be immature and impulsive. This personality constellation partially explains the increased incidence of irritability, suicide attempts, and intermittent explosive disorder. Those with epilepsy are stigmatized, feared, and subject to difficulties in obtaining a job, driving an automobile, and maintaining a marriage. These psychosocial difficulties along with any associated mental retardation contribute to the dependency, low self-esteem, and overall borderline personality traits present in many such patients. In addition, the experience of epileptic auras may contribute to the development of personality disorders.

Gastaut-Geschwind Syndrome Although there is no general personality profile of an epilepsy patient, a group of traits termed the *Gastaut-Geschwind syndrome* occur in a subset of patients with complex partial seizures. Some epilepsy patients with a temporal limbic focus develop a sense of the heightened significance of things. These patients are serious, humorless, overinclusive, and have an intense interest in philosophical, moral, or religious issues. Occasionally, patients with epilepsy experience multiple religious conversions or experiences. In interpersonal encounters, they demonstrate “viscosity,” the tendency to talk repetitively and circumstantially about a restricted range of topics. They can spend a long time getting to the point, give detailed background information with multiple quotations, or write copiously about their thoughts and feelings *(hypergraphia).* Viscosity may particularly occur in patients with left-sided or bilateral temporal foci.

A 39-year old man developed seizures following a contusion of the left temporal region. His seizures began with stereotypical voices and generalized to tonic-clonic seizures. He was extremely circumstantial and tangential, stressed every detail, and had difficulty getting to the point. Ironic and minor philosophical insights were fascinating to him. He wrote 30-page rambling letters to his physician, and his writings were full of metaphors and quotes. An example of his writing was as follows: “I became overwhelmed by the sentiment of a letter composed in my head before reaching paper. The sentiment of this letter continued to expand in all dimensions until it seemed no longer connected to any specific ideal, but more to an all-pervasive color, yellow, and a smell, like burning leaves. I felt deliriously happy, but I felt in danger as well. Afterwards I got an acute attack of aphasia and could do nothing but shrug. My prior prophet voices, which went away with the Dilantin, were saying something profound that I needed to get down on paper. It seems as though I am a prophet and I will never have another problem for the rest of my life.”

Conclusive proof that epilepsy patients with a temporal lobe foci are disproportionately prone to the Gastaut-Geschwind syndrome has remained elusive. Most of the early studies used the MMPI, a test that proved insensitive to most of the specific traits attributed to epilepsy. Studies with the Bear-Fedio Inventory, an MMPI-like instrument developed to assess these “epileptic traits,” found that epilepsy patients with temporal lobe foci were sober and humorless, dependent, circumstantial, and had strong philosophical interests. In addition, those with a left-sided focus had a more reflective ideational style and maximized their problems whereas those with a right-sided focus had emotional tendencies and minimized their problems. Further investigations with the Bear-Fedio Inventory described these seizure patients as having viscosity in interactions, prominent religious interests, a pronounced sense of personal destiny, and deepened affect. However, other applications of this inventory found the same characteristics in patients without epilepsy who had psychiatric disorders or comparable physical disabilities. Although these personality characteristics do occur in some epilepsy patients, they may not be specific for patients with seizure disorders.

Variably Related to Ictus

Mood Disorders Depressive disorder is the most prevalent neuropsychiatric disorder in epilepsy, occurring in 7.5 to 34 percent of epilepsy patients. Depression is also the main diagnosis among patients with epilepsy in mental hospitals. Depression is twice as common in epilepsy patients as in comparably disabled populations, suggesting that much of the depression in epilepsy patients is more than just a psychological reaction to a disability.

Most patients with epilepsy have a chronic interictal depression or dysthymia. These patients frequently have accompanying paranoia and hallucinations, emphasizing the continuum with psychotic disorders. These depressed patients tend to have frequent complex partial seizures, particularly with a left-sided temporal focus. The experience of certain psychic auras, especially those with cognitive content, may predispose to interictal depression. Several investigators also report increased seizure control or a decrease in seizures prior to the onset of interictal depressive symptoms. Patients with this alternating depression experience relief with a seizure or electroconvulsive therapy.

There are other associations of depression with epilepsy. The rare occurrence of ictal depression may not only outlast the actual ictus but may lead to suicide. Depression also occurs periictally. Episodic mood disturbances, often with agitation, suicidal behavior, and psychotic symptoms, may occur with increasing seizure activity. Finally, postictal depression is common, and, a prolonged depressive state occasionally follows complex partial seizures even when ictal experiences do not include depression.

Mood disorder due to epilepsy with manic features or with mixed features is much rarer than mood disorder due to epilepsy with depressive features or with major depressive-like features. Rarely, manic symptoms may emerge with an increase in seizure frequency or after seizure control. Although a right temporal focus was suggested as the source of mania in epilepsy, this laterality has not been established.

Dissociative States A specific association of epilepsy with dissociative identity disorder, depersonalization disorders, possession states, fugue states, and psychogenic amnesia is intriguing but unresolved. Studies of patients with dissociative identity disorder reveal frequent EEG changes but few actual seizures. It is conceivable that temporary personality disintegration occurs in some patients as part of postictal confusion or periictal psychosis, particularly in those with a right temporal focus. In one intracarotid amobarbital (Amytal) study of multiple personality in two seizure patients, the different personalities were precipitated without seizure activity. Persistent alterations in the experience of self and feelings of being taken over by others may occur in patients with auras of derealization and depersonalization. In epilepsy, prolonged periods of compulsive wandering with amnesia have resulted from an admixture of ictal and postictal changes and has been termed *poriomania.* Finally, some patients may have periods of amnesia or “lost time,” possibly caused by complex partial seizures without surface EEG abnormalities.

Aggression Lay people have accredited to epilepsy aggressive and violent acts and have even used the epilepsy defense in criminal proceedings. This belief peaked in the nineteenth century when the criminologist Cesare Lombroso promoted the association of epilepsy with aggressive, sociopathic tendencies. Investigators have bolstered this association with studies showing aggressive verbalizations with stimulation of the amygdala and interictal defensive rage in cats with epileptic hippocampal lesions. Among patients in a maximum-security mental hospital, the violent patients had focal temporal slowing or sharp waves on EEG and dilated

temporal horns or small temporal lobes on computerized tomography (CT) scans. These results suggest that high violence rating scores are associated with abnormal temporal electrical discharges on EEG and temporal lobe abnormalities on CT. Moreover, patients with left temporal lobe seizure foci have higher scores on hostile feelings than other patients with epilepsy.

A 37-year-old left-handed man with epilepsy presented with aggressive episodes. The seizures consisted of an olfactory aura followed by “spacing out” or alteration of consciousness for approximately 1 minute. In addition to these complex partial seizures the patient had occasional secondary generalized tonic clonic seizures with urinary incontinence and tongue-biting. During the postictal period, as he began to recover consciousness he experienced an overwhelming sense of threat or of having been harmed. These feelings became focused on any individual who was in his immediate environment. That person was believed to have beaten or otherwise hurt him and was going to harm him further. The patient felt compelled to attack these individuals, often inflicting significant physical injury. Although his postictal confusion would clear in about 1 hour, his sense of being harmed or threatened slowly diminished over about 24 hours after a seizure. After the resolution of these feelings, he felt great remorse over the harm that he had done. Nevertheless, on several occasions he was charged with aggravated assault. Sleep-deprived EEGs confirmed the presence of left anterior temporal epileptiform activity. The patient's aggressive postictal episodes abated with control of his complex partial seizures with carbamazepine.

Although aggression can occur in relation to an ictus, as in this patient, most aggression among epilepsy patients is not related to epileptiform activity. Aggression in epilepsy is usually associated with psychosis or intermittent explosive disorder and correlates with subnormal intelligence, lower socioeconomic status, childhood behavior problems, prior head injuries, and possible orbital frontal damage. Moreover, although the prevalence of epilepsy among prison inmates has been 2 to 4 times that among the general population, studies from the United Kingdom and the United States have not found more violent crimes among prisoners with epilepsy than prisoners without epilepsy.

Can violence itself be a seizure? Following the 1976 case of a New York city policeman who had never had seizures and successfully claimed the epilepsy defense, criteria for ictal violence were proposed that included video-EEG telemetry (Table 2.4-6). Since then, epilepsy has rarely if ever been proved to directly result in premeditated violence. Such acts require a series of coordinated steps that rarely occur as manifestations of seizures. Simple violent automatisms, such as spitting or flailing the arms, can occur at the onset of complex partial seizures, and secondary violent automatisms can occur as a response to an unpleasant or emotional aura or periictal sensation (Table 2.4-7). More commonly, nondirected violent movements, aimless destructive behavior, or angry verbal outbursts occur during postictal delirium when patients misinterpret attempts to protect or restrain them.

1. The diagnosis of epilepsy is established by at least one specialist in epilepsy.
2. The presence of epileptic automatisms are documented by history and by closed-circuit TV-EEG telemetry.
3. The presence of violence during epileptic automatisms is verified in a videotape-recorded seizure in which ictal epileptiform patterns are also recorded on the EEG.
4. The aggressive act is characteristic of the patient's habitual seizures, as elicited by history.
5. A clinical judgment is made by the epilepsy specialist attesting to the possibility that the aggressive act was part of a seizure.

Table 2.4-6 Criteria for Assessing Ictal Violence in Epilepsy

Period	Cause
Interictal	Impulse-control disorder
	Mental retardation or cognitive impairments
	Personality disorders
	Schizophrenia-like psychosis of epilepsy
	Medication-related
Prodrome	Mounting tension, irritability
Ictal	A direct manifestation of the seizure
	Violent automatism
	Reaction to a negative aura
	Subtle, seizure equivalents
Postictal	Resistive
	Poriomania and somnambulism
	Postictal psychosis
	Postictal persistent perception of threat

Table 2.4-7 Mechanisms of Aggression Among Epilepsy Patients

Sexuality Patients with epilepsy tend to be hyposexual. Both men and women experience disturbances of sexual arousal and a lower sexual drive. Some patients have a disinterest in all the usual libidinous aspects of life, including loss of erotic fantasies or dreams, and may suffer from impotence or frigidity. Other patients with epilepsy claim sexual desire but experience physiological signs of decreased sexual arousal. Men have an increased risk of erectile dysfunction, suggesting a neurophysiological component, and studies of sex hormones suggest the possibility of a subclinical hypogonadotropic hypogonadism. Substantial improvement to the point of public hypersexuality can occur after seizures are brought under control. Moreover, prior to temporal lobectomy, most epilepsy patients are hyposexual, but nearly a third of them have an increase in libido after the operation, providing that their seizures are controlled.

Other sexuality changes are rare. Individual cases of transvestism, fetishism, and gender dysphoria are not frequent enough to exclude a coincident association. True ictal sexual manifestations are also unusual; however, libidinous feelings, erotic sensations, sexual remembrances, and even orgasm do occur, although rarely and primarily in women, probably from seizure discharges in the amygdala. In addition, ictal masturbation has occurred with absence status. A woman with nymphomania proved to have incidental sexuality from sensory simple partial seizures caused by a tumor in the sensory cortex, representing her genital region.

Suicide The risk of completed suicide in epilepsy patients is four to five times greater than among the nonepileptic population, and those with complex partial seizures of temporal lobe origin have a particularly high risk, up to 25 times greater. A comparison of suicide attempts among patients with epilepsy and comparably handicapped controls without epilepsy has reported that 30 percent of those with epilepsy had attempted suicide as compared to 7 percent of the controls. This increased risk of suicide continues even long after temporal lobectomy and successful control of seizures. Most suicidal behavior among epilepsy patients is not directly caused by reactions to the psychosocial stressors of having a seizure disorder. Rather, these patients are likely to attempt suicide in conjunction with borderline personality behaviors and are likely to complete suicide because of psychosis. Contributors to successful suicides include paranoid hallucinations, agitated compunction to kill themselves, and occasional ictal command hallucinations to commit suicide.

A 26-year-old woman had her initial seizure during her first pregnancy at age 18. Her seizures included echoing sounds “like walking in a cave,” a motionless stare with stereotypical automatisms, postictal confusion, and occasional secondary generalized tonic-clonic seizures. Because of a variable response to anticonvulsant medications she underwent EEG and closed-circuit television video-EEG (CCTV-EEG) telemetry that documented complex partial seizures from a right temporal focus as well as nonepileptic seizures. The patient, who had six children by six different men, had prominent feelings of inadequacy and isolation, and was considering cutting her wrists “just to see if anyone cared.” Her multiple suicide attempts and threats resulted in five psychiatric hospitalizations. During one period of time, she complained of decreased menses, weight gain, stretch marks, increased appetite and sleep, and exhaustion. She insisted that she was pregnant despite six negative pregnancy tests and multiple evaluations.

Other Behavioral Changes Other psychiatric disorders may be associated with epilepsy or epileptiform EEG activity. Anxiety disorders occur among epilepsy patients and must be distinguished from simple partial seizures manifesting as anxiety or panic attacks. Among the impulse-control disorders, intermittent explosive disorder is characterized by a prodromal mounting tension and irritability, postictal remorse, and increased temporal spikes on EEG. Among the somatoform

disorders, some epilepsy patients have a conversion disorder, often manifest as nonepileptic seizure events. Finally, patients with epilepsy are subject to other behavioral difficulties stemming from their epilepsy such as adjustment disorders, subtle cognitive effects of seizures, and the potential behavioral effects of anticonvulsant medications.

PATHOLOGY AND LABORATORY EXAMINATION

Neurodiagnostic Tests In addition to the routine laboratory data and toxicology screens used to exclude reactive seizures, several neurodiagnostic tests are useful in the assessment of epilepsy. EEG is the most widely used confirmatory test for seizures; however, single EEGs are frequently normal and must be repeated, particularly with provocative maneuvers such as sleep. Occasionally, CCTV-EEG telemetry for an extended period of time is necessary to capture seizure activity. Neuroimaging procedures such as CT scans and magnetic resonance imaging can more precisely visualize a seizure focus or even a mesial temporal sclerosis (Fig. 2.4-4). Other tests that occasionally aid in localizing the seizure focus include quantitative EEG, SPECT scans, and PET scans. PET scans may show interictal hypometabolism around the temporal seizure focus and are also useful in the presurgical assessment of patients with medically intractable seizures. Neuropsychological examinations, particularly during a Wada test, further help in localizing and lateralizing memory and language prior to surgery.

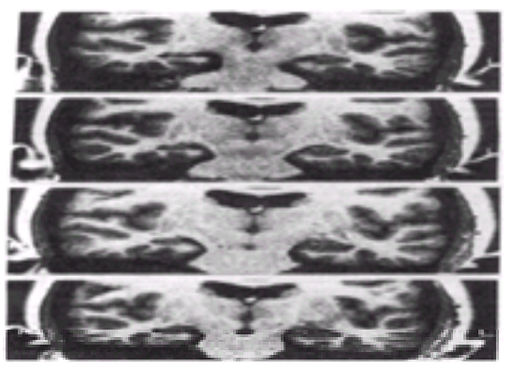

FIGURE 2.4-4 A series of magnetic resonance imaging scans demonstrating mesial temporal sclerotic changes in the left hippocampal region. (Reprinted with permission from Engel J Jr: In vivo imaging of the temporal lobe limbic system. In *The Temporal Lobes and the Limbic System*, Trimble MR, Bolwig TG, editors. Wrightson Biomedical Publishing, Petersfield, England, 1992.)

Neuropathology The common pathological findings in epilepsy are mediobasal temporal lobe lesions. About two thirds of adults with epilepsy have a temporal lobe focus and two thirds of these have mesial temporal sclerosis with pyramidal cell loss in the hippocampus. Theories about the cause of mesial temporal sclerosis include perinatal insults, dysgenesis, and kindling from reactive seizures. Another 20 to 25 percent of those with temporal lobe lesions have tumors such as hamartomas and gangliogliomas. The rest have scars from trauma and other causes or lack a distinct histological lesion.

DIFFERENTIAL DIAGNOSIS

Clinicians must distinguish epileptic seizures from two other transient behavioral events, *syncope* and *nonepileptic seizures (pseudoseizures).* Syncope is a loss of consciousness usually with premonitory lightheadedness, autonomic reactivity, a brief atonic ictus, and little or no postictal confusion. Syncope lacks the many characteristic features of seizures as well as a clear epileptiform EEG. Nonepileptic seizures, on the other hand, are involuntary, psychogenically induced spells that mimic many epileptic behaviors.

Differentiating epileptic seizures from nonepileptic seizures can be extremely difficult, and even epileptologists are incorrect 20 to 30 percent of the time. Patients with nonepileptic seizures are most commonly women between the ages of 26 and 32 years with psychological stressors and poor coping skills. Fifteen percent or more of these patients have a true seizure disorder as well, and nonepileptic seizures may result from the elaborating or “highlighting” of their epileptic seizures. Nonepileptic seizures are most commonly characterized by unresponsiveness with motor activity that does not fit a typical complex partial seizure or a generalized tonic-clonic seizure (Table 2.4-8). In children, pseudoseizures are usually characterized by unresponsiveness, with violent and uncoordinated movements of the whole body. However, every epileptic behavior can occasionally occur, including tongue biting and incontinence, and nonepileptic events are especially difficult to differentiate from the atypical motor behavior of frontal lobe epilepsy. The most helpful differentiation feature may be an ictal duration of 2 or more minutes. In addition, nonepileptic seizures usually occur in the presence of a witness; can often be induced with injections, hypnosis, or suggestions; and are poorly responsive to treatment with anticonvulsant medications. Ultimately, the differentiation may require CCTV-EEG telemetry along with the assessment of the absence of a seizure-induced rise in serum prolactin levels.

Table 2.4-8 Nonepileptic Seizures Versus Epileptic Seizures

Nonepileptic seizures result from a variety of psychiatric conditions. The most common psychiatric disturbance among these patients is conversion disorder. Patients with nonepileptic seizures who have conversion disorder have a high incidence of prior trauma or sexual or physical abuse. The remaining patients with nonepileptic seizures have depression, anxiety disorders, posttraumatic stress disorder, or borderline or other personality disorders. Additional diagnoses associated with nonepileptic seizures are psychosis, impulse control problems, and mental retardation.

One additional differentiation is that of most nonepileptic seizures from those specifically due to the malingering or feigning of epilepsy for secondary gain (Table 2.4-9). Epileptic seizures lend themselves to malingering because of their behavioral and episodic nature and the lack of consistent physical or diagnostic findings.

Malingered Seizures	Nonmalingered Nonepileptic Seizures
Preceding	Ictus
More common in males	Marked female predominance
Less likely to obtain prior abuse history	Prior history of physical or sexual abuse
Less likely to obtain prior psychiatric history	Prior psychiatric history
Evident secondary gain	No clear secondary gain*
No clear emotional precipitants	Frequent emotional precipitants
Seizures are not suggestible	Seizures may be easily suggested
During	Ictus
Seizures under volitional control	Seizures not under volitional control
Conscious awareness of seizures	Subconscious awareness of seizures only
Cannot maintain deficits over time	Able to maintain over time
Errors in seizure behavior are likely to be major distortions	Errors in seizure behavior are likely to be omissions, perseverations, near-misses
Following	Ictus
Angry, anxious on confrontation with the lack of evidence for epileptic seizures	Indifferent, detached
Uncooperative, including circumstantial and evasive answers; may leave against medical advice	Cooperative with the workup, but answers may be devoid of content

* In factitious disorder, gain is the internal behavior itself with the consequent medical attention.

Table 2.4-9 Malingered Seizures Versus Nonmalingered Nonepileptic Seizures

A 33-year-old veteran of the Persian Gulf War presented with a complaint of epileptic spells, beginning 3 years after returning home. The patient claimed that the stress of the war induced his seizure disorder and he requested disability compensation. He described his seizures as the abrupt loss of consciousness associated with jerking movements of his extremities. His episodes occurred irregularly with a frequency of 2 to 4 a week. On admission to the hospital, medical staff observed several seizurelike spells where the patient assumed a flexed posture of both his upper and lower extremities and then shook them uncontrollably and in an asynchronous fashion. During this ictal period, the patient had normal pupillary and corneal reflexes. His seizures lasted nearly 5 minutes and then immediately resolved without postictal confusion. Postictally, he recalled comments and other environmental events that occurred during his seizurelike episodes. EEGs obtained immediately after an event did not reveal postictal slowing, and prolactin levels obtained 15 minutes after a seizure episode were not significantly elevated over baseline levels. His seizures did not respond to anticonvulsant medications, but they abated after he changed his strategy and began to explore compensation for other reasons.

COURSE AND PROGNOSIS

Most patients with epilepsy have a good prognosis. The majority of seizures can be controlled with anticonvulsant medications sufficiently that the patient can live a productive life. Some seizures, such as absence seizures, tend to disappear by adulthood. For patients whose seizures are medically intractable, epilepsy surgery offers a good alternative (i.e., temporal lobectomy or corpus callosotomy) as long as the focus can be localized or lateralized. In addition, most epilepsy patients will not have psychiatric disorders, and others have psychiatric difficulties only if they endure many years of poorly controlled seizures. For those with behavioral problems, anticonvulsant drugs or epilepsy surgery may relieve some symptoms, such as hyposexuality and aggression, but may not affect the emergence of other symptoms, such as psychosis and suicidal behavior.

TREATMENT

Anticonvulsant Medications In the treatment of psychiatrically disturbed patients with epilepsy, a first consideration is the use of psychoactive anticonvulsant medications. Carbamazepine, valproate, gabapentin (Neurontin), and lamotrigine (Lamictal) have significant antimanic and modest antidepressant properties, probably through mood-stabilization effects. They have some efficacy in the long-term prophylaxis of manic or depressive episodes. Carbamazepine and valproate may also ameliorate some dyscontrolled, aggressive behavior in brain-injured patients. Clonazepam, in addition to its anxiolytic properties, can serve as a supplement to other antimanic therapies. Gabapentin also decreases anxiety and improves general well-being in some epilepsy patients. Both carbamazepine and ethosuximide may have value for borderline personality disorder.

Encephalopathic changes occur at toxic levels of all anticonvulsant drugs. Even at therapeutic levels, barbiturates may need discontinuation because of drug-induced depression, suicidal ideation, sedation, psychomotor slowing, and paradoxical hyperactivity in the very young and the very old. Gabapentin may induce aggressive behavior or hypomania, and vigabatrin (Sabril) may precipitate depression. In addition, clinicians need to be aware of the potential emergence of psychopathology on withdrawal of anticonvulsant medications. Anxiety and depression are the most common emergent symptoms, but psychosis and other behaviors may also occur.

Psychotropic Medications A second consideration is the seizure-threshold lowering effect of psychotropic medications (Table 2.4-10). This is usually not a problem but can occasionally reach clinical significance in poorly controlled epilepsy. Psychotropic drugs are most convulsive when the drug is introduced rapidly and in high doses. Clozapine (Clozaril), for example, has induced seizures in 1 to 4.4 percent of patients, particularly when the dose was rapidly increased. When initiating therapy with psychotropic agents it is best to start low and go slow while monitoring anticonvulsant levels and EEGs.

Potential	Antipsychotic	Antidepressants	Other Psychotropics
High	Chlorpromazine Clozapine	Buproprion Imipramine Maprotiline Amitriptyline Amoxapine Nortriptyline	
Moderate	Most piperazines Thiothixene	Protriptyline Clomipramine	Lithium
Low	Fluphenazine Haloperidol Loxapine Molindone Pimozide Thioridazine Risperidone Olanzapine	Doxepin Desipramine Trazadone Trimipramine Selective serotonin reuptake inhibitors	Ethclorvynol Glutethimide Hydroxyzine Meprobamate Methaqualone

Table 2.4-10 Seizure Threshold Lowering Effect of Psychotropic Medications

Drug Interactions A third treatment consideration is the potential for interaction of anticonvulsant and psychotropic medications (Table 2.4-11). Most commonly, an anticonvulsant drug increases the metabolism of a psychotropic drug with a consequent decrease in its therapeutic efficiency. Conversely, withdrawal of anticonvulsant drugs can precipitate rebound elevations in concentrations of the psychotropic medication. Moreover, the initiation of a psychotropic drug may result in competitive inhibition of anticonvulsant metabolism, with elevations of anticonvulsant levels to toxicity.

Anticonvulsant	Indication*	Effects of Psychotropic Drug on Anticonvulsant Drug**	Effects of Anticonvulsant Drug on Psychotropic Drug**
Carbamazepine	SPS, CPS, GTCS	Potentially decreased	Decreased
Phenytoin	SPS, CPS, GTCS	Potentially decreased or increased, rarely toxic levels	Decreased
Phenobarbital and primidone	SPS, CPS, GTCS	Potentially decreased	Significantly decreased
Valproic acid	CPS, GTCS, absence	Potentially increased, rarely toxic levels	Potentially decreased
Ethosuximide	Absence	None known	None known
Clonazepam	Myoclonic	Potentially decreased	Potentially decreased
Gabapentin	Add-on: CPS, SPS, ± 2nd GTCS	No significant interactions known	
Lamotrigine	Add-on: CPS, SPS, ± 2nd GTCS	No significant interactions known	
Vigabatrin	Add-on: CPS, SPS, ± 2nd GTCS	No significant interactions known	
Tiagabine	Add-on: CPS, SPS, ± 2nd GTCS	No significant interactions known	

* SPS, simple partial seizure; CPS, complex partial seizure; GTCS, generalized tonic-clonic seizure.
** Antipsychotic and antidepressant drugs. Lithium and the minor tranquilizers have few drug interactions with anticonvulsant drugs.

Table 2.4-11 Anticonvulsant-Psychotropic Drug Effects on Blood Levels

Compared to older drugs, the new anticonvulsant medications have fewer potential interactions with psychotropic medications. Gabapentin, lamotrigine, vigabatrin, and tiagabine are relatively free of enzyme-inducing or enzyme-inhibiting properties. Felbamate (Felbatol), however, has been withdrawn in the United States because some patients developed fatal aplastic anemia and liver disease.

Surgery Epilepsy surgery is a fourth treatment consideration and is limited to patients with medically intractable seizures. The main operation involves resection of epileptogenic tissue by removal of 4 to 6 cm of the anterior temporal lobe. Over 80 percent of temporal lobectomy patients experience some reduction in their seizure frequency and over 50 percent are entirely seizure-free. Removal of the amygdala and most of the hippocampus may have postoperative behavioral effects. Some patients have an anomia or a verbal memory deficit after resection of the dominant hemisphere, and patients occasionally develop a transient postoperative depression. Others experience a reduction in preoperative depression and relief of hyposexuality, but patients with epilepsy may continue to develop psychosis, personality changes, and suicidal behavior even long after the temporal lobectomy. Moreover, patients with preoperative psychotic symptoms are at higher risk for a poor surgical outcome and postoperative psychosis.

Less common epilepsy surgeries include resection of extratemporal lesions, removal of the epileptogenic hemisphere, and ligation of the corpus callosum. Corpus callosotomy, which aims to prevent the interhemispheric spread of seizures, results in a unique, transient disconnection syndrome of mutism, apathy, agnosia, apraxia of the nondominant limbs, difficulty naming, and difficulty writing with the nondominant hand.

Seizure Management In treating the neuropsychiatric disorders of epilepsy, a final consideration is altering the seizure management itself. In addition to the occasional behavior alleviated by strict seizure control, allowing seizures under carefully controlled conditions, much like ECT, relieves some cases of periictal psychosis, depression, or other behaviors.

SUGGESTED CROSS-REFERENCES

Most of the specific psychiatric syndromes associated with epilepsy are discussed in more detail in the appropriate sections devoted to them. Personality disorders are discussed in Chapter 24, mood disorders are discussed in Chapter 14, and sexual disorders are discussed in Chapter 19. The rest of the neuropsychiatric sections of Chapter 2 are also pertinent to epilepsy.

2.5 NEUROPSYCHIATRIC ASPECTS OF TRAUMATIC BRAIN INJURY

RICARDO E. JORGE, M.D., JEFFREY E. MAX, M.B.B.CH. AND ROBERT G. ROBINSON, M.D.

The neuropsychiatric consequences of *traumatic brain injury* (sometimes referred to as TBI) may be divided into disorders that are also seen in patients without brain injury and those that are unique to patients with brain damage. The disorders also seen in patients without brain injury cover the whole spectrum of psychiatric disorders including cognitive, substance abuse, mood, anxiety, psychotic, somatic, and personality disorders. Many of these disorders are included in the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) as disorders due to a medical condition—traumatic brain injury, in this case (Table 2.5-1). Most of these disorders have not been extensively studied in the population with traumatic brain injury, and much research is still needed in this area. The disorders that are unique to brain injury also cover a wide range of disorders including pathological laughing or crying, apathy, indifference, denial, anosognosia, aprosody, and neglect. Most of these disorders have not been extensively examined in patients with traumatic brain injury.

Delirium due to traumatic brain injury
Amnestic disorder due to traumatic brain injury
Transient
Chronic
Dementia due to traumatic brain injury
Personality change due to traumatic brain injury
Labile type
Disinhibited type
Aggressive type
Apathetic type
Paranoid type
Combined type
Unspecified type
Mood disorder due to traumatic brain injury
With depressive features
With major depressive-like episode
With manic features
With mixed features
Anxiety due to traumatic brain injury
With generalized anxiety
With panic attacks
With obsessive-compulsive symptoms
Psychotic disorder due to traumatic brain injury
With delusions
With hallucinations

Table 2.5-1 DSM-IV Classification of Some Behavioral Syndromes Occurring After Traumatic Brain Injury

HISTORY

The earliest physical evidence of traumatic brain injury due to assault occurred 1 million years ago. A damaged skull from an early hominid found in South Africa showed two posterior fractures that matched with the condylar surfaces of an antelope humerus discovered nearby. The earliest written evidence of brain injuries was found on the Edwin Smith Papyrus, dated 5000 years ago, which contained the first 27 head-injury records. The Hippocratic Corpus included a treatise on head injury with thoughtful comments on skull fractures, delirium, seizures, and coma.

Associations between traumatic brain injury and a variety of neuropsychiatric disorders have been reported in the medical literature for many years. In 1904 Adolf Meyer, for example, identified a number of disorders that he referred to as the *traumatic insanities.* Although he believed that these disorders represented a combination of psychological, social, historical, and biological factors, he suggested that there may be some unique associations between these disorders and specific lesion locations. Studies of war-related head injuries identified the high incidence of psychiatric complications following brain injury. Several of these studies emphasized the importance of frontal lesions in the pathogenesis of behavioral disturbances. The most famous case of frontal lobe injury, however, was that of Phineas Gage, who suffered a penetrating frontal brain injury after an explosion that shot an iron bar through his skull. After the injury, he was described as childish, capricious, inconsiderate, profane, and having poor judgment.

Analysis of large series of cases like the Oxford Collection of Head Injury Records suggest that biological variables such as the extent of brain damage, lesion location, and the presence of posttraumatic epilepsy are important etiological factors in determining the type and duration of psychiatric syndromes.

COMPARATIVE NOSOLOGY

The neurological and neurosurgical literature abounds with clinical descriptions of early and delayed behavioral abnormalities that follow traumatic brain injury. Acute syndromes include confusional states, apathy, agitation, restlessness, irritability, and posttraumatic amnesia. Delayed, often irreversible, consequences of such injury include cognitive disorders (e.g., amnesia, dementia, executive dysfunction), and personality change due to a general medical condition.

The spectrum of psychiatric disorders attributable to traumatic brain injury span almost the entire spectrum of psychiatric disorders. According to DSM-IV, these disorders are categorized as being caused by traumatic brain injury if there is evidence from the history, physical examination, or ancillary studies that the disturbance is the direct physiological effect of brain trauma (Table 2.5-1).

EPIDEMIOLOGY

In the United States the annual incidence of traumatic brain injury can be conservatively estimated as 200 per 100,000 population. Figure 2.5-1 shows the annual incidence of new cases of traumatic brain injury leading either to death or admission to hospital. Most of these injuries occurred among adolescents and young adults, with a second peak occurring among elderly subjects. Approximately 20 percent of hospital admission due to traumatic brain injury were of patients under the age of 15. There was also a significant sex difference—males were two to three times more likely to suffer brain injury than females. African-Americans also had higher rates of such injuries than other groups, a finding that may be explained by increased firearm exposure and higher homicide rates among African-Americans.

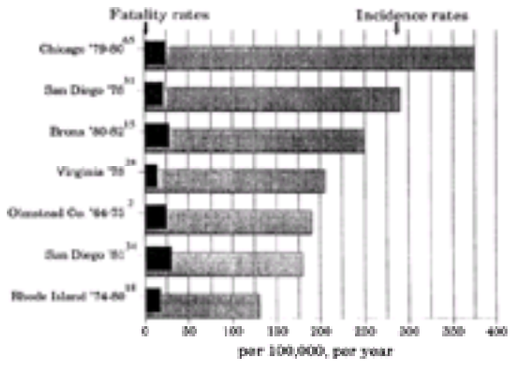

FIGURE 2.5-1 Brain injury incidence and fatality rates from selected U.S. studies. (Reprinted with permission from Kraus JF, McArthur DL: Epidemiology of brain injury. In *Neurology and Trauma*, Evans RW, editor. Saunders, Philadelphia, 1996.)

Low socioeconomic status constitutes another independent risk factor for traumatic brain injury. The single greatest risk factor, however, is substance abuse. Close to one third of brain injury patients had an identifiable alcohol use disorder before trauma, and more than 50 percent were intoxicated at the time of injury. Risk factors for such injury in children include hyperactivity and aggression. In addition, there may be a high rate of preinjury psychiatric disorder in these children. Transport-related cases (i.e., motor vehicle accidents and pedestrians hit by vehicles) are the most important cause of injury, particularly in younger patients. Falls associated with the elderly are the second most prevalent cause of injury. Assaults (especially penetrating injuries involving firearm use) as well as sports- and recreation-related injuries are the next most common causes.

Case-fatality rates vary from 3 to 8 percent among different incidence studies. Since 1979, however, the death rate associated with traumatic brain injury has decreased about 20 percent, probably from multiple causes including legislation, improved safety systems, and enhanced neurosurgical intensive care. Unfortunately, this reduction has been mirrored by an increase in the number of brain-injured survivors who sustain some type of chronic disability.

CLINICAL FEATURES

Acute Behavioral Consequences Head injury encompasses a wide range of severity from patients who die at the moment of trauma to those who do not require medical evaluation or assistance. Most patients admitted to hospital with a head injury diagnosis have a mild injury. A minority of these mildly affected patients will develop acute complications (e.g., brain swelling, intracranial infection) or prolonged postconcussional symptoms. Neuroimaging studies such as computed tomography (CT) and magnetic resonance imaging (MRI) have demonstrated the presence of structural brain lesions in some patients with mild head injury who have not experienced clinical complications.

The most common consequence of head injury is impairment of consciousness, ranging from transient confusion to protracted coma. The Glasgow Coma Scale is commonly used to grade the severity of traumatic brain injury. The scale gives a quantitative estimate of level of consciousness and neurological status based on patterns of eye opening, as well as best verbal and motor responses (Table 2.5-2). Glasgow coma scale scores between 13 and 15 define mild brain injury, scores between 9 and 12 define moderate brain injury, and scores between 3 and 8 define severe injury.

Response	Score*
Eye Opening	
None	1
To pain	2
To sound	3
Spontaneous	4
Motor Response	
None	1
Extension	2
Abnormal flexion	3
Withdrawal	4
Localizes	5
Obey commands	6
Verbal Response	
None	1
Unintelligible sounds	2
Inappropriate words	3
Confused	4
Oriented	5

*Glasgow Coma Scale Score = Eye Opening + Motor Response + Verbal Response (3 to 15).
Adapted from Teasdale G, Jennett B: Assessment of coma and impaired consciousness: A practical scale. Lancet 2:81, 1974.

Table 2.5-2 Glasgow Coma Scale

The early phase of recovery from traumatic brain injury is characterized by disorientation, confusion, and impaired memory function. Apathetic withdrawal, agitation, or severe delirium may also be observed in these patients. *Posttraumatic amnesia* occurs during the period when the patient (who is usually emerging from coma) is disoriented, confused, and has disrupted memory functioning. Deficits are observed in declarative memory (i.e., memory of recent events and times), affecting both anterograde and retrograde processes; procedural memory, in contrast, appears to be relatively spared. Duration of posttraumatic amnesia has been widely used as a measure of severity of the brain injury. It may be assessed using the Galveston Orientation and Amnesia Test (GOAT) or the Children's Orientation and Amnesia Test (COAT), which evaluate orientation to person, place, and time, as well as awareness of the accident and its consequence. Duration of posttraumatic amnesia has proved to be a good predictor of the degree of disability, vocational outcome, and severity of personality change following the injury.

Clinical features of the early phase of recovery from traumatic brain injury are not exclusively characterized by memory impairment. Patients frequently have a decreased level of consciousness and meet DSM-IV criteria for delirium. In addition, patients may present with perceptual disturbances (i.e., illusions or hallucinations), delusional thoughts, psychomotor agitation or retardation, affective lability, and neurovegetative symptoms (e.g., tachycardia, hypertension, diaphoresis, and sleep-wake cycle disruption). Symptoms usually have a sudden onset and a fluctuating course; delirium is most frequently observed in severe cases.

> A 19-year-old man was admitted to a trauma center after a motorcycle accident. He presented with a right epidural hematoma and bilateral contusions in the anterior temporal lobes. He had also a scalp laceration and right maxillary and zygomatic fractures. The postresuscitation Glasgow Coma Scale score was 8. The hematoma was surgically evacuated and the patient was transferred to the intensive care unit. Two days later, the patient became restless and agitated. He removed his intravenous lines and monitoring devices and tried to get out of bed. He was disoriented, incoherent, and aggressive. His behavior suggested that he was experiencing frightening visual hallucinations. A coarse, rapid tremor was noted in both hands and he was diaphoretic and mildly hypertensive. He responded well to a short course of high-potency antipsychotic agents.

Multiple conditions can contribute to the development of delirium in patients with traumatic brain injury. These include structural brain damage, cerebral edema, secondary brain hypoxia, seizures, electrolyte imbalance, infections, and substance (e.g., barbiturates, opioids, steroids, alcohol) withdrawal. Old age, coexistent severe medical disease, polypharmacy, and lesions of the basal ganglia and right hemisphere have also been shown to be significant risk factors.

Chronic Behavioral Consequences

Cognitive Disorders Cognitive disturbances are one of the most important long-term sequelae of severe traumatic brain injury. A 1990 study reported on the cognitive outcome of 127 severely brain-injured patients who were capable of completing serial neuropsychological assessments during a 1-year follow-up period (i.e., excluding those patients with a persistent vegetative state or with very severe intellectual impairment). At 1 year follow-up the brain-injured patients showed slower information processing and greater impairment in memory function compared with a neurologically intact control group. In contrast, linguistic and visuospatial abilities were found to be within the normal range. Patients with mild or moderate head injuries may also show cognitive impairment following brain trauma. These patients complain of lack of concentration and memory deficits during the first weeks following injury; however, spontaneous recovery is the rule for the majority of these patients.

Memory functions are also distinctively impaired in traumatically brain-injured children and adults. Memory deficits are the most frequent chronic cognitive disturbance reported by patients and relatives in traumatic brain injury. Memory dysfunction is characterized by both anterograde and retrograde deficits, faulty sequencing of events, and inefficient encoding and storage strategies. A DSM-IV diagnosis of amnestic disorder due to traumatic brain injury, chronic, may be made for those patients without dementia in whom the memory disturbance causes significant impairment in social or vocational functioning and represents a significant decline with respect to previous levels of performance. However, patients manifesting an isolated memory deficit are rare.

Attentional deficits are among the most frequent neuropsychological symptoms observed in brain-injured patients following resolution of posttraumatic amnesia. Attention consists of multiple processes subserved by interrelated neural networks. Patients may present with restricted verbal or visuospatial attentional span, altered

vigilance patterns (i.e., sustained attention deficits), or slowed information processing. The most consistent findings, however, are associated with performance in the most demanding tasks (e.g., in divided attention paradigms such as the Paced Auditory Serial Addition Task).

Linguistic competence is also frequently affected by traumatic brain injury. Approximately one third of severely brain-injured patients admitted to a rehabilitation facility showed fluent (51 percent), nonfluent (35 percent), or global (14 percent) aphasic syndromes. Aphasia tends to resolve in the majority of cases during the first year following trauma. Anomia, however, constitutes the most prevalent chronic linguistic deficit. Brain-injured patients may also have high-order language alterations and present with a defective narrative discourse, a lack of semantic coherence, aprosody, and impaired pragmatics of communication, all of which result in impoverished and disorganized language and in a reduced communication proficiency.

A prominent defect in control or executive functions has been consistently described in patients who survive severe head injury. Executive functions include goal formation, planning, selection of adequate response patterns, and monitoring of ongoing behavior. When confronted with a demanding environment, the adaptive functioning of brain-injured patients is often impaired. The patient is dismally affected by this lack of initiative, rigid thinking, and faulty problem-solving ability. Several neuropsychological tasks were specifically designed to quantify these deficits. These include the Wisconsin Card Sorting Test, the Goldberg Executive Control Battery, the Tower of London test, and the trail making test. The executive dysfunction observed in patients with brain injury is strongly associated with dysfunction of fronto-subcortical pathways.

In contrast to what happens with memory and control functions, visuospatial and praxic abilities are usually preserved in the long-term following traumatic brain injury, probably because of the relative sparing of posterior association cortices.

Finally, unawareness *(anosognosia)* or denial of deficits is a cognitive disorder frequently observed in brain-injured patients, particularly in those who have suffered extensive frontal lobe damage. This constitutes a severe behavioral sequel that impedes realistic goal-setting and interferes with the rehabilitation process.

DEMENTIA *Dementia* is a syndrome defined in DSM-IV by impairment of memory and at least one other cognitive domain in the absence of an alteration of consciousness. The cognitive defect must have a significant impact on the social and occupational functioning of the involved subject. Dementia due to head trauma is characterized by prominent memory and executive dysfunction with relatively preserved visuospatial, praxic, and primary linguistic functions. In addition, these patients may be severely apathetic and withdrawn and demonstrate markedly slow information-processing. Physical examination may reveal the presence of extrapyramidal signs.

> A 40-year-old white male was severely injured in a motor vehicle accident and experienced protracted coma of 1-month duration. An MRI performed at 2 weeks from injury revealed the presence of widespread diffuse axonal injury. At 6-month follow-up, the patient presented with a mild left hemiparesis, right hemidystonic symptoms, and a left peripheral facial palsy. Neuropsychological testing disclosed substantial memory deficits, frontal lobe dysfunction, and significantly impaired problem-solving ability. Visuospatial and linguistic skills ranked within the lower average range. His hygiene and self-care were poor and he hoarded garbage in his pockets and under his bed. He had frequent bursts of severe aggressive behavior, but overall he remained abulic and withdrawn. Lithium (Eskalith) was effective in controlling his aggressive behavior.

A chronic subdural hematoma in the elderly may present as a progressive dementia. In addition, there is some evidence that previous traumatic episodes constitute a risk factor for the development of Alzheimer's disease.

PERSONALITY CHANGES Traumatic brain injury patients may experience significant personality changes. These patients have been described as irritable, childish, inconsiderate, capricious, anxious, or aggressive. They lack foresight and misjudge the consequences of their actions. Disinhibition is a frequent and striking clinical feature that may lead to antisocial behavior; conversely, patients may become apathetic, abulic, and withdrawn.

Some investigators group these changes into two distinct syndromes: a *pseudodepressed personality syndrome* (personality change due to traumatic brain injury, apathetic type), which is characterized by apathy and blunted affect, and a *pseudopsychopathic personality syndrome* (personality change due to traumatic brain injury, disinhibited type), characterized by disinhibition, egocentricity, and sexual inappropriateness.

DSM-IV defines personality change due to traumatic brain injury as a persistent personality disturbance that represents a change from the individual's previous personality profile (or a deviation of normal development in children) and is attributable to the pathophysiological changes triggered by brain trauma (Table 2.5-1). The disturbance must not occur exclusively during the course of delirium and cannot be diagnosed if dementia is present. In addition, the disturbance must not be better accounted for by another mental disorder (e.g., mood disorder or substance abuse).

> A 42-year-old construction worker fell from the second floor of a new building. He was in coma for 3 days and remained amnestic and disoriented for about 3 weeks. A CT scan showed bilateral orbitofrontal and anterior temporal hemorrhagic contusions.
>
> Six months after the injury he had undergone a significant personality change. He spent most of his day watching television and refused to reinitiate his usual activities. He ate and gained excessive weight. His wife complained of his frequent and often inappropriate sexual demands and stressed his lack of intimacy. He was also easily upset, shouting and making threats when he felt provoked. He was less sensitive to other people's feelings. A trial of carbamazepine (Tegretol) with therapeutic blood concentrations and the maintenance of a numerical record of outbursts resulted in significantly reduced irritability and outbursts.

DSM-IV further categorizes this condition into the following types: labile, disinhibited, aggressive, apathetic, paranoid, combined, and unspecified type. Disinhibition, antisocial conduct, and hypersexuality have been linked to the occurrence of orbitofrontal lesions; apathy has been linked to medial frontal lesions; and aggression and poor impulse control have been associated with anterior temporal lesions.

A common co-occurrence of disorders involves personality change due to traumatic brain injury and attention deficit/hyperactivity disorder in children. Occasionaly, this co-occurrence may be associated with secondary mania. This constellation of symptoms may be related to a neuroanatomical model of disinhibition implicating ventral frontal and temporal lobe structures.

> A 7-year-old male presented to a pediatric brain injury clinic almost 2 years after a severe traumatic brain injury in which he was struck by a car. The injury resulted in encephalomalacia of a portion of the left frontal lobe and ventriculomegaly. The child's development until the injury was apparently normal. After the injury he required a 1-month inpatient rehabilitation. He had trouble sustaining attention and following instructions. Less problematic, although present, were symptoms of distractibility, interrupting others, impulsivity, and disorganization. He was fidgety, had trouble playing quietly, talked excessively, and shifted from one uncompleted activity to another in rapid succession. He was treated with a hydantoin (Dilantin) prophylactically for 7 months. Within 1 month of discontinuing this hydantoin he became violent toward family members and school personnel in response to minimal provocation, mostly when he was tired. This would last for up to 20 minutes and he usually required restraint. These episodes declined in frequency in response to initiation of carbamazepine, but the child remained potentially dangerous. Cognitive testing revealed intelligent quotient (I.Q.) in the borderline range, with deficits in attention, memory, perceptual-motor integration, and processing speed. Complex partial seizures were also noted. He has been followed for 2 years while on 250 to 300 mg of carbamazepine a day. Outbursts continued to be problematic but less frequent for 1 year, after which they no longer occurred. Attention-deficit/hyperactivity disorder symptomatology was dominated by inattention and disorganization with no evidence of impulsivity or hyperactivity any longer.

Depressive Disorders Mood disorders appear to be a frequent psychiatric complication of traumatic brain injury and they may play a relevant role in shaping long-term outcome. The reported frequency of depressive disorders following such injury has varied from 6 to 77 percent. This variability may be due to the lack of uniformity in the psychiatric diagnosis. Review of the literature on this issue reveals that most of the studies had relied on rating scales (e.g., Hamilton Rating Scale for Depression) or a relative's reports rather than on structured interviews and established diagnostic criteria. Studies in the early 1990s, however, have used structured interviews and criteria from the revised third edition of DSM (DSM-III-R) to ascertain the prevalence of mood disorders in this population.

A 1993 study found that 17 out of 66 patients (26 percent) developed major depression while 2 patients (3 percent) developed minor depressive disorders immediately following traumatic brain injury (i.e., approximately 1 month after brain injury). There were also 11 patients who developed a delayed-onset major depressive episode point during a 1-year follow-up period. Thus, 47 percent of patients with follow-up data developed major depressive disorder during the first year after the traumatic

episode. Minor depressive disorder was diagnosed in another 8 patients during the course of the year (Fig. 2.5-2).

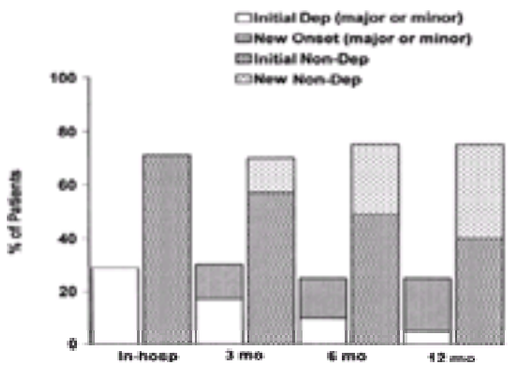

FIGURE 2.5-2 The percent of traumatic brain injury cases (N = 66) who were depressed (major or minor) in the immediate short-term period following injury and at each follow-up time period. The patients depressed initially improved over time but new cases developed so that the overall rate of depression remained relatively stable. (Data from Jorge RE, Robinson RG, Amdt SV, Starkstein SE, Forrester AW, Geisler F: Depression following traumatic brain injury: A 1 year longitudinal study. J Affect Disord *27:*233, 1993.)

When compared with their nondepressed counterparts, patients with major depressive disorder did not show significant differences in demographic variables or in the type or severity of brain injury. There was, however, significantly greater frequency of previous personal history of psychiatric disorders in the group with major depression. In addition, these patients had a significantly poorer premorbid social functioning than patients without depression. Cross-sectional analysis at 3, 6, and 12 months follow-up evaluations showed that poor social functioning was the strongest clinical correlate of major depressive disorder (Fig. 2.5-3). Although patients with depression showed poor premorbid social functioning levels, the fact that the occurrence of major depression was significantly associated with a poor psychosocial outcome suggests that it may negatively influence posttraumatic psychosocial adjustment.

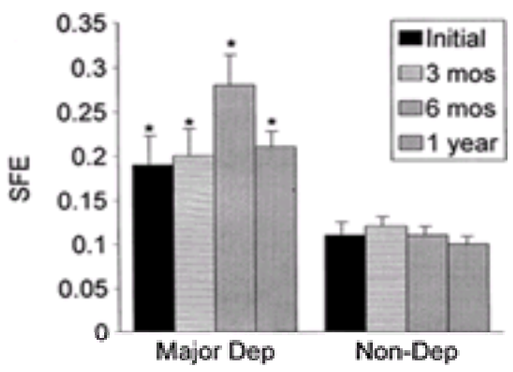

FIGURE 2.5-3 Social function exam (SFE) scores over the first year following brain injury in patients with major depressive disorder or no mood disturbance. Social functioning during the initial evaluation reflected impairment prior to the injury, while the follow-up evaluations reflected social functioning in the month prior to evaluation. Patients with depression consistently had more impairment in social functioning than nondepressed patients. (Data from Jorge RE, Robinson RG, Arndt SV, Starkstein SE, Forrester AW, Geisler F: Depression following traumatic brain injury: A 1 year longitudinal study. J Affect Disord *27:*233, 1993.)

A 42-year-old engineer had a motor vehicle accident when returning from a convention. He suffered multiple injuries, including a diaphragmatic rupture and a left fronto-temporo-parietal subdural hematoma. When admitted to the hospital, the patient was hypotensive and hypoxic. His diaphragm was repaired and the subdural hematoma was evacuated with the urgent intervention of two surgical teams. The patient remained in coma during the following 72 hours. Posttraumatic amnesia lasted for almost 3 weeks. At this point, the neurological exam disclosed a right hemiparesis and a left lateral rectus palsy. The patient was mildly hypophonic and dysarthric. Forty days after the accident he was transferred to a specialized rehabilitation unit. A neuropsychiatric evaluation was completed once his posttraumatic amnesia had cleared. Neuropsychological tests were within normal limits. The patient conveyed a profoundly depressed mood and feelings of hopelessness. He stated that he would never be able to recover, that his career was ruined, and that it would have been better if he had died in the accident. He had no appetite and refused to participate in physical rehabilitation. He also had significant sleep problems. Treatment of depression was initiated with paroxetine (Paxil) at a dosage of 20 mg a day. After 3 weeks, the patient's mood was significantly improved and he became involved in the rehabilitation program. At 6-month follow-up, he was no longer depressed and had returned to work.

There is empirical evidence supporting an association between depression due to traumatic brain injury and specific lesion locations. Studies of war injuries found that several years after penetrating brain injury, depressive symptoms were more common among patients with right than left hemisphere lesions. Depressive symptoms were also more frequent among patients with frontal and parietal lesions than among patients with other lesion locations. Recent studies have reported that lesion location may also play an important role in the development of mood disorders in the immediate posttrauma period. In one series, major depression following traumatic brain injury was associated with the presence of left dorsolateral frontal or left basal ganglia lesions (Fig. 2.5-4).

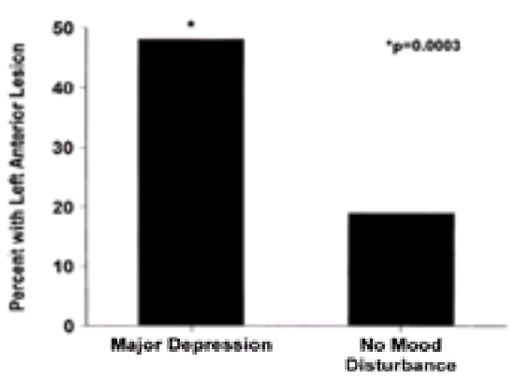

FIGURE 2.5-4 Percent of patients with major depression or no mood disturbance at 1 month following head injury who had evidence on CT scan of injury involving the left dorsolateral frontal cortex or the left basal ganglia. Because patients with traumatic brain injury frequently have multiple areas of injury, a logistic regression analysis was used to examine the independent effects of each area of injury. The strongest effect of lesions on major depression was found in this left anterior brain region (Wald c^2 = 12.97, df = 1, *p = 0.0003). (Data from Fedoroff JP, Starkstein SE, Forrester AW, Geisler F, Jorge RE, Robinson RG, et al: Depression in patients with acute traumatic brain injury. Am J Psychiatry *149:*918, 1992.)

The association between left anterior lesions and major depressive disorder held up only during the period immediately after the injury because delayed-onset depression was not related to the presence of specific lesion locations. Late-onset depressions were associated, however, with a personal history of psychiatric disorder and with poor social functioning levels. Thus, psychosocial factors appear to be more important in the long-term effects of raumatic brain injury.

Secondary Mania Secondary mania (mood disorder due to a general medical condition, with manic features) and hypomania have been reported in a number of

medical conditions such as thyroid disease, uremia, vitamin B_{12} deficiency, or following open heart surgery. Mania has also been associated with traumatic brain injury.

A recent study reported on 20 patients who developed mania after closed head trauma. There was a significant association between mania and the presence of posttraumatic seizures, predominantly of the partial complex type *(temporal lobe epilepsy).* There was no association, however, with family history of bipolar I disorder among first-degree relatives.

A prospective study found that 6 out of 66 patients with traumatic brain injury (9 percent) developed secondary mania at some point during the first year following the injury. Although manic episodes were short-lasting (approximately 2 months), the presence of an expansive mood had a mean duration of 5.7 months. Secondary mania was not related to the type or severity of brain injury, the presence of posttraumatic epilepsy, the degree of physical or intellectual impairment, level of social functioning, or the presence of family or personal history of psychiatric disorder. Secondary mania was, however, associated with the presence of basotemporal lesions (Fig. 2.5-5). This is consistent with the findings in patients with mania secondary to stroke. A small series of secondary mania has been described in consecutively hospitalized children and adolescents. The syndrome was associated with severe brain injury, a family history of mood disorder, and possibly with anterolateral temporal lobe lesions. The development of abnormal electrical activation patterns in limbic networks, functional changes in aminergic inhibitory systems, and the presence of aberrant regeneration patterns may all play a role in the genesis of these syndromes.

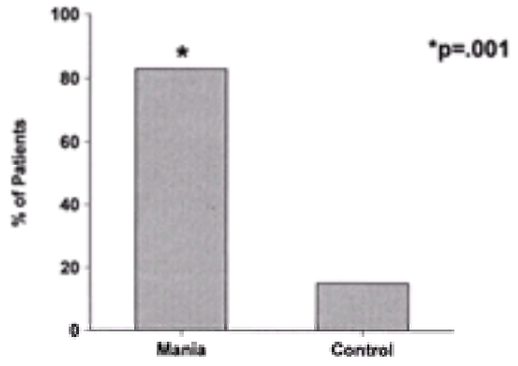

FIGURE 2.5-5 The frequency of basotemporal lesions among patients with traumatic brain injury who developed mania sometime during the first year following stroke compared with patients who did not develop mania. (Data from Jorge RE, Robinson RG, Starkstein SE, Arndt SV, Forrester AW, Geisler FH: Secondary mania following traumatic brain injury. Am J Psychiatry *150:*916, 1993.)

The diagnosis of mania following brain injury is based on DSM-IV criteria for mood disorder due to traumatic brain injury with manic features or with or mixed features (Table 2.5-1). As in the case of the depressive disorders, the mania must be thought to be a direct physiological consequence of the brain injury. The diagnosis only requires that the predominant mood be elevated, euphoric, or irritable. This obviously does not require the same specificity of syndrome as a manic episode or a major depressive episode. The aforementioned prospective study required that patients meet the more rigorous criteria for a manic episode.

A 31-year-old married man with two children was struck in the head when a welding tank exploded, sending large and small pieces of metal in all directions. He suffered an intracerebral bleed in the right basal ganglia and white matter surrounding the anterior horn of the right lateral ventricle. Within a few days he became manic, staying up all night, selling things he owned for ridiculously low prices, and buying a new car he could not afford. He believed that he would become a famous songwriter and was hypersexual. He was admitted to hospital where he was treated successfully with lithium and low-dose haloperidol (Haldol). He remained euthymic for about 6 months and he discontinued his medications. Although he continued to experience significant behavioral changes, manic symptoms did not recur during a 2-year follow-up period.

The differential diagnosis of mania due to traumatic brain injury should include substance-induced mood disorder, psychotic syndrome disorder due to epilepsy, and personality change due to traumatic brain injury. Substance-induced mood disorder occurs following intoxication or withdrawal from drugs and is another important differential diagnosis among patients with traumatic brain injury who frequently have a history of substance abuse.

Anxiety Disorders There is a paucity of studies on the prevalence and clinical correlates of anxiety disorders in the traumatically brain-injured population. The available data, however, suggest that anxiety disorders are a frequent psychiatric complication of traumatic brain injury (Fig. 2.5-6). DSM-IV classifies anxiety disorders due to a medical condition according to the predominance of either generalized anxiety, panic attacks, or obsessive-compulsive symptoms (Table 2.5-1).

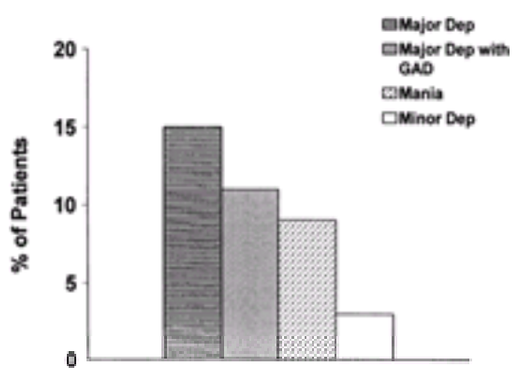

FIGURE 2.5-6 The frequencies of several neuropsychiatric disorders during the hospitalization immediately following traumatic brain injury. Most of the patients had moderate injury (Glasgow Coma Score of 8 to 12) but some had severe injury. Major depressive disorder was the most common disorder particularly when it is combined with group having generalized anxiety disorder plus major depression. (Data from Robinson RG, Jorge RE: Mood disorders. In *Neuropsychiatry of Traumatic Brain Injury.* Silver JM, Yudofsky SC, editors. American Psychiatric Press, Washington, DC, 1994.)

Anxiety disorders following traumatic brain injury may manifest themselves in a variety of ways. Pathological worrying, free-floating anxiety, and autonomic symptoms are commonly associated with anxious depressions. Rigidity of thinking, obsessions, and ritualistic compulsions may also be observed following brain trauma. The onset of obsessive-compulsive symptoms, however, is usually preceded by generalized anxiety. There are also case reports of patients experiencing panic attacks after traumatic brain injury. Posttraumatic stress disorders are characterized by recurrent intrusive recollections, distressing dreams, and flashbacks of the traumatic event. Patients with posttraumatic stress disorder show features of increased arousal such as difficulty falling or staying asleep, exaggerated startle response, and irritability. They lose interest in social activities and avoid thoughts, feelings, or circumstances associated with the event.

A 33-year-old certified nurse was assaulted while walking to her job in a small hospital. She received several blows to her head and was admitted unconscious to the emergency room. A CT scan showed a depressed skull fracture and right temporal and parietal contusions. She regained consciousness during the first 12 hours of admission and was confused and disoriented for the following 3 days. After this, she had an uneventful course and a good recovery. One month after trauma she received a complete neuropsychiatric evaluation. She complained of intrusive recollections of the moments previous to the assault, which were associated with great psychological distress, sweating, and palpitations. She was also disturbed by nightmares in which she suddenly found herself in an intensive care unit connected to a ventilator, incapable of talking or asking for help. She avoided the hospital's surroundings and was unable to walk alone. She also complained of decreased concentration and memory impairments. The results of her neuropsychological tests, however, were within the normal range.

A prospective study of 66 patients with traumatic brain injury found that 7 patients (11 percent) met DSM-III-R criteria for both generalized anxiety disorder and major depression whereas 10 patients met criteria for major depression alone, but none had generalized anxiety disorder alone. The duration of the generalized anxiety disorder was 1.5 months on average, but the mean duration of depression associated with generalized anxiety disorder was 7.5 months whereas depression alone had a mean duration of 1.5 months (Fig. 2.5-7). The presence of anxiety disorder was not associated with any background characteristic; severity of head injury; or severity of social, physical, or cognitive impairment. Anxiety disorder plus depression, however, was significantly associated with right hemisphere lesions while depression alone was associated with left anterior lesions. In addition, a study of veterans of the Vietnam war with penetrating brain injuries found that anxiety symptoms were associated with the presence of right orbitofrontal cortex lesions. These findings suggest that anxiety disorder due to traumatic brain injury is often accompanied by depression and that the mechanism of anxiety may be different than that of depression alone. Anxiety may be mediated by pathophysiological changes provoked by right hemisphere lesions.

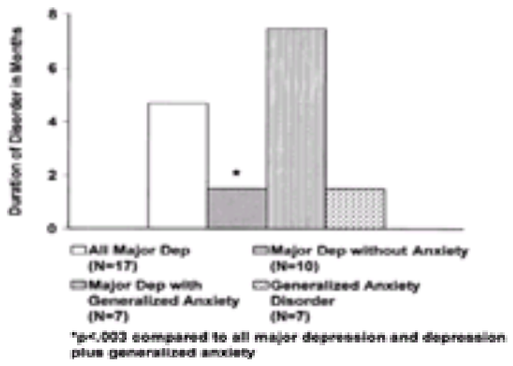

FIGURE 2.5-7 Duration of depression among patients with major depressive disorder or generalized anxiety disorder following traumatic brain injury. Patients with major depressive disorder without anxiety disorder had depressions significantly shorter in duration than patients with major depression and generalized anxiety disorder. Patients with anxiety disorder alone had relatively brief anxiety disorders. (Data from Jorge RE, Robinson RG, Starkstein SE, Arndt SV: Depression and anxiety following traumatic brain injury. J Neuropsychiatry Clin Neurosci *5:*43, 1993.)

Psychotic Disorders Psychotic disorders due to traumatic brain injury are often associated with seizure disorder. In addition, the epileptic foci are often located in limbic or paralimbic cortical regions. Psychotic episodes may be temporally linked to seizures or may have a more prolonged interictal course. In the latter case, the clinical picture is characterized by the presence of partial seizures.

Electroencephalographic and functional neuroradiological studies (e.g., single photon emission computed tomography [SPECT] and positron emission tomography [PET]) will usually define ictal and interictal disturbances. Clinical manifestations include personality changes, mood instability, paranoid ideation, poor control over aggression, disinhibited behavior, and hypersexuality. However, these patients lack the pervasive alteration of mood that characterizes major depressive episodes or manic episodes.

PATHOLOGY

The first level of categorization of head injuries divides them into *closed* or *penetrating* injuries depending upon the integrity of the meningeal covering. Missile wounds are the most frequent cause of penetrating brain injuries. They tend to produce discrete lesions that may be complicated by infection or hemorrhage. On the other hand, motor vehicle accidents are the most frequent cause of closed trauma, which represents the majority of traumatic brain injuries. Diffuse brain damage is a prominent feature of closed head injury (Table 2.5-3).

1. Focal Lesions
Contusions and lacerations
Intracerebral hemorrhage
Intracranial-extracerebral hemorrhage (epidural and subdural hematomas, subarachnoid hemorrhage)
Focal ischemic lesions
2. Diffuse Lesions
Diffuse axonal injury
Diffuse ischemic damage

Table 2.5-3 Neuropathological Classification of Traumatic Brain Injury Lesions

Primary brain damage is produced by contact and inertial forces that occur at the time of injury. Contact forces may result in laceration to the scalp, skull fractures, intracranial hemorrhages, contusions, and intracerebral hemorrhages. Inertial loading consists of acceleration on deceleration and rotational forces, which result in diffuse axonal injury and eventually in acute subdural hematoma from the tearing of subdural bridging veins (Figure 2.5-8).

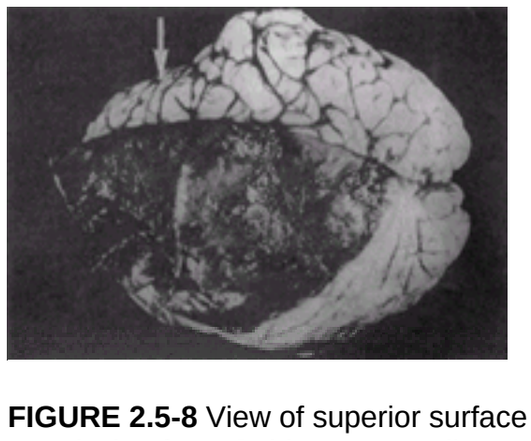

FIGURE 2.5-8 View of superior surface of brain showing subdural hematoma (dura folded back) and compression of right frontal region (*arrow*). (Reprinted with permission from Golden A, Powell DE, Jennings CD: *Pathology: Understanding Human Disease*, ed 2. Williams & Wilkins, Baltimore, 1985.)

Secondary brain damage is produced by pathological processes that are initiated at the moment of injury but span a variable period following the traumatic episode. These include brain damage secondary to ischemia (e.g., that resulting from associated hypotension or hypoxia), brain swelling, raised intracranial pressure (with consequent reduction of cerebral perfusion pressure), and infection.

Focal lesions consist of contusions and lacerations that usually occur at the surface of the brain (Table 2.5-3). They are more prominent at the crest of cerebral gyri

and have a predilection for the frontal and temporal poles. Lacerations are usually accompanied by extracerebral hemorrhages (burst lobe). Intracranial-extracerebral hemorrhages occur in the epidural space (i.e., between the skull and the dura), the subdural (i.e., between the dura and the arachnoid), or the subarachnoid space. Intracerebral hemorrhages are often multiple, involving the frontal and temporal lobes and basal ganglia and may have a delayed onset (i.e., hours or days after trauma). Finally, ischemic damage may produce focal lesions from traumatic vascular lesions (e.g., arterial dissection, vascular distortion and compression, and venous thrombosis) or from arterial vasospasm.

Diffuse lesions include diffuse axonal injury that occurs preferentially within the corpus callosum, thalamus, and dorsolateral quadrants of the upper brainstem. Pathological processes include fragmentation of the axolemma, axonal transport disruption, axonal bulb formation, astrogliosis, and microglial activation. Although usually associated with immediate and persistent coma, lesser degrees of axonal disruption may also be seen in patients with a lucid interval or even in patients who suffered mild brain injuries. Diffuse injury also includes ischemic damage, which is highly prevalent among patients with severe head injuries. A seminal neuropathological study reported that severe ischemic damage was present in 27 percent of 151 cases, moderately severe ischemic damage was present in 43 percent, and mild damage was found in another 30 percent of cases.

The influence of these different patterns of injury on the psychiatric disorders following brain trauma has not been extensively studied. Previous studies have stressed the importance of diffuse brain injury as a predictor of long-term disability of such patients. Another study, however, did not find significant differences in neuropsychological outcome between two groups of patients with focal or diffuse patterns of injury. Furthermore, both focal and diffuse lesions usually coexist in traumatically brain-injured patients. A recent study suggests that adaptive dysfunction in children is significantly correlated with the depth of the lesion, a finding previously observed in other age groups.

LABORATORY TESTS

Neurochemical Changes Since the late 1980s there has been intensive research on the complex neurochemical changes occurring after brain trauma. This was undertaken in an attempt to identify specific interventions that could modify the pathological processes resulting in diffuse neuronal death. For example, increased activity of basal forebrain cholinergic systems has been identified in patients with traumatic brain injury. Pathological excitation of basal forebrain nuclei following acetylcholine release, however, may result in structural damage of these nuclei and persistent behavioral deficits. Furthermore, such brain injury activates the sympathoadrenomedullary axis as well as the ascending cathecholaminergic pathways. Circulating levels of catecholamines have been shown to significantly correlate with severity of injury as measured by Glasgow Coma Scale scores (Fig. 2.5-9).

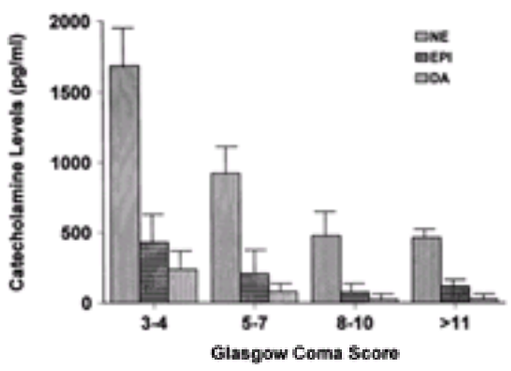

FIGURE 2.5-9 Mean ± SEM catecholamine concentrations within 48 hours of head injury in patients grouped by initial Glasgow Coma Scale score. (Reprinted with permission from Hamill RW, Woolf PD, McDonald JV, Lee L, Kelly M: Cathecholamines predict outcome in traumatic brain injury. Ann Neurol *21:*438, 1987.)

The neurotoxic effects of the excitatory amino acids glutamate and aspartate have been studied at length. Overactivity of these neurotransmitter systems plays a role in neuronal damage associated with diverse types of injury. These neurotoxic effects are mediated through changes in the membrane conductance of sodium and calcium ions. Traumatic injury is associated with the formation of highly reactive oxygen free radicals, which in turn effect the peroxidation of cell membranes, cytosolic proteins, and nucleic acids. There is also evidence of activation of complement proteins as well as different cytokines such as interleukin-1b and tumor necrosis factor.

Patients with traumatic brain injury may also present with structural and functional changes of the hypothalamic-pituitary axis. Hormonal responses to trauma include increases in adrenocorticotropin, cortisol, growth hormone, and prolactin concentrations. In contrast, gonadotropins, sex steroid hormones, and thyroid hormone concentrations decrease following trauma. The presence of elevated prolactin levels is strongly associated with hypothalamic damage and it has been hypothesized that the changes in adrenocorticotropic hormone (ACTH) and cortisol concentrations that occur in TBI patients may mediate changes in mood. The magnitude, regional distribution, and relation of the temporal course of these neurochemical changes to mood disorders remains largely unexplored and constitutes an interesting field for further investigation.

Neuroimaging Recent advances in neuroimaging techniques have certainly increased the understanding of the relationship between structural abnormalities and behavioral disturbances following traumatic brain injury. CT and MRI are routinely used for the evaluation of these patients. CT is still the most efficient means of detecting surgically treatable hematomas and is the study of choice for evaluating patients with rapid changes in their neurological status. Figure 2.5-10 shows the sites of most common injury as seen on neuroimaging. MRI, however, is more sensitive in detecting the more prevalent posttraumatic nonhemorrhagic lesions (e.g., cortical contusions and deep white matter lesions) and in identifying small subdural collections. A delayed MRI scan (i.e., 2 weeks after injury) would be indicated in those patients whose initial instability favored an emergency CT scan but were later treated medically or were left with persistent neurological deficits after a neurosurgical procedure. There is also some evidence that functionally significant lesions may be better evaluated by late MRI scanning. Posttraumatic atrophic changes can be quantified using MRI volumetric studies; for example, changes in left hippocampal volume may be indicative of verbal memory functioning.

FIGURE 2.5-10 Area of maximum shear strain and expected distribution of traumatic intra-axial lesions for the three orthogonal planes of rotational acceleration as predicted by Holbourn. The expected location of traumatic lesions are shown for rotation in the sagittal **(A)**, coronal **(B)**, and axial **(C)** planes. A greater frequency of lesions is to be anticipated in the more darkly shaded regions, which represent areas of maximum shear strain. (Reprinted with permission from Gentry LR, Godersky JC: Head trauma. In *MRI of the Brain and Spine*, SW Atlas, editor. Raven, New York, 1991.)

Functional neuroimaging studies, for example, PET and SPECT, provide additional information with regard to the metabolic rates of cortical and subcortical structures as well as of the status of specific neurotransmitter systems. Both PET and SPECT have greater sensitivity than CT and MRI in detecting local abnormalities in brain-injured patients with long-term deficits. The correlations between these radiological abnormalities and specific neurobehavioral deficits, however, have generally

been weak and require further study.

Electrophysiological Studies Conventional electroencephalogram (EEG) recordings are currently used in trauma intensive care units for monitoring procedures and to diagnose brain death. The EEG is also invaluable in the diagnosis of status epilepticus and is the primary diagnostic procedure to localize a posttraumatic epileptic focus. The chance of finding an abnormality on routine EEG can be increased by using nasopharyngeal, anterior temporal, or sphenoidal leads. Video-EEG monitoring and 24-hour ambulatory recordings may be useful in the differential diagnosis of patients presenting with unclear paroxysmal behavioral disturbances. Polysomnography permits the diagnosis of atypical sleep disturbances that may occur in brain-injured patients. These include atypical night terrors, sleep apnea, nocturnal myoclonus, and restless leg syndrome. Visual, auditory, and somatosensory evoked potentials are useful to localize the level of injury to the central nervous system; auditory evoked potentials are particularly effective in detecting brainstem pathology.

Finally, quantitative EEG is currently used as an adjunctive diagnostic technique in the evaluation of slow-wave abnormalities associated with brain injuries and in the diagnosis of posttraumatic temporal lobe epilepsy.

COURSE AND PROGNOSIS

Course and prognosis of patients with traumatic brain injury involves the longitudinal analysis of neurological, neuropsychological, psychiatric, and psychosocial variables. Some of these variables are readily operationally defined, while others are more elusive and difficult to quantify. The Glasgow Outcome Scale has been widely used as a measure of the long-term outcome of these patients. It consists of five levels of outcome: (1) death, (2) persistent vegetative state, (3) severe disability (conscious but dependent in activities of daily living, (4) moderate disability (disabled but living independently), and (5) good recovery (mild neuropsychiatric sequela but able to resume an otherwise normal life). Although crude, the scale is appreciated for both its validity and high reproducibility.

The long-term outcome of patients with brain injury is primarily related to the severity of the injury, the type and location of the intracranial lesion, and the efficacy of the immediate medical and surgical treatment. Outcome is also influenced by concurrent factors that include age, socioeconomic status, educational level, previous psychiatric disorders (e.g., history of alcohol or drug abuse, personality disorders, etc.), and premorbid social functioning levels. Finally, the quality and extent of rehabilitation services and the availability of social and vocational support also play a significant role in outcome.

The National Institutes of Health (NIH) Traumatic Coma Data Bank was initiated by the National Institute of Neurological Disorders and Stroke in order to characterize the natural history of traumatic head injury and to evaluate the determinants of recovery. Of 746 severely head-injured patients studied in this cohort, 243 patients (32.5 percent) died, 325 patients (42 percent) were either severely disabled or in a vegetative state, 138 (18 percent) had moderate disability, and the remaining 50 (7 percent) had a good recovery as measured by the Glasgow Outcome Scale at the time of hospital discharge. Another study analyzed the outcome of 170 patients with moderate head injuries at 3 months following traumatic brain injury. According to the Glasgow Outcome Scale, 38 percent of patients with moderate head injury made a good recovery, 49 percent were left with moderate disability, and 10 percent of patients had severe disability; the mortality rate was 3 percent. The same authors found that the majority of patients with mild head injury (78 percent) made a good recovery, 22 percent of patients were left with moderate disability, and there were no patients experiencing severe disability.

Cognitive disturbances are among the most important factors in long-term disability following severe traumatic brain injury. A 1992 study reported on a group of 50 patients with mild and moderate head injury and correlated different neuropsychological measures obtained in hospital and at 1 and 3 months follow-up with serial MRI findings. The group with traumatic brain injury had significantly greater neuropsychological impairment than a control group. These cognitive deficits showed an impressive recovery during follow-up and were not consistently related to specific lesion locations. MRI abnormalities were present at baseline in 40 (80 percent) of these patients and gradually resolved by 3 months. Other studies have reported that 18 percent of patients with severe head injury had returned to gainful employment and 62 percent of former students had returned to school by 6 months follow-up. For those not back to work or school at 6 months, 31 percent of the former workers and 66 percent of the former students had returned by 12 months. The three most significant predictors for returning to work or school were age, intact verbal abilities, and speed of information processing. A series of moderate head injury cases revealed that 69 percent of patients who had been gainfully employed before the injury were unemployed at 3 months' follow-up.

The NIH traumatic coma data bank found that outcome following severe brain injury in children and adolescents was poorest in the 0 to 5 age range, followed by the 11 to 15 age range, and the 6 to 10 age range. These findings suggest that younger children are at greater risk following the relatively diffuse type of injury associated with traumatic brain injury, which runs counter to the findings of relative sparing of function (plasticity) following more focal childhood brain lesions. Factors predictive of the development of a new psychiatric disorder in children during the first 2 years after the injury include increasing severity of injury, preinjury family dysfunction, preinjury psychiatric disorder in the patient and in family members, and lower socioeconomic status.

Furthermore, behavioral changes associated with brain injury may disrupt interpersonal relationships and pose a great burden to family members. During the first year after the injury, more than two thirds of relatives experienced moderate to severe degrees of burden as a consequence of the behavioral changes in the family member. Significant predictors of family functioning outcome at various points during the first 2 years after childhood brain injury include preinjury family functioning and the development of a new psychiatric disorder in the child. Thus, it is not surprising that psychosocial adjustment and community reentry have become the targets of rehabilitation efforts. The patient's motivation and a history of alcohol or drug abuse as well as awareness of cognitive and physical impairments have been shown to exert a significant effect on rehabilitation outcome.

TREATMENT

Biological Treatment Patients with brain injury are more sensitive than normals to the side effects of medications, especially psychotropic agents. Dosages of these drugs must be prudently increased so as to minimize the adverse effects (i.e., start low, go slow). However, the patient must receive an adequate therapeutic trial with regard to dosage and duration of treatment. Brain-injured patients must be reassessed frequently in order to determine changes in treatment schedules. Special care must also be taken in monitoring drug interactions. In addition, if there is evidence of a partial response to a specific medication, augmentation therapy is warranted, considering mechanisms of action and adverse effects of the second drug.

Agitation and violent behavior may also occur during the early stage of recovery (e.g., when the patient is emerging from coma) and may require the use of sedative medications. Low doses of high-potency antipsychotic medications (e.g., haloperidol) may be useful in this context, particularly when the agitated behavior stems from psychotic ideation or hallucinatory experiences. Besides their neurological and cardiovascular adverse effects, there is experimental evidence that these drugs may be detrimental for recovery; thus, they must be promptly tapered as soon as the patient stabilizes.

Benzodiazepines [e.g., lorazepam (Ativan)] are also helpful in the management of acute agitation and aggression. Oversedation, poor coordination, and cognitive disturbances are their most common adverse effects; paradoxical rage is a rare complication. Dosages should be progressively reduced as symptomatic relief is obtained. There are also reports on the use of carbamazepine, amantadine (Symmetrel), and clonidine (Catapres) for the treatment of acute agitated states.

There is also some evidence of the clinical efficacy of dopamine agonists (e.g., bromocriptine [Parlodel]) or in patients with poor motivation and frontal lobe deficits. Chronic aggressive disorders may be treated with anticonvulsants (e.g., carbamazepine or valproic acid [Depakene], b-adrenergic receptor antagonists (e.g., propranolol [Inderal] or pindolol [Visken]), antidepressants (e.g., amitriptyline [Elavil] or sertraline [Zoloft]), or lithium.

There is only one small double-blind, placebo controlled study of the efficacy of pharmacological treatments of depression in traumatically brain-injured patients. In this study the antidepressant effectiveness of desipramine (Norpramin) was significantly greater than placebo. Selection among competing antidepressants is usually guided by their adverse effect. Mild anticholinergic activity, minimal lowering of seizure threshold, and low sedative effects are the most important factors to be considered in the choice of an antidepressant drug in this population. Tricyclic drugs have important anticholinergic effects that may interfere with cognitive and memory functions; in addition, they may lower the seizure threshold. Selective serotonin reuptake inhibitors (SSRIs) are antidepressants that appear to have milder adverse effects. The most common adverse effects include headache, gastrointestinal complaints, and insomnia. Diminished libido and sexual dysfunction may be an additional concern. Fluoxetine (Prozac) (starting at 10 mg/day), sertraline (starting at 25mg/day), or paroxetine (starting at 5 to 10 mg/day) are among the most useful drugs in this group.

Trazodone (Desyrel) is an antidepressant that also inhibits serotonin reuptake. Treatment is started at low doses (50 to 100 mg) at bedtime following a snack; the dosage may be gradually increased every 3 to 4 days up to 400 mg. The most troublesome adverse effects are sedation and orthostatic hypotension.

There have been no systematic studies of the treatment of secondary mania. There are, however, several reports of potentially useful treatment modalities. A double-blind, placebo-controlled study in a single patient with secondary mania following traumatic brain injury concluded that clonidine (600 µg/day) was effective in reverting manic symptoms, carbamazepine (1200 mg/day) did not elicit mood changes and levodopa (Dopar) and benserazide (375 mg/day) resulted in an increase of manic symptoms. Lithium, carbamazepine, and valproate therapies have also been reported to be efficacious in individual cases. Lithium has been reported to impair cognitive performance in traumatically brain-injured patients; in addition, it may lower seizure threshold. Some authors limit its use to patients in whom bipolar disorder preceded the onset of the injury.

Carbamazepine is a mood-stabilizing drug that should be gradually increased to obtain therapeutic blood levels (8 to 12 µg/ml). Complete blood counts should be obtained every 2 weeks for the first 2 months of therapy and every 3 months thereafter. Liver function tests should be obtained every 3 months. Frequent adverse effects include sedation, dry mouth, gastrointestinal upset, drowsiness, impaired concentration, ataxia, nystagmus, and rash. Severe complications include pancytopenia, aplastic anemia, and cholestatic jaundice.

Valproic acid is another mood-stabilizing medication that can be progressively increased from 500 mg a day up to the dosage necessary to obtain plasma concentrations between 50 and 100 µg per ml. The maximum recommended dosage is 60 mg per kg daily divided into two to four doses. Valproic acid has potentially serious adverse effects. These include hepatotoxicity, which ranges from a discrete elevation of transaminases and serum ammonia levels to irreversible liver failure; hemorrhagic pancreatitis has also been reported. Less serious adverse effects include drowsiness, tremor, gastritis, and increased weight. Liver function tests and serum amylase levels should be monitored.

For the treatment of anxiety disorders, buspirone (BuSpar), a drug that has an agonist effect on serotonin (5-hydroxytryptamine [5-HT]) subtype 1A (5-HT $_{1A}$) receptors and an antagonist effect on dopamine type 2 (D_2) receptors, has proved to a safe and efficacious anxiolytic agent. The initial dosage is 15 mg a day given in three divided doses and it may gradually be increased (5 mg every 4 days) to up 50 mg a day. The most common adverse effects are dizziness and headaches.

Pathological laughing and crying may respond to treatment with antidepressant medications. There is, however, a great variability in treatment response among brain-injured patients with some showing a rapid response at relatively low doses and others requiring more time and a full dose schedule. Furthermore, there are case reports of successful treatment of apathetic states with psychostimulants. These include dextroamphetamine (Dexedrine) (8 to 60 mg/day), methylphenidate (Ritalin) (10 to 60 mg/day), and pemoline (Cylert) (56.25 to 75 mg/day). They are given twice a day, with the last dose given at least 6 hours before sleep in order to prevent initial insomnia. Treatment is begun at lower dosages, which are then gradually increased. Patients taking stimulants need close medical supervision to prevent abuse or toxic effects. The most common adverse effects are anxiety, dysphoria, headaches, irritability, anorexia, insomnia, cardiovascular symptoms, dyskinesias, or even psychotic symptoms.

Electroconvulsant therapy (ECT) is not contraindicated in brain-injured patients and may be considered if other methods of treatment prove to be unsuccessful. ECT should be administered with the lowest possible effective energy, using pulsatile currents, with an interval of 2 to 5 days between treatments and a reduced number of treatments for a complete course (i.e., 4 to 6 treatments). Nondominant unilateral ECT is preferred. Even transcranial magnetic stimulation has been reported to be successful in four patients with major depression developing after brain injury.

Behavioral Treatment Behavioral deficits in self-care habits (e.g., feeding or personal hygiene), interpersonal skills (e.g., disinhibited behavior), problem solving, or response to environmental stress may be amenable to behavioral intervention. Behavioral rehabilitation programs shape behavior based on the principles of operant conditioning (e.g., contingency contracts and token economies). Their goal is to increase the patient's repertoire of social and independent living skills, generalizing their use from the rehabilitation environment to the more demanding conditions of community life.

Controlled treatment trials of psychotherapy in any of the neuropsychiatric disorders resulting from brain injury have not been conducted. There are, however, reports of the utility of cognitive behavioral therapy, group therapy, and family therapy in the treatment of depression or other neuropsychiatric disorders. The utility of specific psychological interventions for each neuropsychiatric disorder needs to be developed.

SUGGESTED CROSS-REFERENCES

Basic neurological issues are discussed in Section 1.1. Neuroimaging is covered in Section 1.15 and Section 1.16. Neuropsychological tests used to evaluate neurological and psychiatric patients are described in Section 7.4 and Section 7.5.

Delirium, dementia, and amnestic disorders are covered in Chapter 10. The neuropsychiatric complications of stroke and epilepsy are discussed in Section 2.2 and Section 2.4, respectively.

2.6 NEUROPSYCHIATRIC ASPECTS OF MOVEMENT DISORDERS

DAVID GORDON DANIEL, M.D., MICHAEL F. EGAN, M.D. AND STEVEN S. WOLF, M.D.

In common to all extrapyramidal movement disorders is dysfunction of circuits involving cortico-basal ganglia-thalamic loops or the cerebellum. The former circuits funnel information from anterior cortical regions into the striatum. This information is funneled to the thalamus and then the circuit is completed back to the cortex, particularly anterior, motor, and multimodal cortical regions. The basal ganglia and thalamic influences modulate cortical motor activity and integrate input from the cerebellum. In motor function the basal ganglia have “switching” and “braking” functions that orchestrate smooth movement by coordinating facilitation and suppression of motor activity. The frontal corticostriatothalamic loops can be divided by type into separate parallel circuits with motor, oculomotor, limbic, and prefrontal targets. This explains, in part, the association of basal ganglia disease with cognitive, emotive, motor, and oculomotor features.

The primary components of the basal ganglia are the caudate nucleus, the putamen, and the globus pallidus. The caudate and putamen nuclei are sometimes referred to as the *striatum.* The striatum receives afferent fibers from the cortex. The output of the striatal regions can be divided into two segregated circuits, the direct, dopamine type 1 (D_1) receptor-mediated striatonigral loop, and the indirect, dopamine type 2 (D_2) receptor-mediated striatopallidal loop (Fig. 2.6-1). The former projects directly to the internal segment of the globus pallidus (GPi) and substantia nigra pars reticulata (SNr). The indirect loop first goes to the external segment of the globus pallidus (Gpe), then to the subthalamic nucleus (STN), and then to the globus pallidus and substantia nigra pars reticulata GPi/SNr. Normal motor function is produced by the coordinated action of both in regulating thalamic excitatory influences on the cortex. Relative overactivation of the direct pathway leads to hyperkinetic movements such as are seen in Huntington's chorea, Levodopa (Larodopa)-induced dyskinesias, tardive dyskinesia, and tic disorders. Relative overactivation of the indirect pathway leads to hypokinetic symptoms, such as are seen in parkinsonian syndromes.

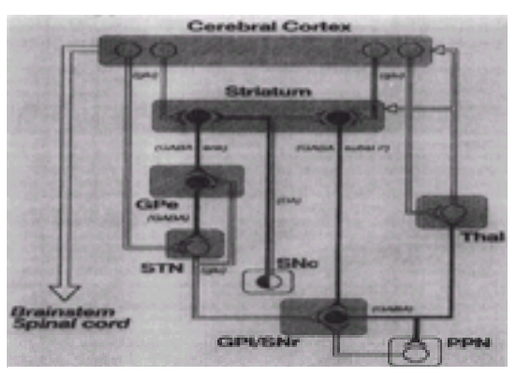

FIGURE 2.6-1 Schematic diagram of the circuitry and neurotransmitters of the basal gangliathalamocortical circuitry, indicating the parallel ‘direct' and ‘indirect' pathways from the striatum to the basal ganglia output nuclei. Inhibitory neurons are shown as filled symbols, excitatory neurons as open symbols. Abbreviations: DA, dopamine; enk, enkephalin; GABA, g-aminobutyric acid; Gpe, external segment of globus pallidus; Gpi, internal segment of globus pallidus; glu, glutamate; PPN, pedunculopontine nucleus; SNc, substantia nigra pars compacta; SNr, substantia nigra pars reticulata; subst P, substance P; STN, subthalamic nucleus; Thal, thalamus. (Reprinted with permission from Alexande GE, Crucher MD: Functional architecture of basal ganglia circuits: Neural substrates of parallel process. Trends Neurosci *13:*266, 1990.)

Cortico-basal ganglia-thalamic loop function requires balanced activity of several neurotransmitters and neuromodulators (Fig. 2.6-1). Cortical areas send excitatory glutaminergic projections to input areas of the striatum. Inhibitory nigrostriatal dopamine projections facilitate conduction through the direct pathway, and inhibit the indirect pathway. Excitatory cholinergic projections balance the inhibitory effects of dopamine. g-Aminobutyric acid (GABA), acting as an inhibitory transmitter, is released at terminals of the striatonigral pathway. Substance P and enkephalin act as neuromodulators. In addition to modulating disordered movement, most of these substances are considered important in the pathophysiology of disorders of reality testing, cognition, and emotion.

PARKINSON'S DISEASE

Introduction Parkinsonism describes characteristic clinical motor manifestations of disrupted nigrostriatal-modulated basal ganglia activity. The complex interconnections of the basal ganglia and cortical, limbic, and thalamic circuitry intimately link parkinsonism with disorders of cognition, mood, and reality testing. Treatment of parkinsonism with dopaminergic or anticholinergic agents may further disrupt normal homeostatic balances related to psychiatric, cognitive, and motor function. Parkinsonism is a syndrome of multiple etiologies in which at least two of the following four cardinal clinical signs are present: resting tremor, bradykinesia, rigidity, and postural instability (Table 2.6-1). The terms “primary parkinsonism,” “idiopathic parkinsonism,” and “paralysis agitans” are used interchangeably with *Parkinson's disease.*

Table 2.6-1 Known Causes of Parkinsonism

Definition The fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) recognizes several psychiatric phenomena that occur secondary to Parkinson's disease. A clinically significant mood disorder believed to be secondary to Parkinson's disease is referred to as *mood disorder due to Parkinson's disease.* Types include, with depressive features; with major depressive-like features; with manic features; and with mixed features. Dementia due to Parkinson's disease is characterized by “the presence of a dementia that is judged to be the direct pathophysiological consequence of Parkinson's disease.” Prominent delusions

or hallucinations that are judged to result from the direct physiological effects of Parkinson's disease or its treatment are referred to as *psychotic disorder due to Parkinson's disease.* Types include with delusions and with hallucinations. Prominent delusions or hallucinations judged to be the direct physiological effect of a drug treatment for Parkinson's disease are termed *substance-induced psychotic disorder.* Delirium caused by Parkinson's disease or its treatment is termed by DSM-IV *delirium due to Parkinson's disease* and *substance intoxication delirium*, respectively.

History Parkinsonian-like syndromes were described in ancient Egyptian and Indian texts dated to the twelfth century bc and circa 1000 to 2500 bc respectively. The latter described treatment with a levodopa-containing herb, *Mucuna puriens.* Shortly after John Parkinson's description in 1817, Jean Martin Charcot documented the therapeutic effects of anticholinergic belladonna alkaloids. The role of the substantia nigra was first proposed in 1895, and in 1912, Friedrich Lewy first described what came to be known as the *Lewy body.* Around 1957 it was noted that dopaminergic precursors reversed reserpine-induced parkinsonism; shortly thereafter, reductions in dopamine concentrations were demonstrated in postmortem brain tissue of patients with parkinsonism. In 1960 efforts began to treat Parkinson's disease with levodopa (Laradopa) and within the decade clinically significant results had been achieved.

Epidemiology Most estimates of the prevalence of Parkinson's disease range between 1 and 2 per 1000. Primarily a disease of later life, Parkinson's disease occurs in less than 1 percent of cases before age 30. The prevalence increases markedly with age to around 1 per 100 after age 65; males and females are affected approximately equally. The disease is more common in industrialized countries. Depressed mood may be the most common psychiatric complication of Parkinson's disease, with prevalence estimated between 20 and 63 percent, depending on the criteria for depression and the subpopulation studied. Cognitive impairment, ranging from mild to severe in intensity, is present in the majority of patients. DSM-IV notes that prevalence estimates for dementia in Parkinson's disease range from 20 to 60 percent. Increased risk of dementia is associated with older age, advanced disease, atypical neurological features, and depressed mood. Estimates of the prevalence of psychotic symptoms vary widely with stage of illness, setting, degree of cognitive impairment, and past history of psychosis. The prevalence of delusions and visual hallucinations during dopamine replacement therapy has been estimated at 15 and 20 percent respectively, but may be much higher in the later stages of Parkinson's disease.

Etiology In Parkinson's disease, hypokinetic motor manifestations result from overactivation of the indirect feedback loop secondary to loss of the modulating effects of the pars compacta of the substantia nigra dopaminergic projections to the neostriatum (caudate-putamen nuclei of the basal ganglia) (Fig. 2.6-1). The disease becomes clinically detectable when approximately 70 percent reduction in neostriatal dopamine levels occurs. The best explanation for its late onset may be a combination of normal depletion of dopamine with aging, which occurs at a rate of approximately 13 percent by decade, combined with vulnerability from an earlier disease-related insult that lowers dopaminergic reserve. Experimental models of parkinsonism suggest that earlier onset may be delayed by compensatory mechanisms such as increased activity and dopamine release by surviving neurons, reduction in dopamine reuptake sites in the synaptic cleft, and receptor supersensitivity. One of the best animal and human models of parkinsonism is exposure to a byproduct of synthetic narcotic synthesis, *N*-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP). MPTP is a neurotoxin that selectively damages the substantia nigra and causes motor abnormalities similar to those seen in Parkinson's disease that are partially reversible with levodopa. Free radicals and other toxic metabolites are prime suspects in the pathogenesis of Parkinson's disease. Dopaminergic neurons are considered vulnerable to oxidative stress via a variety of pathways. However, degeneration may occur in multiple other neurotransmitter and anatomical systems, contributing to a wide range of dysfunction. For example, cholinergic imbalances and degeneration of neurons in the hypothalamus, sympathetic ganglia, dorsal motor nucleus of the vagus, and myenteric plexus may contribute to autonomic dysfunction.

Psychiatric Manifestations Depression has been noted prior to observation of extrapyramidal signs in 34 to 43 percent of patients with Parkinson's disease. Theoretically, deficits in mesocortical or mesolimbic dopamine systems could affect mood before the clinical threshold for motor signs from nigrostriatal dopamine degeneration is attained. Impairment of serotoninergic or noradrenergic function could also contribute. Psychosocial reaction to disability is likely to play an etiological role in depression in Parkinson's disease. The cognitive deficits follow a primarily “subcortical” pattern believed to be associated with degenerative processes in the basal ganglia, thalamus, and brainstem. Dopaminergic deficits and Lewy bodies are seen in cell bodies in the ventral tegmental areas that project to areas related to motion and cognition, including the nucleus accumbens, olfactory tubercle, central amygdaloid nucleus, cingulate, prefrontal lobes, entorhinal cortex, and hippocampus. Damage to the mesocortical dopamine projections may be particularly injurious to executive functions linked to the frontal lobe, and appears sensitive to dopamine replacement. Cholinergic deficits could impair memory. Psychosis in Parkinson's disease may have several concurrent causes including dopamine imbalances innate to Parkinson's disease, dopamine replacement therapy, anticholinergic therapy, dementia, and delirium. In Parkinson's disease, delusions and hallucinations in the context of a clear sensorium were reported prior to the dopamine replacement era. In theory, damage to mesocortical-cortical-subcortical feedback loops could interfere with cortical modulation of limbic activity and lower the threshold for psychosis. The most common cause of psychotic symptoms in Parkinson's disease is dopamine replacement therapy, presumably by stimulation of postsynaptic D_2 receptors in the mesolimbic tracts. Because cerebral compensatory mechanisms are tenuous, patients with Parkinson's disease are vulnerable to decompensation into delirium by a wide variety of medical, surgical, and toxic insults. Any medication that alters central nervous system (CNS) function may cause delirium, even at what appear to be subtherapeutic dosages. Sleep disturbance in Parkinson's disease may have multiple concurrent causes including age-associated sleep patterns, depression, delirium-related disturbance in sleep-wake cycle, the rigidity and bradykinesia of Parkinson's disease, recurrence of tremor with awakening, and dopaminergic drugs.

Diagnosis and Clinical Features

Motor Manifestations The clinical diagnosis of Parkinson's disease is confirmed at autopsy in around 80 percent of cases. The diagnosis of Parkinson's disease requires an unexplained progressive condition with at least two of four essential features: bradykinesia, tremor, rigidity, and postural instability. Bradykinesia is a state of globally decreased motor activity manifest by slowness, decreased spontaneity, and subjective feelings of apathy. Parkinsonian tremor is rhythmic, relatively slow (3 to 6 cycles per second), present at rest, worsened by stress, and affects the limbs, head, lips, and tongue. Parkinsonian muscle rigidity may be continuous (“lead-pipe”) or ratchetlike (“cog-wheel”) when the joint is passively moved. Subjectively, muscle stiffness or muscle aching and incoordination may be experienced. Bradykinesia and rigidity may result in drooling, micrographia, hypophonia, and a festinating gait, consisting of small shuffling steps, bent posture, and decreased arm swing. Diminished postural stability may lead to falls; the motor manifestations generally progress with aging.

Clinical Manifestations Depressed mood often precedes the onset of motor symptoms and is accompanied by sleep and appetite disturbance, anhedonia, psychomotor retardation, and anxiety. Guilt and remorse are often less prominent than in other forms of depression. Depression in Parkinson's disease is associated with increased cognitive deficits. Although the pattern of cognitive deficits is conceptualized as primarily subcortical in Parkinson's disease, there is much overlap with executive, visuospatial, and other cortical functions. The cardinal features, predominantly subcortical patterns of cognitive impairment, include slowed information processing, apathy, depression, memory deficits, and difficulty manipulating acquired knowledge. Compared to patients with Alzheimer's disease, in patients with Parkinson's disease word fluency, attentional skills, information-processing speed, and motor aspects of speech are more prominently impaired and loss of recognition memory, loss of intellectual aspects of language, aphasia, agnosis, and apraxia are less prominent. Psychotic syndromes may occur in clear or impaired sensoriums, with or without dementia. Common symptoms include hallucinations, vivid dreams, nightmares, and paranoid ideation. In contrast to schizophrenia, visual hallucinations are more common than auditory ones; paranoia is generally not systematized; the sleep-wake cycle is generally disturbed; and formal thought disorder, loose associations, blocking, and bizarre affect are uncommon. In the so-called benign hallucinosis of Parkinson's disease, the patient's insight into the disease origin of the hallucinations is preserved. It is not unusual, however, for this state to progress to more florid psychotic states in which the patient lacks insight. In psychosis associated with dementia of Parkinson's disease, disorientation and confusion may be prominent. Clinical features of delirium in Parkinson's disease may include relatively rapid onset (hours to weeks), confusion, altered sensorium, fluctuating levels of consciousness and confusion, disturbed sleep-wake cycle, and global cognitive deficits. Patients may be agitated, or in states of “quiet delirium,” may exhibit psychomotor retardation or depressed levels of consciousness. Delirium may be superimposed on preexisting dementia or psychotic states. Early stages of delirium may be characterized by a nocturnal pattern called *sundowning* in which agitation and confusion become worse at night. Recognition of delirium is important because it may be reversible, or if undetected progress to death. Physical and neurological examinations, blood chemistries, and reevaluation of all medications with potential for direct or indirect central nervous system effects are essential. Radiography (X-ray) of the chest, computed tomography (CT) scan or magnetic resonance imaging (MRI) of the brain, or lumbar puncture may be appropriate diagnostic interventions to determine the underlying cause.

Pathology and Laboratory Examination Postmortem studies suggest that approximately 50 percent of nigral neurons must be lost before motor manifestations of Parkinson's disease develop. Damage is primarily to the ventrolateral portion of the nigra, which loses its pigmentation and appears pale. Reductions in dopamine and its metabolite correlate with degeneration of the dopamine-releasing neurons, which have their bodies in the pars compacta of the substantia nigra and whose neurons terminate in the neostriatum. In Parkinson's disease characteristic eosinophilic cytoplasmic inclusions called Lewy bodies are found in the substantia nigra, locus ceruleus, dorsal vagal nucleus, and nucleus basalis of Meynert, and in lesser concentrations elsewhere in the nervous system. The potential primary versus secondary roles of Lewy bodies in the pathophysiology of Parkinson's disease is unknown. In intellectually impaired patients with Parkinson's disease reduced choline acetyl transferase in the cerebral cortex and substantia innominata and cell loss in the nucleus basalis of Meynert have been observed, but not uniformly, and unlike in patients with Alzheimer's disease are not consistently accompanied by neurofibrillatory tangles and amyloid plaques. In a minority of cases the neuropathology of Parkinson's disease may be similar to that seen in Alzheimer's disease; this is particularly likely in the most severely demented Parkinson's disease patients, who also

may share metabolic patterns (i.e., temporo-parieto-occipital deficits) seen in Alzheimer's disease.

Differential Diagnosis Potentially preventable or reversible causes of parkinsonism and their treatment include Wilson's disease (copper chelation), hydrocephalus (drainage), subdural hematoma (drainage), tumor (surgical recision), hypoparathyroidism (hormone replacement), non-wilsonian hepatocerebral degeneration (treatment of hepatic failure), neuroleptics (reduction of dosage or change of agents), calcium channel blocker intoxication (reduction of dosage or change of agents), multiple lacunar infarctions (treatment of hypertension), toxin intoxication such as manganese, MPTP, or carbon monoxide; and pugilistic parkinsonism. In Parkinson's disease MRI may reveal thinning of the low signal band produced by the substantia nigra but the usefulness of this finding for early diagnosis is limited because it may not be evident early in the disease. However, the diagnosis of several secondary causes of parkinsonism may be assisted by MRI, including vascular parkinsonism (high T2 signal in striatum or brainstem), multiple system atrophy (low signal in putamen), progressive supranuclear palsy (midbrain atrophy-enlarged posterior third ventricle), olivopontocerebellar atrophy (atrophy of cerebellum and pons), Fahr's disease (parathyroid dysfunction, basal ganglia calcifications), and hydrocephalus (ventricular enlargement without gyral atrophy).

In vivo brain imaging techniques that examine blood flow, metabolism, dopamine binding, or ^{18}F-fluorodopa (FDG) uptake are being increasingly utilized to study Parkinson's disease (Fig. 2.6-2). These techniques may have predictive value for presymptomatic states or to confirm diagnoses in the future. Positron emission tomography (PET) studies of Parkinson's disease using a labeled dopamine precursor, ^{18}F-flurodopa, indicate an overall reduction in dopaminergic innervation in the striatum and are consistent with the pattern of dopamine deficits seen in postmortem studies. Striatal uptake of FDG correlates with motor performance in Parkinson's disease, particularly bradykinesia. FDG PET scanning has been shown to demonstrate preclinical dopamine deficts in at-risk patients exposed to MPTP and in a normal control who later developed parkinsonian symptoms. A theoretical application would be to identify potential candidates for protective therapy, if such could be established. PET and singal photon emission computed tomography (SPECT) studies of glucose metabolism and cerebral blood flow in patients with dementia due to Parkinson's disease indicate that some patients may share patterns of temporal-parietal deficits with patients with Alzheimer's disease. However, such patients do not necessarily have Alzheimer's disease-like pathology upon postmortem examination. At this time PET scanning cannot distinguish with certainty among causes of dementia due to Parkinson's disease and is not considered to be useful as a routine clinical tool.

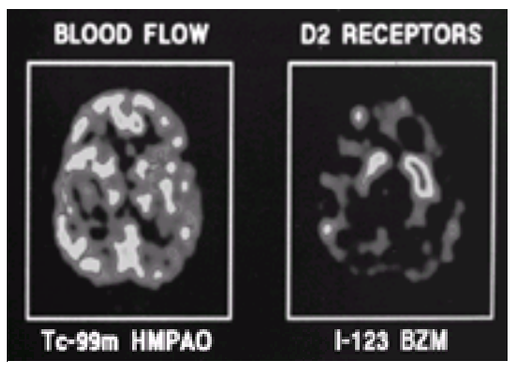

FIGURE 2.6-2 Regional cerebral blood flow, visualized with Technetium-99m HMPAO (**left panel**), and dopamine D_2-receptor binding, visualized with ^{123}I-iodobenzamide (I-123 BZM) (**right panel**), in a patient with hemiparkinsonism. Individuals with Parkinson's disease may present with markedly asymmetric symptoms. In this case, I-123 BZM uptake is markedly increased in the basal ganglia contralateral to the affected limb, whereas blood flow is unaffected. The increased uptake reflects increased D_2-receptor availability, either because of receptor upregulation or depletion of competing dopamine for the D_2 sites. (Courtesy of Michael Knable, D.O., and Daniel R. Weinberger, M.D.) (See color Plate 2.)

Differential diagnosis of depression from manifestations of Parkinson's disease and dopamine replacement therapy is difficult because of shared psychomotor retardation, psychomotor agitation, sleep disturbances, sexual disturbances, anorexia, and fatigue. Anhedonia may be difficult to distinguish from facial masking and bradykinesia.

Course and Prognosis Although motor manifestations of Parkinson's disease usually progress with age, heterogeneity and irregularity in rate is the rule. Tremor-dominant patients generally have a later onset, less cognitive disturbance, and a more favorable prognosis. The rate and outcome of cognitive deterioration is exceedingly variable, ranging from subtle to severe.

Treatment Aims of treatment may be protective, symptomatic, or restorative. Protective therapy aims to prevent or slow the destruction of dopaminergic neurons by hypothetical mechanisms of oxidative stress. Identification of risk factors and presymptomatic markers for Parkinson's disease are essential components of this strategy. Clinically unsubstantiated interventions include facilitation of processes that lead to deactivation of free radicals and augmentation of mitochondrial and other cellular defenses and reparative processes via antioxidants, free radical scavengers, and inhibitors of monoamine oxidase (MAO) and glutamate antagonists. Vitamin E therapy has produced modestly encouraging but inconclusive benefits. Large double-blind clinical trials of MAO type B (MAO_B) inhibitors in Parkinson's disease found an increase in the time from diagnosis to dopamine replacement therapy. Although the interpretation that $MAOI_B$ inhibitors may prevent destruction of dopaminergic neurons or otherwise alter the course of Parkinson's disease independent of symptomatic improvement remains controversial, they are frequently used in practice, particularly early in the disease. Ongoing investigational approaches seek relatively high MAO_B selectivity without amphetamine-like metabolites.

Symptomatic treatment consists primarily of strategies that enhance dopaminergic transmission by increased dopamine synthesis, dopamine agonists, enhanced dopamine release inhibition of dopamine uptake, and inhibition of dopamine catabolism. Amantadine (Symmetrel) is sometimes used as an initial monotherapy. Levodopa, a precursor of dopamine, is the mainstay of treatment. Carbidopa, a peripheral dopa decarboxylase inhibitor, increases the CNS bioavailability of levodopa and reduces peripheral adverse effects. When in treatment levodopa should be initiated remains controversial because motor fluctuations, dyskinesias, and treatment resistance are frequent late complications of therapy and may be related to cumulative levodopa exposure. Dopamine agonists such as bromocriptine (ParLODel) or pergolide (Permax) are commonly used as adjunctive treatment, often with a view to prevent or reduce motor complications from levodopa therapy. Anticholinergic therapy seeks to obviate the effects of dopaminergic imbalances in producing overactivity of cholinergic neurons and is sometimes used as an initial monotherapy for mild symptoms, or as an adjunct for sialorrhea or tremor. Peripheral and central anticholinergic side effects are a source of toxicity in the elderly.

Recent advances in symptomatic treatment of Parkinson's disease have occurred along two primary lines. Newer agents such as pramipexole (Mirapex), ropinirole, and cabergoline selectively target dopamine D_2 and D_3 receptors in an attempt to ameliorate parkinsonian motor symptoms with fewer adverse effects. Of these, the nonergoline agents pramipexole and ropinirole have been the most extensively studied as means of delaying the introduction of levodopa and onset of dyskinesias early in treatment and as adjunctive therapies later in the illness. Although, cabergoline has the potential advantage of relatively long action and once daily dosing, no application has been filed in the United States for use in Parkinson's disease. A second line of available new therapies are useful in delaying the wearing-off effects of levodopa. Tolcapone and entacapone increase the bioavailability of levodopa by inhibiting a major route of catabolism via plasma catechol- *O*-methyltransferase (COMT).

The frequency of surgical procedures for Parkinson's disease patients declined dramatically after the introduction of dopamine replacement therapy. Recently interest in surgery has increased with improvements in stereotactic instrumentation, MRI localization, and electrophysiological monitoring procedures. Indications for possible surgery include a combination of unilateral tremor with relatively little bradykinesia; cognitive, speech, or gait disturbance; treatment resistance or intolerance to medicinal treatment; and absence of medical risk factors. Tremor may be reduced by lesions of cortical areas 4 or 6, the globus pallidus, the ventrolateral thalamus, and the ansa and fascicularis lenticularis. In theory, grafting of dopamine-releasing living tissue could have reparative effects in Parkinson's disease. Despite initial optimism, autopsies have shown that grafted adrenal medullary autographs do not survive. The favorable clinical response seen in a third of patients may result from nigral sprouting related to the procedure itself or nerve growth factors released from the dying graft. Fetal midbrain tissue has the theoretical advantage of differentiating and forming synaptic contacts with striatal tissue. Genetically engineered donor tissue and brain-derived neurotrophic factors are investigational approaches.

Treatment of depression due to Parkinson's disease should be accompanied by an assessment of psychological reactions to the illness, psychosocial stressors, potential medical factors such as hypothyroidism and vitamin B_{12} or folic acid deficiency, and consideration of iatrogenic causes. The effect of dopamine replacement

therapy on mood in Parkinson's disease has yet to be fully delineated. If a dopaminergic agent is suspected to exacerbate depression, the lowest effective dosage may be used or substitution of another agent considered. Placebo-controlled evidence suggests that tricyclic antidepressants including desipramine (Norpramin, Pertofrane), impramine (Imipramine), and nortriptyline (Pamelor, Aventyl) may have useful antidepressant properties in some patients with Parkinson's disease. The anticholinergic effects of such agents may have a salutory effect on motor function. Selective serotonin reuptake inhibitors (SSRIs), presumably by feedback on dopaminergic systems through serotoninergic circuits originating in the dorsal raphe circuits, have the potential to produce extrapyramidal side effects. MAO_B inhibitors have not been established as effective treatments for depression in Parkinson's disease. Electroconvulsive therapy has been reported to produce rapid but short-lived improvement in mood, bradykinesia, and rigidity in some patients with Parkinson's disease; proposed mechanisms include increased postsynaptic dopaminergic activity and decreased presynaptic autoreceptor sensitivity. Early in the illness dopamine replacement therapy may remediate some cognitive loss in Parkinson's disease, particularly in memory, executive function, and general intellectual ability. Later in the illness pharmacological intervention may emphasize minimization of drugs such as anticholinergic and sedative-hypnotic agents because they may exacerbate cognitive deficits.

Pharmacotherapy of agitation requires a risk-benefit assessment of the advantages and adverse effects of the medication employed. Sedative-hypnotics, including benzodiazepines, may worsen confusion or disinhibit patients and tolerance may develop to soporific effects; these agents may be associated with daytime sedation, falls, and hip fractures. Short-acting agents may lack propensity to accumulate high blood levels and multiple metabolites, but may cause sharper rebound anxiety. Propranalol (Inderal), buspirone (BuSpar), trazodone (Desyrel), and anticonvulsant agents such as valproic acid (Depakene) may reduce agitation in some patients. Tricyclic antidepressants with sedating and anticholinergic properties may provide sedation and have motor benefits. However, anticholinergic antidepressant and antiparkinsonian agents have the potential to exacerbate memory and other deficits.

In the treatment of psychosis related to dopaminergic replacement therapy patients may be exquisitely sensitive to small doses of high-potency antipsychotics. In contrast, low-potency antipsychotics such as thioridazine (Mellaril) may cause fewer motor effects but more anticholinergic-induced cognitive impairment. Newer serotonin-dopamine antagonists with relative specificity for mesolimbic (A10) compared to nigrostriatal (A9) dopaminergic tracts may broaden the therapeutic window of antipsychotic treatment of Parkinson's disease. Multiple investigations have found that clozapine (Clozaril), at lower dosages and blood levels than used in the treatment of schizophrenia, is efficacious and well tolerated in the treatment of dopamine–replacement-induced psychosis. The use of clozapine in Parkinson's disease has been limited by the necessity for weekly blood monitoring, cost, and its nonmotor adverse effects. There is currently optimism over potential utility of serotonin-dopamine antagonists such as risperidone (Risperdal), olanzapine (Zyprexa), quetiapine (Seroquel) and investigational agents such as sertindole (Serlect) in the treatment of dopaminergic psychosis. Preliminary evidence suggests substantial variation in their motor therapeutic windows in this context. New investigational treatments for psychotic disorders such as highly selective 5-HT_{2A} receptor antagonists, raise optimism for even larger therapeutic windows. In delirium the primary intervention is correction of the underlying systemic, neurological, or iatrogenic cause. Judicious use of antipsychotic medication may be required for control of agitation.

Nonpharmaceutical interventions may helpful. Behavioral disorders such as wandering, agitation, disturbed sleep-wake cycle, and aggressive and hypersexual behavior may respond to familiar routines; clues to time, place, and situation; consistent caregivers, and social interactions. Caregiver education and support groups are essential to maintaining morale, compliance, and consistency of approach.

PARKINSONIAN SYNDROMES

Secondary parkinsonism should be suspected clinically when clinical features atypical to Parkinson's disease are seen such as paucity of tremor, prominent or early gait or autonomic disturbance, pyramidal or cerebellar signs, or a cortically dominant pattern of dementia (Table 2.6-1). With CT, MRI, or postmortem examination a wider pattern of degenerative changes is seen, which explains the additional clinical features. Unlike in Parkinson's disease, SPECT and PET scanning may indicate decreased density of postsynaptic dopamine receptors, explaining in part poor response to levodopa. Parkinsonism-plus syndrome describes multisystem degenerative disorders characterized by both parkinsonian and other neurological features.

Diffuse Lewy Body Disease Lewy body diseases are a spectrum of neurodegenerative disorders associated with motor, cognitive, or psychiatric dysfunction. After Alzheimer's disease, diffuse Lewy body disease is the second most common form of dementia, but its prevalence is difficult to estimate because of the lack of standardized diagnostic criteria. Most cases develop later in life, typically between ages 50 and 80, with males affected more often than females. Diffuse Lewy body disease typically presents with neuropsychiatric features such as hallucinations (often visual), delusions (often paranoid), and memory loss. An insidious, progressive dementia with typically cortical features such as apraxia, aphasia, and agnosia usually ensues. A fluctuating course is considered characteristic. In contrast to Parkinson's disease, motor symptoms, especially rigidity and shuffling gait, usually in the absence of prominent tremor, appear relatively late. Lewy bodies are characteristic eosinophilic intracytoplasmic inclusion bodies found most abundantly in the brainstem in Parkinson's disease. In diffuse Lewy body disease, Lewy bodies are found throughout the brainstem, striatum, thalamus, and cortex. Characteristic patterns of ubiquitin-immunoreactive, *tau* protein-negative degenerative changes in the CA 2-3 region of the hippocampus distinguish diffuse Lewy body disease from Alzheimer's disease. However, in approximately half of cases of diffuse Lewy body disease, typical neuropathological changes of Alzheimer's disease are seen as well; choline acetyltransferase activity is frequently low. The course is progressive with an average survival of less than 7 years following diagnosis. As with Parkinson's disease, extrapyramidal features frequently benefit from dopamine replacement and are exacerbated by neuroleptic agents; some patients appear to benefit from cholinomimetic drugs.

Supranuclear Palsy Progressive supranuclear palsy, first described by Steele, Richardson, and Olszewsky in 1964, is a neurodegenerative syndrome characterized by parkinsonian motor features, impaired ocular motility, prominent postural instability, subcortical dementia pattern with prominent frontal lobe pattern, pseudobulbar signs, and poor response to dopamine replacement.

The prevalence of diagnosed supranuclear palsy is only approximately 1 percent that of Parkinson's disease. A community survey suggests a prevalence of approximately 1.5 per 100,000 for males and 1.2 per 100,000 for females. In approximately 95 percent of cases initial diagnosis occurs after age 50 and mean age of onset is around age 62. Although supranuclear palsy patients are more likely than controls to have lived in rural areas, no other geographic, toxic, infectious, or genetic factors have been established. Neurochemically, marked reductions are seen in striatal dopamine as in Parkinson's disease, but in contrast to Parkinson's disease striatal D_2 receptors are reduced as well. The latter may in part contribute to the characteristically poor responsiveness to dopamine replacement. In contrast to Parkinson's disease mesolimbic dopamine systems are relatively spared and there is widespread cholinergic neuronal damage subcortically, including to the nucleus basalis of Meynert and striatal interneurons. The earliest presenting symptom is often postural instability. Characteristic vertical gaze disturbances, particularly downward, appear relatively late. Rigidity of facial muscles may lead to a characteristic “worried” or “astonished” expression. Pseudobulbar palsy in supranuclear palsy may be characterized by dysarthria, dysphagia, and emotional lability. In contrast to Parkinson's disease, predominance of axial rigidity, minimal resting tremor, symmetric presentation, and unresponsiveness to dopamine replacement are common.

The most consistently affected areas on postmortem examination are the substantia nigra, subthalamic nucleus, and globus pallidus. Marked atrophy of the midbrain and pontine tegmentum are seen with relative sparing of the cerebrum. In contrast to Parkinson's disease, the entire nigra is damaged in patients with supranuclear palsy. Microscopically, neuronal loss with granulovacuolar degeneration and gliosis are seen. Unlike in Alzheimer's disease patients, the neurofibrillatory tangles seen in patients with supranuclear palsy are more likely to be straight than helical and are not found in association with beta amyloid. After the earliest stages, MRI or high-resolution CT scanning may indicate atrophy of the midbrain and anterior temporal lobes, and enlargement of the third ventricle without cerebellar atrophy. PET measures of cerebral glucose metabolism and SPECT measures of cerebral blood flow indicate a bilateral superior frontal dominant pattern of hypometabolism, in contrast to the medial frontal, temporal–parietal-dominant, and diffuse patterns typical of Pick's disease, Alzheimer's disease, and Parkinson's disease, respectively.

Psychiatric Features The psychiatric and cognitive manifestations of supranuclear palsy are highly variable. Estimates of the prevalence of significant cognitive impairment vary from approximately 60 to 80 percent depending on length of illness and are predominantly subcortical in character with slowed thought, prominent frontal lobe features including perseveration; impaired verbal fluency, executive functioning, and mental flexibility; and emotional lability. Visually related cognitive tasks are especially impaired. Aphasia, apraxia, and agnosia are usually not prominent. Affective lability and depression are common. The latter may be difficult to distinguish from apathy and psychomotor retardation. Mania and schizophrenia-like psychoses are rare. When delusions occur they are usually neither bizarre nor systematized. Insomia, multiple awakenings, and abnormal sleep architecture are common. The progression of supranuclear palsy is little altered by currently available therapeutic interventions. Response of motor and ocular manifestations to levodopa and dopamine agonists is usually transient and very mild. Because postsynaptic D_2 receptors are lost, dopamine replacement–induced dyskinesias are rare. Mesolimbic dopamine tracts are relatively spared by supranuclear palsy and dopaminergic psychosis has been reported.

Secondary and tertiary tricyclic drugs and SSRIs have been reported to improve emotional lability or motor symptoms in some patients with supranuclear palsy. The experimental a_2-antagonist idaxozan was reported to produce improvement in motor function and balance in some patients. Nonspecific cholinomimetic agents have

produced cognitive improvement in some patients.

WILSON'S DISEASE (PROGRESSIVE HEPATOLENTICULAR DEGENERATION)

Progressive hepatolenticular degeneration is an autosomal, recessive, systemic disorder of metabolism in which copper accumulation is associated with cirrhosis of the liver, degenerative changes in the basal ganglia, and damage to other organs. Following its initial description by Wilson in 1912, progressive hepatolenticular degeneration became known as *Wilson's disease.* Evidence of excessive copper deposition in the brain was noted around 1940, and successful chelation therapy was described by Cummings in 1951. Copper is primarily removed by biliary excretion; Wilson's disease has been linked to a defect in a recessive gene on chromosome 13 involving copper transport by hepatic lysosomes. Copper accumulates systemically and interferes in local metabolism, causing cell necrosis and death. The prevalence of Wilson's disease is estimated at 30 per million. The gene frequency has been estimated between 1 in 100 and 1 in 180. Hepatic presentations are usually seen between ages 8 and 16. It occurs among all races, but is most prevalent among Eastern European Jews, southern Italians, and residents of the smaller Japanese islands. The onset of neurological symptoms is usually in the second decade, and rarely after the third decade, although onset in the fifth decade has been reported. Slightly more cases are reported in men than women. Women are more likely to present with liver disease and men with neurological disease.

The most common presentations, in descending order, are neurological, hepatic, psychiatric, orthopedic, ophthalmological, hemolytic anemia, and cardiac. Neurological presentations are protean, but typically begin with basal ganglia signs of tremor or rigidity. The classic “wingbeating” tremor is localized to the arms, usually absent at rest, and is elicited by extension. Parkinsonian or intention tremors may also be seen. Parkinsonian rigidity, dystonic postures, and occasionally choreo-athetotic movements are seen. Dystonia and rigidity of laryngeal, pharyngeal, and facial musculature may result in dysarthria, dysphagia, hoarseness, drooling, and the classic vacuous or fixed open-mouthed smile. The tendency for motor disorders to predominate in the bulbar musculature contrasts with parkinsonism. Loss of coordination, convulsions, coma, and delirium may occur. Liver involvement may present with asymptomatic elevation of transaminases, hepatosplenomegaly, jaundice, or hepatitis, which eventually progress to cirrhosis. Treatment for psychiatric manifestations prior to recognition of Wilson's disease is common. Symptoms are usually in the affective and behavioral realm, including depression, mania, irritability, disinhibition, and nonspecific personality changes; schizophrenia-like psychoses are rare, Although dementia may occur, cognitive changes are not consistent, occur relatively late, and are relatively mild compared to motor changes. Kayser-Fleischer rings, which are not specific to Wilson's disease, are usually present by the time neurological symptoms occur and consist of copper-colored granules of copper on Descemet's membrane at the limbus of the cornea. Although early in the course a slit lamp may be required for detection, later they may be seen by ophthalmoscope or even by the naked eye. Diagnostically, serum free copper and urinary copper concentrations are increased, and serum ceruloplasmin, which binds copper, is decreased. Liver biopsy reveals elevated copper content. CT scanning and MRI often but not invariably indicates enlarged ventricles, and both cortical and brainstem atrophy is present. MRI also typically reveals abnormal signals of the lenticular, caudate, dentate, and thalamic nuclei. Without treatment, Wilson's disease is an inevitably progressive, fatal disease. Dietary restriction of copper, potassium sulfide, or zinc to reduce absorption, and chelating agents such as penicillamine may result in clinically significant improvement of neurological and hepatic signs, disappearance of Kayser-Fleischer rings, reversal of hypodense areas on CT, and improvement in cognition and behavior. The earlier treatment is initiated, the better the prognosis for preventing or reducing damage. Attempts at symptomatic relief of motor symptoms by dopaminergic or anticholinergic agents have produced inconsistent results.

MULTIPLE-SYSTEM ATROPHY

Multiple-system atrophy is a neurodegenerative syndrome in which parkinsonian, autonomic, cerebellar, and pyramidal signs are prominent. Compared to Parkinson's disease, autonomic dysfunction is more pronounced, the distribution of neuropathology is wider than in Parkinson's disease, and Lewy bodies are not prominent. Three variants of multiple-system atrophy are recognized: olivopontocerebellar atrophy, striatonigral degeneration, and Shy-Drager syndrome. In a given patient, the clinical and neuropathological features of these variants often overlap. Preliminary evidence suggests that a characteristic neuronal cytoplasmic inclusion may be found in multiple-system atrophy.

Olivopontocerebellar Atrophy First described in 1900 by Dejerine and Thomas, olivopontocerebellar atrophy is clinically distinguished by ataxia and other prominent cerebellar features. The prevalence of olivopontocerebellar atrophy is estimated at 2 per 100,000, although it is higher in some areas. Men are affected almost twice as frequently as women. The average age of onset is approximately 28 years and 50 years for the familial and sporadic varieties, respectively. The cause of olivopontocerebellar atrophy is unknown; deficiencies in glutamate dehydrogenase have been detected but are not specific to olivopontocerebellar atrophy.

The most prominent clinical manifestations are relatively late onset of progressive ataxia of the trunk and limbs; dysarthria; scanning speech and other cerebellar signs; parkinsonian symptoms including akinesia, rigidity, and resting tremor; loss of equilibrium; loss of sphincter control; mood syndromes; a variety of personality changes; sleep disturbances; and deterioration in cognitive function. The frequency and severity of cognitive deficits is uncertain; when present, they usually include memory deficits and are predominantly subcortical in nature. Aphasia, apraxia, and agnosia are usually absent.

On postmortem examination, marked atrophy of the cerebellum, ventral pons, and olive are seen. Degenerative changes in the substantia nigrum and striatum are seen when parkinsonian symptoms are prominent. Degeneration of the posterior columns, spinocerebellar tracts, vagal nuclei, and sacral autonomic nuclei may also be seen. In contrast to Parkinson's disease, Lewy bodies are not prominent. Reduced activity of choline acetyltransferase and acetylcholinesterase, and degenerative changes in the nucleus basalis of Meynert have also been reported.

Polysomnography may reveal abnormal sleep architecture and not infrequently, sleep apnea. Abnormalities may be missed on CT scanning early after onset, but eventually include increased fourth-ventricular width, enlarged cerebellopontine cistern size, and cerebellar atrophy. T2 weighted MRI images may indicate demyelination of transverse pontine fibers. Reduction in PET measures of local cerebral metabolic rates for glucose in the pons and cerebellum may precede discernible structural changes on CT or MRI.

Striatonigral Degeneration First described by Adams and colleagues in 1961, striatonigral degeneration is a rare form of multiple-system atrophy in which rigidity is very prominent. In contrast to Parkinson's disease autonomic dysfunction including orthostatic hypotension and incontinence tremor occur commonly in striatonigral degeneration; tremor is mild or absent, levodopa response is poor, and progression is rapid. Attention and some frontal lobe cognitive functions are impaired, but memory and verbal intelligence measures are usually preserved. Neuropathologically, in contrast to patients with Parkinson's disease, the substantia nigra of patients with striatonigral degeneration is relatively well preserved and marked degenerative changes with gliosis are seen in the putamen, and to a lesser extent, the caudate. The putamen is hypodense on T2-weighted MRI, and PET scanning indicates reduced glucose metabolism in the striatum and frontal cortex.

Shy-Drager Syndrome First described in 1960, this syndrome usually presents with autonomic dysfunction, which may precede motor signs by up to three years. It occurs more frequently in men and is usually diagnosed after age 50. Preganglionic lateral horn degeneration may be seen at autopsy in thoracic spinal segments.

The signs and symptoms may include orthostatic hypotension and erectile, bladder, and rectal sphincter dysfunction. Orthostatic hypotension may cause light-headedness or fainting and is not accompanied by the expected compensatory tachycardia. Supine blood pressure is usually unaffected. Extrapyramidal signs, cerebellar signs, and corticospinal signs appear later. Sleep disturbances occur frequently and may include sleep apnea. Dementia may occur late but is not a regular or predictable manifestation. Laryngeal stridor and breathing irregularities may occur. Death usually occurs within 15 years of diagnosis and may result from pneumonia due to inspiration.

NEUROLEPTIC-INDUCED PARKINSONISM

The form of secondary parkinsonism most commonly seen by psychiatrists is neuroleptic-induced parkinsonism, defined in DSM-IV as “parkinsonian tremor, muscular rigidity, or akinesia developing within a few weeks of starting or raising the dose of a neuroleptic medication (or reducing a medication used to treat extrapyramidal symptoms).” Approximately 50 percent of outpatients undergoing long-term treatment with conventional neuroleptics will develop parkinsonian symptoms at some time. Neuroleptic-induced parkinsonism is presumed to be caused by occupancy of D_2 receptors in the striatum. It occurs most commonly with high-potency antipsychotics with relatively weak anticholinergic affinity, and less frequently with low-potency conventional antipsychotics and atypical antipsychotics, both of which have relatively high affinity for serotonin (5-hydroxytryptamine [5-HT]) type 2 (5-HT_2) receptors compared to D_2 receptors. Varying degrees of typical parkinsonian tremor, muscular rigidity, akinesia, and postural instability may occur. Psychiatric complications may include depression and apparent intensification of deficit symptoms. Neuroleptic-induced parkinsonism must be distinguished from other psychiatric states such as catatonia, posturing, and the psychomotor retardation of depression. It may coexist with or be confused with neuroleptic malignant syndrome, Parkinson's disease, and other movement disorders. Although neuroleptic-induced parkinsonism typically begins 2 to 4 weeks after initiation of neuroleptic treatment, symptoms can begin rapidly after initiation of treatment or a dosage increase, or develop very slowly. Treatment consists of dosage reduction, addition of an antiparkinsonian agent such as an anticholinergic or amantadine, or transition to an atypical agent or one with lower potency. If after discontinuation of an antipsychotic neuroleptic-induced parkinsonism persists in excess of 3 months

for an oral agent or 12 months for a decanoate formula, a noniatrogenic etiology is likely.

HUNTINGTON'S DISEASE

Definition Huntington's disease, first reported in the medical literature by George Huntington in 1872, is a familial form of a progressive movement disorder characterized by chorea and dementia.

Epidemiology Family studies demonstrate Huntington's disease to be an autosomal dominant disorder. Although it affects only about 2 to 9 per 100,000 persons, within families this rate is 50 percent. This devastating disorder typically has an age of onset of around 35 and is relentlessly progressive, ending in death within 13 to 15 years after diagnosis.

Etiology Huntington's disease is one of the bright spots in the molecular biology revolution. Linkage to chromosome 4 was reported in 1983, and the gene, named *IT-15*, was definitively identified in 1993. The disease-bearing allele is not a simple, single mutation, but is characterized by an unstable region of deoxyribonucleic acid (DNA) that has many repeated segments of a simple 3 base pair sequence, CAG. People without Huntington's disease typically have 11 to 34 repeats of the CAG trinucleotide sequence; patients with Huntington's disease have 37 to 86 CAG trinucleotide repeats. Interestingly, the number of repeats can vary from generation to generation. For example, if a father with Huntington's disease has 50 repeats, his son could inherit the Huntington's disease gene from his father but show 60 or 70 repeats. This phenomenon of repeat expansion may explain *genetic anticipation*, a phenomenon whereby off-spring develop a disorder earlier than their parent. It appears that the number of trinucleotide repeats affects age of onset, probably because of increased neurotoxicity from increased CAG repeat number.

The IT-15 gene product, termed the *Huntington gene*, is a previously unidentified protein whose function remains unknown but is widely expressed throughout the brain and in other body regions. Animal “knockout” models suggest the protein is essential in early development. The CAG repeats appear in the 5' region of the first exon and are translated into an extended polyglutamine region in the protein. This additional sequence is thought to produce a gain of function, in contrast to the loss of protein function that probably occurs with autosomal recessive disorders. The toxic effects of the mutant Huntington gene have been hypothesized to occur through altered interactions with other proteins, and may induce neurotoxicity via effects on glutamate neurotransmission, apoptosis, free radical damage, or some other mechanism.
