Distribution The fact that half-life is directly proportional to a drug's apparent volume of distribution is frequently overlooked by clinicians. The proportion of adipose tissue increases from 33 percent in younger women to 48 percent in the old and from 18 to 36 percent in men. For drugs that distribute in body fat (the vast majority of psychotropics), the volume of distribution increases with age, leading to a longer half-life and drug accumulation. For water-soluble drugs such as lithium (Eskalith) or digoxin (Lanoxin), volumes of distribution decrease in older patients, reducing the margin of safety, that is, transient increases of the plasma concentrations of these drugs will not be buffered to the same degree in older adults. The volume of distribution is also affected by the extent of binding to plasma proteins. Age-associated illness may reduce serum albumin concentration and possibly increase a_1 acid glycoprotein. Most psychotropic drugs are transported in the blood extensively bound to these plasma proteins. Drug displacement from plasma proteins was previously of considerable concern because the protein-bound drug represents an enormous, pharmacologically inactive reservoir. It is now recognized that not only is free drug pharmacologically active, but it is also more available for metabolism and tissue distribution. Therefore, an increase in the absolute concentration of free drug (e.g., by reduction in plasma proteins or a displacement interaction) would be immediately buffered, and a new equilibrium rapidly established. Binding-mediated changes alone are now considered unlikely to be clinically important. However, when plasma drug monitoring is used to adjust tricyclic antidepressant or anticonvulsant dosages, the total drug concentrations (free plus protein bound) are usually reported. Although a change in absolute drug concentration caused by a change in protein binding is transient, the new equilibrium in the proportion of bound and free drug may appear to be an alteration in the drug's plasma concentration. In practice, this might be of concern if a severe intercurrent illness increased a $_1$ acid glycoprotein concentration in patients who were well maintained on a monitored medication. In these circumstances, an increase in bound drug might be interpreted as an increase in the drug's plasma concentration. Determining unbound drug concentrations in these situations is useful for lidocaine (Xylocaine), theophylline (Theo-Dur), phenytoin (Dilantin), and digitoxin (Crystodigin).

Metabolism Drug metabolism transforms lipid-soluble compounds into more water-soluble derivatives that can be more effectively eliminated and may be less active pharmacodynamically. Biotransformation of drugs is categorized as either phase I (oxidation or reduction) or phase II (conjugation). A large group of heme-containing enzymes that vary in substrate preferences, collectively called cytochrome P450, is responsible for oxidative (phase 1) drug metabolism. At least 16 human P450 isoenzymes have been identified, each with distinct, although partly overlapping, substrate specificity. As more is learned about both the diversity and specificity of the cytochrome P450 enzymes, a structure is emerging for categorizing potential drug-drug interactions and age-associated changes. Recent evidence suggests that there is not a uniform, age-associated decline in liver metabolism by the cytochrome P450 isozymes. In old adults, however, reductions in hepatic mass and blood flow place greater emphasis on interindividual differences in drug metabolic capacity. These metabolic differences may be genetic or may result from interactions of multiple medications. Isoenzyme specificity suggests that inhibition or induction of a given P450 isoenzyme will affect all drugs metabolized by that specific enzyme. A drug may be a substrate for one cytochrome P450 isoenzyme at a time or simultaneously for more than one. A drug can be both a substrate and a competitive inhibitor for the same isozyme or it can be a noncompetitive inhibitor of a different enzyme.

Cytochrome P450 (CYP) isoenzyme 2D6 (CYP 2D6) is the isozyme specifically responsible for hydroxylation of many antidepressants (e.g., nortriptyline [Pamelor, Aventyl], desipramine [Norpramin, Pertofrane], paroxetine [Paxil], venlafaxine [Effexor]), and several antipsychotics (perphenazine [Trilafon], thioridazine [Mellaril], and risperidone [Risperdal]). Approximately 7 percent of the white population are genetically poor CYP 2D6 metabolizers. To date, studies conducted in older, unmedicated volunteers have not found an age-associated decline in CYP 2D6 activity. Nevertheless, many drugs commonly used by older patients competitively (e.g., perphenazine) or noncompetitively (e.g., quinidine [Quinora]) inhibit this enzyme, leading to significant interactions. Genotype analyses have consistently found an association of mutations impairing CYP 2D6 activity with Parkinson's disease.

CYP 2C19 is responsible for the metabolism of diazepam (Valium), mephenytoin (Mesantoin), omeprazole (Prilosec), and several barbiturates. In addition, the demethylation of tertiary tricyclic antidepressants is also partly dependent on CYP 2C19. The incidence of the poor metabolizer phenotype in a young, white population is approximately 3 percent but was 18 percent in a Japanese sample. Some preliminary evidence suggests that CYP 2C19 functioning declines with age.

The CYP 3A4 isoenzyme metabolizes numerous medications including lidocaine, diltiazem (Cardizem), verapamil (Calan), erythromycin (Eryc), sertraline (Zoloft), and alprazolam (Xanax). Serious toxicity has occurred when the CYP 3A4–mediated clearance of terfenadine (Seldane), astemizole (Hismanal), cisapride (Propulsid), midazolam (Versed), and triazolam (Halcion) is diminished. Clearance of drugs specifically metabolized by CYP 3A4 appears to decline with age; for example, alprazolam and triazolam clearances in elderly adults are only 50 to 80 percent of those in young adults. In particular, evidence indicates that CYP 3A4 activity is greater in younger women than in men and postmenopausal women and that this enzyme has a substantial role in estrogen metabolism. These gender- and age-related pharmacokinetic differences have been demonstrated for several 3A4-type drugs such as nefazodone (Serzone), whose plasma concentrations are substantially higher in older women than in younger women. Unlike CYP 2D6 activity, CYP 3A4 activity may be increased (induced) by other drugs, such as carbamazepine (Tegretol), barbiturates, and steroids.

Tacrine (Cognex), clozapine (Clozaril), fluvoxamine (Luvox), theophylline, and caffeine are metabolized by CYP 1A2, which is deficient in approximately 12 percent of the population, while 20 to 40 percent are rapid metabolizers. CYP 1A2 also contributes to the demethylation of some tertiary tricyclic drugs and readily undergoes induction by cigarette smoking, cruciferous vegetables, charcoaled meats, and certain medications such as omeprazole and phenobarbital (Luminal). Inhibition and induction magnify an already marked, 60-fold variation in CYP 1A2 activity. This metabolic variation mandates the close monitoring of theophylline treatment and may be important in interpreting results from fixed-dose medication trials such as those conducted with tacrine.

Beyond oxidative metabolism, systematic study of phase II metabolism in older patients has been neglected. In general, drugs such as lorazepam (Ativan) or oxazepam (Serax) accumulate less than more lipid-soluble drugs and undergo single-step conjugative elimination. Glucuronidation, however, may not be an immutable process; it is significantly affected by malnutrition. Despite the common assertion that phase II metabolism does not change with age, significant reductions in oxazepam's elimination have been found in those older than 80.

Excretion The average glomerular filtration rate decreases by 50 percent between the ages of 20 and 70. Age alone, however, cannot be used to predict renal function, because at least one third of older patients may maintain relatively stable renal function. Serum creatinine concentration may not appear elevated in the face of declining renal function, since there is often a decline in muscle mass (the major source of creatinine) with age and debilitation. Decreased renal clearance may affect excretion of psychotropic drug metabolites and lithium in older patients. Accumulation of active hydroxylated metabolites of antidepressants such as nortriptyline, bupropion (Wellbutrin), and venlafaxine has been observed in older patients, with uncertain clinical consequences. Risperidone is metabolized by CYP 2D6 to a 9-OH metabolite that possesses dopamine antagonism comparable to that of risperidone. Since this metabolite may accumulate in older patients, unanticipated extrapyramidal adverse effects may occur because of variable renal as well as hepatic function.

The fact that nonsteroidal anti-inflammatory drugs and angiotensin-converting enzyme inhibitors may reduce lithium's clearance (possibly through effects on renal blood flow) deserves particular emphasis given their widespread use in the elderly. An interesting and important example of an age-related interaction putatively mediated by diminished renal clearance is the finding that 1 mg of alprazolam dramatically increased serum digoxin concentrations in those older, but not younger, than age 65. Low-salt diets and the possibility that selective serotonin reuptake inhibitors (SSRIs) may cause inappropriate antidiuretic hormone secretion with concomitant hyponatremia (particularly in older patients) may be additional sources of interactive complications with lithium.

PHARMACODYNAMICS

Underlying differences among patients related to age or illness require careful consideration with regard to pharmacotherapy. As patients age they exhibit a general reduction in homeostatic mechanisms (e.g., postural control, orthostatic circulatory responses, thermoregulation, visceral muscle function, laryngeal reflexes, hypoxic responses, higher cognitive function). This may interfere with the ability to adapt to changes in the environment and may be manifest as adverse drug experiences. For instance, all psychotropic drugs may increase the risk of falls and hip fracture and may increase cognitive impairment. Similarly, reduced b-adrenergic receptor sensitivity contributes to diminished baroreceptor reflex responses, while coronary artery disease, reductions in the heart's intrinsic sinus rate, and damage to conduction pathways predispose to arrhythmias. Orthostatic hypotension is a major risk in elderly adults that mitigates against the use of lower-potency antipsychotic drugs and tricyclic drugs. Orthostatic hypotension may be detected by measuring blood pressure immediately upon, and 2 minutes after standing. One should check for pretreatment orthostatic hypotension before prescribing any drug known to affect blood pressure. Careful assessment is mandatory whenever an antihypertensive drug is combined with a psychotropic drug. Membrane-stabilizing (quinidine-like) properties of some psychotropic drugs may delay cardiac conduction and seriously interact with either underlying pathophysiology or antiarrhythmic medication. Electrocardiographic (ECG) changes have been noted most frequently for the tricyclic drugs and antipsychotics of the diphenylbutylpiperidine (i.e., pimozide [Orap]) and piperidine (e.g., thioridazine) types. The risk of antipsychotic and tricyclic drugs interacting with cardiovascular drug is considerably amplified, since many of these medications intersect both metabolically and dynamically. For example, quinidine and diltiazem not only inhibit cardiac conduction but CYP 2D6 as well. Patients with preexisting conduction disturbance require increased watchfulness. In older patients treated with antipsychotics long term, obesity, poor nutritional status, and increased triglyceride concentrations may contribute additional cardiovascular risk factors.

Specific receptor and neurotransmitter changes associated with senescence, such as reductions in dopamine type 2 (D_2) receptors or acetylcholine content, result in increased sensitivity to D_2 antagonists and antimuscarinic agents. Neuroleptic-induced adverse effects are common and frequently troubling in older patients. In particular, the association of neuroleptic use with significant cognitive impairment, declines in activities of daily living, and significant falls (with concomitant risk of hip fracture) is of grave concern in frail elderly patients. Drug-induced parkinsonism appears to be more common and more persistent after medication withdrawal in older patients than in younger patients. Prospective studies demonstrate a very rapid and high incidence of onset of tardive dyskinesia in older patients who take antipsychotics for relatively brief periods of time (cumulative incidence reported to be 26 to 45 percent over 1 year).

Two groups of drugs cause anticholinergic effects: those used therapeutically for their anticholinergic properties (e.g., oxybutynin [Ditropan], benztropine [Cogentin]), and those with anticholinergic effects that are incidental to their main actions (e.g., amitriptyline). Peripheral manifestations of anticholinergicity include dry mouth, tachycardia, blurring of vision, urinary retention, and constipation. Common difficulties in older patients such as constipation, xerostomia, glaucoma, and urinary retention may be markedly exacerbated by even modestly anticholinergic medications. Tachycardia in patients with preexisting myocardial ischemia is of particular concern, since these effects appear not to be ameliorated by time. Anticholinergic effects on the central nervous system may range from subtle changes such as apparent worsening of depression, mild confusion, and impairment of recent memory to frank delirium.

Older patients require smaller doses of anticoagulants to achieve the same degree of anticoagulation obtained in younger individuals. Although confounded by effects of other medications and hepatic dysfunction, older adults are probably more sensitive to anticoagulants. Pharmacokinetically, fluvoxamine and sertraline increase warfarin (Coumadin) serum concentration. However, increased bleeding times observed when either paroxetine or fluoxetine were combined with warfarin have been attributed to a pharmacodynamic interaction. Concurrent therapy need not be avoided, but close monitoring is advisable whenever an SSRI is combined with warfarin.

In addition to problems that can be anticipated, the fact that most of the data on a new drug's effects were obtained in younger patients means that unexpected adverse effects are not infrequent in older patients. For example, fluoxetine has been associated with problematic weight loss in older patients and with the syndrome of inappropriate antidiuretic hormone secretion (SIADH). While SIADH is a rare adverse effect of many psychotropic medications including tricyclic drugs and all SSRIs, most reports of antidepressant-induced SIADH have involved patients older than 65 years and have implicated fluoxetine. In an analysis of 760 reports of hyponatremia associated with SSRIs, the median time to onset of the hyponatremia was 13 days (range, 3 to 120 days). In older patients, fluoxetine has also been associated with insomnia, nervousness, delirium, apathy, agitation, and parkinsonism or worsening of motor disability in patients suffering from idiopathic parkinsonism. Although all of these unanticipated effects have now been reported with other SSRIs, it is not possible, at present, to determine the differential geriatric adverse-effect profile of the more recently introduced medications, given the much longer and more extensive use of fluoxetine in the United States and the lack of comparative trials.

The greatest threats to successful pharmacotherapy in older patients are patient nonadherence with medication regimens and drug-drug interactions. High-risk medications, including anticoagulants, antihypertensives, and antiarrhythmics (including digitalis) have been consistently emphasized in long-term, comprehensive surveys of adverse drug reactions in older patients. Physicians need to be particularly vigilant and knowledgeable when these high-risk medications are prescribed. As patients age, pharmacodynamic changes and concomitant illness significantly alter their response to medication. Psychiatrists treating older patients should use a set of routinized procedures: (1) identify patient risk factors such as medical status, use of high-risk medications, diet, and alcohol use; (2) take a thorough drug history, involving caregivers and relatives, be sure to include over-the-counter medications, and update patient's record regularly in a prominent place; (3) educate patients and caregivers about their medications and dosing regimens and monitor compliance; (4) be knowledgeable about drug actions and clearance; (5) use the lowest effective dosages and avoid unnecessary polypharmacy, but don't undertreat; and (6) if the patient's physical or cognitive state deteriorates, always suspect an

adverse drug reaction.

51.4 TREATMENT OF PSYCHIATRIC DISORDERS

51.4C PSYCHOPHARMACOLOGY: ANTIDEPRESSANTS AND MOOD STABILIZERS

CHARLES F. REYNOLDS, III, M.D.

GOALS AND RATIONALE FOR THE PHARMACOLOGICAL TREATMENT OF DEPRESSION IN LATER LIFE

The goals of pharmacological treatment of major depressive disorder in later life include not only the decrease and resolution of depressive symptoms but also the prevention of relapse and recurrence. Hence, long-term use of these agents is probably the rule, not the exception. Treatment goals also include restoring psychosocial functioning, relieving excess disability, improving patient compliance with other medical therapies that they might otherwise refuse because of hopelessness or pessimism caused by depression, and easing the adaptation to irreversible losses.

Depression in later life should be treated because it usually persists in the absence of treatment and causes distress to patients and burden to caregivers, leads to excess health care use, and is associated with substance abuse. Treatment of depression in elderly adults improves day-to-day functioning and self-care for maintaining and improving health. Treatment benefits outweigh the risks, and the risks of not treating are great. The risks of no treatment or of inadequate treatment include chronic depression, cognitive impairment, worsening of physical illness, poor compliance with medical treatment, social impairment, reduced quality of life (satisfaction, ability to cope), and suicide. Most elderly individuals who commit suicide have late-onset major depressive disorders. Mood disorders play a greater role in suicides of elderly patients than in those of younger patients; and the group at highest risk for suicide is white males aged 80 to 84 years old. Geriatric depression frequently occurs in a complex medical and psychosocial matrix. The major causes of late-life depression include medical disease and attendant disability, psychosocial factors, and genetic factors. The consequences of depression in later life include excess mortality and suicide, anxiolytic dependence and alcoholism, cognitive impairment, disability, medical symptoms, and increased health care use.

With respect to the distribution of depression diagnoses in elderly adults, major depression is just the tip of the iceberg. Other forms of clinically significant depression include minor depression, dysthymia, brief recurrent depression, and mixed anxiety-depression. The estimates of prevalence vary widely depending upon the clinical setting. Prevalence rates for all forms of late-life depression are highest in cognitively intact nursing home patients (about 60 percent), intermediate in chronically ill primary care patients and hospitalized patients (about 25 percent), and lowest in community residents (about 10 percent). In such settings the clues to depression include help seeking with persistent complaints of pain, headache, fatigue, and insomnia; frequent calls and visits; and high utilization of services. Additional clues to depression in elderly hospitalized patients include delayed recovery, treatment refusal, and problems with discharge. In the nursing home patient, depression should be suspected in the presence of apathy, failure to thrive, agitation, and delayed rehabilitation.

Antidepressants with particular relevance to elderly adults include the secondary amine tricyclic drugs, such as nortriptyline (Aventyl, Pamelor) and desipramine (Norpramine); the selective serotonin reuptake inhibitors (SSRIs), citalopram (Celexa), fluoxetine (Prozac), fluvoxamine (Luvox), paroxetine (Paxil), and sertraline (Zoloft); the monoamine oxidase inhibitors (MAOIs) such as phenelzine (Nardil) and tranylcypromine (Parnate), and miscellaneous agents including bupropion (Wellbutrin), trazodone (Desyrel), nefazodone (Serzone), and venlafaxine (Effexor). Agents considered unsuitable for use in elderly adults because of significant adverse effects include amitriptyline (Elavil), imipramine (Tofranil), and clomipramine (Anafranil). The amount of information available from controlled clinical trials in elderly adults is relatively meager; hence, drug recommendations are extrapolated from small numbers of older patients (mostly under age 75) or from younger and middle-aged adults.

TRICYCLIC DRUGS

The advantages of tricyclic drugs include decades of use, superior efficacy for inpatients with melancholia, generally predictable kinetics, and once-daily dosing. Limitations include orthostasis, constipation, tachycardia, urinary retention, dry mouth, cognitive impairment, delirium, and sedation. In addition, an electrocardiogram is required prior to therapy and may be necessary during therapy.

Therapeutic blood concentrations of 80 to 120 ng/mL of nortriptyline and more than 115 ng/mL of desipramine are to be targeted. Starting dosages of both nortriptyline and desipramine are 10 to 25 mg at bedtime. Steady state occurs in about 5 days. An overall efficacy rate of 80 percent was reported for nortriptyline in combination with interpersonal psychotherapy for elderly patients with recurrent major depression. Similar efficacy rates have been reported for desipramine monotherapy. The use of tricyclic drugs such as nortriptyline or desipramine allows compliance to be verified via monitoring of blood concentrations. At the same time, their use is less straightforward than that of the SSRIs. For example, a wide dosage range necessitating individual titration is characteristic. In frail, medically ill, elderly patients, lower dosages of nortriptyline or desipramine may suffice to yield therapeutic steady-state levels. Even at lower dosages, however, frail, medically ill elderly patients may not tolerate tricyclic drugs.

SELECTIVE SEROTONIN REUPTAKE INHIBITORS

The SSRIs are generally as effective in elderly patients as tertiary tricyclic drugs. Many clinicians prefer newer SSRIs because of their lower adverse-effect burden, which allows more-adequate dosing and longer-term use. SSRIs are associated with less orthostasis than tricyclic drugs, are less likely to cause cognitive impairment, and have reduced anticholinergic and cardiovascular adverse effects. They can be prescribed with once-daily dosing, require limited dosage adjustment, and are safe in overdose. The limitations of these agents include nausea, headache, restlessness, sexual dysfunction, decreased heart rate, occasional insomnia, inappropriate antidiuretic hormone secretion, and variable drug-drug interactions related to inhibition of the P450 enzyme system, which is important to the metabolism of many drugs. A number of antidepressants, SSRIs and nefazodone in particular, are highly metabolized by the cytochrome P450 enzyme system in the liver. Of the 30 or more proteins in the cytochrome P450 (CYP) family, CYP 2D6, 3A4, 1A2, 2C9, and 2C19 are principal enzymes in the oxidative metabolism of antidepressants. Potential drug interactions should always be considered.

A low starting daily dosage of paroxetine (10 mg), sertraline (25 mg), citalopram (10 mg), or fluoxetine (10 mg) should be considered, together with more-gradual dosage increases in elderly patients, particularly those above age 75. Final dosages will range from 20 to 60 mg a day of paroxetine, 50 to 200 mg a day of sertraline, and 10 to 60 mg a day of fluoxetine or of citalopram. Titration is thought to minimize adverse effects. Therapeutic blood concentrations are not established for clinical use and testing is not widely available. A recent placebo-controlled, multisite study of fluoxetine in geriatric depression showed rather low efficacy. Moreover, the work of Steven Roose and Alexander Glassman showed that older cardiac patients with severe melancholic depression respond better to nortriptyline than to fluoxetine. Although SSRIs have fewer cardiac adverse effects, they may be effective only in some types of geriatric depression. This issue requires further investigation in controlled clinical trials because of the meager database available at this time.

MONOAMINE OXIDASE INHIBITORS

The MAOIs have been found effective and safe in depressed patients in their 60s but tend to be underused in elderly adults. Their advantages include few anticholinergic effects and no effects on cardiac conduction. For most elderly patients, problem interactions with food and drugs can be minimized through patient education and collaboration among treating physicians. Limitations in their clinical utility include both hypotension and hypertension, insomnia, and somnolence. The

starting dosages of tranylcypromine and phenelzine are 10 mg a day and 15 mg a day in two doses, respectively. In general, maximum dosages do not typically exceed 40 to 50 mg a day for tranylcypromine and 75 to 90 mg a day for phenelzine. A recent study from the National Institute of Mental Health by Trey Sunderland and coworkers supported the efficacy of high-dosage selegiline (Eldepryl) in treatment-refractory elderly depressed patients.

BUPROPION, NEFAZODONE, AND VENLAFAXINE

Bupropion, nefazodone, and venlafaxine are important additions to the pharmacotherapeutic armamentarium for treating late-life depression, although information on their use in elderly adults is limited. Advantages of bupropion include efficacy equal to that of tricyclic drugs and SSRIs in the treatment of major depressive disorder, fewer adverse effects than with tricyclic drugs, no adverse effects of cognitive impairment or sedation, minimal cardiotoxicity, and relative safety in overdose. Precautions in the use of bupropion include the need to use divided dosing and/or a sustained-release formulation to minimize the propensity to induce seizures and the need to administer the last daily dose well before bedtime to avoid insomnia. In geriatric patients, bupropion may be initially prescribed at 50 to 75 mg twice daily with the dosage gradually increased to approximately 300 mg in two or three divided doses. Drug interactions are generally not a significant problem with bupropion, but it should not be administered concomitantly with an MAOI antidepressant. Bupropion may be helpful in depressed elderly patients with Parkinson's disease.

Nefazodone has several advantages for the treatment of geriatric depression: sleep-promoting and early anxiolytic effects, few adverse effects, safety in overdosage, and absence of sexual adverse effects. Higher dosages (300 to 500 mg a day) are required for clinical efficacy and twice-daily dosing is required, which may limit compliance. Its sedating property may make it beneficial or less acceptable, depending upon the patient.

Venlafaxine selectively inhibits both noradrenaline and serotonin reuptake and reportedly has efficacy in adult treatment-refractory patients with major depression. Patients respond to a relatively wide range of daily doses, and no dosage adjustment is necessary based upon age. The use of venlafaxine entails several precautions. Nausea may be minimized by beginning with lower dosages of 25 mg daily and gradually titrating up to a therapeutic dosage. Blood pressure must be monitored because higher dosages (in general, above 225 mg a day) can be associated with sustained increases in blood pressure. The drug must be administered in two to three divided doses a day, which may hinder compliance. A sustained-release formulation has recently become available.

ESSENTIALS OF PATIENT MANAGEMENT

Managing the depressed geriatric patient includes educating the patient and family about the nature of the illness and the fact that it is treatable. Patients and their families need to understand that treatment takes time (4 to 12 weeks), that treatment adherence is critical, and that adverse effects can be expected but are amenable to supportive countermeasures. Weekly contact during the early phases of short-term treatment is recommended for individualizing treatment, providing encouragement and support, reviewing questions and concerns, and monitoring safety (including suicidal potential). Rating scales may be useful for documenting patient response. Common errors in practice include underdosing, discontinuing treatment too soon, failure to consider possible drug interactions, and polypharmacy. If a patient has not begun to respond by 6 to 8 weeks, compliance should be reevaluated, dosage or plasma concentration should be optimized, and referral to a geriatric psychiatrist experienced in treatment resistance should be considered.

One must bring a longitudinal model of depression to treatment. Short-term treatment is intended to induce remission. Incomplete remissions do occur and promote relapse. Recurrences after a longer period of recovery are also common. Treatment should be maintained for at least 6 months after remission from an uncomplicated first episode of major depression and for longer periods after a second or third episode. Many older patients have chronic depression that requires indefinite maintenance therapy. Long-term prevention of new episodes is best achieved by maintaining patients on the same dosage of antidepressant medication that was used successfully to treat the acute episode. The Pittsburgh study of maintenance therapies in late-life depression found that recurrence rates over three years was 20 percent in patients maintained on the combination of nortriptyline (80-120 ng/mL) and monthly interpersonal psychotherapy, 43 percent on nortriptyline, a year later, 64 percent on monthly interpersonal psychotherapy, and 90 percent on placebo.

TREATMENT OF PSYCHOTIC DEPRESSION IN LATER LIFE

Psychotic depression is a severe illness with profound depressive symptomatology accompanied by delusions and, less frequently, by hallucinations. Psychotic depression poses a risk for suicide, usually by violent means. For this reason, recognition and treatment of psychotic depression can be life saving. Both young and elderly patients with psychotic depression respond poorly to short-term treatment with tricyclic drugs or placebo. Combinations of tricyclic drugs and antipsychotics appear to be effective in psychotic depression in both controlled studies of younger patients and naturalistic treatment studies of elderly patients. The most frequently prescribed antidepressants are nortriptyline and desipramine at plasma concentrations comparable to those of younger adults (80 to 120 ng/mL for nortriptyline or more than 115 ng/mL for desipramine). Perphenazine (Trilafon) is the antipsychotic used in most studies of psychotic depression, and in studies conducted at the University of Pittsburgh, it appears to be effective at daily doses of approximately 32 mg. It is unclear if elderly patients respond to lower dosages of antipsychotics or whether risperidone (Risperdal) is effective and better tolerated than perphenazine. Because combined drug therapy may not be tolerated by elderly patients, electroconvulsive therapy is frequently the treatment of choice in geriatric psychotic depression.

TREATMENT OF BIPOLAR DISORDERS IN LATER LIFE

Bipolar disorders constitute 5 to 10 percent of the diagnoses of elderly psychiatric inpatients. In principle the management of mania in elderly patients is similar to that in younger patients; however, an effort should be made to identify patients with mania induced by drugs or medical or neurological disorders and treat the underlying condition.

Lithium (Eskalith) and anticonvulsants remain the first-line short-term treatment for geriatric mania, although some experts and clinicians feel that valproate (Depakene) should be the first-line treatment. Elderly patients require 30 to 60 percent lower lithium dosages than younger adults to develop equivalent plasma concentrations because age-induced decrements in glomerular filtration rates and renal blood flow reduce lithium excretion. Starting dosages of 75 to 150 mg a day may reduce adverse effects and improve compliance. The half-life of lithium is about 24 to 30 hours in the seventh decade of life. Therefore, steady-state pharmacokinetics are anticipated 5 or more days after stabilization of the daily dosage. Lithium plasma concentrations of 0.8 to 1.2 mEq/L often are not tolerated by elderly manic patients. The onset of lithium action is slow and may require several days or weeks. Lorazepam (Ativan) or low dosages of high-potency antipsychotics may be used in the early treatment of elderly patients who are severely agitated.

Elderly patients may be particularly vulnerable to lithium adverse effects. For example, delirium can develop at lithium concentrations at or even below the therapeutic lithium plasma concentration range. Delirium and cerebellar dysfunction may last for weeks after discontinuation of lithium use. Lithium-induced tremor is more frequent in older patients than in younger patients. Lithium can worsen Parkinson's disease or produce parkinsonism in neurologically intact elderly patients. Lithium can worsen cognitive function, especially in demented patients. Sinoatrial block can be caused by lithium, a risk that is increased by the concurrent use of digitalis and b-adrenergic receptor antagonists (beta-blockers). Elderly patients often received drugs that increase lithium plasma concentrations, including thiazide diuretics, nonsteroidal anti-inflammatory drugs, or angiotensin-converting enzyme inhibitors.

The anticonvulsants carbamazepine (Tegretol) and valproate are effective antimanic agents in younger adults. Case reports suggest that both agents are effective in geriatric mania, including organic mania. Anticonvulsants appear to be effective in both lithium responders and nonresponders. Some evidence suggests that anticonvulsants are more effective than lithium in rapidly cycling patients and in patients with dysphoric mania. Hematological and liver function tests are needed prior to treatment with carbamazepine and valproate. Carbamazepine can cause sedation, confusion, and ataxia in a dose-dependent fashion. Complete blood counts are needed frequently, since carbamazepine can cause leukopenia white blood cell (WBC) counts below 4000/mm ^{3} in approximately 2 percent of cases. Half of the patients who develop carbamazepine-induced leukopenia have a drop in white count within the first 16 days of treatment. Valproate causes leukopenia in 0.4 percent of patients, which is comparable to that with tricyclic drugs.

Continuation and maintenance treatment is necessary in elderly bipolar patients who achieve remission of a manic or depressive episode. Although studies of geriatric populations are lacking, studies of younger patients suggest that lithium, carbamazepine, and valproate are effective in preventing both depressive and manic episodes. For this reason, continuation and maintenance treatment with these drugs should be considered for elderly patients.

TREATMENT OF DEPRESSION ASSOCIATED WITH MEDICAL ILLNESS AND WITH COGNITIVE IMPAIRMENT

The NIH Consensus Conference on the Diagnosis and Treatment of Depression in Late Life stated that “the hallmark of depression in older people is its comorbidity

with medical illness.” Compelling evidence from placebo-controlled clinical trials indicates that antidepressant medications are efficacious in patients with common comorbid medical disorders as diverse as stroke, Parkinson's disease, Alzheimer's disease, cancer, ischemic heart disease, chronic obstructive pulmonary disease, and arthritis. Analogous results have been obtained in placebo-controlled studies of tricyclic drugs in an inpatient rehabilitation unit, where treatment of depression could facilitate recovery from acute illness or injury and in a residential care setting, where patients were characterized by extreme old age and the interacting effects of many of the common disabling medical disorders of later life. However, drug-drug and drug-disease interactions can make older patients highly vulnerable to the adverse effects of tricyclic drugs; approximately 30 percent of a residential care population, average age 85, could not tolerate treatment with nortriptyline at therapeutic plasma concentrations. Thus, careful monitoring of both potential adverse effects and plasma concentrations is necessary to optimize safety of these agents in frail elderly patients.

There is a growing anecdotal literature on the use of psychostimulant medications such as methylphenidate (Ritalin) for the short-term treatment of depressive symptoms in elderly patients with significant medical illness. This is supported by suggestive results from a recent small-scale placebo-controlled crossover study.

In treating depression associated with cognitive impairment, one must recall that cognitive impairment can result from depression or from a separate dementing disorder. In either case the depression should be treated, following the basic principles that apply with older patients. Medication use should be supervised, and caregivers should assess the benefits and monitor for adverse effects of treatment. Patients with dementia of the Alzheimer's type are highly sensitive to increased cognitive impairment from anticholinergic medications. Therefore, antidepressants with the lowest anticholinergic effects are preferred, which include the SSRIs, nortriptyline, bupropion, nefazodone, and venlafaxine.

Depression in elderly adults is widespread, particularly in primary care settings, acute medical and surgical wards, and long-term care settings. Geriatric depression has serious consequences if not recognized and adequately treated, including suicide. Depression in later life can be accurately diagnosed and effectively treated. It typically requires long-term treatment because it tends to be a relapsing illness. Elderly patients benefit as much from treatment as younger patients, although response tends to be slower and more brittle, with higher relapse rates particularly in patients over age 70. Augmentation strategies such as lithium use may be helpful. Both antidepressant medication and psychotherapy have long-term efficacy in prevention of recurrence, with combined treatment being superior to medication alone, psychotherapy alone, or placebo.

51.4 TREATMENT OF PSYCHIATRIC DISORDERS

51.4D PSYCHOPHARMACOLOGY: ANTIANXIETY DRUGS

JAVAID I. SHEIKH, M.D., M.B.A., AND CYNTHIA T. M. H. NGUYEN, M.D.

Anxiety disorders as a group are the most common psychiatric conditions in late life. Because few controlled studies of the management of anxiety in older patients exist, much of the knowledge of the use of anxiolytics in the elderly is necessarily based on evidence from clinical trials in younger populations and on clinical experience.

Various classes of antianxiety medications have traditionally been used to manage anxiety disorders in late life. These include benzodiazepines, azapirones, tricyclic antidepressants, monoamine oxidase inhibitors (MAOIs), dopamine receptor antagonists, b-adrenergic receptor antagonists, barbiturates, anticonvulsants, and antihistamines. Newer antidepressants such as selective serotonin reuptake inhibitors (SSRIs), selective serotonin-noradrenaline reuptake inhibitors (SNRIs), and serotonin (5-hydroxytryptamine [5-HT]) type 2 (5-HT_2) receptor antagonists have recently emerged as the first-line treatment for several anxiety disorders and mixed anxiety-depression syndromes in younger patients. Although investigations of these medications in the treatment of anxiety in older adults are lacking, clinical experience suggests similar efficacy in late life. Because of their adverse-effect profiles, the newer antidepressants seem to be much better tolerated by older people than the anxiolytic medications used in the past. Some older anxiolytic medications (e.g., barbiturates, chloral hydrate [Noctec]) are now rarely used, while others (e.g., MAOIs, tricyclics, b-adrenergic receptor antagonists, anticonvulsants, neuroleptic compounds) may be used as alternatives in treating patients refractory to the SSRIs, SNRIs, and 5-HT_2 antagonists. Newer medications are being investigated (e.g., bretazenil and abecarnil, partial benzodiazepine receptor agonists) that may prove useful in treating anxiety disorders in older patients. In prescribing any medication, however, the special physiological vulnerabilities of anxious older patients should be borne in mind.

GENERAL PRINCIPLES

Several factors complicate psychopharmacological management of the anxious older patient, including comorbid conditions, polypharmacy, and physiological changes associated with aging. The risks of adverse effects of psychopharmacology are greater in older adults than in younger patients. Older patients are more likely than younger people to have concurrent medical illnesses that may be exacerbated by the adverse effects of medications. Similarly, several medical illnesses can mimic or produce symptoms of anxiety. These potentially treatable physical illnesses need to be sought and ruled out before antianxiety medications are administered.

The average older person typically takes six to eight different medications a day. That is, although elderly persons constitute 12 percent of the population, they are prescribed 25 percent of all medications and as a group are the largest consumers of over-the-counter drugs. Thus, the adverse effects of drug-drug interactions occur more commonly in older patients because the risk of adverse drug interactions increases substantially with polypharmacy.

Age-related changes in pharmacokinetics put older patients at higher risk of adverse drug effects. The most important of these changes are decreased absorption, decreased protein binding, increased volume of distribution of lipophilic drugs, decreased hepatic function, and decreased renal excretion. The overall effect of these changes associated with age is that many medications are eliminated more slowly and metabolized less efficiently in older patients than in younger ones. Chronic kidney, liver, or heart disease can further delay drug clearance.

ANXIOLYTICS

Several classes of compounds are used as anxiolytics. Some medications (e.g., barbiturates, chloral hydrate) used as anxiolytics in the past with higher risks of adverse effects in older patients are omitted.

Benzodiazepines Over the past three decades, benzodiazepines have been the most frequently prescribed anxiolytic agents for both young and older patients. Benzodiazepines remain the mainstay of pharmacological therapy for acute symptomatology of generalized anxiety disorder. In addition, the efficacy of benzodiazepines in panic disorder and obsessive-compulsive disorder has been shown in several studies.

As a general principle, older patients are more sensitive to both the therapeutic and the toxic effects of the benzodiazepines. Low doses are recommended, as higher doses that are therapeutic in younger patients may prove toxic in geriatric patients. These medications are beneficial because they have a rapid onset and little effect on cardiovascular status. However, potential complications of long-term benzodiazepine use in older patients include excessive daytime drowsiness, cognitive impairment and confusion, psychomotor impairment and risk of falls, depression, paradoxical reactions, amnestic syndromes, respiratory problems, abuse and dependence potential, and breakthrough withdrawal reactions. Because of these complications, use of benzodiazepines for more than a few weeks is generally not recommended.

Deciding which benzodiazepine to use depends on half-life, potency, and metabolic pathway. Benzodiazepines undergo stepwise hepatic metabolism. The long half-life benzodiazepines such as chlordiazepoxide (Librium), chlorazepate (Tranxene), diazepam (Valium), and flurazepam (Dalmane) undergo both phase I and phase II reactions. Phase I reactions tend to be prolonged in older patients, leading to drug accumulation. These long half-life benzodiazepines are metabolized via oxidative pathways into active metabolites that stay in the system even longer. Phase II (conjugative metabolism) reactions are not affected by age. Therefore for older patients, short half-life benzodiazepines (e.g., lorazepam [Ativan], oxazepam [Serax], and temazepam [Restoril] are preferred because they require only phase II metabolism and are inactivated by direct conjugation in the liver.

Although benzodiazepines are very similar in efficacy, high-potency benzodiazepines such as clonazepam (Klonopin) and alprazolam (Xanax) are preferable in panic disorder because low-potency ones would be extremely sedating at therapeutic doses. Likewise, clonazepam is preferred in obsessive-compulsive disorder.

The use of benzodiazepines as the primary treatment for anxiety disorders on an ongoing basis is problematic because of the many possible complications of long-term use. However, in clinical situations, it is not unusual to encounter patients who have been on these medications for a prolonged (more than 6-month) period. Since newer antidepressants such as SSRIs, SNRIs, and 5-HT_2 antagonists are increasingly being considered as the first-line treatment in various anxiety disorders, older patients on long-term benzodiazepine therapy should be assessed for appropriateness of treatment with these antidepressants. Benzodiazepines should then be slowly tapered to avoid severe withdrawal symptoms.

Conversely, because of the delayed onset of the therapeutic effects of antidepressants, concurrent use of a benzodiazepine in the first few weeks of treatment may help to alleviate severe symptoms of anxiety. A general approach for a patient with panic disorder, with severe anticipatory anxiety, for example, is to start administering alprazolam at 0.25 mg orally three times a day and titrate up to therapeutic levels as tolerated. Clonazepam is almost as potent as alprazolam, but it has a longer half-life. Older anxious patients can be given as little as 0.25 mg twice a day initially and increased gingerly. After a few weeks, benzodiazepine use is tapered slowly while the patient continues to receive the chosen antidepressant.

In treating patients with a mixed picture of depression and anxiety, which is one of the most frequently encountered presentations in geriatric psychiatric practice, short-term use of a benzodiazepine concurrent with an SSRI and SNRI may be warranted if immediate relief is needed for severe symptoms of anxiety.

Benzodiazepines have moderate success in managing anxiety and agitation associated with dementia but can cause sedation, cognitive worsening, and ataxia, as

well as paradoxical disinhibition and agitation.

A summary of pharmacokinetics and average daily doses in geratric patients of commonly used benzodiazepines can be found in Table 51.4d-1.

Drug	Half-Life (h)	Active Metabolites	Average Daily Dosage (mg)	
			Adult	Elderly
Alprazolam	12–15	Yes (minor)	0.5–6	0.25–3
Chlordiazepoxide	7–28	Yes (many)	25–100	5–50
Clonazepam	18–56	Yes	1–8	0.5–4
Clorazepate	30–200	Yes	15–60	7.5–30
Diazepam	20–60	Yes	5–30	2–15
Halazepam	15–50	Yes	20–160	20–80
Lorazepam	10–20	None	1–6	0.5–3
Oxazepam	5–15	None	15–90	10–45
Prazepam	25–200	Yes	20–60	10–20

Table 51.4d-1 Pharmacokinetics and Average Daily Dosage of Commonly Used Benzodiazepines

Azapirones Buspirone (Buspar), an azapirone derivative and a 5-HT $_{1A}$ partial agonist, has been shown in clinical trials to be as efficacious as benzodiazepines and better than placebo for generalized anxiety disorder. Buspirone is well tolerated and is devoid of the sedation, psychomotor impairment, and potential for abuse seen with the benzodiazepines. Although its adverse-effect profile is suitable for use in geriatric patients, its effectiveness for generalized anxiety disorder remains somewhat inconsistent in clinical situations.

In subsyndromal mixed anxiety-depression, if the patient presents with predominant anxiety, buspirone may be beneficial. Buspirone has also shown modest success in managing anxiety and agitation associated with dementia in some case studies, but controlled investigations are lacking.

Antidepressants Several classes of compounds initially approved for use as antidepressants have increasingly been used as antianxiety drugs during the last decade. Recent studies have provided empirical support for their use for various anxiety disorders.

Tricyclic Drugs Several studies have documented the efficacy of various tricyclic drugs in panic disorder. Imipramine (Tofranil) has been used the longest and has been extensively studied. At least one study has shown a tricyclic drug to be superior to a benzodiazepine for generalized anxiety disorder. Clomipramine (Anafranil) is being studied and may prove efficacious in generalized anxiety disorder. Results of controlled trials show clomipramine to be superior to placebo for treatment of obsessive-compulsive disorder.

Use of tricyclic drugs has been declining, especially in the older patient population, because of the risk of adverse effects (e.g., anticholinergic toxicity, orthostasis, cardiac toxicity, memory impairment, delirium, seizures) and the increased use of the newer antidepressants (SSRIs, SNRIs, and 5-HT $_2$ antagonists) with their more favorable adverse-effect profiles.

Monoamine Oxidase Inhibitors Phenelzine (Nardil) has proved effective in treating panic disorder and agoraphobia. In addition, phenelzine was found to be equal to clomipramine in efficacy for obsessive-compulsive disorder, but adverse effects and dietary restrictions that go along with MAOIs make use of these medications more problematic in older patients. Sudden hypotensive episodes observed in patients on MAOIs can be particularly dangerous in geriatric patients because of the risk of falls.

Selective Serotonin Reuptake Inhibitors Several SSRIs, including citalopram (Celexa), fluoxetine (Prozac), fluvoxamine (Luvox), paroxetine (Paxil), and sertraline (Zoloft), have shown efficacy superior to that of placebo and similar to that of tricyclic drugs for panic disorder in controlled trials.

Given their efficacy and favorable adverse-effect profile, the SSRIs should now be considered the drugs of choice for panic disorder. These medications may be given in a single daily dose to maximize compliance. However there is a 2- to 4-week delay in onset of action, so medication education must be emphasized when prescribing. In addition, the SSRIs, especially fluoxetine, may be activating and may cause increased anxiety. Some anxious geriatric patients who already tend to overemphasize somatic symptoms may find the gastrointestinal distress commonly associated with SSRI use intolerable. Older patients therefore should initially be given these medications in very small daily doses (e.g., a half of a 25-mg tablet of sertraline or a half of a 20-mg tablet of citalopram). Dosage can be increased as tolerated.

Fluoxetine, sertraline, fluvoxamine, and paroxetine have all been found to be superior to placebo for treatment of obsessive-compulsive disorder. Comparisons found fluvoxamine, sertraline, and paroxetine to be equal in efficacy to clomipramine. Most older patients tolerate SSRIs better than clomipramine, so they should be considered first-line medication treatment for obsessive-compulsive disorder in geriatric patients.

The SSRIs are presently being studied in clinical trials for their efficacy in generalized anxiety disorder. In mixed anxiety-depressive disorder, if the patient has a predominant depression, or depressive and anxious symptoms in equal proportions, SSRIs or newer antidepressants (SNRIs, 5-HT $_2$ antagonists) are the treatment of choice. In the management of anxiety and agitation in older patients with dementia, controlled studies on efficacy have shown mixed results.

Other Antidepressants There is emerging evidence that SNRIs such as venlafaxine (Effexor) and 5-HT $_2$ antagonists such as nefazodone (Serzone) may be efficacious for panic disorder and generalized anxiety disorder. Further, nefazodone has also demonstrated efficacy in open-label studies with younger patients suffering from posttraumatic stress disorder. Several case reports show efficacy in treating anxiety and agitation associated with dementia with trazodone or nefazodone.

Antipsychotic Agents Clinical experience suggests that low-dose, high-potency dopamine receptor antagonists such as haloperidol (Haldol) and fluphenazine (Prolixin) (e.g., 0.25 to 0.5 mg twice a day of haloperidol) can be modestly effective in treating anxiety and agitation associated with dementia. These drugs can cause sedation, cognitive worsening, extrapyramidal reactions, or late-developing adverse effects such as tardive dyskinesia. Their use should be limited to acute situations and for brief periods, with frequent evaluations and documentation of need. Serotonin-dopamine antagonists, such as olanzapine (Zyprexa), risperidone (Risperdal), or quetiapine (Seroquel) have a lower incidence of treatment-related adverse effects and may be preferable in the older patient population. Recent evidence from a controlled trial shows that risperidone is superior to placebo in the management of agitation associated with dementia. Neuroleptic drugs are also used as potentiating agents with SSRIs in the management of obsessive-compulsive disorder. Pimozide (Orap) is used as an adjunct in patients with obsessive-compulsive disorder and Tourette's disorder. In older patients, antipsychotic drugs should generally be used in low dosages and with extreme caution.

Anticonvulsants Valproate (Depakene) and carbamazepine (Tegretol) show moderate effectiveness in the treatment of anxiety and agitation associated with dementia. However, carbamazepine has a high risk of potential toxicity and may not be desirable for use in older patients.

b-Adrenergic Receptor Antagonists Some reports suggest that b-adrenergic receptor antagonists may be efficacious in some geriatric patients with anxiety and agitation. Propranolol (Inderal) showed moderate success in several studies, but due to the risk of hypotension and a possible risk of developing congestive cardiac failure, they are rarely used with older patients. Controlled studies in younger patients suggest that b-adrenergic receptor antagonists may have some efficacy in treating autonomic symptoms associated with generalized anxiety disorder and panic disorder but not the cognitive aspects of anxiety.

Antihistamines Antihistamines such as hydroxyzine (Atarax, Vistaril) and diphenhydramine (Benadryl) are sometimes used in clinical settings to manage mild anxiety, in spite of the dearth of studies demonstrating efficacy or safety. Prolonged use of these medications, however, is fraught with potential problems in older patients, such as anticholinergic effects, excessive sedation, confusion, and disorientation.

SUGGESTED CROSS-REFERENCES

The epidemiology of disorders of late life is covered in Section 51.1b. Section 51.4b, Section 51.4c, Section 51.4c, Section 51.4d, Section 51.4e, Section 51.4f, Section 51.4g, Section 51.4h, Section 51.4i, Section 51.4j, Section 51.4k, Section 51.4l, Section 51.5a, Section 51.5b, Section 51.5c, Section 51.5d, Section 51.6a cover psychological treatments in the elderly. Anxiety disorders are extensively discussed in Chapter 15, and anxiety disorders in late life are discussed in Section 51.3c. Biological therapies are covered in Chapter 31.

51.4 TREATMENT OF PSYCHIATRIC DISORDERS

51.4E PSYCHOPHARMACOLOGY: ANTIPSYCHOTIC DRUGS

DAVID L. SULTZER, M.D., AND HELEN LAVRETSKY, M.D.

The use of antipsychotic medications to treat psychiatric syndromes in the elderly can be clinically challenging. Older patients demonstrate heterogeneous individual responses to antipsychotic medications, are sensitive to adverse effects, often have comorbid medical conditions, and are at high risk for adverse drug interactions. In addition, antipsychotic medications are prescribed to treat a variety of psychiatric syndromes in the geriatric population.

Despite the clinical complexities, antipsychotic medications are frequently prescribed to elderly persons. Most studies find that at least 30 percent of nursing home residents have an antipsychotic medication ordered, frequently without clear evidence of a psychiatric symptom or diagnosis and often with limited monitoring of medication effects over time. Concern about such practices has resulted in federal legislation (Omnibus Budget Reconciliation Act) that requires documentation of the specific indication for neuroleptic treatment in nursing homes.

Until recently, there has been little systematic study of antipsychotic medications in the geriatric population. Dosing strategies, patterns of short-term adverse effects, predictors of clinical response, long-term effectiveness, prophylactic value, and adverse effects resulting from prolonged use are not well understood. Fortunately, studies focusing on these clinical parameters in older patients are beginning to help provide better treatment guidelines.

TREATMENT PRINCIPLES

Prescribe Antipsychotic Medications Only for Specific Clinical Symptoms Thorough clinical evaluation and accurate diagnosis provide the framework for effective treatment. An older patient with several medical conditions, neurological illness, and mixed symptoms that include delusions, dysphoria, anxiety, and behavioral disturbance requires careful evaluation that leads to a clear *Diagnostic and Statistical Manual of Mental Disorders* fourth edition (DSM-IV) differential diagnosis and an individualized treatment plan. Specific target symptoms should be clearly identified prior to antipsychotic treatment and carefully monitored over the course of treatment. Medication intervention for poorly defined behavioral eccentricities often provides limited clinical benefit, obscures the treatment endpoint, and unnecessarily exposes the patient to medication risks.

Dose-Response Relationships Vary Widely Across Individuals Pharmacokinetic and pharmacodynamic changes associated with aging have a prominent impact on the relationship between dose and clinical response in older patients. Reduced protein binding, reduced hepatic metabolism, and alterations in neuroreceptor densities and neurotransmitter concentrations all likely contribute to enhanced antipsychotic medication effects. Studies measuring neuroleptic plasma concentrations indicate that patients over age 60 achieve concentrations in blood that are 2- to 3-fold higher than those of younger patients at a given oral dose, although not all studies agree. There is also considerable heterogeneity in age-related pharmacokinetic and neuroreceptor alterations. Thus, the efficacious and adverse effects of a particular antipsychotic dosage may vary considerably among older patients. In addition, the time required for antipsychotic response is typically longer than in younger patients. Initial dosage should be relatively low and dosage increases should be titrated cautiously to determine the optimal dosage for an individual patient.

Anticipate Adverse Effects Although antipsychotic treatment is usually effective for elderly patients with specific target symptoms, many experience an unwanted consequence of antipsychotic treatment. Older patients are particularly sensitive to anticholinergic, hypotensive, and extrapyramidal effects of neuroleptic drugs because of age-related changes in neurotransmission and reduced homeostatic mechanisms and are at high risk for tardive dyskinesia. Some atypical antipsychotic medications may be efficacious with fewer adverse effects than dopamine receptor antagonists, but there has been limited experience with their use in the elderly population and in those with comorbid medical conditions.

Consider Potential Drug Interactions Approximately 75 percent of community-dwelling elderly persons in the United States take prescription drugs, and each takes an average of three to five different prescription and nonprescription medications. Even more medications are consumed in nursing homes. Such frequent use of multiple medications, coincident with age-associated pharmacokinetic changes, raises the likelihood of additive medication effects and adverse interactions with antipsychotic drugs. Reviewing the specific prescription and over-the-counter medications that a patient is taking, eliminating unnecessary drugs, and reviewing potential interactions prior to prescribing an antipsychotic agent is crucial.

Monitor Medication Effects Over Time and Adjust the Treatment Plan The heterogeneity of clinical responses to antipsychotic treatment that can be expected in the elderly population provides a strong rationale for careful longitudinal monitoring. Some beneficial effects of antipsychotic medication treatment such as improved sleep may occur within a few days, whereas gradual improvement in delusions and thought disorder may occur over 6 to 8 weeks. Similarly, excessive sedation, hypotension, or acute extrapyramidal signs may develop within the first day of neuroleptic treatment, yet rigidity or gait disturbance may emerge after 6 weeks of neuroleptic treatment at a stable dosage. In addition, noncompliance with a medication regimen among older patients has been reported to vary between 40 and 75 percent, which indicates that monitoring medication use is essential.

ANTIPSYCHOTIC MEDICATIONS

Traditional antipsychotic agents, also referred to as neuroleptics or dopamine receptor antagonists, are thought to ameliorate psychosis via blockade of the dopamine type 2 (D_2) receptors in the mesolimbic system. Serotonin-dopamine antagonists (SDAs), also called “atypical antipsychotics,” have been introduced more recently. Although the term “atypical” is variably defined, these medications are generally associated with few extrapyramidal effects, improvement in negative symptoms of schizophrenia (apathy, blunted affect, emotional withdrawal), and prominent interactions with serotonergic receptors in the brain. SDAs include clozapine (Clozaril), risperidone (Risperdal), olanzapine (Zyprexa), and quetiapine (Seroquel). Antipsychotic medications are listed in Table 51.4e-1, with usual dosages in elderly persons, adverse-effect profiles, and relative affinity for dopamine type 2 (D_2) and serotonin (5-hydroxytryptamine [5-HT]) type 2(5-HT_2) neuroreceptors. The dosage ranges are broad, underlining the need for careful titration in individual patients. Optimal dose ranges and adverse effects of the SDAs are not well characterized in the geriatric population, particularly among those with dementia or other neuropsychiatric illness. However, the adverse-effect profiles of some of these agents are encouraging and they are increasingly prescribed for older patients. Age-related pharmacokinetic changes may have a smaller impact on clearance of olanzapine than other antipsychotic agents, although pharmacodynamic alterations of aging warrant use of lower doses of both the SDAs and dopamine receptor antagonists.

Medication	Brand Name	Dosage Range[a] in Elderly Patients (mg/day)	Adverse Effects[b]			Receptor Affinity In Vitro	
			Anticholinergic Effects	Extrapyramidal Effects	Hypotensive Effects	Dopamine Receptor (D_2)	Serotonin Receptor (5-HT_2)
Chlorpromazine	Thorazine	10–300	+++	+	+++	++	++
Thioridazine	Mellaril	10–300	+++	+	+++	++	+
Loxapine	Loxitane	5–75	++	++	++	++	++
Molindone	Moban	5–75	++	++	+	++	+
Perphenazine	Trilafon	2–32	++	++	++	++	+
Thiothixene	Navane	1–15	++	+++	++	+++	+
Fluphenazine	Prolixin	0.5–5	+	+++	+	+++	+
Haloperidol	Haldol	0.5–5	+	+++	+	+++	+
Clozapine[c]	Clozaril	12.5–300	+++	-	+++	+	++
Risperidone[c]	Risperdal	0.5–5	+	+	+	+++	+++
Olanzapine[c]	Zyprexa	2.5–20	++	+	+	++	++
Quetiapine[c]	Seroquel	25–250	+	-	+	+	+

[a] medication effects: -, none; +, mild; ++, moderate; +++, marked.
[b] Routine clinical dose ranges are listed. Higher or lower doses may be indicated in some cases.
[c] Optimal dose ranges and adverse effects listed are based on limited experience.

Table 51.4e-1 Antipsychotic Medications

Outcome studies indicate that the overall efficacy of antipsychotic medications is similar, although SDAs appear to have a beneficial effect on the negative symptoms of schizophrenia and clozapine may be particularly effective in treatment-resistant patients. Previous history of clinical response to a particular agent and an individual's sensitivity to specific adverse effects are the most important factors in choosing a medication. In general, low-potency antipsychotics and multiple antipsychotic medications are avoided. Many older patients tolerate oral antipsychotic doses once a day, although some patients have fewer adverse effects with more-frequent smaller doses and lower peak blood concentrations. Depot preparations of haloperidol (Haldol) or fluphenazine (Prolixin) may benefit some patients with schizophrenia who require maintenance treatment, particularly when compliance is likely to be poor. However, low initial dosages and careful dosage titration are required because of erratic intramuscular absorption and prolonged clearance rates in elderly persons.

Adverse Effects Adverse effects of antipsychotic medications in the elderly are listed in Table 51.4e-2 and the relative frequency of anticholinergic, extrapyramidal, and hypotensive effects among different agents is shown in Table 51.4e-1.

Anticholinergic effects	Cognitive impairment,* delirium,* dry mouth, blurred vision, constipation,* urinary retention,* tachycardia,** exacerbation of narrow-angle glaucoma
Acute extrapyramidal effects	Rigidity,* bradykinesia,* tremor,* dystonia, akathisia
Tardive movement disorders	Tardive dyskinesia,* tardive dystonia, tardive akathisia
Cardiovascular effects	Hypotension,* tachycardia,* electrocardiogram changes (nonspecific *T*-wave changes, increased QT interval)
Other adverse effects	Sedation,* falls,* cognitive impairment,* elevated prolactin concentration, sexual dysfunction, weight gain, neuroleptic malignant syndrome, elevated hepatic enzyme values, jaundice, hyponatremia, seizure, skin photosensitivity, retinopathy, agranulocytosis, nasal congestion

* Effects that are particularly common or severe among older patients, even with treatment at low dosages.

Table 51.4e-2 Adverse Effects of Antipsychotic Medications in Elderly Patients

Anticholinergic Effects Peripheral anticholinergic symptoms such as constipation and urinary retention are particularly common in older patients, as many are bothered by these problems prior to medication intervention. Central anticholinergic symptoms include poor attention, impaired memory, and behavioral disturbances. These symptoms can result in diagnostic confusion and can be particularly debilitating in patients with preexisting cognitive impairment.

Extrapyramidal Effects Older patients are sensitive to acute extrapyramidal effects, which include parkinsonism, dystonia, and akathisia. Several studies have suggested that the geriatric population is more susceptible to neuroleptic-induced tremor and less susceptible to acute dystonia than younger age groups. Older patients with rigidity or tremor prior to medication treatment are most likely to develop neuroleptic-induced parkinsonism. Overall, extrapyramidal signs are evident in up to 80 percent of older patients treated with neuroleptics, they may emerge after months of treatment at a stable dosage, and can lead to difficulty in swallowing and falls. Acute extrapyramidal symptoms do not generally occur with SDAs, although risperidone may induce these symptoms at low dosages (e.g., 1 to 2 mg a day) in older patients, particularly those with dementia. Akathisia due to neuroleptics may be mistaken for increased agitation in a patient with dementia and behavior disturbance, which the clinician may erroneously respond to by raising, rather than lowering, the dose. Treatment with anticholinergic agents such as benztropine (Cogentin) or trihexyphenidyl (Artane) to ameliorate extrapyramidal symptoms is best avoided to reduce risk of anticholinergic toxicity, although low dosages (e.g., benztropine 0.5 mg twice daily) may be prescribed cautiously. Low-dose propranolol (Inderal) may improve akathisia, and amantadine (Symmetrel) may also help reduce rigidity, but these medications can also cause adverse effects.

Tardive Dyskinesia Advanced age is one of the strongest risk factors for development of tardive dyskinesia. A recent study found that the cumulative incidence of tardive dyskinesia among patients over age 45 was 26 percent after 1 year, 52 percent after 2 years, and 60 percent after 3 years of neuroleptic treatment. Older patients may develop tardive movements after a shorter period of neuroleptic exposure than young patients, and the movement disorder remits less frequently after neuroleptic discontinuation. Risk factors for tardive dyskinesia remain incompletely understood, but the research literature indicates that duration of neuroleptic exposure, female sex, mood disorder, medical illness, history of extrapyramidal symptoms or anticholinergic drug use, and subtle movement disorder prior to neuroleptic treatment, in addition to advanced age, confer greater risk. Most of the SDAs are not expected to cause tardive dyskinesia, although longer outcome studies are needed. A few cases of tardive dyskinesia in patients treated with risperidone have been reported.

Cardiovascular Effects The principal cardiovascular effects of antipsychotic medications are hypotension and tachycardia. Orthostatic hypotension is a particular concern in elderly persons because of age-related limitations in vascular regulation and postural reflexes that can increase the risk of falls. Agents that most frequently cause hypotension (Table 51.4e-1) should be avoided, and blood pressure, pulse, and orthostatic symptoms carefully monitored.

Other Adverse Effects Several other adverse effects may occur with antipsychotic treatment (Table 51.4e-2). Elderly persons tend to be susceptible to these because of reduced homeostasis, medical illness, or concurrent medications. SDAs are not generally associated with the adverse motor and anticholinergic effects of traditional neuroleptic drugs, although excessive sedation, hypotension, and weight gain can occur with these agents, and the profile of effects in the geriatric population is not well characterized. Dose-related extrapyramidal symptoms may occur with risperidone treatment, and anticholinergic effects can be prominent with clozapine treatment. Olanzapine may also have anticholinergic effects. Clozapine treatment often causes sedation and hypotension in addition to anticholinergic effects and is associated with a dose-related seizure risk. Potentially fatal agranulocytosis occurs in approximately 1 percent of patients treated with clozapine, which necessitates frequent blood cell monitoring. Clozapine is thus reserved for patients with prominent psychosis who respond poorly to other antipsychotic agents or have severe tardive dyskinesia. Initial dosages should be very low and the dosage increased slowly; many elderly patients respond to less than 100 mg a day.

Medication Interactions Because older patients frequently take multiple medications, adverse medication interactions are an important clinical concern. Medications that often influence antipsychotic medication effects are listed in Table 51.4e-3. The clinical impact of these interactions varies considerably, depending on the extent of pharmacokinetic effects, genetic polymorphism of metabolic enzyme systems, and involvement of single or multiple metabolic pathways. Inhibitory interactions can lower antipsychotic clearance by 50 percent, and inducing interactions may double antipsychotic clearance. Antipsychotic drugs can also influence the effects of a coadministered medication. For example, concentrations of tricyclic drugs in blood may be higher when neuroleptic medications are concurrently taken.

Medication	Impact on Antipsychotic Medication Kinetics or Clinical Effects
Serotonin reuptake inhibitors, tricyclic drugs, monoamine oxidase inhibitors	Increased concentrations in blood due to reduced metabolism
Benzodiazepines, barbiturates	Increased sedation and risk of falls Possible increased hypotension
Lithium	Increased extrapyramidal symptoms Possible increased risk of delirium Possible increased risk of neuroleptic malignant syndrome
Anticholinergic medications	Delayed gastrointestinal absorption
Carbamazepine	Enhanced hematological toxicity with clozapine
Carbamazepine, phenytoin, phenobarbital	Reduced blood level due to enhanced metabolism; less likely for olanzapine and risperidone
Antacids	Delayed gastrointestinal absorption
Cimetidine	Increased concentration in blood due to reduced metabolism Possible decreased gastrointestinal absorption
Erythromycin, chloramphenicol, ketoconazole	Increased concentration in blood due to reduced metabolism
Propranolol	Increased concentration in blood due to reduced metabolism Hypotension
Opioids	Increased sedation and hypotension
Ethanol	Increased sedation
Cigarette smoking	Reduced concentration in blood due to enhanced metabolism

Table 51.4e-3 Antipsychotic Medication Interactions in Elderly Patients

THERAPEUTIC INDICATIONS

Early-Onset Schizophrenia, Now Older The course of illness among patients with typical onset of schizophrenia in the second to fourth decade of life is heterogeneous. Positive symptoms such as delusions and hallucinations as well as symptoms of thought disorder may be less severe among patients over age 65, and antipsychotic dosages are typically lower than those in younger patients. If negative symptoms are prominent, trial of an SDA may be indicated. Some patients who have been maintained for many years on antipsychotic drugs with prolonged remission of psychotic symptoms may warrant a trial off medication. Relapse may occur, however, and predictors of relapse are not well understood. Some studies find older patients and those with later onset of illness to be at lower overall risk for relapse, but careful monitoring is important.

Late-Onset Schizophrenia Approximately 15 percent of patients with schizophrenia develop their first psychotic episode after age 45. New onset of psychotic symptoms in an older person demands careful evaluation for medical, neurological, or pharmacological causes. Some evidence indicates that patients with late-onset schizophrenia may respond to lower neuroleptic dosages than those with early-onset schizophrenia who are now older.

Delusional Disorder Delusional disorder is characterized by nonbizarre delusions without prominent hallucinations, disorganized behavior, or functional deterioration and tends to occur in mid to late adulthood. Delusional thoughts are often circumscribed and may not require intervention, but a trial of antipsychotic medication is indicated when the delusions have a significant adverse impact on social relationships or behavior. Treatment is often complicated by the patients' lack of insight regarding their beliefs or need for treatment.

Mood Disorder With Psychosis Elderly patients with major depression or mania may present with psychotic symptoms. Short-term treatment with antipsychotic medication may be beneficial, although antidepressant or mood-stabilizing pharmacotherapy is primary. Antipsychotic medication should generally be discontinued following remission of psychosis. Electroconvulsive therapy may be indicated if psychosis, appetite disturbance, or mood symptoms are particularly severe.

Dementia and Delirium Delusions, hallucinations, and agitated or aggressive behavior are major sources of morbidity among patients with Alzheimer's disease and other dementias. Approximately 30 to 40 percent of patients with Alzheimer's disease have delusional thoughts, and at least 25 percent of patients exhibit aggressive behavior. Delusions among patients with dementia are often transient and easily modified by suggestion and thus may not warrant pharmacological intervention. However, delusional thoughts of persecution or misidentification may be severe, and treatment is indicated if the patient is significantly distressed or the delusions contribute to a behavior disturbance.

The term “agitation” refers to a broad range of inappropriate verbal or motor behaviors, and pharmacological intervention is again reserved for situations in which distress is prominent or safety or basic care is compromised. Medical problems that cause behavior disturbance in dementia should be identified: dehydration, infection, urinary retention, pain, or adverse medication effects. Behavioral management strategies should be instituted before medication intervention. Adjusting the physical environment, redirecting distressed patients, talking calmly with patients, and promoting appropriate social interactions and activities, combined with caregiver education and support, can significantly reduce problem behaviors and their impact.

Many studies have explored the efficacy of antipsychotic medication treatment for psychosis and agitation in patients with dementia, although methodological flaws limit the conclusions that can be drawn. Most studies indicate that delusions usually respond to antipsychotic treatment. Dosages are low to moderate. Approximately two thirds of patients with agitated behavior improve with neuroleptic treatment, although the response is generally modest, and some patients do not benefit from the medication. No difference in efficacy among neuroleptic drugs has been consistently demonstrated. High-potency agents are recommended and most patients respond to low dosages (e.g., haloperidol 1 to 2 mg a day). Some patients may require only a very low dose (e.g., haloperidol 0.25 to 0.5 mg a day), and adverse effects are often prominent with haloperidol dosages above 2 mg a day. The concentration of neuroleptic drug in blood required to improve agitation appears to be considerably lower than that required to improve schizophrenia. Cognitive impairment and subtle extrapyramidal symptoms prior to treatment indicate greater risk for neuroleptic-induced parkinsonism.

Patients with delirium require careful medical, neurological, and laboratory evaluation to identify the conditions that are contributing to the mental status change. Antipsychotic medications should be prescribed only when necessary to maintain safety and basic care, as these medications can contribute to the mental status changes and cloud the clinical picture.

SDAs may have an important role in managing psychosis or aggression in patients with dementia, because of their favorable adverse-effect profiles and their impact on the serotonergic system, which may mediate aggressive behavior. Although clinical experience is growing, only a few structured trials in mixed populations have been reported. Risperidone has been shown effective, but dosages are lower than those prescribed for elderly patients with schizophrenia, and much lower than dosages for young patients. Initial risperidone dosage is 0.5 mg a day, and the total daily dose rarely exceeds 3 mg. Extrapyramidal symptoms may occur within this dosage range. Clozapine may ameliorate psychosis or aggression in some elderly patients with dementia, although adverse effects can be prominent, even at very low dosages and many patients are unable to tolerate clozapine. A range of 12.5 to 100 mg a day is recommended in this population, with very cautious titration. Newer SDAs, including olanzapine and quetiapine, may provide benefit with fewer adverse effects. Specific effects and guidelines for their use will be better understood with results from structured trials. Trazodone (Desyrel), other serotonergic medications, and anticonvulsants also ameliorate agitated behavior in some patients and are often well tolerated.

There has been little systematic study of long-term antipsychotic medication use by cognitively impaired patients with psychosis or behavior disturbance, despite concern for potentially excessive use. However, several investigators have examined the consequences of neuroleptic drug discontinuation or dosage reduction in elderly nursing home residents. Results indicate that many patients without active psychotic symptoms or specific behavioral disturbances do not deteriorate following antipsychotic reduction, and some patients demonstrate improvement in blunted affect and social withdrawal. However, a significant minority (5 to 45 percent in different studies) do deteriorate clinically, which supports the importance of careful monitoring.

Other Challenging Circumstances Elderly patients with psychosis and parkinsonism due to Parkinson's disease, diffuse Lewy body disease, or cerebrovascular disease involving subcortical structures are often extremely sensitive to extrapyramidal adverse effects of neuroleptic medications. Dopaminergic medications should be reduced to as low a dosage as possible, as these agents frequently contribute to psychosis or behavior disturbance. If antipsychotic intervention is necessary, low dosages of midpotency agents (e.g., loxapine [Loxitane], perphenazine [Trilafon]) may be helpful without marked increase in parkinsonism. Alternatively, SDAs may improve psychosis without exacerbating parkinsonism. Low dosages of clozapine (e.g., 12.5 to 100 mg a day) or olanzapine (2 to 15 mg a day) benefit some patients. Risperidone may exacerbate parkinsonism, even at low dosages. Newer atypical agents offer a distinct theoretical advantage in this population, but clinical experience is limited. Electroconvulsive therapy is often effective for mood and psychotic symptoms in patients with Parkinson's disease and also ameliorates the movement disorder in most patients.

Older patients with psychosis and a long history of neuroleptic treatment often have tardive dyskinesia. The natural history of tardive dyskinesia varies considerably, and continued neuroleptic treatment may not worsen the dyskinesia. However, the lowest effective dosage should be prescribed to reduce the likelihood of all adverse effects, including exacerbation of tardive movements, and anticholinergic medication should be discontinued if possible. A trial of an SDA may be indicated, as the risk for worsening the dyskinesia is likely lower, although longitudinal clinical data are lacking. Interestingly, several cases of improved tardive dyskinesia following clozapine treatment have been reported.

SUGGESTED CROSS-REFERENCES

Section 51.3e and Section 51.3f describe diagnostic considerations, clinical phenomenology, and overall treatment strategies for elderly patients with psychosis due to schizophrenia, delusional disorder, or dementia. Section 51.4b presents the general principles of psychopharmacology in elderly patients. Section 51.6a describes the psychiatric aspects of long-term care. A general description of somatic treatment of schizophrenia can be found in Section 12.8. Other psychotic disorders are covered in Chapter 13. Cognitive disorders, including delirium and dementia, are covered in Chapter 10. Mood disorders are presented in Chapter 14. Dopamine receptor antagonists are presented in Section 31.17, and serotonin-dopamine antagonists are presented in Section 51.26. Medication-induced movement disorders are covered in Section 31.4.

51.4 TREATMENT OF PSYCHIATRIC DISORDERS

51.4F PSYCHOPHARMACOLOGY: ANTIDEMENTIA DRUGS

LON S. SCHNEIDER, M.D.

So-called antidementia drugs are by definition medications intended to improve cognitive function in patients with dementia. The term has regulatory significance with the Food and Drug Administration (FDA) since it differentiates these medications from cognition enhancers, medications that might be expected to improve cognition without reference to a particular illness. Worldwide, a broad range of putative cognition-enhancing agents is available for prescription, including piracetam derivatives, ergoloid mesylates (Hydergine), cholinesterase inhibitors, cholinergic agonists, and selegiline (Eldepryl), antioxidants, vitamins, food supplements, so-called neutraceuticals, and various plant derivatives, including extracts of *Ginkgo biloba*. In the United States the latter four groups of the products are regulated by the FDA only with respect to apparent safety and inappropriate advertising claims; efficacy for the conditions being treated need not be addressed.

The medications available for prescription in the United States that are indicated for treating cognitive impairment currently include only ergoloid mesylates and the cholinesterase inhibitors tacrine (Cognex), donepezil (Aricept), and revastigmine (ENA 713, Exelon, Novartis). The three cholinesterase inhibitors are specifically indicated for dementia of the Alzheimer's type, and thus are considered antidementia. Results of clinical trials performed throughout the world, however, suggest that other medications available in the United States might have efficacy in patients with Alzheimer's disease, including selegiline, various estrogen preparations, vitamin E, and anti-inflammatories.

Alzheimer's disease is the most common idiopathic dementia associated with aging and hence the most common target for antidementia therapeutics. Vascular dementia is the next most common. Although the causes of Alzheimer's disease are unknown (except for rare early-onset familial/genetic cases), a substantial part of the pathophysiology is sufficiently understood to allow rational development of symptomatic or potentially disease-modifying treatments. The pathophysiology of Alzheimer's disease is characterized, in part, by the deposition of insoluble b-amyloid, early loss of synapses, and death of predominantly acetylcholine-containing neurons, along with an atypical inflammatory response and excess production of toxic, oxidizing free radicals. The framework for clinical trials in Alzheimer's disease developed during the last decade after the general acceptance of research-based diagnostic criteria for the dementia of Alzheimer's type (e.g., National Institute of Neurological Communicative Disorders and Stroke [NINCDS] Alzheimer's Disease and Related Disorders Association [ADRDA] and the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* [DSM-IV] criteria) provided a better understanding of its underlying pathology, and the development of mechanism-based pharmacological therapeutics.

Until the 1980s medications were proposed for dementia treatment based on clinical experience or prevailing theories of dementia and aging. Examples of such earlier claimed treatments included psychostimulants (to increase attention) and vasodilators (to increase blood flow) and hyperbaric oxygen (to enhance metabolism). Only one medication, ergoloid mesylates, was approved in the United States for the ill-defined condition, senile mental decline, which was based on unvalidated diagnostic constructs such as “cerebral insufficiency” or “cerebral deterioration.” The mechanism of action of ergoloid mesylates is unknown but may involve complex neurotransmitter and vascular effects.

REGULATORY AND METHODOLOGICAL CONSIDERATIONS

FDA guidelines for establishing that a drug has antidementia efficacy require that patients meet accepted diagnostic criteria for a primary, well-accepted dementia such as Alzheimer's type, that trials use double-blind, placebo-controlled, parallel-group designs; that at least one trial be of 6 months' duration; and that improvement be obtained on both an accepted cognitive instrument and a clinician's global assessment, thus ensuring a clinically meaningful effect rather than a measurable but trivial cognitive effect.

From the FDA perspective, behavioral or functional (e.g., activities of daily living) changes that result from treatment are of secondary importance, even though improved functional status may have a major impact on maintaining independence and quality of life. However, improvement in behavior or functional activities in the absence of improved cognition does not allow a drug to be labeled antidementia.

For clinical trials in Alzheimer's disease, the Alzheimer's Disease Assessment Scale (ADAS) cognitive subscale has become the standard cognitive change measure and a clinician's interview–based impression of change instrument the measure of “clinical meaningfulness.” The ADAS cognitive subscale provides a summary score that reflects measures of word recall, naming, following commands, constructional and ideational praxis, orientation, word recognition, spoken language, comprehension of spoken language, word finding, and recall of test instructions.

Regulatory guidelines do not exist for the treatment of other dementias (e.g., vascular dementia, Parkinson's disease, Lewy body variant of Alzheimer's disease), other cognitive disorders, age-associated cognitive decline (DSM-IV), or cognitively unimpaired persons, in part, because of a lack of general expert consensus on the validity of the proposed diagnostic criteria. Although there are efforts to gain recognition of functionally significant but mild cognitive loss such as age-associated memory impairment (age-associated cognitive decline) or minimal cognitive impairment, the vagueness of the definitions and underlying pathology limit their general acceptance and hence the acceptance of treatments for such unrecognized conditions. The appropriateness of treatment of unimpaired persons with cognitive enhancers is controversial. Similarly, no guidelines exist for the treatment of cognitive deficits associated with schizophrenia, attention-deficit disorders, or depression, despite the existence of diagnostic criteria.

PHARMACOLOGICAL TREATMENT OF SYMPTOMATIC BEHAVIORS

Patients with Alzheimer's disease often experience such behavioral symptoms as depression, anxiety, psychosis, agitation, aggression, apathy, withdrawal, and vegetative disturbance (e.g., sleep or appetite change). These symptoms frequently lead to psychotropic medication treatment (both appropriate and inappropriate), physical restraint, and institutionalization. Behavioral symptoms burden caregivers and are considered among the most stressful aspects of caregiving. Various psychotropic medications are effective for pharmacological intervention and may improve many of these symptoms.

The treatment of symptomatic behaviors begins with a careful characterization of the target symptoms. Symptoms such as agitation, aggression, or delusions can result from chronic or recurrent psychiatric disorders; can represent the first manifestation of a new psychiatric disorder; or can indicate a change in medical status. A comprehensive medical evaluation will uncover potentially treatable underlying physical conditions that can exacerbate behaviors. Moreover, patients with dementia are at increased risk for developing superimposed deliria. (“Agitation” is often used to describe a range of nonspecific behaviors in elderly adults, including wandering, pacing, uncooperativeness, and verbal outbursts.)

Patients with dementia are sensitive to a variety of factors that may influence behavior, including sensory impairment, environmental disruption, or altered daily routines. Consequently, environmental manipulations may be helpful. Many patients with dementia experience anger, sadness, and denial, which may improve with nonpharmacological interventions. Various behavior-management techniques, including cognitive-behavioral management, may be helpful for moderately to severely impaired individuals. Supportive psychotherapy and counseling may benefit patients with mild cognitive impairments. Caregivers often need greater awareness that

their own behaviors influence the patient. Counseling about the nature of the patient's illness often helps relatives cope better.

DRUGS TO TREAT DEMENTIA

Drugs to treat dementia can be grouped into two broad categories: those intended to improve cognitive function symptomatically and those intended to modify the course of illness. Table 51.4f-1 lists available drugs for treating the cognitive symptoms of dementia.

Cholinesterase inhibitors
FDA-approved for dementia of the Alzheimer's type
Tacrine
Donepezil
Investigational
Rivastigmine
Metrifonate
Galantamine
Other medications available on the U.S. market
Anti-inflammatories (e.g., ibuprofen)
Estrogens
Conjugated estrogens (Premarin)
Estradiol
Vitamin E
Selegiline

Table 51.4f-1 Medications for Dementia

CHOLINERGIC DRUGS

The cholinergic hypothesis of dementia is based on observations of massive decline of the cholinergic basalocortical projections; reductions in the activity of choline acetyltransferase, the key enzyme in acetylcholine synthesis; a marked loss of cholinergic cell bodies in the nucleus basalis; correlations between choline acetyltransferase reduction or nucleus basalis cell reduction and neuritic plaque densities in cortical areas; and correlation of the cholinergic deficits with the decline in cognitive test performance. Many other neuronal systems are affected besides the cholinergic one, including an equally pronounced decline in the noradrenergic projections from locus ceruleus to cortex, and there is currently greater research emphasis on the classic, amyloid neuritic plaques and neurofibrillary tangles.

Nevertheless, the observations that cholinergic deficits represent the most pronounced transmitter deficit and one of the early events in the dementia process evoked considerable focus on cholinergic restitutive strategies. The cholinergic hypothesis of dementia treatment implies that if the cholinergic deficit is responsible for cognitive or behavioral changes, then potentiation of central cholinergic function should improve cognitive and behavioral impairment associated with Alzheimer's disease. Thus far there have been three main cholinergic approaches to Alzheimer's disease treatment: the use of precursor loading, cholinesterase inhibition, and direct, cholinergic agonists. Cholinergic treatment approaches include precursor loading, direct cholinergic receptor stimulation, cholinesterase inhibition, and (potentially) the use of cholinotrophic growth factors.

Precursor Loading Early investigations focused on the use of acetylcholine precursors, including choline and phosphatidylcholine (lecithin), in analogy to the use of dopamine precursors in Parkinson's disease. Numerous trials with precursors, however, have been unimpressive and have not reliably improved cognitive function.

Direct Cholinergic Stimulation Direct cholinergic agonists enhance responsiveness to released acetylcholine and minimize the presynaptic inhibition of further release by intrasynaptic acetylcholine concentrations. Thus far, however, direct muscarinic or nicotinic receptor agonists have not proven useful in enhancing cognition in Alzheimer's disease. Neither the older nor the newer relatively more muscarinic receptor subtype-specific investigational medications such as SB 202026, melameline, xanomeline, AF102B, and Lu25-109 have proved useful under investigation. Marketed cholinergic agonists such as arecholine or bethanechol (Urecholine) cannot be recommended because they have inadequate central nervous system (CNS) penetration, a high frequency of adverse cholinergic effects, and minimal efficacy. Although nicotine and nicotinic agents, including transdermal nicotine, and newer nicotinic receptor modulators do improve attention, arousal, and concentration in adults, their usefulness in cognitive impairment syndromes such as Alzheimer's disease has not been adequately demonstrated. Although there has been some interest in the possibility that cigarette smoking may prevent the onset of Alzheimer's disease or may mitigate symptoms, the evidence is conflicting, and it cannot be recommended.

Cholinesterase Inhibitors The most common and successful approach thus far to symptomatic treatment of Alzheimer's disease has been cholinesterase inhibition. In early studies, physostigmine (Synapton) elicited modest cognitive improvements but required individualized and frequent dosing because of its short duration of action (1 to 2 hours), which limited any potential clinical usefulness. Cholinesterase inhibitors inhibit CNS acetylcholinesterase in the synaptic cleft, thus preventing the degradation of endogenously released acetylcholine. However, progressive presynaptic cholinergic neuron loss continues, so production of acetylcholine diminishes progressively over time.

The several cholinesterase inhibitors that are, or soon will be, available for treatment of the cognitive symptoms of Alzheimer's disease can be grouped into three classes according to their structure and mode of inhibition: (1) reversible tertiary and quaternary amines (e.g., tacrine, donepezil, or galantamine); (2) pseudo-irreversible carbamates (e.g., sustained-release physostigmine and rivastigmine); and (3) the irreversible organophosphate inhibitor, metrifonate (Memron). Currently, tacrine, donepezil, and rivastigmine have been approved for marketing, and New Drug Applications are pending for three (metrifonate, sustained-release physostigmine, and galantamine).

Tacrine Tacrine is a centrally acting, reversible, cholinesterase inhibitor. It was approved by the FDA in September 1993 for the symptomatic treatment of Alzheimer's disease.

CLINICAL EFFICACY Tacrine has significant effects (compared with placebo) on the ADAS cognitive subscale, clinical global assessment, and measures of daily function. In one 12-week parallel-group trial, patients receiving 80 mg improved significantly on the ADAS cognitive and clinical global ratings. In another 30-week study, 663 patients randomized to three dosage treatments showed significant treatment effects in the 120-mg and 160-mg daily dosage groups on the ADAS cognitive subscale and clinical global ratings. Other trials have generally supported these effects.

PHARMACOKINETICS Tacrine is readily absorbed orally and is cleared by the liver through first-pass metabolism. Maximum concentrations are reached within an hour. Bioavailability is approximately 17 percent but is highly variable. Half-life is approximately 2 to 4 hours, and steady-state levels are achieved in about 24 hours. Higher doses and multiple dosing can prolong its elimination half-life, and plasma concentrations are not proportional to dose. At least three active metabolites are produced, mainly by cytochrome P450 isoenzyme 1A2 (CYP 1A2) hydroxylation of the ring positions 1, 2, and 4, and subsequently undergo glucuronidation and elimination. However, the enzyme is readily saturable, so at higher, more therapeutic doses, more of the drug avoids hepatic elimination. Coadministration with food decreases bioavailability by 30 to 40 percent. Men have lower plasma concentrations than women; cigarette-smoking lowers plasma concentrations.

DOSING Optimal response occurs between 120 and 160 mg a day. Treatment is initiated at 10 mg four times a day for 6 weeks, with weekly monitoring of transaminase enzymes (specifically, alamine aminotransferase [ALT]). If after 6 weeks the patient is tolerating the treatment and ALT is less than three times the upper limit of normal (3× ULN), the dosage should be increased to 20 mg four times a day for a second 6-week period. If tolerability remains satisfactory and ALTs are below 3× ULN, then the dosage should be increased to 30 mg four times a day for a third 6-week period. Finally, the dosage is increased to 40 mg four times a day. ALT activity should be monitored within 6 weeks of the last dosing change. After this period, monitoring may be reduced to every 3 months. The management of elevated ALT activity is detailed in the package insert, but basically it requires decreasing or temporarily discontinuing medication and raising or starting it again after ALT activity returns to normal.

DRUG INTERACTIONS Since tacrine is eliminated principally by CYP 1A2, drugs that share this elimination pathway may interact with it. Theophylline (Theo-Dur) concentrations may double when tacrine is added, and cimetidine (Tagamet) will increase the peak concentrations of tacrine by about 50 percent. Importantly, the use of agents with anticholinergic actions counteracts the effects of cholinesterase inhibitors such as tacrine. These include amitriptyline (Elavil) and other tricyclic drugs,

many antipsychotics, benztropine (Cogentin), and diphenhydramine (Benadryl) among others.

Donepezil Donepezil is a piperidine-based, specific, reversible inhibitor of acetylcholinesterase, specific to brain acetylcholinesterase, with little to no effect on peripheral butyrylcholinesterase. The advantages of donepezil over tacrine are no increased transaminase overactivity, once-daily dosing, and possibly milder cholinergic adverse effects.

CLINICAL EFFICACY Two multicenter, placebo-controlled studies comparing donepezil 5 and 10 mg a day with placebo for 12 and 24 weeks, respectively, and another 24-week trial conducted in Europe together involved about 1350 patients. Both studies found statistically significant benefit in both the ADAS and clinicians' rated improvement. The 10 mg a day dosage tended to show a greater effect than the lower dosage early in the course of treatment; but both dosages are more effective than placebo. In both U.S. studies neuropsychological scores approached those in the placebo group 3 to 6 weeks after discontinuation of donepezil.

PHARMACOKINETICS Oral bioavailability approaches 100 percent, with peak concentrations in 4 hours and linear pharmacokinetics. The drug accumulates at a constant rate, reaching steady-state in about 2 weeks. It has a relatively slow clearance, with a long elimination half-life of 70 hours. It is extensively bound to plasma proteins including a_1-acid glycoproteins. It is both excreted unchanged in the urine and extensively metabolized by CYP 2D6 and CYP 3A4 hepatic enzymes to active and inactive metabolites.

DOSING Treatment should be started with 5 mg a day for 2 to 4 weeks and if tolerated raised to 10 mg a day. The efficacy or appropriateness of higher dosages has not been established.

DRUG INTERACTIONS Inhibitors of CYP 3A4 and CYP 2D6 (such as ketoconazole [Nizoral] and quinidine [Duraquin]) and inducers of CYP 2D6 and CYP 3A4 (such as phenytoin [Dilantine], carbamazepine [Tegretol], dexamethasone [Decadron], and phenobarbital [Solfoton]) could either inhibit donepezil metabolism or increase its rate of elimination, but this is not known and may not be clinically significant in view of its high protein binding and very low therapeutic concentrations of 2 to 12 ng/mL.

Rivastigmine Rivastigmine is a pseudo-irreversible, carbamate, selective acetylcholinesterase subtype inhibitor. It is characterized by its selective binding and inactivation of acetylcholinesterase subtypes in specific regions of the brain. It is approved in several countries and is currently being reviewed by the FDA for marketing approval in the United States.

CLINICAL EFFICACY Four placebo-controlled trials of 6-month duration, using both fixed and adjustable doses and involving 2800 patients, many with concomitant illnesses and taking multiple medications, showed significant effects on cognition, ADAS, clinical global impression, and functional activities.

PHARMACOKINETICS Rivastigmine is well absorbed; very little binds to protein. Although the elimination half-life is less than 2 hours, enzyme inhibition lasts approximately 9 hours. Rivastigmine is not metabolized by the hepatic microsomal system. Rather, after binding to acetylcholinesterase the carbamate portion of rivastigmine is slowly hydrolyzed (hence, the pseudo-irreversibility), conjugated to a sulfate, and excreted renally.

DOSING The recommended starting dosage is 1.5 mg, increased to 3 mg twice a day after 2 weeks and to 4.5 mg twice a day if necessary.

DRUG INTERACTIONS Rivastigmine's metabolism does not depend on liver P450 enzymes; therefore no drug interactions related to the P450 system have been observed.

Metrifonate Metrifonate is a prodrug without intrinsic activity that is nonenzymatically converted to 2,2-dimethyldichlorovinyl phosphate (dichlorvos, [DDVP]), which has a long duration of cholinesterase inhibition. Since 1967 it has been used to treat schistosomiasis, largely in developing countries. It was approved for marketing in July 1998. DDVP is marketed as Trichlorfon, an agricultural insecticide.

CLINICAL EFFICACY Two 6-month, placebo-controlled, phase III studies showed significant cognitive effects and improvements in severity and clinicians' global impressions, with the typical expected cholinergic symptoms.

PHARMACOKINETICS Metrifonate is readily absorbed and has linear pharmacokinetics. Clinical response has been associated with extent of cholinesterase inhibition rather than drug concentration. Approximately 2 percent of the maximal concentration of the active drug (DDVP) reaches the CNS, suggesting a considerable blood-brain barrier or a rapid metabolism that limits accumulation in the CNS. The red blood cell cholinesterase inhibition half-life is nearly 2 months, and thus it is considered essentially irreversible.

DOSING No recommended approved dosage has been determined, but it is likely to be approximately 50 mg a day. Metrifonate is currently under review by the FDA. Recently, it was discontinued from all of the approximately 3000 subjects receiving it because of concern about the development of myasthenia and respiratory failure in a small number. It remains to be seen whether or not metrifonate will be approved.

Galantamine Galantamine (Reminyl) is an investigational cholinesterase inhibitor that also has nicotinic modulating effects. Early studies suggest that it is about as effective as other cholinesterase inhibitors. It is marketed in several European countries.

Adverse Effects of Cholinesterase Inhibitors As expected, the most common adverse effects of cholinesterase inhibitors involve those related to cholinergic excess, including nausea, vomiting, diarrhea, dyspepsia, anorexia, fatigue, and weight loss. In addition myalgia or muscle cramps occur in approximately 7 to 9 percent of patients, indicating direct myoneural effects (but not with rivastigmine, which specifically inhibits only certain CNS acetylcholinesterase subtypes). The frequency of the cholinergic adverse effects generally is less than 15 percent and often no greater than that with placebo in clinical trials. In general, they tend to be mild and short-lived (less than 2 or 3 days) and tend to occur when dosage is increased. Medication dosage can usually be maintained or temporarily lowered and then raised. Fatigue also tends to occur and occasionally there is an observable decrease in heart rate of 4 to 7 beats per minute, possibly due to enhanced vagal effects.

Direct hepatotoxicity is associated only with tacrine and is the most common abnormal finding with this drug. Approximately 30 percent of patients have aminotransferase activity exceeding three times the upper limits of normal, with the extent of the elevation correlating with the degree of hepatocyte injury. The elevations tend to occur about 5 to 7 weeks after the start of treatment; 95 percent occur within the first 12 weeks. The ALT elevations tend to be transient and return to normal within 6 weeks. Women are more likely to develop this than are men. Although no hepatic failure or hepatic deaths have been attributed to tacrine, patients taking tacrine need to be monitored weekly during the dose-titration phases.

Contraindications There are relatively few absolute contraindications to cholinesterase inhibitors, and they relate to the unique chemical properties of each drug. Donepezil is contraindicated in patients with hypersensitivity to piperidine derivatives. Information on interactions and contraindications of metrifonate are unavailable currently. Relative contraindications include potentially any illness that might be exacerbated by a cholinergic drug, such as asthma, pulmonary disease, and gastrointestinal ulcer disease.

Clinical Application and Treatment Implementation for Cholinesterase Inhibitors Currently, donepezil is probably the medication of choice since it has a simpler titration schedule than tacrine and no potential for hepatotoxicity. Extensive postmarketing experience with donepezil has revealed no serious adverse events. As newer cholinesterase inhibitors become available their differential pharmacology will require more-complex treatment decisions. These medications have only been demonstrated to be effective in outpatients with mild-to-moderate Alzheimer's disease (Mini-Mental State Examination score between 10 and 26). Many experts believe that efficacy is also apparent in both the more mildly and more severely cognitively impaired.

DURATION OF TREATMENT AND DISCONTINUATION Clinical trials with cholinesterase inhibitors have lasted only 6 months. In some trials, when medication is discontinued patients return within 3 to 6 weeks to the cognitive level of those who received placebo, indicating an overall symptomatic effect. Thus treatment with cholinesterase inhibitors needs to be somewhat longer than 6 months, but the overall duration is not known. One observational study with tacrine suggested that patients receiving more than 30 mg four times a day survived in the community and avoided nursing home placement for considerably longer than patients receiving 20 mg four times a day. Discontinuation of cholinesterase inhibitors has been associated with marked worsening of cognition and occasional episodes of confusion;

therefore tapering is recommended.

OTHER COGNITIVE ENHANCERS

Although cholinesterase inhibitors have been the most studied class of medications for Alzheimer's disease, a broad range of other drugs and supplements are either available for prescribing in some countries or currently undergoing clinical trials.

MONOAMINE OXIDASE TYPE B INHIBITORS

Propentophylline Propentopylline is a xanthine derivative that inhibits both adenosine uptake and phospodiesterase. Increased intrasynaptic adenosine concentration may reduce excitatory amino acid transmission associated with neurotoxicity. In addition, it may stimulate nerve growth factor (NGF), a cholinergic trophic factor, and inhibit free radical production that may be neurotoxic. In clinical trials over 6 and 12 months, patients with Alzheimer's disease or vascular dementia showed better in cognitive and global function than those receiving placebo. Phase III trials are ongoing.

Ergoloid Mesylates Ergoloid mesylates, the longest-used, putative cognition-enhancing drug, is still one of the more commonly prescribed drugs worldwide. It is not commonly prescribed in the United States because of lack of efficacy. It is currently used primarily for patients with dementia, age-associated cognitive symptoms, or just memory complaints. The agent has mixed and complex actions on central a-adrenergic, dopaminergic, and serotonergic receptors.

The FDA reviewed and approved ergoloid mesylates in 1978 and previously for “idiopathic decline in mental capacity” at dosages of 3 mg a day. Although numerous randomized, double-blinded, placebo-controlled clinical trials in a variety of elderly patient populations generally yielded positive effects, the studies are difficult to interpret because of such methodological limitations as inadequately diagnosed and clinically heterogeneous subjects, overreliance on a particular outcome instrument (the Sandoz Clinical Assessment Geriatric), a focus on improvement of individual behavioral symptoms, lack of attention to cognitive outcome, and variable doses and study durations. The clinical meaning of the results is unclear.

Nootropics The term nootropic is derived from the Greek *noos*(mind) and *troepin* (forward). The nootropics are a drug class with diverse actions and are structurally related to piracetam. They are cyclic analogues of g-aminobutyric acid (GABA) and are also related to glutamate, an excitatory amino acid. In addition to piracetam, they include oxiracetam, pramiractam, and aniracetam. These agents may protect the CNS from potential damage from hypoxia or drug intoxication. Nootropics may enhance the CNS microcirculation by reducing platelet activity and adherence of red blood cells to vessel walls. They may improve memory and learning, but no antidementia mechanism has been established. Clinical trials of nootropics in patients with Alzheimer's disease cannot be interpreted because they have not used accepted rigorous diagnostic criteria. Nootropics, however, are marketed for the treatment of dementia and cognitive impairment in many countries other than the United States. Some evidence suggests efficacy in attention-deficit disorder.

MEDICATIONS TO SLOW THE CLINICAL PROGRESSION OF ALZHEIMER'S DISEASE

Treatments for dementias exist that might slow neurodegenerative processes. Atypical inflammatory responses, the production of oxidizing free radicals, and deposition of insoluble and possibly toxic b-amyloid are part of the neurodegenerative process. Therefore, anti-inflammatories and antioxidants might have a role in the treatment of progressive dementias. The neurotrophic and cholinergic properties of estrogens may be useful in women.

Anti-Inflammatories Patients with rheumatoid arthritis who received long-term anti-inflammatory treatment had a lower risk for Alzheimer's disease than controls without rheumatoid arthritis. Twins who used anti-inflammatory medications had a lower risk for Alzheimer's disease than their cotwins: The risk of Alzheimer's disease was reduced in a cohort of people using anti-inflammatories. A placebo-controlled trial of indomethacin (Indocin) supports a potential role for at least nonsteroidal anti-inflammatory drugs. A 1-year, placebo-controlled trial of low-dosage prednisone (10 mg a day) by the National Institute on Aging (NIA) Alzheimer's Disease Consortium showed no advantageous effect, however. Because of gastrointestinal and other potential adverse effects from anti-inflammatory agents, the newer anti-inflammatory cyclo-oxygenase-2 inhibitors may offer promise, and such trials are ongoing.

In the absence of efficacy trials and considering their adverse effects nonsteroidal anti-inflammatory drugs (NSAIDs) cannot be recommended for either prophylaxis or treatment of Alzheimer's disease. Because of media attention and their availability over-the-counter and by prescription, some patients or caregivers may use or request them from physicians, but no clear guidance can be given. Effective dosage ranges are not known. Adverse effects including gastrointestinal bleeding are common, especially with long-term use.

Estrogens Estrogens may improve cognitive function through cholinergic neuroprotective and neurotrophic effects. For example, estradiol replacement enhances learning in ovariectomized rats; it also increases choline acetyltransferase and acetylcholine concentrations after ovariectomy. Clinical evidence of a possible effect of estrogen replacement therapy includes an inverse relationship between estrogen replacement therapy and death-certificate diagnoses of dementia, several case-control and cohort studies in which 40 to 50 percent reductions in the risk of developing Alzheimer's disease were reported, and several clinical reports suggesting that estradiol, estrone, and conjugated estrogens enhance cognitive function in patients with Alzheimer's disease. Furthermore, estrogen replacement therapy might augment the response to cholinesterase inhibitors such as tacrine. Adverse effects of estrogen replacement therapy are generally dose dependent and include endometrial hyperplasia and cancer, uterine bleeding (when taken with a progestin), breast tenderness, and nausea, among others. Because of the enhanced relative risk for endometrial cancer, periodic administration of progestins is recommended for women with intact uteri.

The evidence for estrogen replacement therapy is stronger for a protective effect than for a symptomatic one. An ongoing NIA-sponsored clinical trial is assessing the effect of conjugated equine estrogens (Premarin) on cognition in women with Alzheimer's disease. Another ongoing trial is assessing whether hormone replacement therapy delays onset of Alzheimer's disease (National Institute of Health Women's Health Initiative). In summary, a possible role for estrogen replacement therapy appears promising but is not substantiated.

Antioxidants Vitamin E (a-tocopherol, 1000 IU a day) or selegiline (5 mg twice a day) given alone to a group of moderately impaired patients with Alzheimer's disease delayed the time until patients required nursing home placement, died, or lost their ability to perform activities of daily living. Overall the time to these endpoints was approximately 7 months longer than with a placebo. There were no effects on cognition on this group of patients who were more severely impaired than those in other studies. Adverse effects included falls and syncope in selegiline patients (9 and 10 percent, respectively), a-tocopherol (14 and 7 percent), and the combination (22 and 16 percent). A subsequent 12-month placebo-controlled trial of transdermal selegiline in patients with milder Alzheimer's disease however, revealed no significant effects overall. The former is the only study assessing the potential efficacy of Vitamin E, and the sample size was small. Nevertheless, these results are promising, especially in light of the few adverse effects reported. Currently, no information exists concerning any prophylactic effects of these interventions.

Adjunctive and Combination Therapy It is not known whether combining medications such as cholinesterase inhibitors with other drugs increases efficacy. Pilot studies comparing combinations of cholinesterase inhibitors with drugs such as selegiline suggest only their feasibility, not efficacy. The combination of selegiline and vitamin E did not confer any added benefits over either agent alone in one study. Theoretically combining cognition-enhancing drugs with complementary mechanisms of action might be more useful than monotherapy. Consequently, many experienced clinicians may judiciously apply combination therapy.

VASCULAR DEMENTIA

Vascular dementia is a heterogeneous disorder and etiology must be considered. Some vascular dementia may be due to larger vessel stroke and sequellae, other to small vessel disease and ischemia. Potential interventions can be conceptualized as preventutive, disease modifying, or symptomatic. Hypertension is a significant risk factor for stroke and vascular dementia. Effective treatment of hypertension and hypercholesterolemia reduces cerebrovascular morbidity and mortality. Warfarin (coumadin) and aspirin seem to reduce the risk of stroke in patients with atrial fibrillation. Ticlopidine (Ticlid), aspirin, and dipyridamolc (Persantine) may prevent future stroke in patients with transient ischemic attacks or ischemic stroke. Antiplatelet agents may prove effective in preventing further vascular damage preceding and during dementia. Agents that reduce damage after stroke may be relevant to vascular dementia, including thrombolytic agents, calcium- and sodium-channel antagonists, *N*-methyl-D-aspartate (NMDA) receptor antagonists, glutamate synthesis inhibitors, glutamate-release inhibitors, GABA antagonists, gangliosides, aminosteroids, antioxidants, growth factors, and antiapoptotic agents. The efficacy of these agents in vascular dementia patients remains to be determined. Nimodipine (Nimotop), a calcium channel blocker, may improve the outcome of ischemic stroke when administered early in its course and may also improve cognitive function in some patients with dementia.

Treatment Once vascular dementia occurs, control of risk factors for stroke could help prevent further cognitive decline. Clinical observations suggest that among vascular dementia patients with hypertension, those with better cognition had systolic blood pressure above 135 mm Hg, and those who deteriorated had lower systolic blood pressure, and daily aspirin (325 mg) improved or stabilized cognition. Cessation of smoking and control of blood lipids may also be associated with improved cognition.

Metabolic or anti-ischemic approaches may be helpful. These include pentoxifylline (Trental), a hemorrheological agent; propentopylline, a phosphodiesterase inhibitor with neuroprotective properties, and nimodipine, a calcium channel blocker. Other classes of agents currently under consideration include glutamate antagonists, cholinergic enhancers, and cholinesterase inhibitors. The rationale for the latter involves the commonality of mixed vascular domentia and Alzheimer's disease and shared pathophysiological mechanisms between the two.

FUTURE DIRECTIONS

Current treatment options for Alzheimer's disease include the cholinesterase inhibitors tacrine and donepezil. Rivastigmine and galantamine may be available soon. Cholinergic agonists have not proved successful. Other drugs that affect the cholinergic system are in development. Antioxidants, selegiline, anti-inflammatories, and estrogens are marketed worldwide, not for the treatment of cognitive deficits and are not indicated for dementia, and their efficacy remains unproved. Although no currently available antidementia treatment has dramatically improved the cognitive impairments of Alzheimer's disease, the improvements are nonetheless clinically meaningful and considerable. The efficacy of these treatments for other cognitive disorders remains to be established. Worldwide research and development efforts offer promise of more effective approaches in the future.

SUGGESTED CROSS-REFERENCES

Biological therapies are the subject of Chapter 31. Other aspects of geriatric psychiatry can be found in the other sections of Chapter 51. Section 51.3e provides a broad discussion of Alzheimer's disease and other dementing disorders.

51.4 TREATMENT OF PSYCHIATRIC DISORDERS

51.4G ELECTROCONVULSIVE THERAPY

DONALD P. HAY, M.D., ELSA M. ZAYAS, M.D., AND GEORGE T. GROSSBERG, M.D.

First described by Ugo Cerletti and Lucio Bini in 1938, electroconvulsive therapy (ECT) has been used effectively to treat a variety of mental disorders in elderly adults. ECT is frequently misunderstood and feared by both health professionals and the lay public. In elderly adults, ECT is a safe and effective treatment for affective disorders, major depression (especially delusional depression), mania, schizoaffective disorders, and movement disorders and dementia with behavioral disturbances.

In the 1940s and 1950s ECT was used widely to treat many disorders. Its use declined with the advent of psychopharmacological agents. The last decade has seen a resurgence in the use of ECT. It is safe and effective, especially in elderly persons, who may be particularly sensitive to medication adverse effects and who may have comorbid medical problems.

HISTORY

ECT has undergone modifications since it was first introduced. These include the use of anesthesia, neuromuscular blocking agents, oxygenation, and electroencephalographic (EEG) and cardiovascular monitoring. The technique itself has been modified by the use of variable electrode placement and pulsed square-wave stimulation apparati. Successful use of this high-technology treatment now requires a team approach that includes the patient and family, the treating psychiatrist, the primary care physician, the anesthesiologist, and other specialists when appropriate.

EDUCATION

Mental illness in elderly adults poses both diagnostic and treatment challenges. Patients and their families must understand that ECT is safe and effective. The advantages of ECT should be discussed with the patients and their families, who must understand that concomitant medical illnesses and conditions can interfere with the safe and effective use of medications, and that severe and debilitating psychopathology necessitates a rapid treatment response. A psychiatrist or other well-informed mental health professional with expertise in the field can answer questions and alleviate concerns and misconceptions.

THEORETICAL ISSUES

The mechanism of action of ECT remains theoretical. Induction of a generalized seizure by electrical stimulation of the brain has been considered necessary for therapeutic efficacy. Traditionally it was thought that to be effective seizures needed to last at least 25 seconds peripherally and 40 seconds centrally, and although generally clinically correct, this concept is being reexamined.

Noradrenergic, serotonergic, and g-aminobutyric acid (GABA)-ergic neurotransmitters are believed to play a role in the efficacy of ECT. Animal studies with electroconvulsive shock have noted changes in serotonergic, GABAergic, and noradrenergic neurotransmission. Dopaminergic system involvement is indicated by the positive response of motor symptoms of Parkinson's disease and other movement disorders to ECT.

TECHNIQUES

Pre-ECT Evaluation The elderly individual with comorbid psychiatric and medical conditions must be carefully evaluated when one is considering ECT. Assessment includes the patient's medical history, the presence of a prior psychiatric illness, a prior response to medications, and a prior response to treatment with ECT.

The patient's cognitive status should be carefully assessed initially and monitored during the course of treatment. Cognitive functioning (especially short-term memory) should be evaluated prior to subsequent treatments in a series. One can use any standardized cognitive assessment scale such as the Mini-Mental State Examination. Any significant cognitive changes from baseline may require discontinuation of treatment. Cognitive impairment per se should not be a contraindication to the use of ECT. An ECT record sheet may be helpful to record and monitor the cognitive status of patients during their index series and continuation or maintenance ECT (Table 51.4g-1). The ECT record sheet should include the patient's identifying information, diagnosis, current medications and dosages (psychotherapeutic and nonpsychotherapeutic medicine), NPO status of the patient from the night before, removal of dentures, any recent acute medical problems, and a notation of heart and lung auscultation. The record sheet should also include the medications used before, during, and after the procedure, and it should have a place to record vital signs (blood pressure and pulse) prior to stimulus application and during the seizure as well as the peak vital signs and the posttreatment values.

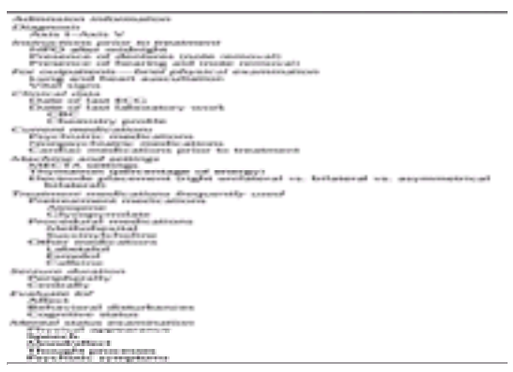

Table 51.4g-1 Components for ECT Record Sheet

The ECT record sheet should also include monitoring of the affective symptoms (A), behavior (B), and cognitive functioning (C) (termed the ABCs of geriatric psychiatry) to guide the treatment course and monitor response.

Evaluating the risk-benefit ratio by assessing affect, behavior, and cognitive symptoms helps the physician determine when it is advisable to initiate, continue, or

terminate treatment. One should evaluate the benefits and the potential risk for each patient prior to a treatment. For example, if a patient is at high risk because of cardiac disease or an arrhythmia but the benefits are high, one would proceed with the treatment after consultation with a cardiologist and anesthesiologist. If a patient is at high risk and the benefits of treatment are low, one would not proceed. Not giving the treatment may at times be more potentially dangerous than giving it.

INDICATIONS

The indications for ECT in elderly adults are the same as those for younger patients. The principal indications for ECT described in the American Psychiatric Association (APA) Task Force Report are mood disorders, schizophrenia and disorders with an affective component, catatonia, and schizoaffective disorder. Mood disorders including depressive disorders with or without melancholic features, depressive disorders with psychotic symptoms, and mania also all respond to ECT. ECT is effective and safe in elderly persons with comorbid medical conditions that may place them at a higher relative risk. Catatonia has been reported to be successfully treated with ECT and should be the treatment of choice for patients who do not respond favorably to antipsychotic agents or antidepressants. In addition, ECT can be effective treatment for the signs and symptoms of the movement disorder of Parkinson's disease, with or without comorbid depression.

Patients who are suffering from depression with comorbid cognitive deficits have also been reported to respond favorably to ECT. When the cognitive impairment is a direct result of the affective disorder, both the affective and the cognitive symptoms frequently respond to a course of ECT without a worsening of the patient's cognitive functioning. Patients suffering from poststroke depression may benefit from a course of ECT. ECT is an effective treatment for patients with agitation secondary to dementia.

RISKS

There is no absolute contraindication to the use of ECT. In considering the use of ECT, one must weigh the risk-benefit ratio of giving the treatment versus the risk-benefit ratio of not giving the treatment. Increased intracranial pressure is a relative contraindication to the use of ECT.

Elderly patients frequently have comorbid cardiovascular disease and may be at increased risk of suffering adverse effects from psychotropic medication. Despite the presence of comorbid cardiac disease, ECT has reportedly been used safely in this population. The most frequent complications found in patients with cardiovascular risk factors who received ECT were ventricular arrhythmias, ischemic events, atrial arrhythmias, and sinus bradycardia.

ECT can be safely administered to patients receiving anticoagulant therapy, and those with heart valve prostheses and preexisting cardiac arrhythmias, but a cardiology consultation should be obtained. These patients should continue taking their cardiac medications and should take their blood pressure medications before a treatment. Medications administered during the treatments are similar to those used in younger adults: methohexital (Brevital), succinylcholine (Anectine), glycopyrrolate (Robinul), esmolol (Brevibloc), labetalol (Normodyne), or caffeine. The concurrent medications that the patient is receiving should be evaluated. Some medications should not be administered during a course of ECT. It is recommended that lithium (Eskalith) be avoided during a course of ECT because of the increased risk of delirium. Theophylline (Theo-Dur) has been reported to prolong seizure duration, leading to status epilepticus. It has been recommended that patients on theophylline be switched to inhaled bronchodilators prior to treatment. One study reported seven patients who received ECT safely while receiving theophylline; however, these authors recommended that theophylline concentrations should be low or that theophylline not be coadministered with ECT.

Benzodiazepines have anticonvulsant properties and the literature suggests that they can shorten seizure duration and decrease treatment efficacy, particularly in unilateral ECT. Benzodiazepines should be avoided whenever possible. If a patient requires benzodiazepines, consider using short-half-life benzodiazepines and do not administer them immediately before treatment. Benzodiazepines should be tapered as much as possible before and during treatment series.

ASSESSMENT

Patients being considered for ECT should undergo the same evaluations as their younger counterparts, outlined in the American Psychiatric Association Task Force Report. These recommendations include (1) a psychiatric evaluation to establish the indication for ECT and (2) a complete medical evaluation including the history of the present illness, a complete physical examination, chemistry profile, cellular blood count, chest X-ray film, and electrocardiogram. Neuroimaging or a neurology consultation should be obtained when indicated by clinical findings.

Careful attention should be paid to orthopaedic status of elderly adults. Spinal films, once routinely recommended, are now obtained only when an adequate reason for concern exists, such as the possibility of compression or other fractures, osteoporosis, or spinal degeneration, especially if accompanied by pain. These conditions may require special considerations (including increasing the dosage of succinylcholine and carefully evaluating the degree of muscle blockade). Elderly patients frequently require an anesthesia consultation before treatment is initiated. In addition, comorbid medical conditions may prompt the treating psychiatrist to obtain other consultations (e.g., a cardiology consultation for an apparent cardiovascular risk or a pulmonary consultation for a patient with chronic obstructive pulmonary disease [COPD] or asthma). Elderly patients frequently have poor dentition (e.g., missing or loose teeth) that may pose potential treatment problems. A dental consultation may be warranted. Dentures should be removed prior to ECT unless they are sturdy and their removal would be more damaging or pose a greater danger to unprotected single or few teeth.

Informed consent is frequently a most difficult and challenging aspect of the treatment of elderly patients. Patients should be assessed for their capacity to give informed consent, since an elderly patient's cognitive status may be limited by either depressive symptomatology or by comorbid cognitive impairment. The patient and family need to be told about ECT, including the procedure, the risks and benefits, the possible adverse effects, and the mortality risk (see below). The family and the patient should be encouraged to openly discuss their fears and concerns. In most states in the United States, if the patient cannot give informed consent, a court order is required. Treating psychiatrists should become familiar with the regulations that govern ECT in their state.

ADVERSE EFFECTS

The mortality rate associated with ECT is approximately the same as that for anesthesia alone, approximately three or four deaths per 100,000 treatments or one death per 10,000 patients treated (or per 40,000 treatments). Cardiac complications with ECT include arrhythmias, T wave and ST segment changes, ischemic events, atrial arrhythmias, and sinus bradycardia. Post-ECT arrhythmias can be treated with lidocaine, and atropine can be use to treat bradyarrhythmias. Lidocaine (Decadron) should be avoided pre-ECT as it reportedly increases seizure thresholds, thereby inhibiting seizure induction.

Although relatively rare, central nervous system adverse effects can include interictal confusion that can persist on the days that patients do not have a treatment. Patients most likely to develop interictal confusion have been found on magnetic resonance imaging (MRI) to have subcortical white matter and basal ganglia lesions that preceded the ECT. Patients also may infrequently experience prolonged seizures or status epilepticus that may be treated with either further administration of the same barbiturate anesthetic used during ECT or benzodiazepines such as diazepam (Valium) and or lorazepam (Ativan), which can be given intravenously. However, benzodiazepines increase the risk of falls. Postictal excitement characterized by motor agitation, disorientation, and poor response to commands is reported to occur in 12.5 percent of patients. The usual treatment is intravenous benzodiazepine, although this may be avoided by increasing the pretreatment anesthetic dosage. ECT produces no structural brain changes.

Cognitive impairment or memory loss is a more frequently cited adverse effect of ECT, by far the adverse effect most feared by patients and family. Cognitive changes in elderly patients involve decreased orientation, attention, calculation, and recall. Cognitive adverse effects are frequently related to the form of ECT administered, including electrode placement, electrical dosage, stimulus wave form, and preexisting cognitive impairment. Bilateral electrode placement is associated with more persistent and severe memory impairment. In contrast, unilateral electrode placement is associated with fewer complaints of memory loss. Memory impairment increases in severity as a function of the number of treatments received. ECT may interfere with memory consolidation, with the most recently acquired information being the most vulnerable.

A newer technique for electrode placement, described for use especially in elderly patients, is a position termed “asymmetrical bilateral.” In this method, one electrode is placed above the left eye, with its lateral edge bordering the intersection between the forehead and the temple, while the right-sided electrode is placed in the standard frontotemporal position. This method has been used effectively and safely in elderly patients, with minimal cognitive adverse effects.

There may be an increased risk of post-ECT falls in elderly patients, which may result in other complications such as hip fractures. Patients should be closely monitored for post-ECT gait dysfunction or falls. Post-ECT headaches have also been noted. One retrospective study found that 5.5 percent patients developed

new-onset headaches, while 31 percent of patients who had a previous history of headaches reported worsening. Headaches can be treated symptomatically.

MEDICATIONS

Pretreatment with an anticholinergic medication is recommended to decrease the effect of parasympathetic discharge on the heart immediately after the delivery of the electrical stimulus. In elderly adults, b-adrenergic receptor antagonists (e.g., esmolol and less frequently labetolol [Normodyne]) are frequently used during a treatment to minimize changes in heart rate or blood pressure. Administration of a b-adrenergic receptor antagonist without prior administration of an atropinic medication may result in bradyarrhythmias. The most frequently used atropinic agents are glycopyrrolate and atropine. An atropine synthetic (glycopyrrolate) is preferable because it does not cross the blood-brain barrier and is thus reportedly less likely to cause postictal confusion in this potentially vulnerable population.

b-adrenergic receptor antagonists may be used pre-ECT in patients with known cardiac risk factors. Some authors have concluded that esmolol can effectively control the hyperdynamic response to ECT. Of concern is the rate-pressure product (i.e., the cardiac rate times the systolic blood pressure). A rate-pressure product above 20,000 may indicate ischemia in a significant number of elderly patients. The rate-pressure product can be controlled by lowering either component. Esmolol (duration of action, 3 to 5 minutes) can lower the rate as effectively as labetolol (duration of action, 3 to 5 hours).

The anesthetic agent of choice for ECT in elderly adults is methohexital, usually given at a dosage of 1 mg/kg. Methohexital reportedly results in rapid recovery of consciousness, is 2.5 times more potent than thiopental, and induces fewer arrhythmias than thiopental. Etomidate is safe and well tolerated when used for ECT. Seizure duration is longer with etomidate than with thiopental but is equivalent to that with methohexital.

Succinylcholine is the muscular blockade agent used most frequently in ECT. After the anesthetic induction is completed, a lower extremity should be cuffed off with a blood pressure cuff prior to the administration of succinylcholine to be able to visually monitor seizure activity. One should observe the patient for fasciculations, which may take longer in elderly patients whose circulation time is frequently slower. Complete paralysis can be determined by testing for absence of a patellar deep tendon reflex or absence of facial or radial nerve reflexes with a hand-held nerve stimulator.

Seizure duration during a course of ECT may become too brief for clinical benefit. Using higher-energy stimulation in elderly patients may increase the risk for adverse events. Caffeine given as an intravenous bolus can prolong the seizure. Caffeine augmentation has not been associated with significant cardiovascular or cognitive effects. During each treatment the patient should be well oxygenated. Patients should be continuously monitored cardiovascularly with an electrocardiogram recording, blood pressure monitoring, and a pulse oximeter.

Electrode Placement Electrode placement can be bilateral or unilateral nondominant, which in most patients is right unilateral, or asymmetrical bilateral, sometimes used in elderly patients to try to minimize the cognitive effects of ECT. Bilateral ECT is more powerful than right unilateral ECT and is associated with more memory impairment. The seizure threshold increases with age and reportedly increases 47 percent on average from the first to the sixth treatment, which requires adjustment of energy settings. Older patients have shorter seizure durations. Debate currently exists in the literature concerning whether other parameters of ictal EEG such as the postictal amplitude and immediate poststimulus spectral amplitude may be more indicative of efficacy than seizure duration.

In 1990 the APA Task Force on ECT recommended that stimulus intensity be adjusted to the individual needs of each patient. Two different empirical procedures have been used to arrive at the stimulus intensity, the fixed dose and the stimulus titration methods. The fixed dose is empirically derived on the basis of the patient's age. In the stimulus titration method a series of stimuli is given to estimate seizure threshold. Both methods have been used in elderly adults, but there are concerns that the titration method may induce subconvulsive seizures that could potentially result in such cardiac effects as bradyarrythmias or asystole. This is of special concern in those with comorbid cardiovascular risk factors.

FREQUENCY OF TREATMENT

The frequency of treatments varies from three times per week in North America to twice weekly in Great Britain. Usually between four and nine treatments are required for efficacy of an index series in elderly patients. The number of treatments in a series is determined by the patient's response. Relief of symptomatology is weighed against any evidence of confusion or cognitive impairment.

CONTINUATION AND MAINTENANCE ECT

After patients have had an effective course of ECT, one should consider the option of continuation ECT (given in the first 6 months after an index series) or maintenance ECT (continuing longer than 6 months after the index series). Frequently these patients have not responded to medication or have a higher risk of experiencing adverse effects. Harold Sackeim found in a prospective study that the patients more likely to relapse after ECT were those treated after ECT with the medication they had previously failed to respond to or they had received an inadequate trial. The literature reports that 50 percent of patients not treated with medications post-ECT relapse within the first 6 months following an index series of therapy. This relapse rate is not related to the length of the initial index episode or to the number of prior episodes of affective disorder. Patients who received continuation ECT following an index episode were less likely to have relapsed at 5-month follow-up. A course of continuation ECT is recommended for treatment-resistant patients or those who may be at an increased risk for medication adverse effects. Maintenance ECT is reported to be a safe, well-tolerated, efficacious treatment with minimal adverse effects, especially for elderly or psychotic patients.

Ambulatory ECT is becoming a primary mode of treatment, with increasing numbers of patients receiving ECT in an outpatient setting. The Association for Convulsive Therapy Task Force on Ambulatory ECT has established criteria recommending inpatient ECT based on diagnosis and for patients who may be at increased risk for medical complications.

The first index treatment is frequently administered to an elderly patient while the patient is hospitalized, to minimize the possibility of medical complications. The procedure for ambulatory ECT should be the same as that for inpatient ECT. Ambulatory ECT should involve a team consisting of the treating psychiatrist, an anesthesiologist, and the nursing staff. Caregivers for elderly individuals are integral partners in ambulatory ECT; they are responsible for communicating to the team any pretreatment considerations, administering pretreatment medications and managing the patient posttreatment (including driving). Caregivers should accompany the patient for the treatment because patients are not allowed to drive to and from the treatment.

RESEARCH AND EVALUATION

The safety and efficacy of ECT in elderly patients has been demonstrated repeatedly. Research continues in the areas of treating patients with comorbid medical conditions, and novel uses for ECT (e.g., treatment of chronic pain). Research and development of new protocols for ambulatory ECT is ongoing. Furthermore, interest is growing in the legal aspects of ECT, especially in the areas of physician privileging, the patient's capacity to give informed consent, and the legal statutes that govern treatment.

SUGGESTED CROSS-REFERENCES

Schizophrenia is presented in Chapter 12 and schizophrenia in the elderly in Section 51.3f. Mood disorders are covered in Chapter 14 and mood disorders in elderly patients in Section 51.3d. A more general discussion of ECT is presented in Sections 31-33. Basic electrophysiology is discussed in Section 1.9.

51.4 TREATMENT OF PSYCHIATRIC DISORDERS

51.4H PSYCHOSOCIAL TREATMENTS: GENERAL PRINCIPLES

JOEL SADAVOY, M.D., F.R.C.P.(C)

Psychotherapy of elderly persons comprises several modalities and is applied to a heterogeneous array of patients. Psychotherapy is delivered within a social context that differs for each of these elderly individuals and has an important influence on treatment that must be considered individually.

Regardless of the type of psychotherapy used, therapists for aged patients must understand, acknowledge, and incorporate into the treatment the array of psychosocial factors that form the context of the patients' problems and the matrix of the patients' life, within which they are supported or fail. In psychodynamic terms, this matrix may be viewed as the holding environment, the adult version of what parents provide an infant. As with children, when the holding environment fails to support and enhance, the individual comes under psychological stress. Persons in their environment are reflected in the environments within the persons. Psychotherapists will be most helpful and effective when they work simultaneously with both the external and internal worlds of elderly patients.

DEFINITION

The term “psychosocial” refers to social and environmental elements in individuals' lives that interact with their intrapsychic processes. Such elements include interpersonal relationships, role functions, societal attitudes, economics, physical environment, culture and ethnicity, and spiritual beliefs.

RELATIONSHIPS

Old age assaults the integrity of the patient's social network. Perhaps most profound are the changes associated with spousal bereavement, producing sudden role change, isolation, abandonment, economic disruption, and altered interpersonal relationships. Beyond bereavement, marital relationships also are changed by physical or cognitive impairment that shifts patterns of dominance and responsibility. For example, the basic nurturing role previously carried out by a loving wife now falls into the unaccustomed hands of her husband in the face of her decline with Alzheimer's disease. He experiences not only loss but the need to offer comfort and care, behavior and feelings with which he has always been awkward. Guilt, resentment, and some anger emerge as a consequence.

Intimacy similarly shifts, often toward distance and isolation. Friendships easily maintained during younger, more active years often become more difficult to sustain. Driving is more challenging, evening and night travel more fearsome, and gathering places less welcoming and accommodating. Illness and other age-related events such as bereavement take their toll on friendship networks. Hence, even for those with naturally outgoing personalities, the avenues for establishing and maintaining new friendships are often blocked. Like Swiss cheese, friendship networks become riddled with holes that gradually coalesce over time. One effect is the erosion of relationships in which old persons' history, accomplishments, desires, and ambitions are known by their friends. Increasingly, aging fragments and isolates, uncontrollably and inexorably. While certainly not universal, this process of change contributes to creating an atmosphere during psychotherapy of elderly persons, a context imposed by old age on the therapeutic process. Old patients, often through no fault of their own and despite their efforts, present with a burden of aloneness. This can create in therapists the anxious sense that they must do more than treat—respond to an unspoken request for friendship and become for the patient the only place and person to offer a safe, intimate, emotional haven.

Beyond friendship, sexual and other physical intimacy may vanish from the life of the old person, leaving no one to touch or be touched by. The literature suggests that sexuality among elderly persons can remain vibrant and pleasurable; however, over a certain age, elderly persons are often widowed and without partners. Hence, for example, intimate touching may then become the domain of the medical encounter during physical examination or the nonsexual hugging of children, grandchildren, or friends. Physical isolation becomes especially evident in retirement or nursing homes or other institutions where predominantly old women live in an unusually gender-homogenous environment. Whatever sexual or intimate interest remains is put in cold storage, often forever. Psychotherapists and other caregivers must be sharply aware of the patient's needs and reactions under these circumstances, elicit the impact on the patient, and incorporate the reality into the treatment, working toward either change or acceptance.

The psychosocial phenomenon of loss of intimate relationships in old age may have special impact on the form of the psychotherapeutic relationship. Therapists are often cast as a wished-for substitute for the lost relationship. Therapists may feel alone with these patients in their depleted world and experience uncomfortable pressures to adopt the role or behaviors of friend, confidant, protector, advisor, or advocate.

While old age is a time of substantial change that requires great adaptability, satisfactions may still abound. However, they tend to be encountered within a narrower frame that is focused more on family relationships and very close friendships. For many, the loss or unavailability of friendships or relationships promotes a kind of centrifugal emotional force that draws some elderly persons into their families and somewhat away from other relationships. The loss of confiding relationships may have clinical relevance, since some research suggests that these relationships protect against depressive disorder. Effective psychotherapy and environmental interventions that support the patient's need for new relationships can counter some of the effects of loss of confidants.

The increasing importance of family relationships with advancing age adds an element to the psychotherapy of older adults not found as prominently among younger adult patients. Therapists must often consider age-induced dependency issues in families and the conflicts these issues engender, such as forced intimacy and caregiving situations with adult children. For example, conflicts arise over the different perceptions of need that the elderly parent has. Children may be overly anxious and protective; aging parents may inappropriately resist needed help or exaggerate their helplessness. Whatever the pattern, the psychotherapist for the elderly person must take the family system into account, sometimes involving the other family members directly in the therapy or helping the elderly person develop appropriate interpersonal patterns of interaction. In this area as in many others, flexibility in psychotherapeutic technique and interventions is essential. The usual adult-therapist stance broadens when treating elderly persons as psychosocial issues associated with frailty, dependency, and relational shifts impinge. Impelled by these realities, the therapist must often combine the overt roles of advocate, intermediary, and educator with the more traditional psychotherapeutic roles and interventions. Sometimes this means reaching out actively to families, social agencies, or medical caregivers, activities that may be beyond the psychotherapist's usual role. While flexibility is essential, therapists should also examine their motivations to intervene on their patients' behalf. Transference and countertransference-induced forces can lead therapists to inappropriately cross therapeutic boundaries, unwittingly adopting the idealized roles of adult child or spouse, seemingly in response to real psychosocial needs, but actually impelled by dimly understood and often unconscious dynamic forces in the therapeutic relationship. Therapists dealing with relationship changes in aged patients must be prepared to deal with their own attendant feelings of loss, grief, fear, and loneliness prompted by the psychosocial stresses of old age.

ROLE CHANGES

Occupational role changes impose relatively unique challenges on elderly persons. This group is almost universally forced to give up important sources of self-esteem, creative activity, social networks, and the organizing effects of job expectations. Reactions differ. Retirement may be eagerly anticipated and handled well, especially by those who used to be called blue-collar workers. Others, such as professionals, often avoid retirement and may find the loss of their occupational role difficult. Either way, the psychotherapist must appreciate the centrality of work-related roles in structuring life and the changes aging imposes on this structure. These factors are especially relevant in the so-called young-old, 65- to 75-year-olds who are more likely to have just encountered the issues of occupational role

change. These issues generally recede later, either adapted to and worked through or supplanted by other, more pressing issues. However, when fresh, the psychosocial pressures of occupational role change, especially when combined with events such as spousal bereavement, often induce vulnerability and fearfulness and impair the capacity to seek new, alternative sources of gratification.

Parenting roles may change dramatically in old age. Well-established patterns of parental dominance and reliance by children on a strong authoritative parent often suddenly reverse, and conflict, guilt, or fear may invade a previously stable system. Particularly vulnerable are family systems whose members adapted to earlier conflicts by establishing distance (e.g., children moving away). The increasing needs of aging parents may impose pressures on children to care for parents for whom they have had long-standing conflicted feelings. The psychotherapist must be careful to examine and understand the parent-child system and beware of taking stereotyped approaches to the aging parents, since the patterns of parental role changes are quite varied. For example, frailty and fear of being alone and incapacitated often leads elderly patients to complain about the inattentiveness of adult children. Taken at face value, the psychosocial needs of the patient often are indisputable. However, the pattern of the family members' reactions to the patients' needs are rooted in the long history of their relationships with each other. To be effective, the therapist must be sensitive to the emotional forces that are preventing the family from adapting to the new, age-induced needs of the parent.

SOCIETAL ATTITUDES AND RESPONSES

Biases about aging and the aged abound, and the older individual is confronted with them. Some of the North American perspectives on aging are quite negative. For example, the elderly are perceived as no longer productive and therefore of marginal importance to mainstream life or, because of frailty, imposing undue economic burdens on overstretched pension and public support systems. The effective psychotherapist for elderly persons incorporates these issues into the therapy, recognizing with the patient the nature and impact of the messages, and working on appropriate responses. In this role, the therapist can help buffer the sometimes harsh messages that old persons hear daily about those in their age group. A particular issue is the difference between the patient's self-perception—more youthful, involved, and competent—and the perception of younger adults who can only see and react to the apparently universal aging appearance—lost skin turgor, decreased muscle mass, gray hair, and postural change. In other words, the somewhat stereotyped view of old persons by the young delays a more complete and deeper understanding of the truer self-perceptions held by the older individual. This phenomenon has been termed the *normative intergenerational empathic lag*. Older patients in psychotherapy often feel both misunderstood by society at large and ashamed of themselves. The therapist will be most effective if these issues are articulated and explored with aging patients to help them counter societally induced loss of self-esteem and feelings of alienation by confronting distortions and developing techniques to defend against inappropriate stereotyping by those around them.

ECONOMIC AND ENVIRONMENTAL FACTORS

For many, old age is a time of economic and environmental change. Retirement and the many difficulties sometimes imposed by living on fixed incomes, social security, or supplements provided by children can induce real or fantasized anxiety and preoccupation about financial security. These factors can influence psychotherapy in a number of ways (e.g., inducing envious transferential feelings in patients or guilty countertransference in therapists).

Financial restrictions (often real but sometimes imagined) lead to restricted social activity; feelings of isolation, humiliation, and shame; and uncertainty and fear of the future. Like advancing frailty or bereavement, economic difficulties must be actively dealt with in psychotherapy. This involves determining with patients their actual financial situation, separating distortions from reality, uncovering latent meanings about financial security, and then introducing both practical approaches to coping and interpretive understanding of the underlying meaning of the situation to these patients.

Living accommodations is another important psychosocial variable that often changes in old age. The key element that induces psychological stress associated with moving to a new setting in old age is that it is generally a forced move, precipitated by physical or cognitive decline, economic factors, or isolation. Even more than death, the specter of abandonment to an impersonal chronic care facility is most feared by the elderly. The prospect of such a move provokes various forms of abandonment anxiety, including the knowledge that this will probably be their last abode before death, or internal conflicts created by forced interaction with other elderly residents, which living in even the best long-term care environment imposes. Aged patients routinely express their anxiety at being confronted with the pain and disability of their age-peers. They see their own future mirrored in them and become afraid. These feelings can prevent patients from accepting realistic moves to settings where they can receive needed care. Pressing a reluctant, frail patient to accept needed help in an institution can pose ethical dilemmas for the therapist. Not the least of these is the reality that many or most of our institutions are barely adequate to the task of satisfying the needs of their residents. Inevitably, no matter what the setting, the new resident entering long-term care will encounter severe psychosocial stressors, including some loss of individual identity, regimentation to the institutional routines, and loss of privacy. Confronting these realities can be difficult not only for patients, but also for the sensitive therapist who is only too aware of the limitations of the resources on which they must rely.

Psychotherapists of aged patients facing environmental dislocation are most effective if they can uncover the patients' fears and anxieties—abandonment, loneliness, shame, infirmity, pain, or death—and work toward both realistic appraisal of the future and development of skills to combat the specific feared outcome of the environmental transition.

ETHNORACIAL ISSUES

Culture, ethnicity, and race have a profound impact on aging that must be understood and dealt with by psychotherapists, especially those practicing in geographical areas made up of diverse communities. Depending on the specific community, the presence of mental illness may carry with it a profound stigma that stops both patients and their families from seeking care. Hence, such patients often carry societally induced feelings of shame at their inability to cope with their emotional problems. Compounding the more universal problematic aspects of aging, aging members of ethnoracial communities also must deal with barriers to mental health care imposed by language and immigration-related features, such as the feelings associated with leaving their homeland, unanticipated family conflicts, loss of status, or inaccessible spiritual support. Often, newly arrived or even well-established but poorly integrated aged immigrants carry a heavy burden of isolation, unfamiliar with how to travel beyond their neighborhood, unduly reliant on often over-stretched family members, feeling like aliens when they may have expected to feel like respected elders, encountering racist attitudes, or struggling with inadequate finances. To establish an effective therapeutic alliance, psychotherapists must make the patients aware that they are sensitive to these issues by inquiring about them in an empathic, caring, and specific manner. Most important is overtly demonstrating to these patients that they are recognized as individuals who will not be stereotyped by virtue of their culture, ethnicity, or race.

Factors associated with immigration may have special relevance to psychotherapy. For example, those in refugee groups often have hidden histories of severe deprivation and trauma associated with war, political oppression, or famine. The late effects of earlier adult trauma frequently endure, but their presence must be actively sought by the therapist, as patients frequently keep silent about such experiences and their persisting effects.

SPIRITUAL ISSUES

Frequently omitted from psychotherapy inquiry, spiritual issues have profound importance in the lives of many elderly patients. Religious or philosophical beliefs often provide great comfort and enable appropriate acceptance of change, aloneness, or death. Aging patients may return to religion in later years both as a source of comfort and as a social resource. Psychotherapy will be more acceptable to the patient and often more effective when it is based on a carefully elicited understanding of the patient's beliefs and uses the strengths inherent in the patient's faith as an ally in treatment.

SUGGESTED CROSS-REFERENCES

The various psychotherapies are covered in Chapter 30. Sexuality is presented in Section 19.1. Death and bereavement are covered in Section 28.5. Minority issues in geriatric psychiatry are presented in Section 51.6e. Section 51.4i covers individual psychotherapy, Section 51.4j covers cognitive-behavioral therapy, Section 51.4k presents family interventions, and Section 51.4l discusses group therapy.

51.4 TREATMENT OF PSYCHIATRIC DISORDERS

51.4I INDIVIDUAL PSYCHOTHERAPY

JOEL SADAVOY, M.D., F.R.C.P.(C), AND LAWRENCE W. LAZARUS, M.D.

Three elements distinguish geriatric psychotherapy: it is directed to the needs of patients over the age of 65, it requires modification of technique because of the special developmental features of old age, and it requires flexibility to treat the frequent comorbid age-related conditions so prevalent in this age group. Perhaps more often than psychotherapy of other age groups, geriatric psychotherapy must be practiced in a variety of settings. Because of rapid changes during the later years of life, the techniques of geriatric psychotherapy for a given patient must often be attuned to the ebb and flow of relapse, crisis, or chronic decline.

HISTORY

Modern psychotherapy began with Sigmund Freud's attempt to construct a universal model of understanding of human behavior. In the essentially prebiological era of psychiatric treatment, psychoanalytic theory formed the basis for most psychotherapeutic interventions. Unfortunately, this erroneously colored the attitudes of psychiatrists toward psychotherapy of elderly persons. Freud held a particularly gloomy, but highly influential, view of the potential for successful psychoanalytic treatment of patients over the age of 50. He believed that there was too much material to be dealt with in analysis and that the elderly had inelastic mental processes and hence were not educable. These ideas produced inordinate pessimism about the potential for psychological change in elderly adults. As the psychotherapies matured and began to be applied to a broader range of patients, therapists came to recognize that age per se does not preclude therapeutic change. Indeed, in the 1950s and 1960s several analysts wrote enthusiastically of their positive experiences in treating elderly patients. In retrospect, this enthusiasm resulted from treatment of generally intact and relatively vigorous elderly patients.

The quality of evidence supporting psychotherapies for elderly patients is highly variable. While some randomized controlled trials exist, most descriptions of psychotherapeutic outcomes are based on uncontrolled studies, and the bulk of opinions about psychotherapy of elderly patients that appear in the literature reflect the clinical experience of respected authorities. Hence, any recommendations derived from this data should be considered in the early stages of validation and subject to modification as more-careful studies refine the evidence. Nevertheless, the broad consensus of clinicians and investigators in this area of inquiry is that the psychotherapies are important and effective tools for treating the psychiatric problems and disorders of late life.

THEORETICAL ISSUES

A major developmental task of aging is finding restitution for the inevitable biopsychosocial losses associated with this stage of the life cycle. Therefore, loss is one of the most prominent issues discussed by elderly patients. For many elderly persons, it is the cumulative effect of multiple repeated losses, before sufficient time has passed for mourning and resolution, that is so devastating. The older person struggles to maintain ego integrity and a sense of purpose in life at a phase of the life cycle often characterized by diminishing coping resources, increasing self-doubt, and the onslaught of assaults and challenges to self-esteem and a positive self-image. The magnitude of an elderly person's reaction to a loss depends to some degree on the amount of pride and emotional investment in the lost function. Beyond lowered self-esteem, elderly adults experience life changes that can damage their sense of security and safety. For some the world becomes uninviting and dangerous, particularly if they have encountered real events such as falls, personal attack, or inaccessible help at a time of need.

Self-worth, security, and independence depend in part on the individual's ability to maintain physical capacities. Impairment of important psychological functions becomes pronounced when frailty or illness forces restricted function and imposes a new, different, and often unacceptable self-image and personal identity.

Psychological adaptiveness in old age varies widely. Vulnerability to states of depleted self-esteem, insecurity, fear, or anxiety is heightened when an individual cannot adapt flexibly and is too wedded to maintaining or retrieving that which must be relinquished. Problems of psychological adaptation and lost self-esteem occur in late life because of such factors as overdependence on social or work roles, overemphasis on the maintenance of control and mastery in all situations, and unresolved problems with self-esteem. Difficulties with self-esteem may be rooted in maladaptive, unmodified beliefs; unconscious issues such as dependency conflicts; or interpersonally generated psychological reactions like unresolved grief.

Many elderly persons adapt quite well to the challenges imposed by negative societal stereotypes and the losses noted above that threaten to erode self-esteem. Several psychological self-protective mechanisms help to maintain a positive self-image and self-esteem. The elderly individual may focus on past successes, discount messages that do not fit with lifelong self-concepts, refuse to apply general myths and misconceptions about aging to the self, and choose to interact with those who provide an ego-syntonic experience. Some selectively screen out unwanted perceptions such as those that challenge impaired cognitive abilities or produce other anxiety. While often self-protective, such selectivity may also distort reality and promote maladaptive denial.

SUPPORTIVE PSYCHOTHERAPY

Frail, institutionalized, cognitively impaired, or chronically ill elderly patients require such psychotherapeutic techniques as support of healthier defense mechanisms, ventilation, and advice and help with acceptance of diminished capacities and increased dependency needs. In addition, they need caring, nurturing environments and assistance of families with their care giving.

The patient's life history and psychodynamics (obtained from the patient or family members) enables the therapist to institute specific supportive therapeutic strategies.

An elderly woman with progressive cognitive impairment and lifelong personality traits of dependency and passivity is anxious and depressed about entering a nursing home. She may adapt well to the home if assigned to a roommate who is nurturing and protective.

Alvin Goldfarb has described a brief, supportive therapy technique for institutionalized, cognitively impaired patients. The therapist promotes patients' foundering self-esteem, sense of control, and safety by permitting them to develop an apparent special relationship with the therapist, who is perceived as a benevolent and powerful figure. The patients believe they have some control over the benevolent physician. This is accomplished in small, subtle ways. For example, the physician elicits the patient's preferences for the frequency of sessions, daily timetables, diet, or socializing and then acquiesces to the patient's wishes, while maintaining a quiet caution about being unduly manipulative. The technique includes weekly, short (15 minutes) visits and gratifying the patient's realistic requests when possible.

LIFE REVIEW OR REMINISCENCE THERAPY

Robert Butler and others have noted the universal tendency of the aging person to reflect on and reminisce about the past. Reminiscence is characterized by the progressive return of memories of past experiences, especially those that were meaningful and conflictual. To varying degrees, elderly patients in therapy reminisce about the past, search for meaning in their life, and strive for some resolution of past interpersonal and intrapsychic conflicts. Life review therapy systematically

enhances this reminiscing process and makes it more conscious and deliberate. The therapist may guide the process by encouraging the patient to write or tape a biography with review of special events and turning points. Techniques include reunions with family and good friends and looking through memorabilia such as scrapbooks or picture albums. This technique has been reported to resolve old problems, increase tolerance of conflict, relieve guilt and fears, and enhance self-esteem, creativity, generosity, and acceptance of the present.

COGNITIVE-BEHAVIORAL THERAPY

In adapting cognitive-behavioral therapy to elderly patients, the therapist is often more active, redirecting the patient from reminiscence to here-and-now issues. The pace of therapy is sometimes slower than with younger adults, and when appropriate, the therapeutic alliance may be enhanced by permitting the patient to adopt a senior, teaching role with the younger therapist. To compensate for specific deficits such as hearing loss or cognitive slowing, information may be presented in different modalities, such as written material or taped sessions for the patient to take home. With older patients, termination is managed gradually rather than abruptly.

BRIEF (TIME-LIMITED) PSYCHODYNAMIC PSYCHOTHERAPY

Brief, or time-limited, psychodynamic therapy can be considered for elderly patients with clearly defined, age-related problems that can be expected to resolve within a brief period of psychotherapy, such as an adjustment disorder, unresolved grief reaction, or new-onset anxiety disorder. Setting a time limit at the beginning of therapy reinforces the patients' confidence in their ability to resolve problems within a circumscribed period of time, focuses and accelerates the therapeutic process, diminishes their fear of dependency, and accommodates limited financial resources. Brief therapy uses the therapist's psychodynamic understanding of the patient and the patient's transference to the therapist to clarify and help resolve the patient's emotional reactions to a current life stress. During brief dynamic psychotherapy the patient often uses the therapist to validate competency and normalcy, which helps to support and restore feelings of mastery and self-esteem. Symptomatic improvement often exceeds the achievement of insight or self-understanding.

INSIGHT-ORIENTED PSYCHOTHERAPY

The basic approach to insight-oriented therapy for older patients who are physically and cognitively intact is largely the same as that for younger patients. However, most clinicians agree that the themes introduced in therapy by elderly patients are more focused on issues of loss, sexual and physical decline, cumulative trauma, fear of pain and disability, decline in self-esteem, and increasing dependency. During longer-term psychotherapy, the condition and circumstances of the older patient evolve and change. The development of physical illness may require medical referral, collaboration with family members, or advocacy on behalf of the patient for community and other support services. Such active intrusions of the patient's real-life problems into the therapeutic process are not commonly dealt with by psychodynamic therapists, but when treating elderly patients, techniques must be adapted. Therapists are most effective when they learn to integrate different therapeutic modalities while maintaining a psychodynamic focus on the therapeutic relationship, the transference, and the goal of inner conflict resolution. Indeed, the necessity to integrate modalities of treatment is one of the hallmarks of the flexibility necessary to treat and manage the evolving therapeutic issues of elderly patients effectively.

TECHNIQUES

In the initial interview the psychiatrist is active and emphatic in exploring patient and family resistance to therapy. The elderly patient is usually interviewed individually before important information and concerns are obtained from the family. Elderly patients usually respond positively to the therapist's listening, empathic, and encouraging attitude. Some patients like to sit close to the therapist and may welcome such spontaneous warmth as a natural touch on the patient's arm. However, the therapist should evaluate each patient's sensitivities about intimacy and not assume that familiarity is welcome just because the patient is old.

Psychologically less-sophisticated patients who are accustomed to talking about their physical complaints when visiting a physician, initially may feel more at ease if the therapist begins with a medically oriented focus. The therapist may then shift the focus to psychological and social problems. Attention is paid to previously overlooked medical problems and medication adverse effects that may contribute to current psychiatric signs and symptoms.

In general, the therapist of the elderly patient is more active, engaging, supportive, and flexible in the therapeutic approach than therapists of younger patients. The therapist must know the normative, age-related changes that occur in the psychological, cognitive-intellectual, and social life of older people; geriatric medicine; psychopharmacotherapy; family therapy; and community resources. In both office and hospital settings, it is especially useful to work with a mental health colleague, such as a social worker, who is knowledgeable about family therapy and community resources.

Realistic, explicit treatment goals are negotiated with the patient and family as appropriate. Patients must feel that they have obtained something from the initial interview (e.g., empathic understanding, or hopefulness) to increase the likelihood that they will return for subsequent sessions. Telephone reminders to selected patients or family members in advance of the next appointment imparts the therapist's interest and improves patient compliance.

The utility of various forms of psychotherapy for specific clinical indications is slowly being investigated in elderly populations. Overall, for major depressive disorder in elderly patients, psychotherapy may be recommended as an important adjunct to pharmacotherapy or electroconvulsive therapy (ECT) and can be recommended as a primary mode of treatment for some patients with depression without endogenous features. The specific techniques used are tailored to the individual patient. A few clinical trials have examined the combined use of psychotherapy and an antidepressant. While results are mixed, evidence suggests that cognitive-behavioral therapy may augment the effectiveness of antidepressant medication. Some studies strongly suggest that behavioral, cognitive, and brief dynamic psychotherapy are all effective treatments for selected elderly patients with depression. A recent meta-analysis of the efficacy of psychotherapeutic treatments for the elderly supported the conclusion that these treatments are more effective than no treatment under placebo-controlled conditions and established the efficacy of psychosocial interventions in both major depressive disorder and subclinical varieties of depression. However, as in younger patients, no modality of psychotherapy shows clear superiority over another in the treatment of geriatric depression. Thus an integrated approach to psychotherapy for geriatric patients is best, based on their need for cognitive-behavioral, dynamic, and interpersonal psychotherapeutic interventions of various durations.

Behavioral interventions for the elderly have been most commonly used with cognitively impaired residents in institutions, but therapists are increasingly using this approach for outpatients.

CLINICAL ISSUES

Indications for Individual Psychotherapy Elderly adults are a heterogeneous population. The continuum ranges from the normative or healthy older patient whose function is retained and who is relatively unimpaired by physical or cognitive decline to the frail elderly patient. Five categories are normative elderly; normative elderly in crisis; independent frail elderly; dependent, physically frail elderly; and dependent, cognitively impaired, frail elderly. Indications for various modalities of individual therapy are strongly influenced by the position of the patient on the normative-frail continuum. Moreover, because capacities change over time, therapeutic approaches for a given patient may also change.

Even patients at an advanced age can benefit from insight-oriented therapy. This technique is more often effective in patients who retain adequate ego strength and the capacity to mourn losses and tolerate regression and have sufficient time and finances. These qualities are generally found in the normative aging group.

With advancing age, crisis is frequently the stimulus for seeking out psychiatric care, often initiated by a family member or caregiver. Individual therapy during crisis focuses on mourning for lost important relationships or personal capacities and working through conflicts over separation, redirecting energy to more realistic goals, redefining relationships especially with regard to accepting appropriate dependency and reestablishing or developing appropriate defenses to enhance mastery, sense of control, and self-esteem. Psychotherapy during crisis is often integrated with medication and environmental therapies. Brief interpersonal psychotherapy and cognitive-behavioral therapy are useful approaches during the crisis, although longer-term supportive or uncovering (i.e., psychodynamically oriented) therapy may evolve.

Behavioral techniques using operant behavioral conditioning have been applied to a wide range of target symptoms in chronically ill elderly patients, including incontinence, pain, insomnia, wandering, socially inappropriate behaviors, level of activity and participation, communication skills, toileting, bathing, and feeding. Environmental cues are manipulated to increase, decrease, or shape behaviors. Careful analysis of environmental consequences, for example, may uncover inadvertent reinforcers of undesirable behaviors. These techniques are useful for institutionalized and frail elderly patients to reduce the excess disability that often

accompanies dementia. An ABC approach to behavioral management of disturbed behavior may be useful. This technique includes accurate neuropsychological evaluation; defining a specific measurable and observable behavior for modification; determining the antecedents (A) to the onset of the behavior and systematically recording them; recording the type, frequency, and duration of the baseline (B) conditions; tailoring a treatment program (A & B) to alter the behavior, which includes caregiver counseling, introduction of reinforcing, and extinguishing techniques, that is, consequences (C); instituting environmental changes and psychotherapy to assist caregivers; and program evaluation. A major deficiency of behavioral interventions in general is their labor intensiveness and the need to maintain the program. Once the interventions are withdrawn, behaviors tend to return to pretreatment levels in these institutionalized populations.

Various forms of individual psychotherapy have shown therapeutic value for states of bereavement. Psychotherapeutic intervention is particularly effective for bereavement complications such as chronicity, depression, or anxiety disorders. Most interventions include some education, support, attention to the relationship with the deceased as it developed before the death and as it has changed since, and supportive assurances of “normality” for bereaved individuals who need to be reminded that their feelings and experiences are not deviant, abnormal, or fixed.

While psychotherapy of various types has been recommended for treatment of anxiety disorders, the data do not support strong recommendations. Recent preliminary data suggest that cognitive-behavioral therapy can be quite effective in older patients with panic disorder, and may thus be considered as an alternative to pharmacological treatment for selected patients or as an adjunct to pharmacological treatments when patients have behavioral symptoms that can be targeted.

Psychotherapy has shown some value in the management of elderly patients struggling with alcohol abuse. Inclusion of cognitive-behavioral training that addresses themes of self-advocacy, self-esteem, and relapse prevention may aid recovery.

Individual psychotherapy is often helpful in the treatment of sexual dysfunction. For example, premature ejaculation usually responds readily to sex education, reassurance, and sex therapy techniques practiced at home alone or with a cooperative partner.

Limitations Elderly adults are underrepresented in psychiatric outpatient clinics (2 to 4 percent of patients seen) and even more so in private psychiatric practice. The effect of psychotherapy, therefore, appears to be limited by the willingness of practitioners, both psychiatric and primary care, to use it for elderly patients. The completion of a series of regular therapy sessions, whether short or long term, is often limited by such practical considerations as difficulties with finances, transportation, or weather conditions.

Raised in an era when shame was associated with psychiatric problems and treatment, some elderly persons feel embarrassed and indignant when their physician or family suggests consultation with a psychiatrist. Many elderly persons as well as primary care physicians and mental health professionals believe that depression and anxiety are expected concomitants of aging or attribute abnormal psychological states to physical illness. The symptoms themselves—depression, apathy, and hopelessness—prevent older persons from seeking treatment. Patients whose ethnoracial backgrounds differ markedly from that of their therapist may have quite different notions and expectations about a visit to a psychiatrist. Many cultures view mental disorder as shameful. Individuals may fear damage to their families' reputations. For example, elderly patients have expressed fear that their grandchildren may be less marriageable if there is mental illness in the family. Beyond cultural barriers, other access barriers limit care for these groups including language incompatibilities, lack of knowledge of where to obtain psychiatric services, economic issues, a tendency to seek care only after a crisis, and fragmented, difficult-to-access, mental health-care services.

Adult children of an aging parent may minimize the parent's psychiatric symptoms, be ambivalent about assuming a parenting role, and may share their parent's negative stereotypic attitudes toward psychiatry. Practical considerations such as geographical inaccessibility to the psychiatrist's office pose additional barriers to treatment. Physical illness or other crises may arise during the course of longer-term psychotherapies, which sometimes limits the use of psychodynamic psychotherapy because the therapist must shift to a more supportive mode during the crisis period.

Cognitive-behavioral interventions in long-term care settings, while often effective when introduced by a consultant, generally fail if the consultant leaves. Front-line staff in these settings usually lack the training to sustain sophisticated cognitive-behavioral programs on their own.

Complications Whatever the form of psychotherapy, the course may be complicated by issues of transference and countertransference. The patient's feelings about therapy will be influenced by education, socioeconomic status, culture, and ethnicity, which can restrict or enhance the impact of treatment.

Transference is age independent (of both patient and therapist), the determinants stemming from the timeless unconscious. However, developmental theory expands the traditional perspectives by demonstrating that the transference derives not only from significant infantile experience but also from internalized objects encountered in adult life, for example, with a spouse or a child.

While there are no age-specific transferences, the psychodynamic impact of life experiences during old age may increase the emergence of certain forms of transference. For example, frailty leads to dependency conflicts and fears of abandonment, emotions that can easily evoke parental transference deriving from the patient's need for a protector or savior. This form of transference emerges readily in dependent, often-institutionalized patients, even when psychotherapeutic contact is relatively brief and intermittent. Similarly, loss of self-esteem and sources of external admiration, so central to aging, promotes idealizing and mirroring transferences. Bereavement, especially of a spouse, or other loss (e.g., sexual outlets or capacity) may lead to eroticized spousal transference in which the patient unconsciously relates to the therapist as an erotic love object who becomes a fantasy substitute for the lost object. This reaction may be distinguished from classical oedipal transference which also may occur in therapy with elderly patients.

Reverse transference describes a phenomenon of geriatric psychotherapy in which the patient apparently experiences and relates to the therapist as a child and takes a parental stance and role toward the therapist in the treatment dyad. Therapists may experience this transference interaction as demeaning or patronizing and feel uncomfortable with the seeming reversal of dominance. Young therapists or residents in training may find this especially challenging. While therapists of elderly patients often comment on reverse transference, it is generally a transient period of therapy that defensively protects the patient from deeper levels of transference-based affect associated with conflicts over dependency.

Somewhat different is *filial transference*, in which patients deal with the therapist as one of their own children, enacting such unconscious conflicts as rage for not fulfilling wishes for caring to which the patient unconsciously feels entitled or guilt deriving from earlier failures in the parental role.

Countertransference responses of therapists are often intense in treatment of elderly patients, sometimes blocking the therapist's willingness to engage the patient in individual psychotherapy. Less experienced therapists or those in training may initially doubt the applicability of their skills to elderly patients, thus reinforcing preexisting uncertainties about the mastery of their craft. The patient's frailty sometimes induces especially strong withdrawal from using psychotherapy because therapists are unwilling to encounter and confront their own hopelessness and fears of abandonment or mortality. Some therapists withdraw because of fear of being engulfed by the patient's demands and dependency. These factors may be compounded by the added therapeutic burdens of working at a slower pace, overcoming sensory deficits, and dealing with cognitive decline.

Countertransference parallels transference reactions in that therapists may develop strong urges to rescue the patient and do too much, reactions that may derive from unresolved guilt and rage toward their own parents.

Therapists must deal within themselves with the repetitive need for therapy to focus on mourning and acceptance of loss. This is in contrast to the more hopeful perspective of ego development and mastery, which is common in psychotherapy of younger adults and easier for therapists to deal with. Treating elderly patients holds the danger that helpless anxiety or despair may emerge in therapists who have not successfully dealt with their own issues of loss.

Therapists of elderly patients are often surprised by the emergence of erotic countertransference during more intensive therapy and may recoil from or deny its presence or feel uncomfortable about aspects of the patient's sexual feelings, thereby depriving the therapy of crucial areas of work.

The sometimes overwhelming effects of cumulative life trauma are painful for therapists, who may retreat into mechanistic or formulistic approaches, inhibiting their own empathic relatedness.

A young therapist was surprised when a difficult elderly woman complained angrily about feeling manipulated and exposed when sent home to write her life story, a technique the therapist had read was suitable for the elderly. In discussion of the case, it became evident that he felt overwhelmed by the patient's painful life and uncertain of what would be helpful. Rather than engaging her in an attempt to understand her feelings, he prematurely employed a cognitive intervention that made her feel infantilized and rejected.

Idealizing countertransference may inhibit the therapist from recognizing the patient's ongoing conflicts; for example, about sexuality, aggression, self-esteem, and grandiosity.

In approaching termination, many elderly patients need to be assured of the therapist's continued future availability should the stresses associated with advancing age precipitate regression, conflict, and decompensation. While some elderly patients terminate successfully, for many, therapy is an intermittent process to be reactivated as needed. Thus it is often helpful to discuss with patients feelings that may prevent their return to therapy such as shame, fear of disappointing the therapist, and desire for independence.

Contraindications There are few contraindications to psychotherapy, although the form of treatment is carefully tailored to the needs of the patient. Psychoanalytic psychotherapy is approached with caution. The therapist first ensures that the patient retains sufficient ego capacity to deal with regression during therapy, to work through adaptive mourning, and to replace lost sources of self-esteem. Even life review therapy may be contraindicated for patients who have realistic guilt about the past or who become overwhelmed when focusing on unmourned or unresolvable past disappointments and losses.

As in younger populations, cognitive-behavioral therapy is indicated for treatment of acute or chronic depressive disorders, concurrent with antidepressant medications when indicated, and for symptoms associated with personality disorder. Mild cognitive impairment secondary to senile dementia or cerebrovascular accident is not a contraindication to cognitive-behavioral therapy, although severe or suicidal depression or severe cognitive decline requires alternative therapies.

Integrated Therapy Integration of psychotherapies often is the most effective way to proceed.

At the age of 70, Mrs. S. was referred for psychiatric assessment because of her distress over her husband's declining physical state secondary to advanced Parkinson's disease. In the initial interview the therapist tried to determine three separate but interrelated factors: the patient's surface conflicts; the aspects of the conflicts that might be amenable to practical, environmental intervention; and the deeper psychological conflicts that were coloring the patient's ability to deal with the situation.

The manifest problems were loss of her husband's companionship and feeling helpless to cope with his illness. For example, he could not lie comfortably in bed and spent most nights sleeping in a living room chair, a situation that she could not tolerate. Mrs. S. feared her own growing incapacity from many years of arthritis and worried about the fate of her husband should she become immobilized.

In approaching the manifest difficulties, the therapist helped Mrs. S. define the specific areas of emotional conflict (especially her grief at the loss of the husband she once knew) and express and ventilate feelings of fearful anticipation, helplessness, and vulnerability. A cognitive therapy approach was used to help her recognize which parts of her feelings were based on unrealistic thoughts. Focusing on her feelings of failure and aloneness, the therapist helped her understand that others had struggled as she was struggling and that her sense of failure was not her fault but an inevitability of the illness. Concurrently, she was encouraged to distinguish her ideas of what was best for her husband from his actual needs.

At the same time, Mrs. S. examined the practical realities posed by her husband's illness and experimented with alternative methods of coping. For example, she gradually came to accept that there was no harm to her husband if he slept in a chair, as long as he felt comfortable. This simple change in perspective, arising from direct explanation and advice from the therapist, relieved much of her tension and guilt and allowed her to sleep more restfully.

The third concurrent component of therapy was an exploration of deeper sources of feeling. This part of therapy revealed the patient's rage at her husband. She had been unaware of how his illness had reactivated her long-standing belief that she had never been understood or cared for as she had wanted. She spoke of her conflicted feelings about her childhood and her lonely, restricted life with which she appeared to cope on the surface, while actually experiencing abandonment and fear. The therapist actively encouraged her reminiscence in the early phases of therapy, attempting to evoke the emotions that accompanied the memories. Gradually, she moved into a phase of meaningful exploration of her inner state. The resulting improved comfort helped her carry on in her caregiving role but also freed her to begin to seek sources of essential nurturance and gratification for herself.

The successful outcome of this treatment probably delayed Mrs. S.'s own decline and enabled her husband to remain safely at home for a much longer time. This case illustrates both the efficacy of psychotherapy and its potential cost-effective and humanitarian outcome.

Goals of Treatment Psychotherapy is most effective when it is used for specific indications with defined goals. Goals are modified to fit the function, cognition, and psychological capacity of each patient. Generally, the greater the frailty, the more modest are the goals of psychological change. Goals for patients able to undertake dynamic psychotherapy include psychological mastery over the past and its unresolved grief; resolution of adult and childhood sources of shame and guilt; resolution of current interpersonal conflict, especially with spouse or adult children; working through conflicts associated with loss of self-esteem and establishing substitute sources for those that had to be relinquished; coming to terms with failure to achieve ideal aspirations; and, at the most advanced level, processing and integrating unconscious conflicts experienced in the therapeutic transference relationship. George Pollock has termed the creativity and energy that may be released by successful resolution of losses *mourning-liberation*.

In crisis therapy, the goal is to reestablish the patient's best premorbid level of function. Often this requires identifying more realistic levels of function. Examples include acceptance of appropriate levels of dependence or controlling excess, psychologically induced morbidity.

For the more debilitated, frail, elderly patients, psychotherapy goals are often symptom-focused behavioral changes. These include focal interventions; for example, dealing with dementia-related behaviors such as aggression, excess withdrawal, anxious agitation, or delusions. With these patients especially, therapy goals include strengthening the roles of family caregivers and fostering a more appropriate, supportive environment for the patient.

ETHICAL ISSUES

Frail, often-institutionalized elderly patients have limited capacity to use the psychotherapies. They are easily viewed by therapists as beyond help. In allocating scarce resources, therapists struggle with whether to expend effort on this population or reserve it for their more vigorous elderly patients. This is a difficult ethical dilemma since the frail elderly patients are the most dependant, helplessly reliant on caregivers, who in turn are burdened with the role of deciding who shall or shall not receive certain forms of care.

While most forms of psychotherapy require the active participation of patients, and therefore their inherent consent, behavioral interventions may be applied to the patient externally. In using behavioral techniques with frail elderly patients, therapists are advised to exercise caution in distinguishing between externally imposed goals of therapy, that is, a focal symptom that is troublesome to staff, and the overall welfare of an often helpless patient whose ability to consent to, and participate in, setting treatment goals may be limited or impaired.

Clinicians are often confronted with ethical concerns over confidentiality and the patient's decision-making capacity. Both family members and therapists may inadvertently infantilize more frail patients and override their right to participate fully in the therapeutic decision-making process. The psychotherapist must carefully evaluate a patient's ability to make decisions. Similarly, the family's right to know about the patient and participate in therapy is carefully balanced by the preeminent right of the competent elderly patient to confidentiality in the therapeutic relationship. In practice this is often a difficult issue for therapists, especially when families are intrusive, demanding, or litigious.

51.4 TREATMENT OF PSYCHIATRIC DISORDERS

51.4J COGNITIVE-BEHAVIORAL THERAPY

GARRETT C. DAUM, M.D.

Psychopharmacological therapy is often considered the initial treatment of choice for psychiatric illness in the elderly. However, psychotherapy or combined treatment may sometimes be more appropriate and more effective. There has been growing recognition that psychotherapeutic techniques developed for treatment of younger patients can be successfully modified for use with elderly patients. One such technique that has demonstrated success with the older patient, especially those with mood disorders or substance use disorders, is cognitive-behavioral psychotherapy.

HISTORY

Cognitive-behavioral psychotherapy is actually a combination of cognitive and behavioral treatment approaches with considerable overlap in theoretical background and practical implementation. In the 1970s Peter Lewinsohn described a behavioral treatment approach to depression while at about the same time Aaron Beck developed his seminal work in cognitive therapeutic techniques. By the early 1980s these treatment approaches had been modified specifically for use with older depressed patients in large part through the work of Gary Emery, Dolores Gallagher, and Larry Thompson. These techniques have since been applied to patients with diagnoses beyond depression, in areas such as geriatric substance abuse, obsessive-compulsive disorder, and pain management.

THEORETICAL ISSUES

Gerontologists have consistently found greater individual variability, cognitive slowing, and greater correlation of physical and psychological processes in elderly adults than in younger adults. Aging requires adapting to inevitable change and, for many, coping with a succession of losses that come at a time of diminishing resources. Common presenting problems that can lead to depression, anxiety, or substance abuse include changes in lifestyle with loss of societal and financial status, retirement and job loss, relationship problems and loss of familial and social attachments with resultant social isolation, and loss of physical status through somatic changes and illness. Cognitive-behavioral therapy has theoretical advantages for use with elderly adults. Its time-limited nature attends to the limited resources available to many elderly adults. It engages patients by focusing on immediate and relevant concerns and by using concrete tasks. It directly challenges the negative beliefs and stereotypes about aging that may deepen pessimism about treatment success. It can be integrated with other treatment modalities, and, it can counteract inactivity, social withdrawal, and apathy especially common in patients with depression. Further, it has measurable treatment goals and provides individuals with an educational opportunity to develop skills and coping strategies useful for a wide variety of stresses encountered in older life.

TECHNIQUES

Cognitive-behavioral therapy with the older patient is suitable for both individual and group work. The basic principles and techniques used are similar to those developed for younger patients, with the similar goal of identifying and correcting dysfunctional thoughts, beliefs, and self-defeating behavior.

Modifications to traditional techniques have been recommended by researchers in the field to accommodate the unique set of variables presented by persons in this age group. Adaptations suggested for the elderly adult include the need to assess and address potential negative stereotypes about psychotherapy (“I'm not crazy”), presenting treatment as a way to learn new strategies to cope with current life stressors, the need for a thorough psychosocial assessment and medical history to understand the many potential influential factors operating in this age group, the need for the therapist to maintain the structure of the therapy session more actively and prevent patients from reminiscing and digressing from the current focus or becoming overly inclusive in recalling events, and conducting therapy at a slower pace with more repetition of important ideas. Therapists should also be aware of sensory deficits in their patients and make necessary adjustments (e.g., by presenting material using multiple means such as verbal instruction, audio and written handouts, and use of posterboards).

CLINICAL ISSUES

Cognitive-behavioral therapy has been most extensively studied for treatment of depression in cognitively intact, motivated elderly adults. Application of this therapy to older patients suffering from substance abuse, anxiety disorders, personality disorders, and psychosis has been less extensively studied. Additionally, cognitive-behavioral therapy has been used in the treatment of outpatients with Alzheimer's disease (with caregivers included in the treatment process), in geriatric crisis intervention, and as adjunct therapy on a geriatric rehabilitation unit. Behavioral techniques have been found helpful in the treatment of specific behavioral symptoms in cognitively impaired nursing home residents and have been applied to other specific symptoms including insomnia, pain, and chronic obstructive pulmonary disease. When appropriate, cognitive-behavioral therapy adapts well to adjunctive use with other therapeutic modalities such as psychopharmacology, dynamic psychotherapy, and 12-step support groups.

Contraindications to cognitive-behavioral therapy are similar to those of other psychotherapeutic techniques, but cognitive capacity must be assessed especially in terms of executive functioning and ability to understand and retain new material, though cognitively impaired individuals may benefit from therapy geared more toward behavioral strategies. Psychotic symptoms are a relative contraindication, depending on the nature and severity of the symptoms.

Based on limited controlled-research data, some general points can be made concerning successful treatment outcomes. Less successful treatment outcomes have been associated with depressed patients with more severe illness, those with a diagnosis of personality disorders, significantly stressful life events, and patients with a limited social support network. Patients with greater initial motivation to treatment appear to have better outcomes.

> Mr. D., a 62-year-old male veteran with a history of more than 10 years of intravenous heroin and amphetamine dependence, enrolled in a cognitive-behavioral treatment group for elderly substance abusers. Mr. D. had been living on the streets for many months and was plagued by dysfunctional thoughts concerning his self-worth and guilt over continued using of drugs and was very pessimistic about his chance at successful treatment, stating “I'm too old, it's too late for me to change.” Mr. D. was able to engage in treatment and began to develop socialization skills with the older clients in the group. Mr. D. was able to identify and begin to correct his negative cognitions and understand his drug using through the A-B-C chain model of behavior, consisting of antecedents (situations, thoughts, feelings, cues, and urges), behavior (drug using), and consequences. Through a combination of cognitive-behavioral techniques including thought-stopping procedures, anger-tension management coping strategies, and role rehearsals of at-risk situations Mr. D. was able to remain abstinent. As his understanding and coping skills improved, so did his self-confidence and self-esteem. He was eventually able to obtain full-time employment and move into his own apartment.

Goals should be well defined at the start of treatment. They should be mutually agreed upon, realistic, and measurable. Progress of therapy in terms of understanding and learning concepts as well as clinical improvement should be periodically reassessed.

RESEARCH AND EVALUATION

The overall paucity of well-designed research studies, the inherent limitations and difficulties of psychotherapeutic research with older patients, and the

methodological differences between studies make many conclusions preliminary. Studies varied substantially in terms of referral source, treatment duration, individual versus group treatment, attrition rates, and marital status. Additionally, information was usually limited in terms of patients' psychiatric history and comorbid physical conditions. Nonetheless some general points can be made. Overall, cognitive-behavioral therapy is more effective than delayed treatment or wait-list controls. As in younger depressed patients, group and individual cognitive-behavioral therapy appear to have similar efficacies. In addition, efficacy rates are similar in comparisons between older and younger age groups. There are mixed results when psychodynamic techniques are compared with cognitive-behavioral therapy; some studies report no significant differences in improvement while others report more favorable results with cognitive-behavioral therapy. Additionally, one study reported a lower relapse rate after 1 year in the cognitive-behavioral therapy group than in the group receiving psychodynamic therapy. The few studies of cognitive-behavioral therapy with elderly alcohol-abusing patients have demonstrated clear benefit for many patients. Though similar levels of reduction on standardized depression scales are found when studies using cognitive-behavioral treatment are compared with those involving psychopharmacological treatment, differences in the initial severity of illness and treatment duration make comparisons of this type very problematic.

SUGGESTED CROSS-REFERENCES

Mood disorders are covered in Chapter 14 and mood disorders in the elderly in Section 51.3d. Substance-related disorders are covered in Chapter 11 and substance abuse in the elderly in Section 51.3h. Behavior therapy is extensively covered in Section 30.2 and cognitive therapy in Section 30.6.

51.4 TREATMENT OF PSYCHIATRIC DISORDERS

51.4K INTERVENTIONS AND CONSULTATION WITH FAMILIES OF OLDER ADULTS

DEBORAH A. KING, PH.D., CLEVELAND G. SHIELDS, FH.D., AND LYMAN C. WYNNE, M.D., FH.D.

Clinical gerontologists recognized long ago the importance of addressing the mental health problems of older adults within the context of their social world. More than three decades of research has debunked the myth that older adults (i.e., those over 65 years of age) lead lonely, isolated lives devoid of meaningful contact with adult offspring or other family members. Most elderly individuals live independently but maintain regular contact with family. Four out of five have at least one adult child, and when health problems arise, the adult children are the most common caregivers. A small minority (less than 5 percent) of those over 65 live in nursing homes, but a great percentage of them still have regular contact with family members.

Family therapy with older adults is the process of bringing two or more family members together (often from multiple generations) to address problems encountered in the later stages of the family life cycle. Within this developmental context, the goal of therapy may include any or all of the following: (1) to educate and facilitate communication about the unique medical, psychological, and social challenges of aging as they affect the elderly person and the family, (2) to improve the family's ability to negotiate successfully the normative stresses of aging, and (3) to improve the family's ability to solve major problems associated with late-life medical, neurological, or psychiatric disorders.

HISTORY AND THEORETICAL ISSUES

The emerging field of late-life family therapy has its roots in two distinctive but overlapping theoretical approaches to the understanding of human behavior and behavioral problems. Family systems theory maintains that the family functions as a network of interconnected elements so that change in any one individual's status or behavior will affect the status or behavior of other members of the network. Family life cycle theory views the family system as moving through time, encountering both predictable, normative transitions and unique, family-specific challenges. Combining these perspectives, the late-life family therapist interprets the behavioral or emotional problems of an older adult as indications that the family system is having difficulty negotiating a transition or crisis in the unfolding family life cycle. The family therapist's task is to help family members organize or reorganize their resources in a manner consistent with the late-life challenge they are currently confronting.

The family life cycle has been conceptualized as containing successive stages, each with its own specific set of developmental tasks and emotional processes. Most conceptualizations developed to date are unsatisfactory in that they focus on earlier stages of the life cycle during which the family is forming, raising children, and launching children, with little development or differentiation of the later stages of the cycle, such as adjustment to retirement, attainment of grandparenthood, coping with loss and illness, and passing on the family legacy. With advances in medical technology, elderly individuals may actually live more years after their children have left home than they lived when their children were in the home. As well, most life cycle theories feature a traditional idea of family that includes a husband and wife who have children and remain married for life. This stereotypical depiction does not capture the true heterogeneity of contemporary American family life with its childless families, blended families, families of single mothers, gay couples and parents, or other varieties of family experience. In many instances, family therapists must adapt the traditional life cycle model to the particular population and culture with whom they are working.

Other specific approaches to family therapy with older adults have been developed that build upon systemic and life-cycle themes. The contextual approach emphasizes family ethics and seeks to help balance the intergenerational “ledger” so that patterns of caregiving are congruent with the family's history and resources. Behavioral and cognitive-behavioral approaches work with behavioral contingencies in the family and the correction of cognitive distortions. The symbolic-experiential approach emphasizes the family's perceptual construction of who is in and who is out of the family, to help them adjust to changes in family structure caused by major illness and death.

The strength-vulnerability model of health and illness in older adults also builds upon systemic and life cycle themes by postulating that the mental health or illness of individual family members is determined over time by the interaction of individual and family life cycle processes. The model focuses on strengths and vulnerabilities at the level of the individual older adult (e.g., biological health, personal themes, and individual life history) as well as health-enhancing and risk factors at the larger levels of family and other social systems (e.g., family events, themes, relational processes). Central to the strength-vulnerability model and its clinical applicability is the epigenetic theory of family relational development. According to this theory, *attachment and caregiving* is the bond of affection between family members that must be present as a foundation for the development of other interpersonal processes in the family. *Communication* is the development of shared meaning between family members. This process includes sharing important themes and content as well as constructive communication of affect. *Problem solving* is the ability to develop solutions to problems and carry them out cooperatively. Implicitly or explicitly, this process involves the delineation of family roles as they pertain to decision making and authority. *Mutuality* is the long-term commitment to the relationship and the ability to reinvent the relationship over time in the face of life-cycle transitions. These processes develop sequentially in families, so that some attachment and caregiving is necessary for effective communication. Likewise, some effective communication is needed to successfully and collaboratively solve problems. Finally, effective problem solving is a prerequisite to the ability to reorganize and reinvent with mutual understanding those family relationships that accelerate during periods of crisis and life change. The epigenetic pattern is actually circular: if crises are met with successful mutuality, attachment and caregiving will take a new and strengthened form. With unsatisfactory resolution of change, the bedrock of attachment and caregiving will be undermined.

TECHNIQUES

The late-life family therapist must frame interventions that are developmentally congruent with the family's stage of relational and life cycle development. Thus, careful assessment is a necessary precursor to intervention.

Assessment During the initial sessions the therapist evaluates the family's unique strengths and vulnerabilities, including at a minimum the following key points.

Life cycle transitions faced by the family and by individual family members; for example, retirement, grandparenthood, loss of spouse, onset of chronic or degenerating illness

Individual roles assumed by family members; for example, caregiver, breadwinner, matriarch or patriarch, scapegoat

Family relational processes; that is, the quality of attachment or caregiving bonds, communication, and problem solving

Ethnic or cultural factors impacting the family's functioning or the therapist's own reactions to the family

Intervention When initially working with a family, several levels of intervention are considered, each reflecting work at successively deeper strata of family process. These levels should be used as general guidelines for considering the type and intensity of treatment appropriate for a particular family rather than as discrete stages of treatment to be followed in lockstep fashion with every family.

Level One: Psychoeducation and Community Referral Families who exhibit solid attachment bonds, open communication, and good problem-solving skills congruent with their stage of life cycle development do not require ongoing therapy but instead benefit from brief education and consultation regarding a specific

late-life problem. For example, when an older adult develops a new medical or neurological disorder such as Alzheimer's disease, families benefit from information specific to the disorder and its management as well as referral to community agencies and support groups. Usually these families can then organize themselves for effective problem solving pertaining to the care and support of the elderly person. In the case of chronic, deteriorating illnesses such as Alzheimer's disease, however, the family may benefit from brief, intermittent contact with the therapist at those times when the disease worsens. As pleasant and rewarding as these families are to work with, the family therapist must recognize that typically they do not need regular, ongoing professional support.

Level Two: Restoring Effective Problem Solving Often families have solid, positive bonds of attachment with good communication skills and a history of effective problem solving, yet they are temporarily overwhelmed by the intensity and unfamiliarity of a late-life problem, such as severe illness or the declining functional ability of a previously capable older adult. In these cases, effective problem solving may be temporarily stymied because of paralyzing grief reactions or sudden disequilibrium in the previously stable family structure. The family may need to reorganize the lines of authority and decision making to bring them into accordance with their life-cycle transition. For example, when an elderly matriarch or patriarch experiences decline in health or cognitive capacity, the spouse and adult offspring may be unaccustomed to assuming a decision-making role. After receiving clear and direct information about the status of the elder and having an opportunity to grieve about the changes in the once-powerful individual, adult offspring at this level of development can mobilize their resources to solve family problems. Problems of financial management are a common source of family conflict. Adult offspring may believe or have evidence that their parent or parents are mishandling diminishing resources, but the elder may see the problem quite differently.

Mr. and Mrs. C. had just celebrated their fiftieth wedding anniversary when the family started to notice changes in Mr. C.'s behavior. Typically an outgoing and engaging man who “always liked to be in the driver's seat” in regard to most matters of family and civic life, he began to defer decisions about financial matters to his wife and stopped taking the lead in various church activities and fund raisers. The couple had two twin daughters who were married and raising their own children. Despite their busy lives, the daughters maintained close ties with their parents and visited frequently. In fact, they were both inclined to say that their father was the most important man in their lives in terms of giving them guidance and support. As Mr. C. became more reclusive over the next year, they frequently discussed the situation with their mother but never with their father. All of the family members were afraid to discuss their concerns with Mr. C., as they were concerned about hurting his feelings or damaging his pride. However, they finally sought consultation with the family doctor after Mr. C. had gone off for a walk one day and was discovered by neighbors, tearfully trying to find his way back home. Medical workup failed to reveal any reversible medical causes for Mr. C.'s swiftly declining cognitive functions, and a provisional diagnosis of Alzheimer's disease was made. The family was referred to a local memory disorders clinic for counseling and the opportunity to learn about medications that might help slow Mr. C.'s cognitive decline. During an initial meeting, they were given informational material about Alzheimer's disease, antidementia medications, and support groups in town. However, they declined further meetings because Mr. C. said it was unnecessary and they were reluctant to challenge his opinion.

One month later, they called the clinic requesting an urgent appointment because Mr. C. had been involved in an automobile accident. Only Mrs. C. and the two daughters came to the appointment. All were distraught, saying they did not know what to do or how to handle Mr. C. who always had made decisions for himself and everyone else in the family. Mrs. C. disclosed that she was now being treated for depression and felt unable to summon the energy needed to keep watch over her husband. The therapist listened to their concerns and encouraged each of them to share her feelings about seeing her beloved family member change so much. Eventually, the therapist gently suggested that it was necessary for Mr. C. to retire as active head of the family and hand the baton of authority on to the next generation. One of the daughters stated that she had been thinking of the potential benefits of assuming power of attorney for her parents but was frightened to bring this up for fear it would upset her parents. Mrs. C. reassured her daughters that she appreciated their helping out in any way possible. They spent the rest of the session planning a family meeting during which they would gently confront Mr. C. with their concerns. The therapist encouraged them to frame the problem as needing to have him consider treatment so that he could help them cope with the difficulties posed by his illness.

Over the next 2 months, they met with the family therapist three times to get support and problem solve as a family about how to handle Mr. C.'s illness. Mr. C. himself attended two of these sessions and eventually agreed to give up driving and take some medication that might slow the progression of his dementia. He also agreed to turn the management of the couple's finances over to his daughters. This represented a major shift in the authority structure of the family, with the daughters beginning to play a major role in the caretaking of the older generation. After these initial sessions during which they developed new roles for decision making, the family was able to communicate and problem solve effectively regarding the care and management of Mr. C.'s rapidly progressing dementia. However, they met with clinic staff several times for information, consultation, and support over the course of the illness, especially during periods when Mr. C.'s condition worsened and required new behavioral strategies or, ultimately, a higher level of care (i.e., when he became agitated and aggressive, when his medical and behavioral problems became so severe that the family needed to seek placement).

Level Three: Improving Patterns of Communication Some families who care deeply about each other and have solid bonds of attachment communicate little about serious problems facing the family. Some may have a history of arguments and resentment stemming from past crises. Other families have been able to function with little overt communication in earlier stages of the life cycle because they did not experience major loss, medical illness, or cognitive decline. When faced with the tremendous challenges that come with aging, they cannot develop a common understanding of the problem and thus cannot problem solve effectively. Families at this level benefit from active modeling of open communication as well as active structuring of negative or critical communication. Basic techniques of communication training such as active listening can greatly benefit these families.

Level Four: Improving Attachment and Caregiving Bonds Families with negative, weak, or ambivalent bonds of attachment typically have a history of conflict, marginal functioning, and insufficient nurturance between family members. In some of the most difficult cases, adult offspring who were abused or neglected as children are struggling to care for their former abuser. One of the most damaging mistakes a late-life therapist can make at this level is intervening on the level of education, problem solving, or communication without addressing the negative or ambivalent attachment bonds. These families are at risk for elder abuse, and in some cases professional caregivers must be brought in or referral must be made to a long-term care facility. In many instances, however, the technique of family life review can be used to induce empathy for the elder's position, thereby decreasing negativity and possibly forging more-positive bonds of affection between the generations.

Family life review is the process of bringing multiple generations of family members together to weave a coherent intergenerational story. Typically, this process is facilitated by having the family construct a *family genogram*, which is a graphic, multigenerational picture (family tree) that encapsulates family history, structure, and relationships over time. The therapist encourages the family to begin with the story of the elders' families of origin, gradually working down through the themes and experiences of subsequent generations. Learning about the elder's upbringing and early family circumstances or struggles often gives younger family members a different, more empathic perspective on the elder. Some offspring or grandchildren can then establish an adult relationship with the elder rather than continuing to relate solely from the vantage point of children who have their own needs for nurturance and caretaking.

Mr. D. was an 67-year-old widowed, retired salesman who was admitted to an acute psychiatric ward following a near-lethal suicide attempt by overdose on pain medication. He was found unconscious by a neighbor, having written a note to his children giving them information about his bank accounts. On the hospital unit, he was quite withdrawn and depressed, refusing to accept treatment and giving little information to the therapist except to mutter occasionally that he was “worth more dead than alive.”

Telephone calls were made to his two children (a 45-year-old son and a 42-year-old daughter), who immediately came to meet with the treatment team. (Mr. D. refused to attend the first meeting.) They sadly acknowledged that they had seen their father much less in the past year, as their lives were quite full with their own jobs and families. As well, they noted that they had never been as close to their father as they had been to their mother, who died 5 years earlier of lung cancer. When asked to describe their relationship with their father, they revealed his history of alcohol abuse and described their childhood fears of his unpredictable violent rages, during which he would become loud and verbally abusive. Although he had stopped drinking long ago and no longer treated them aggressively, they viewed him as a solitary man who had lost interest in his extended family since the death of his wife. The daughter volunteered that their mother had died from lung cancer 5 years earlier and they were not told of her diagnosis or the specifics of her illness until after her death, supposedly so they would not worry. When the therapist noticed the tears in the daughter's eyes and asked if they had ever really talked about her death as a family, the daughter began to weep quietly.

Recognizing the ambivalent bonds of attachment and closed communication style of the family, the therapist decided not to move immediately into the potentially overwhelming process of family grieving. Instead, attempts were made to get Mr. D. to attend family sessions to “get some family history that will help us learn how better to help you and your family cope with all that's been happening.” Mr. D. agreed to five sessions to be held over the course of the next 3 weeks, with the understanding that the purpose of the meetings was “to help his children” cope with the changes in the family. (The therapy team suggested that the purpose be framed this way to help Mr. D. save face in the family.) The initial sessions were spent conducting a life review, during which Mr. D. was asked to tell his children about his own family of origin. For the first time, he revealed to his son and daughter that he himself had been physically abused by his father. They were moved by their father's story and, for the first time, were able to see him as a vulnerable person who had been deeply wounded as a child. Rather than the powerful, frightening figure who would rage at them during his intoxicated episodes, they could imagine him as a small boy cowering under the blows of his own father.

During the third session, they were able to confront Mr. D. with their own childhood experiences of his drunken rages. After some initial distress during which he attempted to explain away his previous behavior, the therapist helped him ask for their forgiveness. At this point he began to weep quietly and said that he had also asked their mother for forgiveness before she died. As the family shared remembrances of Mrs. D., they were finally able to grieve her loss as a family. In the fifth and final family meeting, they were ready to turn to the issue of Mr. D.'s depression and suicide attempt. Mr. D. described how purposeless and alone he felt after his wife died. He had very few friends and missed seeing his children and grandchildren. Yet he felt that he was of no use to anyone anymore and did not want to “be a drain” on his children. The children responded emotionally that they were not ready to lose both of their parents. With support from the therapist, they were able to convince their father to comply with the recommendations for a trial of antidepressant treatment and supportive counseling sessions.

CLINICAL ISSUES

Indications Clinical experience and research indicate that most serious mental health problems of older adults are more successfully addressed when family members are involved in the treatment. Although caution and clinical judgment must be exercised as to the type and timing of family intervention, substantial evidence indicates that psychiatric problems worsen or resolve less completely when conflictual or chaotic family environments are not addressed in the treatment. Research shows that family factors may be especially important in the following clinical conditions.

Medical or Neurological Illnesses Requiring Caregiving The provision of regular, ongoing care for an elder with chronic or degenerating illness such as Alzheimer's disease can cause serious emotional distress in the caregiver. Research with families of Alzheimer's patients indicates that a combination of individual and family therapy can decrease the level of caregiver depression and delay nursing home placement of the patient. Effective interventions for caregiving families typically focus on a combination of goals, including increasing knowledge about the illness, developing problem-solving techniques for managing difficult patient behaviors and the caregiver's associated emotions, and increasing the caregiver's sense of support.

Research examining the problem-solving conversations of caregiving families reveals that certain patterns of communication can contribute to caregiver depression. For example, negative affect expressed by family members is directly related to the depression level of the caregiver. Depressed caregivers give more empathic responses to family members than less depressed caregivers do, and these empathic responses often engender angry comments from the family members. These findings suggest that depressed caregivers attempt to provide support to other family members but receive angry responses in return.

Late-Life Depression and Suicide Depression is one of the more common and functionally disabling psychopathological disorders of late life. For men, the risk of suicide increases dramatically with age and is often associated with major depressive disorder. Research with mixed-age samples of adults underscores the relevance of family relational factors in the etiology and treatment of depression and suicide. Negative patterns of communication (typically assessed in terms of high levels of criticism) and poor problem-solving skills have been associated with relapse and poor recovery from depressive disorders as well as with increased suicidal behavior. Although less research has focused specifically on older adults, the research that does exist associates higher levels of critical communication and emotional overinvolvement in the adult offspring with higher rates of depressive relapse in the older adult and lower rates of complete recovery. Additionally, family strain is associated with suicidal behavior in depressed older adults.

When viewed from a family-systems, life-cycle perspective, high levels of critical communication and family strain indicate that the family is having difficulty negotiating later life-cycle transitions such as declining physical or mental health in the older generation. Anecdotal clinical evidence indicates that many depressed older adults become suicidal at a normative juncture or transition point in the family life cycle when the elder needs greater closeness and more support from adult offspring because of significant interpersonal losses, change of role status, or physical decline. Yet the younger generations are frequently quite busy managing the needs of their own families or marriage. This developmental crisis occurs gradually in many families but abruptly in others; for example, when a previously capable elder is diagnosed with terminal or deteriorating illness. In these instances, the family's relational development (i.e., their ability to communicate effectively and problem solve successfully) may lag behind their stage of structural development (i.e., when the older generation can no longer make primary decisions). Older individuals can be at increased risk for suicide if they remain isolated or alienated from adult offspring when they are experiencing a developmental imperative to be connected and somehow useful to younger and future generations. If little contact or open communication exists between the generations, the suicidal behavior may represent a means of communicating despair, bringing the intergenerational family together, or both. In such a closed system, elders may come to view themselves as expendable at best or burdensome at worst. The suicidal act may be perceived as the only way to help their successors; that is, these elders perceive it as a means of relieving the family of the burden of having to support or take care of them. Unfortunately, these clinical impressions have not been validated with empirical research, and there are currently no empirically tested models of family treatment designed specifically to address the problem of suicidal older adults.

ETHICAL ISSUES

Elder Abuse Community-based studies indicate that between 3 and 6 percent of individuals over the age of 65 in the United States and other Western countries have experienced abuse, neglect, or both, most often at the hands of a family member. Many states have mandatory reporting laws for elder abuse as well as state- or county-funded protective service programs that work with older adults who have been abused. Family therapists must know the reporting laws in the state where they are practicing and watch for signs of abuse or neglect. Although estimates indicate that one third of actual cases of child abuse are reported, only one of six cases of elder abuse is reported. Older adults are often reluctant to disclose the problem, for fear of retaliation from the abusing family member.

Elderly individuals who suffer from depression are inclined to view themselves as negative and burdensome, and they may actually believe that they deserve maltreatment. There is a need for increased professional awareness of the problem and its warning signs. Research indicates that elders who are cognitively or functionally disabled are at particular risk for abuse, and some who suffer severe disability are unable to report maltreatment. Advanced age, physical and economic dependency on caregivers, isolation, intergenerational conflict, alcoholism (in the elder or caregivers), and mental illness (in the elder or caregivers) have all been associated with increased risk of abuse. Thus, the family therapist must be alert for signs of abuse or neglect, including repeated, unexplained bruises or injuries, malnutrition, fearfulness around particular family members, or, in the case of elders who are being financially exploited, a discrepancy between their ability to pay for personal commodities and their reported level of income. Although the therapist may fear offending the family members or the elder by inquiring about such issues or referring the family to the local adult protective service, most families who are not abusive welcome careful and comprehensive review of the elder's situation. In some

instances, it is useful to frame the referral to the adult protective services as a means of getting access to useful support services in the community.

Although there is some literature on effective community support programs for abused elders, the field generally lacks outcome studies of family therapy for elder abuse or neglect. In part, this is because many of these families have such severely damaged bonds of attachment that caretaking must be arranged outside the family system. Nevertheless, more research is needed to guide family therapists in deciding which families can be treated and which family treatment techniques are the most effective.

End-of-Life Decision Making As advances in medicine extend the survival of more individuals with chronic illness, more older adults and their families are confronted with decisions about the use of life-sustaining measures. Despite the emphasis on individual autonomy and self-determination that is featured in many formal documents and statutes on the subject, recent research indicates that older adults want family members involved in such decisions. Moreover, many elders with terminal and chronically disabling illnesses cannot make decisions for themselves because of cognitive disorders or loss of consciousness. Investigations asking older adults about who they would choose as a surrogate decision-maker indicate that as many as 90 percent of older adults choose family members over friends, doctors, or lawyers. In descending order, they prefer a spouse, adult offspring, siblings, or other family members such as a cousin or niece to make end-of-life decisions for them. Despite the preference of most physicians to have one family member to deal with in such a circumstance, older adults typically prefer that medical decisions be made collaboratively, with input from multiple family members, especially when adult offspring are involved.

When functioning as surrogate decision-makers, adult offspring want to respect their parents' values and wishes. Yet research indicates little agreement between adult offspring and their parents on the importance of factors such as financial strain or burden of care in making a decision about life-sustaining treatment for the parent. Moreover, it is questionable whether adult children actually know their parents' specific preferences in these matters. There is a great need for family therapists and other health care professionals to help facilitate open communication about these matters while elders can still express their wishes.

SUGGESTED CROSS-REFERENCES

Section 30.5 features discussion of family therapy with the general adult population. Normal aging is covered in Section 51.2c. Late-life neurological and psychiatric disorders, such as Alzheimer's disease and mood disorders, are described in Section 51.3d and Section 51.3e. Ethnic and minority issues are covered in Section 51.6e. Ethical issues of late-life are discussed further in Section 51.6c. Section 51.6g includes more information on elder abuse.

CHAPTER 51. GERIATRIC PSYCHIATRY

51.4 TREATMENT OF PSYCHIATRIC DISORDERS

51.4L GROUP THERAPY

MOLYN LESZCZ, M.D., F.R.C.P.(C)

Group treatments play an important role in the comprehensive care of geriatric patients presenting psychological distress. Group therapy entails a broad range of specific models and techniques applied to a heterogeneous population of elderly adults in a variety of settings, and there is a risk of misapplication of models if elderly adults are viewed as a homogeneous population. A unifying principle is that group therapy should provide opportunities for restoration, amelioration, or improved adaptation and coping, related to the participants' age-induced losses of interpersonal, emotional, and cognitive capacities. In all instances, treatment is guided by the therapist's belief in the continued scope for change in later life.

HISTORY

An early tradition of group therapy began with the work of social workers in a variety of settings for seniors including homes for the aged, community centers, and mental institutions in the earlier part of the twentieth century, providing group interventions combining activity and social treatments. Maurice Linden was one of the first psychiatrists to publish in this area. He challenged traditional pessimistic myths about the untreatability of the elderly population. The opportunity he provided psychotic and “senile” institutionalized patients for social engagement and relatedness diminished exaggerated disability, dependence, and withdrawal. The intervention was well tolerated by patients, satisfying to staff, and economical.

Over the last half century, in response to the growing elderly population, the practice of group therapy has evolved to include acute care settings, day hospitals, and ambulatory and community settings. For some elderly patients today, group therapy is a later-life installment of an earlier psychotherapy. Group therapy is regularly integrated with psychopharmacotherapy as part of comprehensive treatment. Within the field of psychotherapy itself, the current approaches synthesize the strengths of cognitive-behavior, dynamic, and developmental models.

Current models include (1) verbal groups for the cognitively intact, including groups for burdened caregivers; (2) verbal groups for the cognitively impaired, including resocialization, remotivation, and reality-orientation groups; (3) activity- and creativity-centered groups, including dance movement, drama, music, art, and poetry groups; and (4) a variety of time-limited homogeneous groups addressing issues such as retirement and bereavement.

THEORETICAL ISSUES

The themes encountered in geriatric group therapy include reactions to loss or decline and the resultant discontinuity with a prior, more valued sense of self. Depression is a frequent disturbance, often comorbid with anxiety, affecting both cognitively intact and cognitively impaired elderly adults.

Loneliness and the lack of social integration are profound risk factors in depression. Higher levels of social support predict a significantly superior clinical course in the treatment of depression. Group therapy provides opportunities to grieve losses and reengage with interests and relationships. It provides real relatedness along with the acquisition of skills needed to generate social integration beyond treatment. Enhanced social support produces a main effect of improved well-being and a secondary, stress-buffering effect, which are particularly important for elderly persons in light of the likelihood of further losses. Combined pharmacotherapy and psychotherapy in the immediate, maintenance, and continuation phases of treatment is an area of important clinical study. It appears that combined treatment produces particularly robust results in treatment of acute problems. Combining drug and psychosocial therapies requires attention to the meaning each treatment has to the individual and cognizance of the risks of devaluing one or the other. Objectives include sustaining durable treatment responses and reducing subsequent affective morbidity, chronic psychosocial invalidism, and poor adherence to nonpsychiatric medical treatment. Treatment compliance can be enhanced through social support, education, and remoralization.

Developmental, psychodynamic, and cognitive-behavior models demonstrate substantial overlap and may be integrated both theoretically and technically. Dynamic or developmental approaches and cognitive-behavior approaches combine into a seamless, integrated whole with the recognition that effective psychotherapy is facilitated by appreciation of the individual's covert, subjective experience of more manifest interpersonal behavior, bridging depth of understanding with skill acquisition. The objectives of treatment include restoration of a sense of the individual's self, which integrates the present with the past; empathic confrontation of cognitive distortions; identification of maladaptive, alienating interpersonal behaviors; acquisition of interpersonal, social, and behavioral skills that the individual can use to enter and maintain a social network; and extending the adaptive cycle outside the in-treatment environment. Within this framework one can work within the same group or even within the same session on a number of interrelated issues.

The integrative model emphasizes the individuals' authorship of their own relational worlds. It combines working in the here-and-now of the group, using interpersonal feedback within the group, with processing of extra-group events and homework, which adds an intensity and relevance that enlivens cognitive and behavioral approaches. Similarly, incorporating the patient's reminiscing about an earlier, more robust sense of self creates opportunities for psychological restoration by recollection and also sets the stage for contemporary use of these valued elements of the self.

Activity- and creativity-centered groups foster social engagement through shared participation in a pleasurable activity and rekindle a sense of self through use of the creative process. Group activities elicit feelings of pleasure and mastery, challenge self-denigrating and constrictive distortions that individuals may have about themselves, and counter the trend toward homogenization within institutional life.

Group therapy may be more acceptable and provoke less anxiety than individual therapy because patients can share concerns and be of mutual help. Regression may also be diminished by participation in the group. Groups generally provide opportunities for behavioral change and may be of particular use for the older person who is less familiar with more abstract psychological issues.

Groups for burdened caregivers have become quite important in response to the increasing number of frail or impaired individuals being cared for by their families in the community. These caregivers are often highly burdened, isolated, overwhelmed, and not infrequently depressed, yet they are the key to implementing any interventions for the identified patient. The most effective groups provide a combination of emotional support and practical information. Groups may give caregivers an opportunity to work through feelings of loss, abandonment, and anger at the burdens imposed on them. Attention within the actual groups to the process of care giving and receiving can help caregivers identify a range of strengths and problems.

Resocialization and remotivation groups for cognitively impaired elderly persons play a significant role, largely in institutional settings. Interpersonal engagement may be achieved through the structure and content of these groups, with an emphasis on maximal sensory stimulation, rather than through active attention to the group process. Further development of nonpharmacological interventions in the treatment of demented individuals is needed to provide maximum rehabilitation opportunities for the retention of cognitive and social abilities.

TECHNIQUES

Technical expertise in the application of group therapies is surpassed in importance only by the therapist's posture of respect, hopefulness, genuine warmth, and empathy. Successful treatment hinges on establishing group cohesion, which may be problematic with demoralized, withdrawn, and self- or other-devaluing patients. Therapist activity must focus on catalyzing group interaction in ways that do not diminish or infantilize the participants. Cotherapy may provide an appropriate level of focus and activation, continuity during therapist absences, and the recognition and working through of countertransferential reactions. Within institutional settings, cotherapy also facilitates transmission of information between the group and other treaters to ensure maximum treatment integrity.

Attention must be paid to maintaining group norms and group integrity, which may also be challenged by patient or institutional resistance. Meetings must be scheduled at an inviolate time in an inviolate location. Active outreach may be required in ambulatory settings to promote regular attendance. Each member should find the therapy self-esteem enhancing and sustaining and a nonfailure experience. The therapist should achieve a balance between support and expression and may need to intervene with active prompting, reinforcement, reframing, and modulation of emotional intensity, emphasizing the invitation for what is desired rather than the rebuke for what is not. The empathic confrontation of projective defenses and resistances to engagement is an important therapeutic task. The therapist may need to be quite active in reinforcing progroup or procohesion exchanges, bolstering patient feelings of worth and belonging. Depressive affect must not overwhelm the group, as depressed elderly persons are particularly prone to the affect of demoralization. Patients must understand that demoralization is a specific reaction and not an obligatory state of aging.

Groups for elderly adults may often be held at midday in ambulatory settings and may be contiguous with lunch, to encourage opportunities for social interaction around mealtime. In institutional settings, group members often are involved with one another outside the group. Opportunities for engagement and interaction outside the group can be used as part of the prescription of behavioral interventions and to facilitate homework. In all instances, a group norm should be established that protects the confidentiality of the group therapy and encompasses extra group contact within the treatment framework.

Therapy groups generally consist of 6 to 10 patients, but activity groups may be much larger and require more than one or two leaders. Session length depends on members' capacities and may vary from 30 minutes daily for cognitively impaired patients to 75 and 90 minutes weekly for more cognitively intact patients. Many group formats are ongoing, but most cognitive-behavioral groups and groups for burdened caregivers are closed and time-limited, lasting from 6 to 20 sessions. The limitations of briefer treatments are being recognized, and treatments are often extended to include maintenance and booster sessions that meet less frequently but over a longer period of time, to extend treatment into maintenance and continuation phases. Special provision may be needed to accommodate hearing impairment through the use of FM amplifying systems.

Self-psychology makes a valuable contribution in psychodynamic group approaches by virtue of the understanding it provides about the inner world of the individual and the consequences of loss of selfobject and self-sustaining relationships, capacities, and functions. Empathic awareness of the impact of loss and decline as experienced subjectively may diminish the risk of collusion with demoralization or engagement in negative interpersonal cycles of criticism and rejection. The group may be used constructively in a self-sustaining mode for mirroring, idealized, adversarial, or twinning selfobject transferences, creating an opportunity for each member of the group to feel valued among a group of peers. Authentic engagement and empathic attunement with peers may diminish patient concerns about not being understood by much younger therapists.

Life review and reminiscing techniques use the natural process of patients' recollections and review of their lives. An empathic appreciation of the subjective meaning of the past to each member of the group is important. Reminiscing can be used as a main treatment focus or as an introductory exercise to stimulate cohesion in beginning groups. Reminiscing can be spontaneous or prescribed in a series of sessions, following a chronological life course sequence. One can use either milestoning (which emphasizes only positive events) or a comprehensive, autobiographical review process that provides an opportunity for mourning, conflict resolution, and acceptance. Encouraging a focus on the past is not without risk. Facilitating the group members' return to dialogue within the here-and-now of the group and eliciting feedback and interaction ensures that morbid self-absorption, preoccupation, and guilt do not exacerbate the individual's disengagement from the group or adherence to the past as a way of avoiding engagement with the present.

Aging often involves a shift from primary control, in which one effects change in the environment to deal with obstructions to one's needs and potentials, to secondary control, in which one's beliefs and attitudes must be realigned to address these obstructions (e.g., decreased mobility and access to social engagement and opportunities). Failing to do so may generate profound difficulties with self-criticism and beliefs about one's incompetence. Cognitive-behavior therapy emphasizes conscious cognition and learning and adapts behavioral strategies and the cognitive therapy model to the group setting, affording opportunities to acquire cognitive and behavioral skills. Dysfunctional cognitions and beliefs that cause depression are identified, confronted, and linked to prescribed changes in behavioral patterns.

This model emphasizes teaching skills, with a persistent focus on patients assuming responsibility and crediting themselves for improvements, stimulating a sense of mastery. Larger problems are deconstructed into smaller, more manageable components. Therapeutic strategies include challenging the patient's processes of generalizing, magnifying, and dichotomous thinking. Patients are helped to generate alternative solutions and responses; reattribute meaning to events; schedule activities with the assertion of pleasurable activities and affects; use time meaningfully; and challenge both the discarding of positive options and the failure to take credit for partial positive gains. Patients may be taught to log the relationship between mood and either pleasurable or aversive experiences and to increase the frequency of pleasure-focused activities. Behavioral prescriptions may be quite explicit and include modeling, role play, didactic sessions, psychoeducation, and review of homework, with feedback provided about each group member's efforts in using prescribed skills to reengage with pleasurable experiences.

A group therapy session for depressed elderly persons in a psychiatric day hospital began with the orientation of a new member to the group, a 79-year-old widower. Mr. J. was responsive to the group members, who discussed the value that they found in open expression to one another and sharing mutual support. They cautioned him that it might take time to feel comfortable within the group and not to be discouraged because like them, he would be likely to feel progressively more comfortable within the group. In fact Mr. J. seized upon this welcome to begin to articulate how he understood his recent onset of depression. Although a widower for some time, he told the group that earlier he had been able to overcome the loss of his wife because she had been ill for some time and they had a long and essentially happy life together. Six months ago, however, his 18-year-old granddaughter was killed by a car when she was jogging. This loss was incomprehensible to him, and the feelings of grief and depression overwhelmed him and made it impossible to find comfort or solace in any activity or relationship. He had disengaged from his life and felt such sadness with the parents of his granddaughter that he withdrew from them as well, refusing invitations to visit. Members of the group immediately expressed support and sadness, recollecting prior losses they had had.

Mrs. G., a 77-year-old woman who had previously participated in the group marginally, was visibly moved in response to Mr. J. This was noted, and with support she articulated her own experience for the first time to the group. Encouraged by Mr. J.'s openness, Mrs. G. started by saying that she was going to talk about some things that she had not talked about previously with anyone in the group. She said that although she too was widowed, a source of recurrent depression was her grief over the loss of her daughter, who had died several years ago at the age of 30. She described how her daughter had been diagnosed with a chronic renal disease at a young age and, in fact, had not been expected to live into her 20s. Her daughter defied the original prognosis, and despite her grim prognosis and over her mother's objection, she married at the age of 22, hoping that she would again defy the grim prognosis she received as a teenager. Mrs. G. told the group that her daughter died a few years later, and they were obviously saddened by this further disclosure. The group leader noted the obvious pain of these losses but seized upon an additional point that Mrs. G. mentioned, namely, that she had felt estranged from her daughter because of her daughter's seemingly “foolish” action of getting married. The greater tragedy she noted was that she had not been able to be as close to her daughter as she had hoped, prior to her daughter's death. She felt pain and guilt about that isolation and estrangement to this day.

With exploration and questioning from group members, she was pushed to try to rethink her daughter's actions as not necessarily foolish and inappropriate but rather as a reflection of somebody who was committed to living life as fully as possible for as long as possible. Living life in the presence of death was underscored as a major challenge that had to be faced. Other members of the group described how they have reacted to the fragility of life by avoidance and withdrawal. The group therapist suggested that this could be an important time to respond to this fragility by moving in the opposite direction—engaging life and the people that mattered to them. It was pointed out that this was happening in this group within the here-and-now, and when asked, Mrs. G. noted her relief in disclosing this guarded secret to the group members. People had chosen to support each other and encourage openness, facilitating necessary psychological work. In so doing, they duly honored the memory of their loved ones. The sadness began to lift in the group as group members were asked to articulate clearly and precisely the areas they could begin to work on, both within the group and outside of the group, and to seize such opportunities and to focus on this in subsequent meetings.

CLINICAL ISSUES

Indications Group therapy may be used as an adjunct to pharmacotherapy or as an independent treatment. Selection criteria should emphasize the homogeneity of

members' ego functions and cognitive capacities, not age alone. Groups homogeneous for these factors develop cohesion more rapidly than groups that must struggle with a member who significantly deviates from the group norm and invites disidentification (e.g., inclusion of a cognitively impaired patient with cognitively intact patients). Although pregroup preparation has not been extensively researched with elderly persons, the evidence supporting its usefulness in other patient populations is quite substantial, and it is routinely incorporated into cognitive and behavioral group treatments. Pretherapy preparation outlining the goals and methods of the group treatment demystifies an otherwise anxiety-provoking situation, helps to establish a therapeutic alliance, and sets group norms regarding regular attendance, confidentiality, and extragroup socialization. It may increase tenure and task adherence and foster hopefulness. Growing successful clinical experience contradicts earlier assumptions regarding elderly adults' capacity to engage effectively in psychotherapy. Many elderly individuals have been able to maintain effective adaptation, until those coping abilities are overwhelmed by loss, transition in roles, or illness. Comprehensive assessment of each individual's emotional, interpersonal, and cognitive status establishes a focus for treatment. Identification of egosyntonic character difficulties, in particular narcissistic pathology or interpersonally alienating behaviors, may be useful in delimiting behaviors that can result in early rejection from the group. Drop-out rates in group therapy in general range from 10 to 50 percent in younger adults and is likely the same in the elderly population. The likelihood of premature termination from treatment increases with increasing severity of depression, comorbid physical illness, and comorbid characteristic difficulties manifested in persistent *devaluation and externalization*.

Contraindications Contraindications are relative and relate more to the specific group than to the general premise of a group intervention. In general, individuals who require acute and active management because they are in crisis, suicidal, or acutely psychotic do not do well in groups. Severe cognitive or sensory impairment may also require exclusion from group therapy.

Goals Notwithstanding the range of group formats described, consensus exists regarding realistic goals of treatment. Although obviously shaped by particular patient needs, in general, the goals of treatment include reduction of symptomatic disturbance; reduction of isolation; restoration of interpersonal skills and engagement within a social network; correction of distortions and cognitive beliefs; restoration of self-esteem; improved cognitive function; acquisition of problem-solving and coping skills; grieving and adapting to loss; and realistic acceptance of one's needs and limitations with effective use of available resources. In institutional settings, group therapy may provide a forum to deal with the imposed changes in life situations and reduced feelings of autonomy, thereby enhancing quality of life by addressing issues of fit or dissonance between the individual and the imposed environment.

Objectives of groups for burdened caregivers include education about the illness process and specific ways of providing care; acquisition of both strategies for dealing with disruptive behavior and problem-solving and stress-reduction skills. Working through loss and grief and facilitating appropriate disengagement that may lead to more realistic decisions about placement are also important objectives. Additional areas of focus include legitimizing the needs of the caregiver and promoting self-care, working through anger and guilt, and addressing relationships with health care professionals. These objectives may be integrated or addressed in a series of modules that emphasize different important aspects sequentially. Quality-of-life concerns for both caregiver and patient are important foci. Groups for the cognitively impaired aim at reducing excess disability and fostering more appropriate social behavior and social functioning, thereby improving quality of life.

ETHICAL ISSUES

Proper patient selection and preparation and competent therapist functioning contribute to a treatment that is generally well tolerated and experienced by participants as humane and supportive. Interventions should be attuned to ethnic and cultural diversity and respect the unique beliefs, customs, and attitudes of identified populations. The therapy group may become very important and meaningful to its members, who may resist ending treatment because of the important social support and self-restorative experience the group provides. This necessitates active focus on transferring skills gained in treatment into the external world, recognizing that treatment is a bridge and not a destination. Therapeutic groups must be well integrated collaboratively into the overall milieu in which the individual resides. Alterations required in the framework of group therapy within institutional settings, along with other factors that contribute to a higher likelihood of extra group contact occurring and even being endorsed, warrants special attention to issues of confidentiality. Extragroup contact and the risk of subsequent subgrouping may be managed by diminishing secretiveness around the extragroup relationships and actively bringing them into the purview of the group. Group therapy is compatible with clinically indicated pharmacotherapy, and its concurrent use is complementary, not antagonistic.

RESEARCH AND EVALUATION

Substantial evidence supports the effectiveness of a range of group therapies with elderly persons. Qualitative reviews note that rationally used and conceptually sound group approaches are as effective as, and significantly superior to, no treatment of geriatric depression. This is clearest for mild or moderate depression, but even for severe depression, group psychotherapy may play an important role allied with pharmacotherapy in the acute, maintenance, and continuation phases of treatment. Structured groups are more effective than unstructured groups. Groups that lack focus or appreciation of the potential to amplify depression by encouraging intense affects beyond the members' capacity to tolerate have the potential for poorer treatment outcomes. Active cognitive and behavioral skill acquisition that addresses interpersonal difficulties and cognitive distortions is superior to reminiscence therapy alone. The focus that cognitive behavior therapy maintains on skill acquisition is particularly effective and leads to significantly improved and durable outcomes at 1-year follow-up.

Meta-analysis of psychosocial interventions in geriatric depression notes that psychosocial interventions (with group therapy particularly prominent) demonstrate a significant effect relative to placebo or no treatment. Positive outcome correlates with the degree of interpersonal engagement and the sense of interpersonal competence and effectiveness experienced by members of the group. Severe comorbid physical illness correlates negatively with successful outcome, and the durability of improvement is reduced by serious physical illness.

Benefits of treatment include reduced anxiety and depression and increased feelings of self-validation, self-acceptance, and self-esteem, with more-realistic awareness of one's strengths and limits. Continuing posttreatment benefits are fostered by improvements in interpersonal and social functioning. Successful outcome in geriatric group therapy is linked to sufficient tenure in treatment, therefore therapeutic strategies that facilitate treatment maintenance are important. Group therapy in the treatment of bereavement generates interesting findings; participants are generally consistent in reporting high satisfaction and positive valuation of the group experience, both for peer- and leader-led groups. However, at 1-year follow-up there appear to be few significant treatment benefits afforded by the intervention. Important questions remain regarding the effective duration and intensity of psychotherapeutic intervention and which patients require what form or intensity of treatment.

Groups for burdened caregivers generally demonstrate satisfaction with the group experience, even though complexities in the measurement of subjective and objective burden, coupled with the progressive deterioration of the care receiver, may confound other outcome measures. The burden of caregiving appears to be substantially greater with cognitively impaired persons than with physically impaired individuals. Treatment benefits reported include significant improvement in feelings of mastery, self-directedness, and problem-solving ability; increased capacity to consider appropriate alternatives to care; delay in institutionalization; improved relationship with the care receiver; improved capacity to grieve; and an enhanced capacity to care for oneself. Both professional- and peer-led groups show significant effects, although the former tends to emphasize the provision of information and problem solving, whereas the latter emphasizes peer support and social networking. Meta-analysis of controlled interventions for burdened caregivers shows that group interventions in general have a small but positive effect on caregiver burden and dysphoria, alongside the participant's subjectively high valuation.

Evaluation of outcomes in the group therapy of cognitively impaired patients are hampered both by a lack of consistency in measures used to determine improvements in cognition, behavior, and orientation and by limited follow-up. Early outcome studies focused on populations of institutionalized, chronic, psychogeriatric patients; documented improved discharge rates, socialization, functioning; and participation in hospital activities. Verbal orientation and socially appropriate behavior may be improved by group interventions, but the gains are generally modest and short-lived without ongoing staff or family reinforcement. Improvements appear to result from behavioral reinforcement rather than being genuine changes in cognition. However, behavioral improvement may endure beyond the active treatment phase and can be further reactivated by the resumption of treatment. Aggressive use of reality orientation techniques in the absence of empathic connection to the patients may result in further depressive reactions and dysphoria. The least equivocal outcome in this area is that staff involved in the more active interventions appear to value highly the opportunity for this form of active and humane engagement with their patients. Indeed, staff's improved morale and involvement may have important therapeutic impact.

SUGGESTED CROSS-REFERENCES

Related topics include cognitive-behavioral therapy (Section 51.4j) and individual psychotherapy (Section 51.4i) with elderly adults. The full spectrum of psychotherapies is discussed in Chapter 30.

51.5 HEALTH CARE DELIVERY SYSTEMS

51.5A FINANCIAL ISSUES

GARY L. GOTTLIEB, M.D., M.B.A.

The importance of financial issues in shaping health care delivery for older people continues to intensify. For more than a century, sources of funding and mechanisms of payment for service have influenced mental health policy for older adults. These economic factors are key determinants of access to care, organization of health care delivery services, and the behavior of providers. Over the last decade, both government and industry have sharpened their focus on health care expenditures. This has stimulated the development of new models of care and has fundamentally changed the relationship between patients and providers.

The historic importance of government policy in shaping the status of psychiatric care for older people cannot be overemphasized. During the nineteenth century, financial responsibility for the care of chronically mentally ill persons and those with dementia was transferred from local to state authorities, causing asylums and almshouses to be replaced by the massive state hospital systems of the first part of the twentieth century. Ultimately, deinstitutionalization to limited community resources resulted in the transfer of a substantial number of older persons with severe and persistent mental illnesses from state hospitals to community nursing homes with sparse psychiatric resources. Reimbursement for nursing home care under Medicaid effectively shifted some of the financial responsibility for this population from the states to the federal government. The federal government's sensitivity to these new expenditures and social concerns about inappropriate care led to the Nursing Home Reform Provisions of the latter part of the 1980s and a set of guidelines for the use of psychiatric technologies in that environment.

In the mid-1960s, the introduction of Medicare and Medicaid created a private market for older adult health care as private practitioners and institutions could be reimbursed fee-for-service at market prices by these insurance programs. The lucrative nature of service delivery, reinforced by the growth of commercial indemnity insurance, drove the development of for-profit hospital care, particularly in freestanding psychiatry. Simultaneously, severe limitation in reimbursement for ambulatory psychiatric services under Medicare prevented the growth of private practice interest in geriatric care while creating perverse incentives for the use of hospital resources.

The health care cost reform of the last generation has similarly reshaped psychiatric service delivery. Medicare has become more attractive than commercial payers to hospitals and to individual providers. Nonpsychiatrist mental health specialists have become included in Medicare and other payment programs, and a greater diversity of providers has made psychotherapeutic services more broadly available to elderly adults. However, downward pressure on the growth of Medicare expenditures and incentives for the growth of managed care limit access to state-of-the-art psychiatric care for older adults.

ECONOMIC AND HEALTH POLICY ISSUES

Rational planning for mental health care services for the coming century requires understanding the projected growth and heterogeneity of older America. Forty years ago, only 1 of every 11 Americans was older than age 65. However, in each of the last three decades, this population has grown substantially and now totals about 35 million people, approximately 12 percent of the American population. More striking, the aging of the post–World War II baby boom cohort will yield approximately 66 million people over the age of 65 by the year 2030, accounting for about a quarter of the overall population.

Differences in life expectancy between men and women and the distribution of ethnic minorities among the older adult population will have important economic consequences. Given that there are approximately 1.5 women for every man older than 65 and about 2.5 women for every man older than 85, the economic effects of income discrimination and traditional work roles experienced by women in young and middle age will be exaggerated as retired women depend on pensions and Social Security derived from preretirement income.

Similarly, ethnic minorities make up a growing proportion of the over 65 population. In 1990, only about 11 percent of persons over 65 were from nonwhite ethnic minorities. By the year 2025, 15 percent of this population will be from minority groups. While life expectancy at birth for whites exceeds that of African-Americans by about 8 percent, by the time people reach age 75, mortality rates for blacks are considerably lower than they are for whites. Of critical economic and social importance, much older black adults have considerably higher rates of poverty and illness than white adults in the same age group. The economic and social discrimination of chronic underprivilege associated with American minority status are exaggerated by the socioeconomic consequences of older age. In this population, accrued social and financial resources are limited, access to preventive and acute health care is poor, and the likelihood of exposure to tobacco, alcohol, and other toxins is higher. This causes a cycle of medical, economic, and social poverty.

Retirement has important effects on economic status and access to health care and insurance. Retirement reduces personal income between 30 and 50 percent. Most Americans still retire in their 60s; about 90 percent of men in their early 50s are in the labor force, while only about 40 percent of men between the ages of 62 and 64 continue to work. Only 10 percent of men and 4 percent women over age 70 are in the active work force. Retirement directly affects health insurance premiums, availability of insurance, and access to some components of the health care delivery system. Recent efforts to restructure both Medicare and Social Security have included proposals to delay eligibility for these programs and thereby effectively delay retirement from 65 to 67. The very tight labor market of the end of the twentieth century and the shift from heavy industry to a service economy may support delays in retirement, particularly for lower- and middle-income Americans.

Currently, most Americans over 65 depend on a combination of Social Security benefits, pension, and income from savings and investments after retirement. Reduced income after retirement threatens stability of social class for older persons and increases the likelihood that some will experience economic poverty for the first time during late life. About 1 in 8 persons over age 65 have incomes below the established poverty level. About 20 percent of Americans who live beyond age 85 have incomes at or below that level. In contrast, more than 10 percent of persons over 65 have incomes above $60,000 per year, and 13 percent have assets in excess of a quarter of a million dollars. This heterogeneity of distribution of wealth and income among older adults creates major gaps in health and social policy for some segments of the population, while generating controversy regarding entitlements for those with substantial means. These issues are magnified in geriatric mental health care and in long-term care, in which out-of-pocket copayments, deductibles, and direct purchase of services account for a substantial component of total costs.

MEDICARE SYSTEM

Since 1966, Medicare has been the most important insurance program for older Americans. Medicare was designed to provide medical care benefits for older persons participating in the Social Security program. In 1972, Medicare was expanded to cover younger persons with disabilities and older adults outside of Social Security who were willing to pay a premium. In 1973, the program was further expanded to provide medical coverage for people with end-stage renal disease. As of 1997, about 38 million people, or about 13 percent of the American population, were covered by Medicare. About 90 percent of this population is over age 65.

Growth in the older adult population, advances in medical technology, and other increases in the cost of health care contributed to extraordinary growth in health care expenditures over the last generation. Health care costs now account for approximately 14 percent of the gross domestic product, totaling more than $1 trillion per year. Older adults consume approximately 30 percent of this care, and just under 50 percent of that amount is paid for by Medicare.

Various efforts to contain Medicare costs have successfully slowed health care inflation as the twentieth century ends. Cost reduction has resulted from reductions in reimbursement of hospital and physician providers, increased requirements for out-of-pocket payments by individuals, and a shift from indemnity insurance to managed care. Each of these efforts affects access to appropriate psychiatric care for older adults, and each has affected the size and shape of geriatric mental

health specialty care.

Medicare was designed to provide coverage for treatment of acute conditions. Most preventive services, long-term care, ongoing use of pharmaceuticals, and dental services are excluded from traditional indemnity Medicare. Other services, including mental health care, are subject to payment limitations and substantial copayments. Medicare pays for about three-quarters of older adult hospital care, 2 to 3 percent of nursing home care, and just under 60 percent of physician services.

The traditional, unmanaged Medicare program has two components: Hospital Insurance, or Part A, covers inpatient care, limited home care, skilled nursing facility care, and hospice services. Part B, the Supplemental Medical Insurance program, covers services provided by physicians and other professional providers, durable medical equipment, ambulatory medical laboratory tests, some outpatient hospital care, and group therapy services of partial psychiatric hospitals and comprehensive outpatient rehabilitation facilities.

Hospital Insurance (Part A) Americans over age 65 who participate in the Social Security program are entitled to Part A Medicare coverage. The Part A hospital insurance trust fund is supported by Social Security payroll taxes paid by employers and employees. These payroll taxes totaled $115 billion in 1997 and made up 88 percent of the income of the trust fund. The remainder came from interest earned on the monies in the trust fund and other miscellaneous sources. About 22 percent of the 38 million people eligible for Part A received hospital services in 1997. Their utilization rate is approximately four times that expected in younger, commercially insured populations.

Coverage for inpatient care is limited to relatively brief inpatient stays, presumably for the stabilization of acute symptoms. Part A provides coverage for episodes or spells of illness. A *spell* is an episode of inpatient care that starts with hospital admission and ends after the first period of 60 consecutive days outside the hospital after hospital discharge. Persons who are discharged and readmitted numerous times during a given episode of illness who have not been out for 60 consecutive days are considered to be within the same spell. For treatment of any condition in a general hospital, there is no limit on the number of spells or days covered within an individual's lifetime; however, no more than 150 days are covered during each episode.

The first 60 days of each spell are fully paid for after a deductible equal to the average cost of 1 day of hospitalization ($768 in 1999) has been met. The next 30 inpatient days are paid at the same rate less a 25 percent copayment. The last 60 days of covered hospitalization requires a 50 percent copayment. Days 91 to 150 are designated “lifetime reserve days.” Medicare will pay for those days during any single spell of illness, but only once in a beneficiary's lifetime. For example, patients who require five hospitalizations totaling 110 days without a period of discharge of at least 60 days would have 40 days of remaining coverage in their lifetime for future episodes that lasted more than 90 days. Individuals may save these days for future hospitalizations and use other resources to pay for any part of the costs of days 91 to 150.

When Medicare was signed into law, large populations of older adult patients were in state psychiatric hospitals. Legislators feared that the enactment of Medicare would shift the burden of care for that population from state-supported resources to acute care facilities reimbursed with federal monies. Therefore, Medicare coverage for inpatient treatment in free-standing psychiatric hospitals is limited to a total of 190 days over the course of a person's lifetime. If an individual becomes eligible for Medicare during a psychiatric hospitalization, the Medicare intermediary may deem that less than the full 150 days allocated for the spell of illness will be covered. Given improvements in treatment and increased life expectancy, this limitation can easily create undue hardship and prevent continuity of care. For example, a person with a recurrent major affective disorder who suffers several depressive episodes requiring inpatient care after age 65 could easily exhaust the lifetime free-standing psychiatric hospital benefit.

Part A provides coverage for nonacute services if they are used briefly and for “remediable” conditions. To obtain benefits for skilled nursing facility (SNF) care, a beneficiary must have been hospitalized for at least three consecutive days for an acute condition and admission to the SNF must follow within 30 days of hospital discharge. Medicare may cover up to 100 days of SNF care for each episode of illness. Similarly, coverage for home health services is limited to care for acute and remediable conditions.

From 1966 until 1983, Medicare Part A paid for hospital care using a retrospective, cost-based reimbursement system. This system compensated providers fee-for-service for all of those costs deemed allowable under Medicare without an incentive for utilization management. In 1982, after years of skyrocketing growth in Medicare, the Reagan administration signed into law the Tax Equity and Fiscal Responsibility Act (TEFRA). TEFRA created incentives to reduce hospital payments by setting targets for operating costs, and it provided supplemental payments for compliance with specified objectives. Reimbursement was shifted from a retrospective, cost-based approach to a design that would reflect patient mix, geographical location, and training costs. Most importantly, TEFRA replaced cost-based reimbursement with a prospective payment system.

The prospective payment system established by TEFRA uses diagnosis-related groups (DRGs) to classify patients who require similar care into 23 major diagnostic categories, and assigns each discharge to 1 of 468 diagnostic groups. These groups are derived from principal and secondary diagnoses, procedures rendered, and, to a lesser degree, age, sex, complications, and discharge status. The DRG system was revolutionary in creating a case-based approach to reimbursement. Hospitals are paid a fixed amount for each case according to the DRG, regardless of the resources consumed during the hospitalization. If patients require extraordinary resources or extremely prolonged hospitalization, Medicare classifies the patient as an “outlier” and provides additional payment to the hospital at a rate considerably below actual costs. This set of conditions creates an incentive for hospitals to provide efficient care and create an infrastructure of ambulatory services that could shorten or substitute for hospitalization.

Fourteen of the DRGs apply to the treatment of psychiatric disorders. Several studies indicated that while DRGs are modestly effective in predicting utilization for medical and surgical diagnoses, their ability to predict utilization for psychiatric diagnoses is poor. Therefore, the Health Care Financing Administration (HCFA) exempted free-standing psychiatric hospitals and distinct psychiatric units in general hospitals from the DRG system.

Free-standing psychiatric hospitals and psychiatric units in general hospitals continue to be reimbursed retrospectively by Medicare. However since TEFRA was implemented, payment for treatment in psychiatric units is capped at a rate established for each facility on the basis of utilization during its first fiscal year of operation after October 1, 1983. Now, if the actual cost of care per case exceeds the capped rate, the hospital must absorb the loss. However, if the cost is less than the capped rate, a small incentive payment is retained by the hospital. A minor but extremely important provision of the Balanced Budget Amendment of 1997 (BBA) limited the maximum TEFRA rate for psychiatric facilities to 75 percent of the national median. Additionally, the BBA eroded incentive payments for hospitals that were more efficient than the target rate.

Supplemental Medical Insurance (Part B) Medicare Part B is a voluntary medical insurance program that requires a monthly premium payment ($43.80 in 1998) for participation. About 97 percent of Medicare Part A beneficiaries also participate in the Part B program. Part B is supported by a trust fund that includes general revenues from the Treasury, as well as premiums. Premiums cover about 25 percent of the total cost of the program. Part B benefits are subjected to an annual deductible ($100.00 in 1999) as well as a copayment. Nonpsychiatric physician services and psychiatric inpatient care require a 20 percent copayment. While the number of reimbursable ambulatory psychiatric visits is no longer subject to limitation, Medicare requires a 50 percent copayment for psychotherapeutic services.

From 1984 when TEFRA and prospective payment were initiated, until 1992, the rate of growth of Medicare physician costs was more than double the rate of growth for inpatient hospital costs. Policy analysts attributed this growth to uncontrolled prices and increases in the number and intensity of services consumed. In 1989, inflation in physician-related costs and mounting evidence that physicians' behaviors in treating complex medical illnesses were influenced by the high prices of the procedures they performed, led to a sweeping reform of Medicare Part B through the Omnibus Budget Reconciliation Act of 1989 (OBRA-89).

OBRA-89 created standards for expenditures and procedure volumes in an attempt to control the total costs of physicians' services. The law requires that the secretary of health and human services establish specific volume performance standard growth rates for surgical, primary care, and nonsurgical non–primary care services at the beginning of each fiscal year. These standards must be related to medical inflation and changes in the size of the Medicare population as well as changes in service volume and intensity. At the end of each year, the secretary must compare actual growth and expenditures with this volume performance standard and determine any changes in fee schedules for the following year.

OBRA-89 also created a national uniform Medicare fee schedule to replace the local methods traditionally used by intermediaries to set fees for each procedure and for each provider. In 1992, a Resource Based Relative Value Scale (RBRVS) was developed to determine relative values of about 7000 physician procedures and services. The relative value of each of these services is derived from three components: work, practice and malpractice expenses, and the opportunity costs of postgraduate specialty training required. The proportion of each component used in determining the relative value is based on a weighted average of specialty-specific practice expense and malpractice data. In an effort to change provider behavior and reduce incentives to perform highly reimbursed technical

procedures, work is derived from time intensity and stress associated with delivery of the procedure. About 60 percent of the value of each fee is adjusted for local costs. The product of each relative value and a monetary conversion factor determines the fee for each service.

OBRA-89 was a landmark for behavioral health in its provision for direct reimbursement of services provided by psychologists and social workers. It also set criteria for nonphysician providers regarding consultation with a physician. Nonphysician providers must document that a patient has been informed that consultation with the patient's primary care physician is desirable to evaluate medical conditions that could contribute to a patient's well-being. The provider must also document any written or verbal communications with the primary care physician about treatment unless the patient specifically prohibits contact. The law does not require consultation with a psychiatrist.

In general, direct patient contact is required for any reimbursable service. Consultation or other services rendered by telephone and renewals of prescriptions that do not include direct evaluation of clinical conditions are not reimbursable. Medicare allows billing for services required to obtain clinical information from relatives or close associates of unreliable or uncommunicative patients. Family counseling services are only reimbursable when their purpose is to facilitate patient care.

Providers may participate in Part B of the Medicare program in two ways. First, providers may accept assignment and agree to accept the Medicare fee as payment in full. Medicare's fiscal intermediary will pay the provider the approved amount less copayment and deductible directly. The provider is legally required to bill the patient directly for the copayment and the deductible. Second, a provider may choose not to accept assignment. Providers who do not accept assignment may charge patients up to 115 percent of the approved Medicare fee. Medicare reimbursement for providers who do not participate is limited to 95 percent of the approved fee less deductibles and copayment. The provider may then bill the patient directly for the balance of charges up to the 115 percent limit.

All providers must accept assignment from Medicare beneficiaries who also participate in the Medicaid program. Assignment must be accepted for all Medicare recipients who are at or below the federal poverty level, whether or not they have Medicaid as a secondary payer. In an increasing number of states, medical licensure authorities and insurance commissions require that all physicians who participate in the Medicare program accept assignment for patients seen within that state.

MEDICARE RISK IN MANAGED CARE

Since the early 1970s, Medicare has encouraged older Americans to enroll in capitated health plans. Since that time, health maintenance organizations (HMOs) have been able to contract directly with Medicare. Medicare pays the contractor a premium equal to 95 percent of the local adjusted average per capital cost (AAPCC). The AAPCC is based on the individual's county of residence, age, sex, and whether a patient is covered by Medicaid, lives at home or in an institution, works or is retired or disabled. HMOs, while allowed to earn “normal profit margins,” must use savings above a predetermined rate to provide extra services for elderly members. To penetrate a local market, HMOs frequently waive premiums and offer usually uncovered services to induce enrollment. Unlike traditional Medicare, HMOs allow access to primary care and other preventive services in the absence of a primary diagnosis. Additionally, managed care plans usually provide coverage for some portion of outpatient pharmaceutical costs.

The nature of HMO risk contracting with Medicare provides an incentive for HMOs to market to healthy older adult populations who are likely to consume considerably less than the 95 percent of AAPCC. Healthy populations yield substantially greater profit margins, leaving sicker, more-disabled persons to be cared for through direct payments from HCFA in the traditional Medicare program. Several studies have indicated that capitated plans generally enroll healthier and less costly populations than those who remain in fee-for-service Medicare. In one study, in the 6 months preceding enrollment, new members of capitated plans had health care costs that were 35 percent lower than the average costs of patients in traditional Medicare. Some plans profit through marketing to younger older adults (people ages 65 to 70) in settings with a greater likelihood of health and independence. Studies indicate that Medicare has overpaid capitated plans by 5 to 20 percent because of the better health of their members. To reduce financial incentives created by enrolling healthy persons and to pay more fairly for the care of frailer populations, the BBA required that Medicare link payments to HMOs to the health status of their beneficiaries by the beginning of the year 2000. More-frail populations will be eligible for higher payments than healthier cohorts. This should encourage plans to enroll more chronically ill populations and to bring a broader base of the general older adult population into managed care.

Medicare managed care penetration has increased steadily over the last decade. While only 3.6 percent of older Americans were enrolled in HMOs in 1990, this proportion increased to 10 percent in 1996 and over 15 percent in 1998. The Congressional Budget Office estimates that just under 20 percent of Medicare beneficiaries will be in risk contracts by the year 2000. Approximately 100,000 Medicare beneficiaries are joining managed care plans each month. The Medicare Plus Choices Program, a major component of the BBA, is designed to make it easier for various kinds of organizations, including provider-sponsored organizations and preferred provider organizations (PPOs), to participate in Medicare managed care. Medicare Plus Choices is intended to create greater competition among plans.

Managed care plans caring for Medicare recipients have applied the same paradigms to behavioral health care that they have used for their younger commercial populations; the vast majority carve out the behavioral health benefit and capitate the risk for these services to managed care organization vendors. Most managed care organizations are large, publicly traded for-profit entities that function as psychiatric and substance abuse insurance companies in numerous markets regionally and nationally. Managed care organizations generally establish local networks of ambulatory and inpatient providers; establish fee-for-service pricing with those providers, supply medical management, care management, utilization review, and credentialing functions; and pay claims. These organizations are generally very effective in reducing inpatient utilization, which enables them to negotiate significantly discounted prices for services and limit the size of available networks.

A review of the credentialing and procedure manuals for a group of the largest managed care organization nationally found virtually no mention of requirements for specialty training or expertise in the care of older adults or for special consideration of medical comorbidity or frailty. There were no requirements for services to be sited where older adults reside or where access to care may be facilitated for frail or disabled persons. This review suggests that the current model for delivery of managed behavioral health services to older adult Medicare beneficiaries is unlikely to reflect recent advances in behavioral neuroscience. Similarly, most carve-out programs exclude or limit comprehensive assessment, neuropsychological testing, and other routine components of dementia evaluation.

Recently, a number of not-for-profit entities have developed the capacity to be included in full-risk agreements with their medical and surgical colleagues. This has allowed emergence of a new model of behavioral health care, carving in services while locating providers on-site or adjacent to primary care delivery. These programs are serving considerably smaller populations than most managed care organizations, and differences in actual outcomes have yet to be demonstrated.

Managed care continues to be a priority in Medicare policy. The federal government plans to reduce Medicare expenditures by $115 billion by 2002, by broadening the types of coverage available to enrollees. However, reductions in payments to managed care entities by Medicare coupled with complex paperwork requirements have prompted more than 100 managed care plans to leave the Medicare program over the past year. The tension between the financial effects of the BBA and government efforts to attract beneficiaries to managed care plans is likely to persist over the coming years.

About 42 percent of older adults who remain in the traditional Medicare program purchase Medicare supplementary (Medigap) insurance. In 1992, the federal government created standards for private insurance to supplement the federal program. It provided requirements for 10 basic policies. All of these policies must include payment of the Medicare Part A hospital and Part B provider coinsurances. Additionally, all policies must pay the 50 percent copayment for outpatient psychiatric services. More elaborate policies may cover deductibles, SNF coinsurance, outpatient prescription pharmaceuticals, and preventive in-home services. Medigap regulations provide incentives for the use of PPOs by Medicare recipients. This allows insurers to offer lower premiums to members who agree to use a PPO for all of their care. An increasing number of states have authorized insurers to offer this option.

MEDICAID

Enacted in 1965 as a social insurance program to pay for the medical care of Americans with limited financial means, Medicaid is funded through a combination of federal and state matching funds. To receive these matching funds, states must provide a basic benefit package. The program allows states to impose restrictions on the services that they fund and the level of reimbursement. Medicaid reimbursements for psychiatric services for older adults vary substantially by state. However, Medicaid pays about 25 percent of all psychiatric care in the United States.

Between 10 and 15 percent of older Americans are eligible for both Medicare and Medicaid. While older adults represent about 16 percent of all Medicaid recipients, the care that they consume accounts for about 40 percent of all Medicaid expenditures. Most state Medicaid programs have provisions for purchasing Medicare Part B coverage. This allows states to reduce their risk for payment of professional services. In this way, Medicaid functions as a supplementary (Medigap) policy for many older adults. The program covers services after Medicare benefits have been exhausted, and it also covers a variety of services that may not be covered by Medicare,

including prescription drugs and long-term care.

Medicaid's importance to geriatric health care is greatest in its coverage of long-term care services. Medicaid pays for about 42 percent of SNF and intermediate care facility costs. Most states require that persons have limited income and assets to qualify for Medicaid.

The nursing home is an important site of care for older adults with severe and persistent mental illness, including depression associated with medical illness and disability, schizophrenia, and dementia. Deinstitutionalization from state facilities shifted the financial burden of care for many persons with these diagnoses from the states (in state hospitals) to cost sharing with the federal government in its partial support of Medicaid. The nursing home reform provisions of OBRA-87 require preadmission screening for nursing home applicants to determine if active psychiatric illness is present. If active treatment for an identified disorder cannot be provided appropriately in the nursing home, referral for this care is mandated. Nursing homes must demonstrate efforts to provide appropriate care for behaviorally disturbed patients, and appropriate training in management of difficult behaviors is required of all staff members. OBRA-87 requires monitoring of the use of psychotropic medications and restraints in long-term care. While these regulations have added substantial costs, there has been no incremental reimbursement from Medicaid to support them.

OUT-OF-POCKET EXPENDITURES

Health care costs paid directly by older adults from personal or family income or savings are classified as out-of-pocket expenditures. They include premiums for Medicare Part B, private Medigap policies or enrollment fees for Medicare managed care, as well as copayments and deductibles. Charges for uncovered services, including outpatient pharmaceuticals and long-term care, constitute the largest portion of out-of-pocket expenditures. While per capita out-of-pocket spending has declined because of the growth of managed care, the effects of out-of-pocket payments on older adults, particularly those with limited resources, are considerable. It is estimated that Medicare beneficiaries over age 65 who have incomes below the federal poverty level and who are also eligible for Medicaid spend 35 percent of their incomes on out-of-pocket health care costs. Medicare beneficiaries below the poverty level who do not have Medicaid spend half their incomes on out-of-pocket health care costs. Similarly, as the use of long-term care facilities grows, middle-income and lower-middle-income persons will become more seriously affected by growing payments for uncovered services. Notably, numerous levels of long-term care are not covered by Medicaid or Medicare. For example, the growth of assisted living has created increased demand for a level of service that can only be purchased out of pocket.

Prescription drugs are the fastest growing segment of health care costs. Recently, spending for prescription drugs has increased at two to three times the rate of health care inflation. As the twentieth century ends, policymakers are working furiously to slow this growth while debating expansion of Medicare coverage to include pharmaceuticals.

FUTURE DIRECTIONS

In the twenty-first century the growth of the older adult population is the major challenge faced by health care policymakers. Older adults consume health care services disproportionately, and our ability to extend and improve the quality of life depends on expensive technologies and interventions. The recent emphasis on cost reduction while technology and the size of the frail older population grow in parallel creates a clash among humanity, science, and economic stability. Advances in behavioral neuroscience and particularly in geriatric psychiatry can improve quality of life, extend life, and improve the economic productivity of the fastest growing subsegment of the population. Health policy that deals rationally with these variables must consider all of these economic perspectives without the distortion created by an overemphasis on reducing the direct costs of care.

SUGGESTED CROSS-REFERENCES

Section 51.3 covers psychiatric disorders of late life, and Section 51.4 covers psychiatric treatment of older patients. Managed care is discussed in Section 51.5b and Section 52.2, VA medical centers in Section 51.5c, and community services for elderly psychiatric patients in Section 51.5d. Section 51.6a covers psychiatric aspects of long-term care.

CHAPTER 51. GERIATRIC PSYCHIATRY

51.5 HEALTH CARE DELIVERY SYSTEMS

51.5B MANAGED CARE

JEROME V. VACCARO, M.D., AND S. ALAN SAVITZ, M.D.

Managed care has become a core term in the health care lexicon in a relatively short period of time. Through the mid-1980s, the impact of prospective payment initiatives such as health maintenance organizations (HMOs), diagnosis-related groups (DRGs), or other managed care efforts continued to be eclipsed by the more prevalent fee-for-service system. Physicians and other health care providers became accustomed to receiving reimbursement for their services retroactively and encountering little or no clinical oversight of their work. The exceptions to this were the utilization review efforts in place through various organizations (such as hospitals) and by some payers (notably the Health Care Financing Administration [HCFA]). These reviews, however, were always retrospective and rarely affected an individual patient's care. They were designed instead to influence practice patterns in a collegial, consultative manner. In the late 1980s and early 1990s the health care delivery system began to change, and prospective payment, accountability, and managed care became major forces.

DEFINITIONS

Behavioral Health *Behavioral health* is used in this section to denote the combined areas of mental health and chemical dependency. In both the public and private sectors, this term is used increasingly to spur integration of these two areas, since patients often present with comorbid conditions that require unified approaches to clinical care and unified systems of care.

Managed Care *Managed care* is used to denote an effort to bring business controls or effective business principles to health care delivery. Managed care in its current forms has influenced the delivery of clinical care to be continuous, comprehensive, effective for the condition being treated, and cost efficient. With these goals stated, several issues are important. First, under fee-for-service systems, data were not collected in any meaningful way outside research settings, so it is difficult to ascertain the true effects of managed care efforts in a broad sense. However, data from more limited settings (e.g., several private employer–funded plans and a number of Medicaid plans) support increased overall access (in one study, the probability of using any mental health care increased significantly under a managed care program), increased comprehensiveness (particularly in outpatient settings), cost control, and some accountability for outcomes. As of 1998 managed behavioral health care plans covered about 130 million Americans. This has essentially brought control to the cost of behavioral health care while maintaining or improving access to care. The major change has been the sharp decrease in use of inpatient care and extended outpatient psychotherapy.

Medicare The Medicare program is a federally funded, federally run program that provides basic health insurance coverage to most of the elderly population and a portion of the disabled population (e.g., physically disabled or seriously and persistently mentally ill). It began in 1965, when Congress passed legislation introduced by President Lyndon Johnson in 1964. The Medicare program enjoys widespread support, and groups such as the American Association of Retired Persons (AARP) have become vocal and powerful advocates resisting reform measures such as mandatory enrollment in prepaid plans, increased retiree contributions, or decreased benefits.

The Medicare program is composed of two separate components, parts A and B. Part A pays for hospital care, home health care, hospice care, and some skilled nursing services. Part B pays for physician services, outpatient hospital and clinic care, laboratory and other diagnostic tests, and other services. This A and B distinction has become obsolete because of changes in our health care delivery systems (e.g., the emergence of unified or integrated clinical delivery systems), and it presents barriers to effective management of care in our new environment. In fact, the A and B separation can contribute to fragmented care by providing for separate inpatient and outpatient delivery systems. Medicare Part A provides coverage for retired individuals who receive Social Security benefits, those who have received government disability benefits for more than 2 years, and those with end-stage renal disease. Whether or not they are entitled to part A benefits, all persons age 65, and disabled or end-stage renal disease part A participants, may join part B by paying a monthly premium.

While many see the Medicare program as generous, it offers poor catastrophic coverage; no vision, dental, or outpatient medication benefits; and high copayments for many services. Copayments for services vary. For example, a typical copayment for a psychotherapy session may be as high as $20 to $30 under the traditional Medicare system, while such copayments in typical managed behavioral health care plans rarely exceed $10 to $15. Copayments and deductibles for hospital care can be several hundred dollars per stay, where such payments under a managed plan either do not exist or are quite low. In 1998, Medicare recipients paid an average of about $46 a month in premiums for their part B (nonhospital care) coverage. In all, Medicare covers about 45 percent of the annual health care bill for elderly adults. This has led to the emergence of a second system of coverage, including Medigap insurance, retiree benefits programs, and contributions from the Medicaid program.

Medigap Insurance and Retiree Benefits Many elderly individuals purchase additional insurance coverage that pays for some or all of their Medicare premiums, deductibles, and coinsurance and provides coverage for catastrophic illness. Others receive such coverage as a retirement benefit from previous employment. In all, about 65 percent of elderly adults have one or both of these benefits. In 1996, Medigap premiums averaged about $70 per month. Increasingly, employers are attempting to control their own contributions to retirement plans by using managed care.

Medicaid The Medicaid program provides additional coverage for about 16 percent of the elderly population who meet stringent federal and state eligibility criteria (these criteria mainly involve income limits and health care expenditure considerations). Medicaid pays the premiums, copayments, and deductibles for these “categorically” (e.g., an individual falls into a Medicaid-eligible category) eligible individuals. Because of the increased enrollment of Medicaid recipients in managed care plans, the care of dually eligible elderly individuals becomes ever more complex and fraught with administrative challenges (e.g., as states move Medicaid to managed care, and seniors remain in fee-for-service Medicare, care management and delivery become very difficult).

HISTORY

A series of events occurred that were intended to improve behavioral health care while being cost-effective. First, in the 1960s, new services and technologies (e.g., alternatives to inpatient care, psychiatric rehabilitation) were developed through the community mental health movement. Central features of this included avoiding inpatient care, the commitment that care should be community-based, and focusing on a population's needs (e.g., catchment areas) in service planning and delivery. Then in the 1970s, the availability of mental health benefits in indemnity plans increased. These benefits covered inpatient care and some outpatient treatment. Within HMOs, however, minimal benefits were offered, usually limited to emergency assessment and crisis intervention. At the same time, the number of psychiatric inpatient beds grew significantly, especially in free-standing psychiatric hospitals and rehabilitation facilities. Concurrently, training programs for behavioral health specialists increased, especially for master's level clinicians. State boards registered, certified, or licensed these providers to practice independently.

By the 1980s these factors combined to greatly increase the use of services, which caused a rapid escalation in behavioral health care costs in indemnity insurance (fee-for-service) plans. Large employers, particularly those in the Fortune 500, wanted to maintain behavioral health benefits but saw a lack of access in HMOs and rapid inflation in indemnity plans. For example, one such company saw mental health care costs increase between 12 and 33 percent per year during a 2-year period. By the mid- to late-1980s, this led to the establishment of “carve-out” managed care companies that used utilization management techniques to control costs. These “carve-out companies,” now collectively referred to as managed behavioral health care organizations (MBHOs), made the case to large and midsize employers that they could control costs (and in most cases reduce costs from fee-for-service levels) while enhancing or maintaining quality.

Provider networks were initially composed of practitioners and facilities willing to discount their fees. This situation has evolved so that efforts now place more emphasis on quality management and outcomes management in establishing and maintaining provider networks. For example, the American Managed Behavioral

Healthcare Association (AMBHA) publishes a set of outcome and process indicators, the Performance Measures for MBHOs (PERMS), which is now in its second edition (PERMS 2.0). The PERMS indicators include measures such as access to or availability of care, appropriateness of interventions (e.g., the use of family interventions with children), effectiveness of care, and satisfaction with the experience of care. These indicators supplement those published by the National Committee on Quality Assurance (NCQA), referred to as HEDIS (the Health Plan Employers Data and Information Set), which cover more general health care indicators. The general thrust of NCQA and AMBHA efforts is to have managed care plans demonstrate accountability for improving service and treatment outcomes over time, as NCQA accreditation depends on such improvement.

In 1996, the Medicare program had 38 million enrollees, increasing by about 2.5 percent per year since its inception. The costs associated with the Medicare program were $191 billion in 1996 and are projected to rise to over $314 billion per year by 2002. Almost since its inception, it has been predicted that the Medicare Trust Fund (part A) would be bankrupt within 2 to 17 years of the date of prediction (e.g., by 1972, the prediction was that the fund would be insolvent by 1976). Current estimates are that the trust fund will be bankrupt by the early twenty-first century. This latest estimate is more dire because of the rapid aging of the population, the growing imbalance between elderly and younger populations (e.g., the graying of the baby boomers), fears about returning to a large federal deficit, and antitaxation sentiment.

Cost increases have been commonplace in the Medicare program since its beginnings: 17.5 percent during the 1970s, 12.1 percent during the 1980s, and 10.3 percent during the 1990s. The forces that account for these rapid rises include increased numbers of enrollees (aging of the population, inclusion of special populations such as those with disabilities or end-stage renal disease), increases in covered benefits (e.g., home health, hospice), expenses associated with advanced technology, and contributions to the academic enterprise through higher rates of reimbursement.

During the 1990s, the growth in the number of Medicare enrollees in prepaid managed care plans such as HMOs and social HMOs accelerated, so that by 1996 11 percent of recipients (over 4 million people) were enrolled in such plans. This trend is expected to continue and perhaps accelerate through the first decade of the new century. For the most part, Medicare HMO members are satisfied with their experiences in HMOs. In a survey of members, 96 percent of members rated their overall health care by the plan as good to excellent. A comprehensive review of the Medicare HMO program concluded that Medicare HMOs use resources more efficiently (with minor differences in access, quality, and satisfaction) than fee-for-service members. However, this study and others argue that HMOs do not perform as well for chronically ill patients.

Another driving force behind increased enrollment is the fact that the level of covered services under most, if not all, managed Medicare plans greatly exceeds that of the traditional Medicare plan. For example, most managed plans offer some coverage for outpatient medications, and many offer vision and other benefits not covered under the traditional program. Given the more generous benefits, the cost savings, and the maintenance or improvement in the quality of care, one might expect the growth to be even more rapid. Factors limiting growth include the following:

1. *Perceptions that choice is limited in such plans*. This problem was especially true when staff model HMOs (e.g., choice of physicians is limited to physician-employees of the plan) predominated or when network model plans (e.g., choice is limited to physicians contracted with the plan) had small provider panels because of low physician participation. These concerns are less prominent, as both staff and network models have matured and aggressively seek to provide maximum choice (e.g., many plans now offer free access to a wide variety of specialists, and most plans have greatly expanded the number of contracted physicians on their panels). However, public opinion about this matter has been slow to change.
2. *Concern that not all care options will be made clear or available*, either because of improper physician incentives or contractual restrictions promulgated by HMOs. This criticism was levied at some plans in which physicians were given financial and other incentives to limit care (e.g., monitoring specialist referrals). Widely covered criticisms that plans were introducing gag clauses that prohibited physicians from discussing care options with their patients were not verified during a General Accounting Office (GAO) investigation. These concerns have been addressed by increased public scrutiny and consumer sophistication, to say nothing of increased government regulation.
3. *Inadequate geographical coverage of existing HMOs*. In the early phases of managed Medicare programs, especially with the social HMOs, geographical reach limited HMO expansion. By 1996, however, over 75 percent of Medicare enrollees lived in areas served by managed Medicare programs. In addition, the government has become more sophisticated about access, now specifying numbers of physicians and specialists that a plan must have in its network in a given geographical area. In addition, at the insistence of accrediting bodies such as NCQA, plans aggresively monitor indicators of adequate access and must report these.
4. *Concerns that managed plans would not be able to deal with the frail elderly or disabled populations*. The successes of the social HMOs and mainstream managed care plans in developing effective and efficient models of care for these populations, coupled with the increased skill and awareness of regulatory bodies and consumer groups, have allayed many of these concerns. New risk-adjustment methodologies may encourage plans to enroll these individuals. However, these new risk-adjustment plans led to many HMOs exiting certain markets because of concerns about the fairness of payment.
5. *Public outcry about managed care plans*. Recently, public outcry about quality and access under managed care has increased. The use of anecdotes by media reporters has become commonplace, supporting fears about managed care. In a large effort directed by California elected officials, Alain Enthoven and others investigated the issue of public concern about managed care. They concluded that most individuals are satisfied with their managed care plans. Room for improvement existed in relation to chronic care and some other specific areas. Enthoven and colleagues felt that the increased public backlash reflected the fact that managed care was now the dominant force in health care (fee-for-service or indemnity plans ceased to be sustainable by 1997), with resultant consumer fears and, more importantly, physician outrage at their loss of control. This consumer outcry is now a dominant force in efforts to regulate managed care. Whether these regulations are largely rational and accomplish their stated goals of protecting consumers remains to be seen.

Whatever the final rate of growth, clearly managed Medicare plans will increase their penetration and begin to affect quality and overall cost. When considering the impact of managed Medicare programs on behavioral health care, one must recognize that Medicare beneficiaries, with the exception of the seriously and persistently mentally ill, have used very few behavioral health services. For example, depression and chemical dependency, while recognized as prevalent and costly disorders among elderly adults, are rarely diagnosed and treated in this population. As a result, a relatively small portion (generally less than 3 percent of total HMO costs) of Medicare funds has been spent on behavioral health services. Since most organizations use past use to calculate appropriate capitation rates, the amounts allocated to behavioral health in managed Medicare programs tend to fall short of the real need. In addition, when one considers the impact of the aging of the population, with resultant increases in the prevalence of medical-psychiatric comorbidity (e.g., psychosis among the dementia population), the imbalance between demand or need and available resources becomes even more striking. Balancing these forces are the increasing sophistication of geropsychiatry and gerontology and increased awareness of these problems by general medical clinicians, behavioral health providers, consumers, and public regulatory agencies. It is hoped that this imbalance will begin to correct itself as more data are translated into better information reporting in HCFA and managed care organizations, facilitating more rational allocation of resources. Cost-effectiveness becomes an even more important issue in this context, crying out for efforts to decrease costly and resource-wasteful turf battles (e.g., is dementia really a medical or a psychiatric condition?), decrease inappropriate inpatient use in favor of more flexible community alternatives, and increase recognition of behavioral problems.

In the coming years public policymakers will have to struggle with the regional imbalance in reimbursement rates. Under the current system, managed care plans' rates are set at a percentage of current Medicare expenses in a given market (this is the current adjusted average per capita cost [AAPCC] payment methodology). This leads to regional imbalance, for example, in 1996 the rates paid in Miami, Florida, were 2.4 times greater than those paid in Waco, Texas. This imbalance has historical determinants (the rate relates mainly to variations in the use of more expensive [usually inpatient or home health care] interventions), but as Medicare shifts from a retrospective payment system to a prospective payment system, such differences will no longer be sustainable. In addition, policymakers are discussing lowering the rates paid to plans, at a time when more of the disabled and severely ill population are projected to join managed Medicare plans. Suggesting that lawmakers be advised to increase spending to remedy these problems is unrealistic.

TRENDS AND PRACTICAL ISSUES

Managed behavioral health care has not had its full impact in altering geriatric clinical practice. The changes in the structure and practice patterns in our health care system have affected the geriatric population mainly through a halo effect of changes occurring elsewhere in our health care system. That is, general improvements in health care and accountability for outcomes, rather than a changed approach to care and the delivery system of behavioral health care for the geriatric population, have been the main sources of improved outcomes. Until now, the vast majority of geriatric services have been provided under the traditional system, in which care is monitored retrospectively, and payment is rendered for services without prior involvement of clinical experts or care managers outside the doctor-patient dyad. Under managed care, payments are made prospectively, care is continuously monitored, and payers and clinicians are held accountable for clinical care and service outcomes. Geriatric psychiatry is now entering the maelstrom of health care reform activity, and practices will change dramatically through the first decade of the new century.

Perhaps more than any other group, the elderly population requires extensive integration of general health and behavioral health services. The high degree of

medical-psychiatric comorbidity, the profound social and economic challenges of this population, and the sociobehavioral sequelae of the aging process demand careful, far-reaching integration of care to ensure continuity, comprehensiveness, effectiveness, and efficiency.

Special Behavioral Health Care Needs of the Geriatric Population Behavioral disorders among the geriatric population will receive increased attention within managed systems of care, in part because of increased scrutiny by the NCQA of health plan's approach to behavioral health care. In 1997, NCQA adopted rigorous standards for behavioral health care and access to such care; these standards were applied to general health plans in 1999. Behavioral health disorders are extensive (e.g., some estimates of behavioral disorders among the nursing home population are as high as 80 percent), underdiagnosed, and poorly treated. In addition, the reimbursement restrictions of traditional programs such as Medicare prevent creative problem-solving that could decrease behavioral morbidity and mortality among this group. For example, while Medicare will pay for hospital care and in-home care for a severely depressed, medically ill patient, it will not specifically reimburse a psychiatrist for home visits (outside the construct of a home health program) or pay for assertive clinical case management services that might prevent rehospitalization or enhance functioning. Instead, practitioners must attempt to work within organizational structures that are ill-equipped to meet the specific behavioral health care needs of this population.

Winnie was a 78-year-old woman who had been homebound for over 9 months. She had numerous medical conditions, including diabetes, hypertension, mild congestive heart failure, and uncontrolled hyponatremia. She complained of being severely depressed and socially isolated to her primary care physician, who attempted to have her see a psychiatrist. However, Winnie could not go to the psychiatrist's office because of her difficulties and her concerns about stigmatization. After 6 months of poor progress and frustration, the physician referred her to a home health care agency for “mental status checks.”

The home health agency, the only one in Winnie's small town, had no behavioral health experts on their staff, but sent a nurse to Winnie's home. The nurse performed weekly “mental status checks” that consisted of asking Winnie whether she was depressed or suicidal or both; she also “validated Winnie's experience of feeling socially isolated.” Winnie's physician felt frustrated by her lack of progress and was reluctant to offer her an antidepressant medication because of his lack of experience with these agents in severely medically ill patients. Six months after the home health agency became involved in Winnie's care, Winnie enrolled in a managed Medicare program.

Shortly after Winnie enrolled in the Medicare HMO program, her physician called the managed behavioral healthcare organization (MBHO) responsible for the coordination of her care and asked for assistance in helping Winnie. The MBHO ensured that Winnie was seen by one of its mobile geriatric psychiatrists, who prescribed an antidepressant in coordination with her primary care physician, and by a clinical case manager, who ensured that Winnie was linked to a variety of community services to decrease her social isolation. Three months after these interventions, Winnie's medical illnesses were well controlled; she was euthymic and said she now derived satisfaction from her life. This example demonstrates what can be accomplished when administrative barriers to effective care (e.g., benefits limited to established programs or services such as home health care or office-based psychiatry) are removed. In fact, not only are such interventions clinically effective, they are cost-efficient as well.

Increased Use of Nontraditional Services As in the rest of behavioral health care, creative and flexible programing for this population will increase. Already there is a history of innovation in geriatric health care, through the home health and social HMO programs. In the future, there will be decreased use of services such as partial hospitalization and traditional forms of psychotherapy (both of which have been used less by elderly patients) and increased reliance on community alternatives to them. Such a list of offerings will undoubtedly include use of assertive case management programs and services, individually tailored psychosocial rehabilitation services, community-based chemical dependency detection and treatment services, primary care–based and–coordinated depression detection and treatment, and use of existing providers of geriatric services (e.g., senior centers, peer counseling services).

Chemical Dependency Underdetection Some have suggested that chemical dependency among the elderly population has reached epidemic proportions. Especially when abuse of or dependence upon prescription medications is considered, this set of problems is quite extensive. There are numerous barriers to adequate detection: elderly adults rarely seek behavioral health services, primary care practitioners are notoriously poor at detecting these problems, and chemical dependency problems are generally hidden by patients. Primary care practitioners will increase efforts to involve behavioral health providers in designing and implementing detection programs and then delivering effective chemical dependency treatment programs, probably in community and general health care settings. These interventions will be focused and goal-directed with a cognitive-behavioral base. Residential programs are unlikely to hold much sway for a variety of reasons, not the least of which are patient acceptability and cost. Interventions will be carefully monitored for effectiveness and will be judged on the basis of their inclusion of relapse-prevention techniques and use of geriatric-specific 12-step and other community resources.

Depression Underdetection and Inadequate Treatment Many elderly individuals seek help from their primary care practitioners for behavioral health problems along with their general health concerns. In fact, many primary care visits are used by elderly patients when they need behavioral health care for depression, not for health problems. Finally, many health problems are complicated in this population by unrecognized depression. Primary care practitioners lack the time and expertise to detect depression reliably and accurately. In the Managed Care Outcomes Project, researchers found that within a pool of about 12,000 primary care patients, over 1600 of them either carried a diagnosis of depression or were treated with an antidepressant. Only about half of those diagnosed with depression actually received an antidepressant (over 80 percent of these were prescriptions for non-SSRI antidepressants); about half received a benzodiazepine.

Behavioral health providers will be called upon to design effective and efficient ways to identify depression in primary care settings and then treat these disorders, likely in the medical setting. Of paramount concern to the elderly patient and the primary care physician will be the ability to deliver services in medical settings to avoid stigmatization and enhance treatment coordination.

Through initiatives stimulated by NCQA, emphasis on behavioral health, and primary care integration, health plans have begun to develop programs to address primary care practitioners' inadequate recognition and treatment of depression. Plans can use new information systems to identify specific primary care practitioners who, for example, use inappropriate medications (e.g., benzodiazepines, multiple antidepressants) for the treatment of depression. Once identified, they are targeted for internet-based continuing medical education programs. Following the training, their prescribing practices are tracked for improvement. This last component in the training process, ensuring that the training results in actual practice changes, has been the most difficult to demonstrate; perhaps newly available information technologies will aid in this process.

Medical-Psychiatric Interface Perhaps more than with any other patient group, the coordination of general health and behavioral health care is highly significant for elderly patients. Many have significant, chronic medical problems, and great attention has been paid to this area in recent years. In Veterans Affairs settings, HMOs, and other institutions, models have been used that facilitate efficient coordination of these services. The use of practice guidelines and the increased presence of behavioral health care providers in primary care settings will increase. The critical aspect of guideline development—now that so many of these best practices documents exist—is tracking practitioner behavior to ensure that the guidelines are being followed and best practices are being implemented. Only through managed systems of care, in which accountability is fostered through aggressive reporting, are such improvements possible.

Dementia More vexing than any other will be the challenges of coordinated and comprehensive treatment of individuals with dementia. As treatments for the core cognitive symptoms and associated medical complications of this set of illnesses become more advanced, the need for behavioral health services will surely grow. For example, the ability to target early memory deficits for improvement can be augmented by rehabilitation strategies including skills training, family support and education, and environmental manipulations. Our field must improve performance at the interface between psychiatry and medicine in the dementias to decrease fragmentation of care. Protocols to define the limits of psychiatric and medical expertise are being tested now, enabling practitioners to focus their efforts on improving care. Areas of future concern will include the appropriate role for psychiatry (to provide all care for the cognitive and behavioral aspects of these disorders or only for behavioral abnormalities; or to serve as consultants for gerontology or primary care teams); the most efficient ways to design comprehensive, community-based systems of continued care; and the use of established behavioral interventions to rehabilitate demented patients and prevent further disability.

Special Needs Considerations Because of the population focus inherent in managed care efforts, it is feasible to define the special needs of subpopulations such as frail elderly adults and seriously mentally ill patients. More than a decade of experience in treating frail elderly patients in social HMOs will allow continued refinement of the detection of special needs, accommodations in service access and delivery required by this population, and the effective application of novel techniques.

The aging of the seriously mentally ill population has yet to become the subject of much discussion and debate, aside from the occasional article about long-term outcomes for this population. Managed care initiatives will take account of the special needs of seriously mentally ill elderly patients and effect changes in the way services are delivered. For example, clinical case management (e.g., Programs for Assertive Community Treatment [PACT]) and psychosocial rehabilitation models should be revised so that interventions are tailored to the special needs of these individuals. As a result, knowledge about the effective use of community supports

and resources such as senior centers, meals programs, and peer counseling services for seriously mentally ill elderly patients will enhance service delivery and outcome.

SUGGESTED CROSS-REFERENCES

Section 5.3 discusses mental health services research. Chapter 10 covers dementia and other cognitive disorders, and 51.3e covers dementia in the elderly population. Chapter 11 and Section 51.3h cover substance-related disorders. Section 51.5a discusses Medicare and Medicaid, and Section 51.5d discusses VA psychogeriatric services. A more detailed discussion of managed care is presented in Section 52.2.

CHAPTER 51. GERIATRIC PSYCHIATRY

51.5 HEALTH CARE DELIVERY SYSTEMS

51.5C VETERANS AFFAIRS MEDICAL CENTERS AND PSYCHOGERIATRIC SERVICES

WILLIAM W. VAN STONE, M.D., AND THOMAS B. HORVATH, M.D., F.R.A.C.P.

DEFINITION

The Veterans Administration, established by the United States Congress in 1930, was renamed the Department of Veterans Affairs (VA) when it achieved cabinet level status in 1989. The Department, through its Veterans Health Administration (VHA), now administers the largest organized medical care system in the country, including 173 hospitals, 131 nursing homes, 40 domiciliaries, and 470 clinics; 132 VA medical centers are affiliated with 105 accredited medical schools throughout the country. VA health care centers (combinations of hospitals, clinics, nursing homes, and domiciliaries) vary much in size and complexity, but they are all approved by the Joint Commission and their average scores have been 5 to 10 points higher than those of comparable private-sector hospitals. As of January 1999, the VHA employs over 220,000 people and the overall health care budget is 17 billion dollars, of which over $2 billion goes for mental health. The VHA employs 8000 psychiatrists and 1630 psychologists who provide mental health services.

There are 25.1 million veterans, of whom 9.1 percent have service-related disabilities and nearly 4.8 percent are poor. Under the new eligibility rules, over 3.2 million veterans use the VA on an annual basis.

In 1998 the VHA treated 650,000 veterans for mental disorders, including substance abuse, an increase of 20 percent since 1990. Of these, 88,200 needed inpatient care (average length of stay 18 days) and 640,000 received outpatient care with an average of 7 visits per year. On a given working day, there were 8,800 veterans in psychiatric inpatient care and another 117,600 were receiving psychiatric outpatient care.

In recent years numerous government and nongovernment reports have consistently concluded that fundamental changes were needed in the VHA health care system to make it more efficient and responsive to patients, including

- redistribution of VHA health care resources throughout the country to better meet changing regional population needs;
- decentralization of funds, decision making, and clinical care initiatives to regional integrated service networks;
- better access to care through multiple, community-based, ambulatory settings; and
- organization of integrated care delivery around patients' needs with emphasis on primary care teams.

DEMOGRAPHICS

In 1999 veterans age 65 or older numbered 9 million and are estimated to remain in the range of 7.8 to 9 million until the year 2020. Most of these persons will be veterans of World War II and the Korean Conflict until approximately 2010, when aging Vietnam-era veterans will begin to augment that age group. By 2015 the latter cohort will account for 51.9 percent of elderly veterans. Between 1999 and 2010 the number of veterans age 75 years and over will remain stable between 3.7 and 4.4 million.

Throughout the first two decades of the twenty-first century, veterans age 65 years and over will comprise a larger proportion, 37 percent to 46 percent, of the total veteran population than their counterparts in the general population (<20 percent). In 1987 an analysis of discharge data from all VA medical centers showed that approximately one third of all inpatient admissions were geriatric patients who accounted for nearly 41 percent of all hospital days. By 1998 the percentage of discharges of patients over 65 years old had grown to 45 percent. Planning and implementation of programs to meet the needs of the elderly veteran population for physical and mental illness must therefore have a corresponding emphasis.

EPIDEMIOLOGY OF MENTAL DISORDERS IN THE ELDERLY

Although the reported prevalence of mental illness among the elderly varies, conservative estimates for those age 65 years or older include a minimum of 10 percent with dementia of the Alzheimer's type or other dementia, and an additional 15 percent to 30 percent with other psychiatric illness. If an estimate of 30 percent is used, it can be expected that at any time during the period 1999 to 2020 from 2.3 to 2.7 million veterans will need psychogeriatric care. Psychiatric services are generally underused by today's elderly, but that trend is likely to change for VA as the Vietnam-era veterans enter the over-65 age group. Clinical experience suggests that the current, more psychologically oriented generations are less reluctant than their predecessors to acknowledge needing mental health care and thus may be more apt to seek help from the VA.

THEORETICAL ISSUES

Planning for high-quality psychogeriatric care requires the integration of conflicting patient needs in at least two clinical areas: (1) the need for assistance during an ongoing illness versus the need to maintain self-sufficiency and (2) the need for expertise from clinical subspecialists and from multiple clinical disciplines versus the need for one informed primary care provider to integrate the information into a plan. In addition, health care organizations with multiple facilities tend to group patients with similar problems in one location to minimize duplicating scarce specialized services. Travel time to appropriate resources can become a serious barrier to treatment, particularly for elders. These conflicts are playing out in the 22 recently decentralized, cost-conscious VA-integrated service networks (composed of geographically related groups of VA medical centers and clinics).

Levels of Care Older patients presenting with multiple ongoing health challenges must be provided with sufficient support and expertise to manage their symptoms, but not enough to stifle their independence and potential for self-management. In recognition of this wide range of patient needs, in June 1993 the VHA adopted a policy that psychogeriatric programs as well as those in general psychiatry should be organized on a continuum of care that would provide “a full spectrum of interconnected inpatient, outpatient, community, and home-based services which integrate the medical, psychological, social, vocational, and avocational needs of this population in a comprehensive and flexible manner.”

This theoretical continuum of programs has been fleshed out in *Integrated Psychogeriatric Patient Care*, a recent VA program guide created by an ongoing VA psychogeriatric field advisory group. This guide provides recommendations for treatment modalities, organization, space, equipment, staffing, education, research, and quality management. Under today's restricted funding mandates, it is expected that not all potential programs will be vailable or even appropriate at every VA medical center; however, all major components of the continuum must be available within the larger VA integrated service network (VISN). The VHA is experimenting with small, mobile psychogeriatric subspecialty teams to provide consultation, case management, and familial/provider education regarding psychogeriatric issues when needed, along with ongoing care if necessary. Psychogeriatric consultation by teleconference will soon prove to be practical among VA facilities.

TECHNIQUES

In addition to traditional medical and psychiatric assessment, diagnosis, and treatment techniques, the elderly often require additional specialized care to address multiple medical and psychosocial problems. VA psychogeriatric programs are often integrated with those in geriatric medicine as well as with many adjunctive services such as dentistry, dietetics, pharmacy, podiatry, psychology, recreation and rehabilitation therapies, social work, speech and hearing, and the chaplaincy. The Undersecretary for Health has recently declared that VA healthcare is more than just “medical care,” thus approving a whole system of “wraparound services” of a psychosocial nature.

Outreach services and clinical screening tools are often offered in primary care clinics to elderly veterans who may not be inclined to seek mental health services spontaneously. Psychogeriatric consultation provided to the growing numbers of medical primary care teams in VA facilities will enhance their capabilities. Attention to accurate diagnosis and prescription of psychiatric medications to relieve the symptoms of illness, rather than to control behavior, is especially important. In addition to a growing reaction against using medications as a form of restraint for disturbed elderly patients, the use of physical restraints has come under increasing scrutiny, resulting in marked decreases in the use of all restraints in VA settings. Management of disturbing or high-risk behaviors in the elderly requires careful review of diagnoses, the number and dosage levels of medications, and the staff's interpretation of the meaning or intent of the behaviors. Behavioral modification protocols for the elderly tend to be effective only when communication within the caregiving team is open and frequent.

Other psychological interventions for the elderly may include self-awareness training, grief counseling, remotivation therapy, reminiscence review, and intergenerational programs. Staff and family interventions may include behavior management, respite care, environmental modification, and palliative support groups. Organized transportation is considered an essential adjunct to day care programs.

CLINICAL ISSUES

The VA psychogeriatric field advisory group has recommended that clinicians focus more on mild rather than severe mental impairment in the elderly because treatment of the former can prolong the patient's stay at home. The advisory group stressed that training, support, and the availability of respite programs is essential for those who provide care in the patient's home. There is some evidence, however, that respite admissions for those who have dementia may result in a lowered level of functioning and a subsequent increased burden on the caregiver following the patient's return home. The advisory group also recommended a greater emphasis on outreach to patients with untreated depression, because depression can result in intractable physical illness on the one hand or be mistaken for an irreversible dementing illness on the other. Depression may also accompany early clinical dementia.

Clinical practice guidelines for treatment of major depressive disorders including comorbidities of substance abuse and posttraumatic stress disorder were developed by a multidisciplinary group of VA professionals in 1996, distributed to all VA medical centers in 1997, and revised in 1998. These guidelines include a brief screening tool for depression in the elderly to be used in all clinical areas, including primary care, and provide guidance for prescription of psychiatric medications in the elderly as well as special psychosocial interventions. Guidelines were also published for the recognition and treatment of dementia.

Unified Psychogeriatric Biopsychosocial Evaluation and Treatment (UPBEAT), a 3.6 million dollar demonstration project currently being tested at nine VA facilities, is exploring clinical and economic outcomes of screening elderly patients for depression, anxiety, and substance abuse in short-term VA medical and surgical hospital settings. Willing patients with positive symptoms are evaluated by an interdisciplinary psychogeriatric team, after which their progress is followed by case managers. Early findings suggest no reduction in readmissions but a reduction of 5.4 bed days of care for the 12 months following discharge (and consequently lower overall costs) when compared to a randomized “usual care” group.

Recommendations for future psychogeriatric care include using greater care and expertise in the prescription of psychiatric medications, better management of high-risk behaviors, more attention to substance abuse and delayed posttraumatic stress disorder in older veterans, and fuller collaboration with geriatricians regarding management of medical comorbidities, such as chronic obstructive pulmonary disease, diabetes, hypertension, and cardiovascular disease. Psychogeriatric intervention in existing VA and non-VA nursing homes, day care, and home care programs also should be expanded.

ETHICAL ISSUES

Geriatric psychiatrists may be asked for an evaluation of elderly patients' competency and of their ability to understand treatment choices. The VA National Cost Containment Center, in collaboration with the Mental Health Strategic Health Care Group, has published clinical guidelines for the determination of competency. Geropsychiatric advice may also be sought regarding the ailing patient's desires regarding life-sustaining technology where preservation of life versus quality of life issues often present ethical dilemmas. The VA's Clinical Ethics Center at White River Junction published a helpful series of ethical guidelines.

RESEARCH AND EVALUATION

A computer search of medical research articles published since 1990 on geriatric psychiatry and veterans revealed 66 that are relevant. Of these, 27 addressed aspects of posttraumatic stress disorder, including studies of exprisoners of war; 14 explored alcohol abuse, its detection and treatment; 10 studied Alzheimer's disease and related disorders, and the rest addressed other aspects of illness in elderly veterans.

Some major themes expressed in these articles were:

1. Posttraumatic stress disorder is underdiagnosed in elderly veterans, of whom 35 to 52 percent over age 55 were reportedly exposed to combat. Symptoms of posttraumatic stress disorder are less severe in the older veterans as compared to those from the Vietnam era, but are, for veterans of any age, proportional to the actual exposure to combat stress and may be associated with anatomical changes in the brain. Exprisoners of war from any era are especially at risk.
2. Supportive alcohol programs designed especially for elderly patients with alcoholism are more effective than those typically designed for younger persons.
3. Institutionalized veterans with a long-term mental illness fared better when given maximal control over their daily lives.

SUGGESTED CROSS-REFERENCES

An introduction and overview of geriatric society appears in Section 51.1. Dementia of the Alzheimer's type is discussed in Chapter 10 on delirium, dementia, and amnestic and other cognitive disorders and in Section 51.3e on Alzheimer's disease and other dementing disorders. Mood disorders are presented in Chapter 14 and Section 51.3d on mood disorders in late life.

51.5 HEALTH CARE DELIVERY SYSTEMS

51.5D COMMUNITY SERVICES FOR THE ELDERLY PSYCHIATRIC PATIENT

BARRY D. LEBOWITZ, PH.D.

A number of excellent reviews have focused on issues of mental health care for older persons. These reviews reflect widespread agreement on the components of an ideal system: a full multidisciplinary range of clinical, rehabilitative, preventive, and supportive services; comprehensive assessment; case management; aggressive outreach; and seamless coordination of mental health, physical health, and social services. There is also widespread agreement that such a system is a fiction, rarely approached even in the best of circumstances. Five issues are particularly relevant: (1) the growing importance of managed care, (2) the enhanced significance of primary care, (3) the place of comprehensive assessment, (4) the redefinition of outcomes, and (5) the clarification of the role of the family and of the institution.

IMPORTANCE OF MANAGED CARE

The traditional private practice fee-for-service approach to the provision of medical care in the United States is being supplanted by various organized systems referred to as managed care. These systems are characterized by financial arrangements based on capitation, geographical coverage, emphasis on ambulatory care, vertical integration of primary care providers and community hospitals, referral specialists, and restricted use of tertiary care and the academic health center. There are many forms of managed care, including health maintenance organizations and preferred-provider organizations. These organizations use many approaches to control costs by monitoring physician behavior, establishing formal practice guidelines, and routinely applying utilization review and prior approval procedures for all nonemergency care. Another development in managed care has been the proliferation of so-called behavioral health carve out companies. *Behavioral health* defines a broad range of mental health, substance abuse, counseling, employee assistance, and crisis intervention services. These organizations contract directly with employers or with managed care organizations to provide these specialized services under some sort of fixed fee arrangement. This organization then assumes all responsibility for the covered services.

There is great concern that this emerging pattern will result in significant problems because of the financial benefit in failing to recognize, diagnose, and appropriately treat mental disorders. This risk is particularly great with respect to the care of geriatric patients, who characteristically exhibit complex patterns of comorbidity and who may be seriously disadvantaged by the separation of behavioral health services from other health services.

SIGNIFICANCE OF PRIMARY CARE

The scope of responsibility of the primary care sector is being expanded and redefined in the emerging health care system in the United States. At the level of training, emphasis is being moved from specialty and subspecialty care to primary care; the stated goal of many involved in system reform is to allocate as many as one-half the post-medical degree residency positions to primary care disciplines. The primary care physician will assume greater responsibility for diagnosis, treatment, and long-term management in all areas of health care, including care of older patients with mental disorders. Moreover, in most organized systems, access to specialty and subspecialty care will be through the primary care provider who will serve as a referral resource, case manager, and gatekeeper.

A rough rule of thirds characterizes the present situation of care of older persons in need of mental health services: approximately one in three receives care from a mental health professional, another third is treated in primary care, and another third receives no care at all. Compared with midlife adults, older people are more likely to receive mental health care from general physicians than from any other type of professional.

The reliance on nonspecialty care raises concerns about the appropriateness of the treatments provided. General clinicians too often prescribe drugs with significant anticholinergic and mood-altering effects for their elderly patients, even when more appropriate treatments are available. Comorbidity raises other types of concerns. The quality of care and the long-term outcome of treatment for mental disorder are significantly improved in mental health specialty care, medical services are of higher quality, and physical health outcomes are improved in the general health care sector. The widespread use of treatment or practice guidelines, such as those from the Agency for Health Care Policy and Research or those generated within managed care systems or professional organizations, could possibly improve the appropriateness of treatment.

COMPREHENSIVE ASSESSMENT

Comprehensive assessment is one of the foundations of geriatric care. Recent studies clearly demonstrate the benefit of multidisciplinary comprehensive assessment for community-residing older persons. Among the major differences observed between intervention and control groups were significantly improved diagnosis of depression and cognitive impairment and a reduction in long-stay nursing home admissions.

REDEFINITION OF OUTCOMES

As part of the ongoing process to reform the health care system in the United States, treatment approaches in many areas of medicine are subject to intense scrutiny. One such effort is directed toward the efficacy of treatment for severe mental disorders, including disorders of late life. The overwhelming conclusion of this analysis is that a variety of rigorously tested treatments is available, efficacious, and affordable. At the same time, it is recognized that most treatment assessment studies have been too narrowly focused on symptom reduction, and that attention must be paid to the impact of treatment on significant public health factors such as function, disability, quality of life, health care resource use, institutionalization, morbidity, and mortality.

FAMILY AND INSTITUTION

The design and operation of community services for older persons are best seen as complementary to those services provided by the family and by the institution, particularly the nursing home. Using Alzheimer's disease as the model of the effects of chronic stress on the family members responsible for the ongoing care of the disabled older person, research has documented both the psychosocial and psychobiological parameters of the burden of care. Importantly, however, studies have shown that interventions directed at the family caregiver, and not the patient, can have effects on patient outcomes and can delay institutional placement for a significant period.

The nursing home is a critical and unique component of the continuum of community services for older persons with mental disorders. There are no alternatives in the community for patients who require a comprehensive level of care. The proliferation of community based services has resulted in an increased need for nursing home care because the provision of care appropriate to the needs of the chronically disabled results in substantial increases in life expectancy that, in turn, amplifies and expands the role of institutional care. “Alternatives to institutionalization” are not, in fact, alternatives at all and do not displace the need for institutional care.

Community services for the elderly have been developed out of a complex mix of clinical needs, available resources, policy determinations, and political activities. Currently all institutions are under intense scrutiny, and the role and responsibility of government in the provision of services is being reevaluated. Older persons, with their complex patterns of comorbidity and need for ongoing multidisciplinary care, are extremely vulnerable to the plans of those whose notions of health care consist exclusively of neatly balanced graphs, charts, and tables. The challenge is to ensure that the needs of the patients remain at the center of all these discussions.

SUGGESTED CROSS-REFERENCES

An introduction and overview of geriatric society appears in Section 51.1a. Alzheimer's disease and dementia of the Alzheimer's type are discussed in Chapter 10 on delirium, dementia, and amnestic and other cognitive disorders and in Section 51.3e on Alzheimer's disease and other dementing disorders. Mood disorders are presented in Chapter 14 and Section 51.3d on mood disorders in late life. Managed care is discussed in Section 52.2; the impact of managed care on the elderly is discussed in Section 51.5b.

51.6 SPECIAL AREAS OF INTEREST

51.6A PSYCHIATRIC ASPECTS OF LONG-TERM CARE

IRA R. KATZ, M.D., PH.D., JOEL E. STREIM, M.D., AND BUSTER D. SMITH, M.D.

The concept of long-term care has expanded in recent years to include a spectrum of health services required by persons with illnesses and disabilities that interfere with their ability to care for themselves. It can include convalescent care during periods of recovery as well as life-long care for those with irreversible disability. Long-term care can be provided across a wide variety of settings for delivery of health care, including community settings such as home, day-care centers, partial hospital programs, nursing homes, and other types of assisted living or residential care settings.

With the aging of the population in the United States and the resulting increase in the number of elderly patients with chronic diseases and disability, long-term care has become an increasingly important issue in political, economic, and clinical terms. The magnitude of the problem can be estimated by recognizing the number of people who are dependent with respect to activities of daily living. That figure increases from 3.5 percent of those age 65 to 74, to 35 percent of those 85 years of age and older. Although the proportion of people living in nursing homes increases from 1 percent of those age 65 to 74, to 24 percent of those 85 and older, most older patients with self-care deficits live in the community, and most long-term care for elderly persons is in the form of informal assistance, usually provided in the home by the patient's family.

A number of recent changes have occurred in the delivery of long-term care. Over the 10 years from 1985 to 1995, the number of nursing home beds increased by 9 percent to 1.8 million. However, during this time, the number of homes decreased by 9 percent to 16,600, and their occupancy rate decreased by 4.8 percent to 87.4 percent. In spite of an 18 percent increase in the population over age 65, the number of nursing home residents increased by only 3.8 percent to 1.55 million. As a result of these changes, the ratio of nursing home residents to the general population over age 65 decreased from approximately 46.2 per 1000 in 1985 to 41.3 in 1995.

The decline in the proportion of elderly adults residing in nursing homes probably reflects significant growth in other forms of long-term care. For example, in recent years about 11,000 home health and hospice agencies provided care to nearly 2 million patients, and a number of major corporations have begun to view assisted living for older adults as a major growth industry. Other recent changes in long-term care have occurred within nursing homes in response to both marketplace incentives and clinical needs. Nursing homes now offer many of the rehabilitation services historically provided on inpatient units. Many nursing facilities have subacute units that provide step-down care for medical, surgical, or poststroke patients. Others have established special care units for patients with Alzheimer's disease.

Although long-term care options and settings are becoming more diverse, the major recent advances in scientific knowledge about the mental health components of long-term care are mostly from studies in nursing homes. Nursing homes are important sites for mental health services. Results from research in nursing homes can be applied to comparable patients in other long-term care settings.

NURSING HOMES: PROBLEMS AND REFORMS

Nursing homes account for approximately 4.1 percent of elderly Americans, with 1.55 million older people living in nursing homes at any time. This figure, however, greatly underestimates the number of individuals who utilize nursing home services. In 1995 1.7 million people were admitted to nursing homes; two thirds to three fourths of them were discharged after several months. It has been estimated that the number of nursing home residents will double by the year 2020 and triple by 2040, and that the probability that any person will require nursing home care at some point in his or her life exceeds 40 percent. The total costs of institutional care for elderly patients in the United States were estimated for 1993 at $74.9 million, with $36.9 million coming from Medicaid and $4.8 million from Medicare.

Nursing home care represents approximately 8 percent of the nation's total health care costs, but the burden of payment is markedly different from that of other aspects of health care, with approximately 50 percent of costs borne directly by residents and their families and most of the remainder shared equally by the federal and state governments through Medicaid programs. Medicare payments are limited to subacute care. In spite of recent trends toward a leveling of growth, the number of nursing homes and nursing home beds has increased dramatically since the mid-1960s when Medicaid programs were first developed. In parallel, there has been increasing recognition of the problems with nursing home care and the need for reform. As stated in a 1986 Institute of Medicine report “Improving the Quality of Care in Nursing Homes,” many nursing homes provide good care,

> but in many other government certified nursing homes, individuals who are admitted receive very inadequate—sometimes shockingly deficient—care that is likely to hasten the deterioration of their physical, mental, and emotional health. They also are likely to have their rights violated and may even be subject to physical abuse.

Several major issues raised about the quality of nursing home care were related to its psychiatric aspects; they included concerns that physical and chemical restraints were inappropriately being used to control residents' behavior and that psychiatric disorders (primarily depression) were being undertreated. Estimates of the prevalence of the use of physical restraints, such as wrist or ankle cuffs, belts, vest restraints, or geriatric chairs designed to restrict mobility, ranged from 25 to 85 percent. Use of these devices was endemic in spite of evidence from observational studies that they do not safely control agitated behavior as well as suggestions from cross-national studies that similar patient populations can be managed without their use. Surveys of medication use in long-term care facilities found prevalence rates of up to 74 percent for medications that act on the central nervous system.

Antipsychotic agents have been the most frequently prescribed psychotropic medications, with most reports of prevalence in the range of 20 to 50 percent. Evidence suggesting the misuse of those drugs came from findings that variables unrelated to patient characteristics (e.g., facility size, ratio of patients to staff, and the size of the physician's nursing home practice) were directly associated with use of drugs. Substantial numbers of patients received psychotropic drugs without any diagnosis of mental disorder and without any chart note indicating the presence of relevant target symptoms. The importance of this issue for patients, families, and advocacy groups was poignantly captured by the newspaper headline “America's Other Drug Problem.”

Advocates for improving the quality of long-term care were concerned about issues such as the misuse of restraints and the lack of mental health services for patients who needed long-term care because of dementia or psychiatric disorders associated with medical illnesses. However, as policy evolved, these issues became confounded with questions of whether patients with schizophrenia and other persistent and severe psychiatric disorders belong in nursing homes, whether they could receive appropriate treatment in these settings, and whether they were being admitted to nursing homes by states primarily to shift the costs of their care to the federal government. In 1987 the federal government, the largest single source of payment for nursing home care, used Medicaid and Medicare legislation to mandate nursing home reform that was enacted in the Omnibus Budget Reconciliation Act (OBRA) of 1987. OBRA 1987 (with modification in 1990) required preadmission screening and annual resident review (PASARR) to ensure that patients who belong in psychiatric hospitals were not inappropriately admitted to nursing homes. Other regulations stated that “the resident has a right to be free from any physical and chemical restraints imposed for purposes of discipline or convenience and not required to treat the resident's medical symptoms.” OBRA ‘87 requires that “residents who have not used antipsychotic drugs are not given these drugs unless antipsychotic drug therapy is necessary to treat a specific condition as diagnosed and documented in the clinical record,” and “residents who use antipsychotic drugs receive gradual dose reductions and behavioral interventions, unless clinically contraindicated, in an effort to discontinue these drugs.” Regulations also state that each resident must be free from unnecessary drugs, which are defined as any drug used without appropriate indications, in excessive dose, for excessive duration, without adequate monitoring, or in the presence of adverse consequences that indicate that the medication should be reduced or discontinued. Although the definition of unnecessary drugs is rather general, guidelines used by surveyors to monitor facilities' compliance with OBRA regulations focus on antipsychotic, anxiolytic, and

sedative-hypnotic drugs. The primary goal in the implementation of the antipsychotic drug and unnecessary drug regulations is to decrease the use of medications as chemical restraints.

In addition to the PASARR and psychotropic drug regulations, there are also requirements related to the treatment of mental health problems. Under the general quality-of-care provisions that “each resident must receive and the facility must provide the necessary care and services to attain or maintain the highest practicable physical, mental, and psychosocial well-being,” there is a specific provision related to mental health, stating that a facility must ensure that “a resident who displays mental or psychosocial adjustment difficulty receives appropriate treatment and services to correct the assessed problem.” However, implementation of these OBRA requirements for mental health treatment has lagged behind the other provisions related to psychiatric disorders, despite compelling evidence in the clinical literature that psychiatric treatment is a critical part of nursing home care.

OBRA regulations state that each facility's staff must conduct regularly scheduled assessments of all residents using a standardized instrument, the Minimum Data Set (MDS), which was designed to identify clinical problems, including mental health problems. The MDS includes sections related to mental health and mental illness that evaluate customary routines, cognitive patterns, mood and behavior patterns, psychosocial well-being, and activity pursuit patterns. When certain trigger signs are identified, facilities must complete resident assessment protocols (RAPs) that provide guidelines for determining whether the resident's treatment plan should be modified. RAPs address delirium, cognitive loss dementia, psychosocial well-being, mood state, behavior symptoms, activities, psychotropic drug use, and physical restraints. The MDS has been proposed for use as a tool for outcome assessment and research as well as clinical management.

Research indicates that since OBRA reforms, the use of antipsychotic medications in nursing homes has declined by more than one third. Moreover, available data suggest that the decrease in use of these agents has not been accompanied by substantial increases in use of other medications or marked increases in psychiatric or behavioral symptoms. Although OBRA reforms have had some positive effects on psychotropic drug–prescribing practices, they have not, by themselves, decreased the overuse of psychotropic drugs, nor have they reversed the problem of undertreatment of psychiatric disorders. Controlled studies have demonstrated that even after OBRA, educational interventions can decrease overall use of antipsychotic agents while helping to target appropriate patients for treatment. Research over the past decade has also confirmed both the benefits of psychopharmacological treatment in the nursing home (e.g., for major depressive disorder) and the risks of all classes of psychotropic drugs (e.g., as causes of falls). Thus, both clinical and epidemiological data demonstrate that even after implementation of OBRA regulations intended to limit the use of psychotropic medication, there is still a need for appropriate pharmacological treatment of psychiatric disorders.

Nationwide concern over the growing costs of health care for the elderly has led to ongoing debates about how to pay (and who should pay) for long-term care. Federal initiatives to decrease “entitlement” expenditures are giving the states greater discretion over how they spend limited Medicaid funds. As the states experience growing financial pressures, this could undermine recent advances in access to mental health care for elderly nursing home residents.

Medicare reimbursement for nursing home treatment under the most common mental health procedure codes increased 244 percent, from $20.8 million in 1991 to $71.7 million in 1993. During this time, Medicare costs for these codes across all settings increased by only 57 percent, from $353 million to $555.6 million. Although this might have been interpreted as evidence for improvements in case recognition and treatment in nursing homes, it led instead to concerns by the Department of Health and Human Services that Medicare might have been billed for unnecessary or inappropriate services. These concerns suggest the need to develop guidelines for cost-effective and accountable provision of medically necessary treatment, with standards to ensure that nursing home residents who have psychiatric disorders are not undertreated.

MENTAL HEALTH IN NURSING HOMES: CLINICAL ISSUES

Epidemiology Alvin Goldfarb, who investigated nursing home psychiatric care in 1962, estimated the prevalence of psychiatric disorders among nursing home residents at 87 percent. Subsequent prevalence estimates based upon systematic psychiatric evaluations of residents have been comparable. In 1990 Barry Rovner and coworkers found diagnosable psychiatric disorders in 80 percent of a series of new admissions to nursing homes; and Patricia Parmelee and coworkers, who included milder depressions, found approximately 90 percent. In the study by Rovner's group, newly admitted nursing home residents were interviewed by psychiatrists. The distribution of diagnoses is given in Table 51.6a-1. Although the work was completed before implementation of OBRA regulations, only 8.5 percent of the residents admitted to the nursing facility, or 10.6 percent of those with a diagnosable psychiatric disorder, had a history of previous psychiatric hospitalization. That statistic demonstrates that the high prevalence of psychiatric disorders among nursing home residents cannot be attributed to transinstitutionalization and the admission of chronic psychiatric patients. This is consistent with the findings of Bernard Stotsky, who in 1967 demonstrated a high prevalence of psychiatric disorders among allegedly nonpsychiatric nursing home residents. This is explained by conditions such as dementia and depression related to disabling medical and neurological illnesses that make nursing home care necessary.

Any psychiatric disorder	80.2
Dementia (all)	67.4
Complicated by:	
Depression	6.3

Adapted from Rovner BW, German PS, Broadhead J, Morris RK, Brant LJ, Blaustein J, Folstein MF: The prevalence and management of dementia and other psychiatric disorders in nursing homes. Int Psychogeriatr 2:13, 1990.

Table 51.6a-1 Prevalence of Psychiatric Disorders in the Nursing Home (Percentage)

Dementia Dementia of the Alzheimer's type and other dementias are the most common psychiatric disorders among nursing home residents. There have long been concerns that many patients misdiagnosed as suffering from a dementia are inappropriately admitted to nursing homes. Clearly, all patients should receive a comprehensive evaluation before decisions are made about their need for long-term care. Such evaluations, however, may not always be completed before nursing home admission, especially in patients with acute medical problems; in such cases the evaluations should be conducted as soon as possible after admission. Identification and treatment of reversible cognitive impairment can improve the quality of life of a nursing home resident or facilitate return to the community. Thomas Sabin and coworkers reported that 52 of 111 (47 percent) nursing home residents with dementia had a potentially treatable component of their cognitive impairment. Rovner and colleagues found that approximately 7 percent of a series of new admissions to a nursing home (10 percent of those with dementia) exhibited symptoms of a superimposed delirium. The first author and coworkers found that 6 to 12 percent of the cognitively impaired residents of a long-term care facility actually exhibit significant improvements in cognitive performance over a 1-year period as a result of toxic and metabolic encephalopathies or depression.

Of the irreversible dementias found in nursing home residents, dementia of the Alzheimer's type is the most common, followed by vascular dementia. Estimates of the frequency of vascular causes or components of dementia vary from about one third to as much as one half of the total in various studies. Although both types of dementia are irreversible, diagnostic evaluation that distinguishes vascular dementia from dementia of the Alzheimer's type can trigger appropriate medical interventions to decrease the rate of progression.

Psychoses and depression may occur with dementia. Estimating the prevalence of those syndromes is difficult because standard methods of assessment may fail in the presence of severe cognitive deterioration. Nevertheless, available data suggest that hallucinations and delusions are seen in approximately 20 percent of demented residents, that a major depressive disorder occurs in approximately 10 percent, and that less severe depression occurs in a comparable number. Other, less well-defined behavioral disturbances are common; according to the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV), they can be documented in diagnoses of dementia by using the specifier “with behavioral disturbance.” They may include states of both agitation and apathy or withdrawal.

Jiska Cohen-Mansfield and coworkers define agitation as “inappropriate verbal, vocal, or motor activity that is not judged by an outside observer to result directly from the needs or confusion of the agitated individual.” They emphasize that agitation is a symptom, not a diagnostic term. Agitated behaviors can be symptoms of more specific psychiatric syndromes; aggressive behaviors can be symptoms of psychosis, and screaming, a symptom of depression. Agitation can also occur (usually in

patients with dementia) in the absence of other psychiatric symptoms. Factor analysis has identified three types of agitation that are common in nursing home residents: aggressive behavior, nonaggressive physical behavior, and verbally agitated behavior. Although most nursing home residents exhibit one or more agitated behaviors during the course of a week, a smaller number show disturbances of such frequency and severity that they interfere with needed care, represent sources of danger, or cause excess disability.

There is little information on the extent to which agitation can be attributed to biological factors as opposed to problems resulting from unmet needs, environmental irritants, or social conflicts. Evidence for a biological component comes from the finding that tritiated imipramine binding in platelets is lower in Alzheimer's disease patients with agitation or delusions than in controls without behavioral disturbances. Apathy has been less well investigated, but there is evidence that it can be distinguished from depression and that apathetic, withdrawn geriatric patients may respond to stimulant medication.

There has been a movement toward developing special care units for patients with Alzheimer's disease and related disorders that have architecture, administrative structures, staffing, and programing designed to maximize the level of functioning and minimize behavioral disturbances. At present, about 15 percent of nursing homes have some form of special care unit or specialized program for patients with Alzheimer's disease. Although this represents a total of 2500 units and more than 30,000 beds, investigators are still developing specifications for special care units and methods for assessing the outcomes of care. Rovner and his colleagues conducted a randomized clinical trial of a dementia care program that included augmented activities, guidelines for use of psychotropic drugs, and educational rounds and found that active treatment significantly decreased both behavioral symptoms and use of psychotropic drugs. Another type of special care, use of a hospice model for the care of nursing home residents who are in the terminal stages of Alzheimer's disease, may reduce the patients' discomfort, improve their quality of life, and reduce costs.

Depression The National Institutes of Health Consensus Development Conference Statement on the Diagnosis and Treatment of Depression in Late Life emphasized the importance of depression in the nursing home as a problem requiring the attention of clinicians, researchers, and policy makers. Depressive symptoms are associated with increased disability, increased nursing care needs, decreased participation in activities, increased reports of pain, biochemical evidence of subnutrition, increased risk of cognitive deterioration, and treatment refusal.

Recent studies suggest that depressive disorders are the most common functional disorders in the nursing home and related settings. The prevalence of major depression among cognitively intact nursing home residents has been estimated at approximately 25 percent. Although it is an order of magnitude greater than the prevalence observed among older adults in the community, the higher prevalence may have been expected because of the universal presence of chronic illness and disability in long-term care patients. Minor depressive disorder and self-rated dysphoria are also clinically significant in that they appear to represent risk factors for major depressive disorder; hence, treatment of those disorders represents an opportunity for prevention as well as for symptom relief. The importance of depression follows from the fact that it may be a treatable source of distress and increased disability, even in the presence of other irreversible disabling diseases. The coexistence of depression and physical illness, however, raises concern about the validity of the use of standard approaches to psychiatric diagnosis under conditions in which somatic or neurovegetative symptoms of depression may lose their diagnostic specificity. There are also questions about relation between the symptoms of depression and physical illness; and the initial evaluation of nursing home residents with depression must therefore include a medical evaluation seeking specific medical causes of affective and neurovegetative symptoms. When these are present the appropriate DSM-IV diagnosis is mood disorder due to a general medical condition, and the initial intervention should target the medical disorder.

Major depressive disorder in institutional patients is also associated with increased mortality. Although there has been some controversy about whether patients are depressed because they are dying or dying because they are depressed, current evidence suggests that the decreased survival associated with severe major depression remains significant even after controlling for coexisting medical illnesses or disabilities.

Nursing home staff may have difficulties identifying depressive symptoms. Accordingly, there are ongoing needs for staff training in this area. The Geriatric Depression Scale has been validated for use as a screening instrument to identify residents with depressive symptoms. Although there has been controversy about its utility among patients with cognitive impairment, recent findings demonstrate that when administered verbally, it retains acceptable levels of sensitivity and specificity (with a standard cutoff of 10) in patients with Mini-Mental State Examination scores down to 15.

The finding from a double-blind, placebo-controlled study by the first author and coworkers that residential care patients (from a nursing home and congregate apartment setting) with symptoms of major depressive disorder responded specifically to the tricyclic antidepressant nortriptyline (Pamelor, Aventyl) suggests that standard approaches to diagnosis can be applied in the long-term care setting. However, evidence indicates that special problems arise in the treatment of nursing home residents. Low serum albumin concentrations and high levels of self-care disability predict a lack of response to nortriptyline, suggesting that a specific treatment-relevant subtype of major depressive disorder, perhaps related to failure to thrive, may emerge in long-term care patients. The high frequency of adverse effects of nortriptyline (approximately 30 percent) suggests the need for careful monitoring of long-term care patients during treatment and for research designed to optimize the safety and effectiveness of treatment.

Recent reports point to increasing the use of newer antidepressant drugs, such as the selective serotonin reuptake inhibitors (SSRIs) and agents with mixed noradrenergic and serotonergic effects, in nursing home residents. While these agents have adverse effect profiles that might be expected to be better tolerated by frail elderly nursing home patients, there is evidence that they can cause serious adverse events. P.B. Thapa and colleagues have demonstrated that use of SSRIs is associated with a nearly two-fold increase in the risk of falls in nursing home residents. Their study showed little difference in rates of falls between those treated with tricyclic drugs and those treated with SSRIs.

Studies comparing tricyclic drugs, serotonin reuptake inhibitors, and newer antidepressant drugs are in progress. Nevertheless, increasing evidence indicates that major depressive disorder in nursing home residents is a serious, common illness that is treatable. Antidepressants may be the one class of psychopharmacological drugs that is underused in the nursing home, and the Institute of Medicine suggests that one possible indicator of quality care may be the appropriate use of medications to treat residents with depression.

QUALITY OF LIFE

Nursing homes are communities consisting of residents, families, staff, and health care providers in which many patients with chronic disease and disability live out their lives. Accordingly, regulations developed to implement OBRA 1987 include the requirement that “a facility must care for its residents in a manner and in an environment that promotes maintenance or enhancement of each resident's quality of life.” Specific provisions require attention to issues of dignity; individuality; self-determination; participation in resident and family groups; participation in social, religious, and community activities; availability of ongoing activities programs designed in accordance with the resident's interests and well-being, and delivery of all services in a manner that reasonably accommodates the individual needs and preferences of the resident. The high prevalence of psychiatric disorders, primarily dementia and depressive disorders, implies that expertise regarding the psychiatric disorders of late-life is essential to meet quality-of-life and quality-of-care requirements.

A generation of research has established the general principle that both quality of life and health outcomes for nursing home residents are improved when the care environment is designed to foster the resident's sense of autonomy and control. M. Powell Lawton and his colleagues have emphasized that optimizing the resident's quality of life requires attention to the fit between individuals and their care environment. According to his ecological theory of aging and adaptation, the demands from the environment must match the resident's competencies and capabilities. Maximal performance can be elicited when the demands and challenges from the environment slightly exceed the level that would match the resident's current abilities; this may be most appropriate in a rehabilitation program. Alternatively, maximal comfort can be elicited when the environmental pressure is slightly below the resident's current abilities; this may be most appropriate during convalescence from acute illness or injury. According to Lawton, affective or behavioral pathology can occur when environmental demands exceed the zone of maximal performance and become overwhelming or when they fall below the zone of maximal comfort and represent a form of deprivation.

It is an ongoing challenge for nursing home staff to modify demands on the resident appropriately and to determine whether a change in activity level is a matter of changing physical ability or personal preference and when it is a symptom of psychopathology. Nursing homes each day must struggle with the way psychiatric disorders affect medical decision making. Development of institutional policies, procedures, and programs requires that psychiatric consultation be available to nursing home administrators and staff. Nursing homes are in fact neuropsychiatric institutions, and input from mental health professionals is necessary if the homes are to fulfill their missions.

SUGGESTED CROSS-REFERENCES

Alzheimer's disease and other dementing disorders are discussed in Section 51.3e, consultation-liaison psychiatry in Section 25.12, the introduction and overview of geriatric psychiatry in Section 51.1, and mood disorders in geriatric patients in Section 51.3d. Also, clinical assessment and approach to diagnosis in neuropsychiatry is discussed in Section 2.1, psychiatric disorders of late life in Section 51.3, psychiatric problems in the medically ill elderly in Section 51.3a, and psychiatry and medicine in Section 28.1. More-detailed discussions of dementing illnesses can be found in Chapter 10. Further discussion of depression can be found in Chapter 14.

51.6 SPECIAL AREAS OF INTEREST

51.6B FORENSIC ISSUES

BENNETT BLUM, M.D., AND SPENCER ETH, M.D.

CRIMINAL MATTERS

The growth in the geriatric population brings new challenges to psychiatry and issues that were once rare are now common. The elderly are often victims of crimes because, as a group, they are easy to overpower or manipulate and they fear retaliation. Seniors are usually willing to press charges when they are victims of violent crime, but generally do not pursue the prosecution of family members and caregivers. Shame regarding their own behavior, fear of losing their independence, physical fragility, and mental incapacity are common deterrents. Criminals find the elderly an attractive victim population for these reasons. Also, people over 65 currently control over $1 trillion in assets in the United States. Unfortunately, many law enforcement agencies, prosecutors, and judges still tend to be swayed by outdated "antiaging" biases. Psychiatrists may become unwitting accomplices in these crimes. They are uniquely positioned to help patients avoid these tragic and often life-threatening events.

Elder Abuse Definitions At least six commonly recognized forms of elder abuse exist: physical abuse, neglect, self-neglect, emotional abuse, financial abuse, and sexual abuse (Table 51.6b-1). Some authorities consider abandonment a separate category of abuse, but many think it is a specific form of neglect. *Physical abuse* is the use of physical force that is likely to produce pain, injury, or impairment. In addition to acts of violence (e.g., hitting, biting, kicking, pushing, burning), physical abuse also includes physical punishment, force-feeding, and the inappropriate use of restraints or drugs. *Neglect* is the failure or refusal to fulfill one's obligations or duties toward an elderly adult. It often refers to a failure to provide adequate care, food, or shelter. *Abandonment* is the desertion or willful forsaking of an elderly person by a person who has physical custody or has assumed responsibility for the elder's care. *Self-neglect* is behavior of elderly persons that threatens their health or safety. *Emotional abuse* is willful infliction of emotional pain or distress, including such behaviors as insults, threats, harassment, intimidation, humiliation, and enforced isolation. *Financial abuse* is the inappropriate or illegal use of an elderly person's money, property, or assets. *Sexual abuse* is nonconsensual sexual contact or activity with an elderly person.

1. Physical abuse
2. Neglect
3. Emotional abuse
4. Psychological abuse
5. Financial abuse
6. Sexual abuse
7. Abandonment (may be considered a subcategory of neglect)

Table 51.6b-1 Types of Elder Abuse

Incidence The true incidence of elder abuse is not known. Early studies suggested that only 1 of every 14 cases of abuse was reported to authorities; however, results of the most recent national study indicate that 1 of every 5 cases is reported. If this is correct, then approximately 500,000 people over age 60 were victims of elder abuse, neglect, or self-neglect in 1996. Because of methodological problems, the actual number of cases is probably much greater.

In substantiated reports of elder abuse provided to adult protective service agencies, approximately half of all cases involve neglect. Emotional abuse is found in more than one third of cases. Financial abuse occurs in slightly less than one third, and physical abuse occurs in one fourth of substantiated cases. Sexual abuse seems to occur infrequently, but inadequate research has been done in this area to allow definitive comments.

Victimology Any elderly person may become a victim; however, the risk increases with advancing age. People over 80 are much more likely to be abused than people in their 60s. The National Elder Abuse Incidence Study (NEAIS) found that more than half the victims of neglect and nearly half of those financially abused were over 80. Similarly more than 40 percent of victims of emotional and physical abuse were over 80. Generally, women are more likely to be abused than men. Approximately half of physical abuse or financial abuse victims had incomes between $5,000 and $9,999. Two thirds of neglect victims had incomes in the same range, as did 38 percent of emotional abuse victims. Most substantiated cases of elder abuse involved white victims. Less than 10 percent of substantiated cases in the NEAIS involved victims from African-American, Latino, Asian, Pacific Islander, American Indian, or Native Alaskan heritage. Approximately three fourths of the victims were described as "physically frail." Most victims experienced some confusion. Over 40 percent had either moderate or severe depression.

It is not unusual to discover that victims are dependent upon their abusers and feel they must protect the abuser. Many victims will not cooperate with medical personnel, investigators from adult protective services, or law enforcement.

Perpetrators Men are the perpetrators in most substantiated cases of elder abuse; however, women are perpetrators in 40 to 50 percent of cases. Perpetrators generally work alone, but cases involving multiple perpetrators are not rare. In the NEAIS, most perpetrators were younger than 59, but the findings suggest that more than one third were older than 60, and more than 25 percent were over the age of 70. Overall, more than three fourths were white, and approximately one fifth were black. Nearly half of the perpetrators were children of the victim, and one fifth were spouses. All the cases analyzed were substantiated incidents that had been reported to adult protective services or other authorities. It is believed that many cases are never reported.

Self-Neglect Current research indicates that most self-neglecting elderly persons are female, nearly half are 80 or older, and more than three fourths are white. Most experience confusion, but the majority are not depressed.

Reporting Elder Abuse Most states mandate elder abuse reporting; however, states vary widely regarding the recognition of "mandated" versus "voluntary" reporters, the procedures and timing for reporting, as well as the definition of *elder abuse*. For these reasons, practitioners are advised to learn the specific laws for their states.

Financial Abuse The term *financial abuse* encompasses both fiduciary abuse and fraud. A *fiduciary* is a person in a position of trust and responsibility, such as a physician, attorney, caregiver, or spouse. *Fiduciary abuse* is the misuse of this position of trust to exploit another. *Fraud* refers to financial exploitation that results from false promises. The perpetrator of a fraud need not have any prior relationship to the victim; this category includes all types of con artists.

One of the most common forms of fraud is fraudulent telemarketing. Although most telemarketing is legitimate, fraudulent telemarketing is pervasive. According to a 1995 study by the American Association of Retired Persons (AARP), fraudulent telemarketers steal approximately $40 billion per year—much of it from the elderly. The most important finding is that many victims are bright, sophisticated, and socially active. They tend to have strong family and social support, are characterized as

“strongly opinionated,” and are unwilling to believe they were defrauded. Other victim groups include those who are shy, isolated, naive, withdrawn, or easily manipulated. Appropriate psychosocial intervention and training may reduce their susceptibility.

Financial Abuse by Family Members Financial abuse often accompanies physical abuse. Researchers estimate that one case of financial abuse occurs for every two or three cases of physical abuse in the United States. Research from Canada and the United Kingdom indicates that family members alone are responsible for the financial exploitation of approximately 3 percent of the population over 65.

The “Civil Mirage” Although financial abuse is a crime, many law enforcement officers, prosecutors, and judges mistakenly believe it is a matter for civil courts. This attitude is changing as more is learned about the methods used by perpetrators. One tactic of offenders is to obtain control by having victims designate them on Durable Power of Attorney forms (Fig. 51.6b-1 and Fig. 51.6b-2). These forms are used to designate an alternate decision-maker for health care and finances. They authorize the perpetrators to make decisions on behalf of their victims if the elderly persons are deemed unable to make such decisions themselves. Unwitting physicians may be asked by perpetrators to provide a letter stating that an elderly person is impaired. The perpetrator uses these and other documents to control or steal the victim's assets. Elder abuse specialists refer to this misuse of legal documents as the “civil mirage.”

Undue Influence During elder abuse cases psychiatrists are commonly asked whether the victim was unduly influenced. Undue influence, a legal term, refers to a situation in which a person is pressured to act in a manner desired by another. Bowing to the undue influence results in behavior that deviates from that normally expected and may be contrary to the person's needs and interests. To determine whether undue influence occurred, the court must decide that a vulnerable person fell prey to coercion, intimidation, or some other form of manipulation, usually because of some mental distress or disability. The psychiatrist's role is to assist the court by providing a clear clinical description of the person's mental state, stressing particular symptoms that may heighten vulnerability to interpersonal pressure. Salient factors to consider include the nature of the relationship (i.e., fiduciary, romantic, or dependent); the degree to which the suspect person created an environment conducive to manipulation; and the presence of recent medical illnesses, traumatic events, and other psychosocial stressors. The presence of an independent social network may mitigate these factors.

Most general or geriatric psychiatrists are not trained to assess susceptibility to undue influence, nor are they skilled at recognizing the conditions necessary for undue influence to exist. Initial analysis should include consideration of the four essential characteristics of undue influence listed in Table 51.6b-2. The authors strongly suggest that detailed evaluations be performed only by experts in geriatric or forensic psychiatry who have extensive knowledge, skills, and experience in this area. A common but inaccurate belief is that assessment of undue influence is equivalent to the assessment of mental capacity. Although people with impaired mental capacity may be easier to manipulate, undue influence may occur in cognitively intact, and even in intellectually superior, people (Fig. 51.6b-3).

1. The victim must be dependent upon the perpetrator
2. The victim must be prevented from learning and using pertinent information before making a major financial decision
3. The victim's trust, fears, or prejudices must be manipulated by the perperator
4. The victim must acquiesce to the perpetrator's desires; in cases of financial abuse, the perpetrator obtains access to the victim's assets

Table 51.6b-2 The Characteristics of Undue Influence

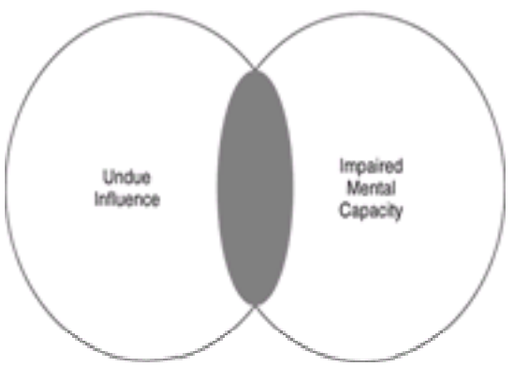

FIGURE 51.6b-3 Relation of undue influence and mental capacity. The overlapping area represents cases most likely to require forensic psychiatric evaluation.

A wealthy widower began dating an attractive woman several decades younger than himself. His children became concerned when he gave his new girlfriend his car and some valuable jewelry. He confided to them that he was ambivalent about the gifts, but she said she would lose interest in him if he did not continue to shower her with expensive presents. He reasoned the money was less important to him than having someone around so as to not feel lonely.

An elderly man became quite reliant upon a young female assistant who lived in his home and made all the arrangements for his medications, meals, and visitors. Eventually, she insisted he allow her to assume responsibility for his business and investment decisions or she would seek other employment. Fearing he would be left alone and unable to provide for his medical needs, he acquiesced to her wishes.

Undue Influence Regarding Wills As part of contesting a will, an attorney may ask a psychiatrist to perform a retrospective analysis of a person who has since died. Although such analyses are inexact, a psychiatrist properly trained and experienced in these evaluations may be able to help the court understand the decedent's mental capacity and susceptibility to undue influence at the time of executing the will. The psychiatrist should clearly distinguish facts known to be true from any assumptions, hypotheses, or opinions. The psychiatrist should also be prepared to confront a rigorous cross-examination.

Mental Capacity The law recognizes different types and degrees of mental capacity. For example, persons may not be able to create contracts or make donations, yet still be able to provide food, shelter, and clothing for themselves. In the context of making financial decisions, psychiatrists must carefully assess all requisite behaviors, besides noting general cognitive or neurological deficits. One model for assessing decision-making capacity, which has been used in state and federal courts, is presented in Table 51.6b-3. The benefit of this approach is the recognition and presentation of the many psychological functions used to make knowledgeable, reasoned, and rational decisions. This presentation helps judges and juries understand how specific impairments affect a patient's decisions, without attempting to negate the patient's ability to perform all tasks. A thorough psychiatric assessment is then used to explain any behavioral or cognitive problems.

To demonstrate mental capacity, persons must
Express desires
Learn new information
Concentrate and remember pertinent information
Identify pertinent parties and their responsibilities
Consider abstract concepts
Consider probable consequences for each major option
Understand the likely impact the decision will have on their life
Choose and maintain a decision
Not make decisions based upon delusions

Table 51.6b-3 Mental Capacity Model

Forensic assessment of undue influence and mental capacity may be aided by use of appropriate screening and evaluation tests described in the section on forensic tests.

Murder of the Elderly Elderly persons are usually considered to be the group least victimized by violent crime; however, most elder deaths are not carefully investigated. Little research has been done in this area, but findings from recent studies suggest that elderly persons have an increased risk of being murdered during a theft-related crime. Beatings are also more likely to occur when the victim is elderly. Because many elderly adults spend most of their time at home, they are more likely to encounter burglars targeting their dwelling. Many perpetrators perceive elderly persons as wealthy, physically vulnerable, isolated, and unable to defend themselves, and therefore a violent confrontation is more likely. Homicides related to interpersonal conflict are less frequent among elderly persons, but they do occur. Elderly spouses are less likely to commit murder than are adult children or acquaintances. The primary motives for elder murder are (1) greed and (2) anger or revenge. An increasing body of anecdotal reports suggests a link between fiduciary abuse and murder. The perpetrator unduly influences an elderly person and then neglects or poisons the victim after obtaining control of the elder's assets. The perpetrator may obtain medication to sedate or poison the victim by posing as a patient, or by posing as the concerned caregiver of a mild-to-moderately impaired elderly adult.

In one particularly heinous case, a boarding home landlady routinely sedated her elderly tenants (causing several deaths) to collect their Social Security checks. She obtained the drugs by complaining of psychiatric symptoms to several physicians. She was later found guilty of multiple counts of murder.

A young woman with a history of theft and drug-related offenses falsely identified herself as a nurse to a lonely, wealthy, elderly man. After becoming his live-in caregiver, she began withdrawing money from his bank accounts. When her actions came under scrutiny by bank officials, she married the man, then proceeded to withdraw several hundred thousand dollars from his accounts. He died 2 months after their wedding from malnutrition and neglect.

A caregiver was inappropriately sedating an elderly patient after the caregiver was granted control of the bank account. The victim did not die but was left penniless.

Elder as Criminal Although it is rarely suspected, elderly adults make up 1 percent of the nation's prison population. Reasons for this include lifelong recidivism, economic hardship, and mental illness. Elderly offenders have committed every known type of crime. Evaluation may be requested to assess an offender's sanity or capacity to waive *Miranda* rights, confess, plea bargain, stand trial, be sentenced, or be executed.

Elder as Witness Elderly witnesses may be questioned on their competence to testify. Assessment of testimonial capacity includes evaluation of the elder's perception, memory, understanding the obligation to testify truthfully, and susceptibility to suggestion.

Suicide People over the age of 65 account for approximately 20 percent of all suicides in the United States. The rate for people aged 80 to 85 is double the overall rate in the United States. The highest risk group are elderly white men who are divorced or widowed. Common life events and risk factors include social isolation, recent bereavement, physical illness, uncontrolled pain, fear of a prolonged death, major change in social status (e.g., retirement), alcohol or other substance abuse, depression, and availability of firearms. Homicide-suicides and assisted suicides are related phenomena.

Homicide-Suicides Homicide-suicides account for approximately 5 percent of all homicides nationally, but regional figures vary widely. Incidence rates range from 0.3 to 0.7 per 100,000 persons under the age of 55 and from 0.4 to 0.9 per 100,000 persons over the age of 55. The phenomenon occurs most often between spouses or people in a consortial relationship. Few studies exist in this area. Data from a recent study suggest that poor health, alcohol abuse, and depression are commonly found in elderly men who kill their wives or girlfriends. In a typical scenario, a depressed elderly husband uses a gun to kill his wife who also has serious health problems.

Mr. X. 96 years old, shot his wife of 72 years then killed himself. His wife was essentially confined to a wheelchair for 5 years and then developed a severe kidney infection. Several months before their deaths, one of Mr. X.'s boyhood friends died. Mr. X. became depressed. Usually known as a friendly and outgoing person, Mr. X. isolated himself in his home. A neighbor noticed that he cried frequently. Mr. X. has told the neighbor there was “no way he would allow himself or his wife to be put in a convalescent home. ‘Not as long as I've got a gun.' ”

Assisted Suicide of the Elderly A recent flurry of attention has been paid to an issue that has traditionally been shrouded in secrecy—physician-assisted suicide as

a health care option for the dying patient. For years some physicians have treated severe pain in terminally ill elderly patients with doses of analgesics that may depress respiration but are necessary for adequate pain control. For example, Sigmund Freud, suffering greatly from advanced oral cancer, requested and received an injection of morphine that probably hastened his death. Although the prescription of medication with the explicit goal of facilitating the patient's death is generally deemed unethical and illegal, public and professional opinions are changing on the issue. At the same time, concern exists that the elderly will become a population at risk for society-condoned murder. As a result, the nation's highest courts have been forced to consider whether informed consent can be extended to include a lethal choice.

When evaluating someone who wants physician-assisted suicide, it is important to remember many treatable medical and psychiatric conditions affect mood and decision-making ability. The public has often heard about the relation between inadequately treated pain and the desire to die—that is, once the pain is treated, suicidal desires abate. Malnutrition also affects mentation and is common among elderly patients. Even slight malnutrition may cause decreased concentration, confusion, and depression, leading to suicidal thoughts. Drugs are well-known precipitants of similar symptoms. Finally, psychiatric diseases, particularly major depressive disorder, impair a person's ability to think clearly or to consider options reasonably. Effective treatment is available for each of these conditions.

The influence of others cannot be overestimated. Vulnerable individuals have been pressured to accede to “suicide” through arguments relating to the expense of staying alive, the depletion of their families' resources, fear of pain or losing control, and the like. An ill person who is frightened, lonely, and perhaps confused can fall prey to authoritative manipulators who sound well meaning.

Crimes against the elderly are sometimes covered up by creating the appearance of a suicide. A 1995 survey performed in the Netherlands indicated that 0.7 percent of all deaths that year were caused by physicians acting without the consent of the decedent. Nearly one fourth of the physicians interviewed said they had ended a patient's life without the patient's explicit request. In the United States, research suggests that many elderly adults who survive so-called suicide attempts—or what could have appeared to have been natural deaths—say that they did not want to die. Many are drugged against their will. Perpetrators have been known to lie to physicians to obtain drugs that are then used to poison an older person.

CIVIL ISSUES

Informed Consent for Medical Treatment Agreeing or declining to provide informed consent regarding health care decisions depends on three elements in the decision-making process: information disclosure by the physician, voluntary participation by the patient, and patient competence.

Information Disclosure Information disclosure involves the communication, in readily understood language, of the nature of the medical problem, the proposed remedy and reasonable alternatives, and the attendant risks and benefits of all the treatment and no-treatment options. Given the amount of possible information any particular patient may wish to know, how should the caring physician explain the necessary and sufficient data? The goal of information disclosure is to enhance the patient's autonomy by encouraging a knowledgeable judgment concerning treatment options. It would seem prudent to offer the patient all pertinent facts.

Determining what constitutes important information depends on what would be relevant and significant for the patient in question or, if that cannot be ascertained, for the hypothetical reasonable patient. A recent California Supreme Court decision suggests that in accord with the standard of practice within the professional community, a physician can limit disclosure to the therapeutic focus and thereby omit information concerning the patient's nonmedical interests (e.g., business affairs).

The pressure of cost containment by the managed care industry has precluded physician members of some managed care organizations from discussing certain innovative or expensive research treatments with patients. This so-called gag rule threatens the informed consent process and consequently jeopardizes the fiduciary relationship between patient and physician.

There are patients whose diseases have progressed to the point at which standard treatments are not expected to confer meaningful benefit. When the chance of improvement is infinitesimal and the cost is exorbitant, is a physician justified in withholding a particular treatment option? Although this futility paradigm seems straightforward, there are inevitable uncertainties concerning the prognosis for any specific clinical intervention. Given this ambiguity, decisions are usually driven by an assessment of the likely burdens and benefits to the patient, the family, other patients, and society at large. For example, given the limited number of organs available for transplantation, should an elderly man who has chronic obstructive pulmonary disease and cirrhosis be offered a new liver? Who should decide? Such prioritizing of acceptable treatments produces a series of protocols or rules that creates a system of health care rationing. To date, American medicine has been reluctant to accept any rigorous form of rationing that eliminates the physician and patient as the responsible decision makers.

Voluntary Participation by the Patient Voluntary participation by the patient refers to the freedom to decide without being subject to undue influence. Voluntary participation is compromised when there is external coercion by family, friends, or even the health care team. The notion of voluntary participation may be expanded to embrace situations of internal influence caused by psychiatric symptoms such as delusion and depression. Undue influence is a legal term indicating that a person has been coerced, intimidated, or manipulated in some fashion to behave according to the desires of a perpetrator.

Competency According to Black's Law Dictionary, *competency* is a legal term that means to be “duly qualified: answering all requirements; having sufficient capacity, ability, or authority; possessing the requisite physical, mental, natural or legal qualifications.” Only a court can decide whether a given person is competent to perform a particular act.

Capacity signifies the “mental ability to understand the nature and effects of one's acts.” Although *capacity* and *competency* are often used interchangeably, *capacity* can also refer to the specific mental functions that are essential to informed decision-making. Psychiatrists may be asked to rely upon their knowledge, skill, and authority to assess a patient's mental capacities to help the court decide an issue of legal competence.

The question of how to address the issue of competency is difficult because there are different ways of organizing the idea. *General competence* implies that a person is functionally capable in all legally relevant domains. For example, in American law an adult is presumed to be generally competent unless a special court proceeding finds otherwise. This application differs from that of “specific competence,” in which it is assumed that particular skills are needed for certain tasks. Common examples of specific competence requiring unique abilities include the competence to marry, to drive a car, and to manage a large corporation. The notion of “specific competence” is fundamental to the assessment of an individual's ability to make informed decisions regarding health care.

Because of their training and practice, medical staff members tend to place a premium on the likely outcome of a patient's treatment decision. This consequentialist perspective can be called *consequence-dependence competency*. Especially in hospital settings patients who adamantly reject their doctors' orders are often deemed by the medical staff as being ipso facto incompetent, until the patient proves otherwise by agreeing to the recommended care. Although the medical team may have good intentions, this response undermines patient autonomy and changes the therapeutic alliance to an adversarial struggle to force the patient to accept what is defined as medically correct. A more legally and ethically appropriate approach to the assessment of competency of the noncompliant patient is to evaluate the patient's ability to comprehend and consider medical information, rather than exclusively focusing on the final decision. Only by emphasizing process over conclusion can consequence-independent competence be determined.

The emotional context of the patient's cognitive repertoire must be included in every assessment. Clearly, depression, anxiety, or mania can affect the patient's ability to listen, understand, and remember new information. In addition, extreme emotional states or lability may render a patient more vulnerable to undue influence.

If the court finds a person incompetent, the judge will appoint a surrogate decision maker. There are two categories of surrogates: guardians and conservators. A *guardian* has the legal authority to make decisions directly affecting the incompetent person's life, such as providing consent for medical treatment or placement into a nursing care facility. In contrast, a *conservator* has the legal responsibility to make decisions about the person's assets and property. Some jurisdictions have combined the two functions so that only one designation is used.

Components of Capacity Three common models of mental capacity exist: the philosophical/legal, medical, and functional models. Each has unique advantages and disadvantages.

PHILOSOPHICAL-LEGAL MODEL According to the philosophical-legal model, mental capacity results from being able to express desires, understand pertinent risks and benefits, appreciate the ramifications of a decision, and think rationally. These four elements are found in all state laws, though they may be combined or rephrased. This model's weakness is the lack of agreement about the definition, and thus the assessment, of each term.

MEDICAL MODEL In the medical model, medical symptoms are linked to incapacity. That is, to the extent that persons have neurological or psychiatric symptoms, they are considered unable to perform certain cognitive tasks and therefore have impaired mental capacity. The strength of this model is its ability to diagnose pathology causing cognitive impairment, recommend treatment, and make prognostic comments. The weaknesses of the model are the questionable association between medical symptoms and real-world functioning and its requirement of medical or neuropsychological expertise, which limits the model's use in routine matters.

One example of a medical model of capacity is found in California's Due Process in Competence Determinations Act. Passed in 1995, this act requires assessment of attention, orientation, memory, thought processes, executive and other cognitive functions, hallucinations, delusions, obsessions, and mood and anxiety disorders when evaluating any type of mental capacity. Although the creators of the legislation emphasize the functional aspects of this assessment, mental health expertise is clearly required. Most police officers and many social workers, public guardian investigators, adult protective service investigators, and attorneys lack this level of expertise, even those who specialize in elder abuse. Specialized training and subsequent long-term supervision is necessary to develop the requisite knowledge, skills, and experience to assess each component appropriately. An inadequate assessment may condemn an elderly person to further abuse; while an overzealous assessment will result in the loss of personal liberties.

FUNCTIONAL MODEL The functional model focuses upon observable behavior. Several mental abilities must be intact to make an informed, reasoned, and rational decision (Table 51.6b-3). Any impairment indicates the need for further investigation.

One of the most important, yet often unrecognized or overlooked, abilities is thinking strategically. To the extent this ability is impaired, a person cannot analyze the probable outcomes of decisions. This is a major component of executive functions, but impairment is often incorrectly attributed to trouble concentrating, mild memory loss, eccentricity, or personal rigidity.

Assessing Capacity The logical and most effective approach to assessing mental capacity follows the models described above. First, use the functional model (Table 51.6b-3) to document the elderly person's behavior, activities of daily living (ADLs), and instrumental activities of daily living (IADLs). ADLs include bathing, grooming, dressing, feeding, bathing, and ambulating; IADLs consist of more complex behaviors, such as shopping, preparing food, taking medications properly, using a telephone, and handling finances responsibly. This assessment is best performed by directly observing elderly persons in their home. If circumstances prevent a home visit, obtain this information from reliable, ancillary sources.

If functional impairments exist, follow the medical model and analyze the elderly person's overall health, medications, and psychiatric condition. A formal mental status examination is essential when evaluating cognitive abilities and should include assessment of attention; concentration; orientation; speech; language; memory; thought processes; emotional, control, and executive functions; insight; judgment; praxis, and constructional abilities. Practitioners may be confused about the technical meaning of the term executive functions. These mental abilities include anticipation, planning, selection, and monitoring of responses. They are critical to attention, memory, and learning and are related to insight and judgment.

Behavioral signs of executive dysfunction include impaired organization of new material, poor recall of recent and remote information, imitation and perseveration, difficulty using tools, and concrete and stimulus-bound thinking. Although not core symptoms of executive dysfunction, several other behaviors commonly coexist: tactlessness, impulsivity, social inappropriateness, mood lability, and irritability. Poverty of speech or profound nonchalance may also exist.

> A wealthy elderly woman had a number of small strokes. Afterward, she wrote multiple checks for the same item, impulsively bought large quantities of items she never used, and gave away her possessions to strangers.

After describing the person's functional impairments, and any psychiatric causes, the psychiatrist may now apply the information to the philosophical/legal model. How do the impairments or pathology affect the person's ability to express desires, understand pertinent risks and benefits, appreciate the ramifications of a decision, or think rationally? Using this approach, psychiatrists can best present clear and cogent reasoning to the court in support of their conclusions.

> An elderly widower wanted to marry a younger woman. His adult children opposed the marriage, afraid that their father might give his money and property to his new wife rather than to them. In the ensuing hearing his children presented an expert witness who testified that the man had dementia of the Alzheimer's type and therefore lacked the capacity to marry. The psychiatrist retained by the man concurred with the diagnosis but proceeded to describe his current level of functioning. The court found that the man had sufficient mental capacity and was therefore competent to marry regardless of his children's opposition.

Neuropsychological Tests Neuropsychological testing may be used to extend and quantify cognitive deficits detected on the mental status examination. Some frequently administered instruments include the Wisconsin Card Sorting Test, the Stroop Color Word Test, the Rey-Osterrieth Complex Figure Copying Test, and the Trails Making Tests of the Halstead-Reitan Neuropsychological Battery. However, these tests are limited by the considerable variability in performance and paucity of normative values across the geriatric age span, from the early 60s to the 90s. Also, only a moderate relation exists between test results and behavior in the real world. The psychiatrist must therefore draw upon as many different sources of data as possible in assessing any patient's functional capacities.

Mini-Mental State Examination The Folstein Mini-Mental State Examination (MMSE), a crude screening tool of cognitive function, has only limited correlation with real-world abilities or behavior. If an elderly person's capacity to make medical decisions; provide self-care; execute wills, trusts, or contracts; or engage in any other financial transaction is at issue, the MMSE should be used only as part of an overall psychiatric evaluation. Relying solely upon the MMSE to assess mental capacity is a misuse of the test. The MMSE has no value for assessing undue influence.

Forensic Tests Several tests have been designed to assess the probability that an elderly person was physically abused. Most have serious practical limitations and are not designed for forensic use, but are instead aids for geriatric practitioners.

Forensic tests are now available to assess the mental capacity to make financial decisions as well as undue influence. The Financial Abuse Screening Tool for Undue Influence (FAST-UI) and the Financial Abuse Screening Tool for Mental Capacity (FAST-MC) are useful for rapid clarification of situations; only the most current editions should be used.

For more in-depth analysis, the Mental Capacity Inventory and Undue Influence Questionnaire are detailed and reliable aids; however, multiple versions exist, and physicians should only use the latest editions of those designated for physicians and psychologists. These tests have been successfully used in state and federal courts.

Although many tests are being developed to assist the assessment of mental capacity to make medical decisions, the MacCAT-T is currently among the most reliable and easiest to use. This test was developed as a result of extensive analysis of laws throughout the country regarding competence to make treatment decisions. The test requires minimal preparation time and can be performed at the bedside.

LIVING WILLS AND DURABLE POWER OF ATTORNEY

The Federal Patient Self-Determination Act of 1990 established the right of patients to execute advance directives if they so choose. One type of advanced directive is the living will (Fig. 51.6b-4), a document prepared by a competent adult that indicates the conditions under which that person wishes to consent to cessation of specific medical treatments. Its purpose is to guide medical staff in delivering care in the event the person becomes terminally ill and incapable of independent decision-making (incompetent). These documents are generally limited in that they cannot provide precise guidance for the myriad of circumstances that might arise while treating a particular patient.

FIGURE 51.6b-4 Sample living will.

The other type of advanced directive is a proxy designation, such as a durable power of attorney that names a preferred surrogate decision-maker in the event the declarant becomes incompetent to make health care decisions (Fig. 51.6b-1). It may also be used to designate a surrogate to oversee financial and other matters (Fig. 51.6b-2). The surrogate can ensure that the preferences of the incompetent patient will be followed in whatever situation may arise, insofar as the surrogate is aware of, or can simulate, the patient's wishes.

A durable power of attorney may be designed to allow people with dementia of the Alzheimer's type to participate in research studies. This disease affects 2 to 5 percent of the population over 65 and 10 to 20 percent of people over 80 years old. Approximately 10 million Americans are expected to be affected by the year 2050. Given this prevalence and the associated personal, social, and economic costs, research into the causes, treatment, and prevention of the disease is necessary. Unfortunately, the disease destroys decision-making capacity; therefore obtaining informed consent for participation in trials is difficult. This problem may be reduced by appropriately appointing a surrogate decision-maker. Obviously, such a durable power of attorney must be assigned before the afflicted person becomes incompetent.

Insufficient attention has been paid to the question of the competence of persons who draw up advance directives. Unscrupulous people have been known to encourage vulnerable elderly persons to appoint them as surrogates in durable power-of-attorney documents, which despite the name may be executed without the involvement of an attorney. Once the document is signed and the person is declared incompetent, surrogates can freely deplete their victims' financial resources.

SUGGESTED CROSS-REFERENCES

Section 7.1 contains basic information on how to conduct a thorough mental status evaluation. Section 51.2c discusses the psychological, sociocultural, and physiological aspects of aging. Section 51.2a has important information on the psychiatric examination of an elderly patient. Section 51.6c and Section 51.6g describe ethical issues and elder abuse. 51.6 SPECIAL AREAS OF INTEREST

51.6C ETHICAL ISSUES

DEBORAH B. MARIN, M.D., AND CHRISTINE K. CASSEL, M.D.

The ethical issues that arise in the practice of medicine are particularly salient in geriatric psychiatry. Age alone places older adults at risk of discrimination regarding their medical care. Dementia, depression, and medical illness are common disorders in the older adult. These conditions and sometimes their treatments can impair patients' ability to communicate their wishes and to exercise their best judgment. Cognitive compromise may interfere with several domains of an individual's functioning, including the ability to choose appropriate medical treatment or make sound day-to-day decisions. Impaired function in any of these activities could have an impact on both the patients and their environment. As a consequence, significant ethical issues may arise during the course of treating these patients.

DEPRESSION AND END-OF-LIFE DECISIONS

The ethics literature pays little attention to depression among older patients. Depression can be successfully treated with medication or electroconvulsive therapy. Most geriatricians recommend serotonin reuptake inhibitors more widely than tricyclic drugs because they appear safer and have fewer adverse effects. Yet, depression is significantly underdiagnosed in community-dwelling and institutionalized individuals. Identifying treatable depression becomes exceedingly important for the psychiatrist who is asked to consider whether a patient is making a competent decision when deciding to refuse life-sustaining treatment. A patient's right to refuse care is a fundamental tenet of our legal system's respect for self-determination. However, we are considered justified in overriding a patient's refusal of life-sustaining treatment if the individual's judgment is clouded by suicidal ideation. In older adults, depression may be difficult to distinguish from sadness resulting from the awareness of life's limited possibilities. Some philosophers argue that people in advanced old age may have a perfectly rational assessment that their life journey has been completed and that death is an acceptable next step. Psychiatrists often argue that such thinking is invariably the result of a treatable depression. Many people now live past the age when normal patterns of developmental psychology were established. It may be necessary to reexamine the degree to which death acceptance is normal in advanced old age.

The question of diagnosing depression is nowhere more focused and important than in the euthanasia and assisted-suicide debate. This nation is engaged in a major social discourse about whether it is ever morally acceptable for physicians to help patients die, either by providing them with a prescription for a lethal dose of medication or more actively through an injection. In 1997 the United States Supreme Court rejected two federal circuit court decisions that argued that people had a constitutionally protected right to assisted suicide. The Supreme Court did not argue whether physician-assisted suicide was illegal or immoral but stated that this topic warrants further discussion. The Court also determined that individual states should be allowed their own legislative and statutory conclusions.

In 1994 a statewide referendum in Oregon approved legalization of a strictly defined measure for physician-assisted suicide. It requires that the patient is terminally ill and makes the request multiple times. It must also be established that multiple opinions concur with the diagnosis and that every attempt has been made to reverse treatable causes of suffering. Specifically, these treatments include appropriate relief of pain and psychological distress. Inherent in the statute is a psychiatric review to determine the presence of a treatable depression. Psychiatrists in Oregon and other states have begun to discuss developing standards that would be meaningful in such a situation. A terminally ill individual may have many of the signs and symptoms associated with depression. Such patients may also wish to die to relieve personal suffering or to ease the burden placed on others. These depressive symptoms may warrant a course of pharmacotherapy, yet pharmacological treatments are not always effective. Questions often arise regarding the appropriate role for psychiatrists in the evaluation and treatment of patients seeking to end their lives. No psychiatric guidelines for such decisions exist, but they remain an important challenge in the years ahead.

DEMENTIA

The prevalence of dementia, in particular Alzheimer's disease and vascular dementia, increases with age. These illnesses pose ethical challenges regarding patient autonomy, capacity, and confidentiality.

Autonomy A physician's role is to choose treatments that enhance a patient's autonomy, or self-determination. Physicians must weigh their concerns for patient autonomy with the desire to do what is best for the individual, a concept called paternalism. The medical profession in the United States espouses the preservation of patient self-determination. Yet, paternalism may be justified if a patient is too ill to make an informed treatment choice or if a therapeutic intervention has benefits that significantly outweigh the loss of autonomy. As a dementia progresses, a patient's capacity to make autonomous decisions decreases, and ethical dilemmas arise from the autonomy-paternalism conflict.

Capacity Psychiatrists are often requested to assess whether a patient is capable of making treatment decisions. Capacity determinations consider the magnitude and type of the decision a patient must make. The specificity of capacity decisions is pertinent to the diagnosis of dementia. Individuals with mild-to-moderate dementia often can direct medical decisions. This domain of decision making may be maintained even if another is impaired. For example, Alzheimer's patients may be capable of consenting to antidepressant treatment, yet may not be able to handle their finances. In contrast, individuals in the severe stage of the illness likely cannot make any treatment decisions.

Confidentiality A basic tenet of the physician-patient relationship is the confidentiality of the information obtained by the clinician. In psychiatry, confidentiality usually pertains to the release of information to other professionals or family members. Cognitively intact patients can request that the physician withhold the release of information, as long as they have not expressed the desire to hurt a specific person. In contrast, demented individuals may not be able to make informed decisions regarding information transfer between their family caregivers and the treating physician.

Mild Stage

Mr. C., a 75-year-old married man with one 36-year-old daughter, came for a psychiatric evaluation that was initiated by his wife. Though reluctant, he agreed, yielding to his family's concerns about his difficulty driving and handling the family finances. During the interview, Mr. C. became increasingly upset by his wife's complaints about his cognitive deficits. The physician requested Mr. C.'s permission to speak with his wife privately for the purpose of history gathering. Although Mr. C. had been an accountant, he could no longer balance his checkbook or remember to pay the monthly bills on time. He frequently asked the same questions and consistently forgot recent events. He used to have an excellent sense of direction, but now his wife had to prompt him to make correct turns when driving to familiar places. He had mild word-finding difficulties but could still clearly convey his ideas.

When interviewed, Mr. C. acknowledged his memory problem. He did not believe it to be serious, although he knew it caused his family great concern. He adamantly denied any difficulty driving. Upon mental status testing, Mr. C. displayed impaired recent memory and mild word-finding difficulty. He stated the wrong day and date but knew the month and location of the interview. He could subtract serial threes but could not perform more complex calculations. At the conclusion of the first visit, the physician explained the need to perform some further tests, after which she would review the findings and provide treatment recommendations at the next visit.

The evaluation revealed a diagnosis of Alzheimer's disease. Prior to the second clinic visit, Mrs. C. called to request that Mr. C. not be informed of the diagnosis if it were a dementia, especially dementia of the Alzheimer's type. She worried that he might have a catastrophic reaction since his sister had died 5 years previously in a chronic care facility in the severe stage of the illness. The physician explained that it was Mr. C.'s privilege to know his diagnosis but did not divulge it over the phone. With appropriate information, the physician explained, Mr. C. could then make the most informed decisions regarding his care. At the second visit, the physician reviewed the findings and treatment options with the family. The daughter asked whether her father or she should be genetically tested.

Comment Alzheimer's disease alters the typical physician–adult patient relationship in which the patient initiates the first contact, serves as the primary informant, and determines whether or not to disclose information to others. A patient's autonomy is often disrupted even before the initial physician contact; family caregivers often initiate the treatment because of their concern about the patient's behaviors. Patient confidentiality is also compromised when a family member serves as an informant or receiver of clinical information. It can be argued that the distress patients experience on learning of the severity of their symptoms outweighs the benefit of being present for this portion of the interview. A physician can choose a paternalistic approach to protect the patient from undue distress and request to speak with the family alone to obtain a history. Most, but not all, studies suggest that most relatives of Alzheimer's disease patients prefer that the afflicted family member not be told the diagnosis, yet they themselves would prefer to be told if they were to develop the illness. However, the data suggest that most Alzheimer's patients cope well with the diagnosis.

A dementia patient's autonomy and confidentiality can be conceptualized as somewhat akin to what is encountered in pediatrics, yet one is dealing with an adult. The patient's well-being and desires are the center of the treatment plan, but the family is likely to be included in communication with the physician and in treatment decisions. One of the most difficult decisions pertains to driving. This activity provides mobility and autonomy to many older adults, particularly if they live in an area that does not provide adequate public transportation. Yet, even mildly impaired dementia patients are at increased risk of vehicular accidents. Most states do not require that a physician report the dementia diagnosis to the motor vehicle bureau. Nonetheless, the physician must discuss the potential dangers of driving with the patient and family.

Dementia patients often cannot give a complete history or understand the severity of their impairment. Also, the patient may not be able to comply with a treatment plan without the family's involvement. Yet, mild- to moderate-stage patients can often participate in treatment planning. A dementia patient's strengths defy the common misconception that a cognitively impaired individual has no capacity. Physicians frequently use the clinical history and cognitive testing to assess a patient's capacity. There are scales to assess capacity, yet they are not widely used. When a patient has capacity, physicians should discuss advance directives. Although patients often do not initiate these discussions with their physicians, they are very receptive to this topic. In respect of patient autonomy, the physician is obligated to engage in these discussions to protect patients in the event that they cannot communicate their wishes.

Genetic testing of Alzheimer's patients also raises ethical concerns. The question arises whether genetic screening should be available to patients and family members who are at increased risk for developing the illness. Since genetic testing has no therapeutic value at this time, it is not recommended as part of standard clinical care for Alzheimer's patients. However, as treatments become available for populations at risk, an ethical issue regarding access to these screening programs is likely to arise.

Moderate Stage

During the 3 years following Mr. C.'s diagnosis, he required a home attendant to help with activities of daily living. Mrs. C. also arranged for all his medical care and the family's financial planning. At times he accused her of being an imposter (Capgras's syndrome) who had murdered his wife; he occasionally was so upset about this that he hit her. Mrs. C. was emotionally spent and financially drained by her husband's behavior and care needs.

Mental status testing indicated that Mr. C. was oriented to self only. He denied having any memory problems or behavioral disturbances. When Mrs. C. raised the possibility of chronic-care-facility placement, Mr. C. screamed that he “did not belong in a home.” His wife and physician both knew that he had been against placement from the beginning of his treatment. The physician discussed the possibility of psychotropic medication for Mr. C.'s behavioral symptoms. She also recommended that Mr. C. enter a day program so that Mrs. C. could get more respite.

Comment In the moderate stage of Alzheimer's disease the patient's reliance on others significantly increases. Day-to-day decisions are commonly made by others, thereby further disrupting an individual's autonomy. Physicians are often faced with the ethical dilemma of prescribing psychotropic medications to cognitively impaired patients who have limited capacity to give informed consent. Optimally, the patient would consent to take medication. A physician's recommendation to treat should consider both the patient and their environment. If pharmacotherapy maintains patients in their homes for a longer period of time, the paternalistic decision to treat actually respects the patient's autonomy.

Nursing home placement poses ethical questions beyond the issue of behavioral management. Generally, cognitively impaired individuals are more comfortable in familiar environments. A new setting, such as a day care center or nursing home, can be disruptive and anxiety provoking; however, nursing home placement may be preferable in some circumstances. Although physicians must assume the role of patient advocate, they must also make every effort to ensure that the family is not overburdened with the caregiving and that the patient is safe. If a patient requires more care than can be given at home, the physician may have to take a decisive stance and recommend placement.

Severe Stage

One year later, Mr. C. was placed into a long-term-care facility, where he sustained a hip fracture. He deteriorated significantly and never regained the ability to ambulate. He required spoon feeding to maintain his weight and hydration. His arms were restrained to prevent him from removing an intravenous line. He could only communicate by demonstrating bodily pain when being moved. He then developed a pneumonia that could necessitate a ventilator. Mrs. C. alluded to her husband's health care proxy and stated that he wanted “no heroic measures” if he became terminally ill.

Comment Over the past decade, there has been a significant tendency to avoid physical or chemical restraints in the medical setting. Restraint use is counter to patient autonomy and of limited therapeutic value. Therefore, clinical use of restraints must be clearly justified.

If a patient's health care preferences are documented, those wishes should be followed. A written advance directive (e.g., living will, health care proxy, durable power of attorney) can provide valuable information. Living wills, unfortunately, are often very general. The treating physician may not know the intent, or even the existence, of the living will. This is one of the major shortcomings of written advance directives. A surrogate or proxy may be available when decisions need to be made (as was the case with Mr. C.) and can respond to the specificity of the information and the situation at hand. However, often such proxies have never discussed the patients' values with them. Thus, physicians should encourage advance directive discussions with family members who may subsequently have to make proxy decisions. The widespread discussions about improving care of the dying in the United States and the controversy about assisted suicide may encourage many families to have these discussions in advance of severe disabilities and incapacity.

Once it is established that the patient does not wish to have life-prolonging measures when quality of life is no longer acceptable by standards that are

when decisions need to be made (as was the case with Mr. C.) and can respond to the specificity of the information and the situation at hand. However, often such proxies have never discussed the patients' values with them. Thus, physicians should encourage advance directive discussions with family members who may subsequently have to make proxy decisions. The widespread discussions about improving care of the dying in the United States and the controversy about assisted suicide may encourage many families to have these discussions in advance of severe disabilities and incapacity.

Once it is established that the patient does not wish to have life-prolonging measures when quality of life is no longer acceptable by standards that are personal and consistent with prior expressed values, then it is acceptable to follow that wish. Indeed, one could argue that a broad interpretation of life-sustaining measures be used, including not only traditional high-tech interventions, such as ventilator support, but also feeding tubes, artificial nutrition and hydration, and antibiotics for infections. If a physician authorizes withholding or foregoing treatment of an infectious illness such as pneumonia, every measure must still be taken to ensure patient comfort. These interventions include proper pain control, management of secretions, and provision of a comforting milieu. The principles of appropriate palliative care include human contact, medication if necessary to treat agitation and anxiety, and availability of the physician for the patient and family.

End-of-life decisions often require extensive discussions with the family. Proxies are often asked to make a health care decision of enormous import at a time when they are actively grieving the loss of their family member. Family members may experience extensive guilt when making these decisions. Many ethicists believe it is appropriate, when life-extending treatment really cannot add any more promise of a meaningful quality of life, for physicians to accept some decision on their own shoulders and inform the family. Rather than asking, “Do you want us to keep your mother alive?” they should say, “It is unlikely that your mother will survive this last illness. Our plan is to make her as comfortable as possible. What can you tell us about what she might have wanted?” This puts family members in a much more open position to share that information rather than feeling that their decision will actually cause the parent's death, which is, of course, not true and an unnecessary burden on the family.

51.6 SPECIAL AREAS OF INTEREST

51.6D SOCIOCULTURAL ISSUES

HUGH C. HENDRIE, M.B., CH.B.

Although interest in the influence of sociocultural factors on the etiology and management of psychiatric disorders has a long history, formal studies in this area are more recent. Cross-cultural research has not been without controversy including whether or not Western concepts of psychopathology can be imposed on non-Western populations. One problem lies within the many different definitions of culture, which range from the broadly conceived "way of life" to the more narrowly conceived "unconscious canons of choice." Certainly, if a broad definition is used to include such lifestyle issues as diet, exercise, and exposure to toxins, cross-cultural research has made large contributions to the understanding of risk factors in nonpsychiatric diseases such as heart disease, stroke, colon cancer, and Parkinson's disease. The distinction between the effects of culture or the effects of social and economic deprivation, particularly in minority populations, is another contentious area. This issue was exemplified recently from the results of the North Manhattan Aging Project where apparent differing rates of dementia between Latino, African-American, and non-Latino white populations were accounted for not by sociocultural membership but by different levels of education across groups. Variations have been reported between minority and nonminority groups on scores on cognitive tests such as the Mini Mental State Examination (MMSE), but again these differences are accounted for to a large extent by lack of educational opportunities in the minority group rather than cultural or genetic differences.

Rapidly increasing ethnic minority populations in the United States have led to a growing interest in and concern about the influence of sociocultural issues on the mental health and well-being of the elderly. Variables such as different languages, values, and beliefs and prejudice and bias between minority groups and health care providers can adversely affect access to care, accurate diagnosis, treatment, and management compliance. Fortunately, these issues are becoming better recognized and educational recommendations for health care providers are included in task force reports from the American Psychiatric Association and the American Society on Aging (Table 51.6d-1). Unfortunately, minority groups still remain underrepresented in most research studies in the United States. Research on sociocultural factors in geriatric psychiatry is still in its infancy. However, a number of interesting and provocative approaches are under way.

Considerations for Developing a Model Program
1. Understand the cultural traditions, historical experiences, and the social and political networks within the community.
2. Identify and involve community leaders, organizations, grantmakers, and advocates in planning and organizing efforts.
3. The planning group and event participants must decide direction and priorities.
4. Define goals based on a realistic timeline.
5. Work to develop community leaders by providing education about aging services and program systems and the skills necessary to effect change.
6. Design interactive sessions that promote discussion and hands-on activities.
7. Be available to provide technical assistance.
8. Conduct monthly follow-up with participants.
9. Form relationships between older participants and community professional leadership.
10. Emphasize issues that directly affect elders' lives.

Adapted from the American Society on Aging: Serving elders of color: Challenges to providers and the aging network. San Francisco, March 1992.

Table 51.6d-1 American Society on Aging: Programs for Minorities

DEVELOPMENT OF CULTURE-FAIR INSTRUMENTS

There are major methodological problems in conducting cross-cultural studies. These include consideration of the age structure of the population, issues of sampling in very different types of communities, some of which lack accurate census data, and the establishment of inter-rater reliability of diagnoses by researchers across sites. A major challenge is the development of culture-free or culture-fair screening and clinical instruments. In addition to translation, a World Health Organization (WHO) study group emphasized the importance of harmonization in this process. *Harmonization* means that the instrument must be harmonious or consistent with the cultural linguistic and educational norms of the subject population. The field of psychiatry has had considerable success in instrument development, for example, the creation of the Alcohol, Drug Abuse, and Mental Health Administration (ADAMHA) and WHO-sponsored international epidemiological interview, sponsored by the Composite International Diagnostic Interview (CIDI), an expansion of the Diagnostic Interview Schedule (DIS), which has now been tested in worldwide field trials. In geriatric psychiatry, the most attention has been paid to develop instruments to identify dementia, a particularly difficult task because diagnosis is based upon elucidating cognitive decline and social impairment. Reliable screening instruments based upon cognitive performance are now available and have been used successfully in cross-cultural studies, including the Hindi Mental State Exam (HMSE) and the Cognitive Abilities Screening Instrument (CASI). A screening instrument has been developed that includes both cognitive testing and informant data about performance in everyday living, the Community Screening Instrument for Dementia (CSI "D"). This instrument has now been used with good sensitivity and specificity in the Cree, African-American, Chinese, and Yoruba populations. The complicated steps necessary to develop a culture-fair instrument are presented in a simplified outline in Table 51.6d-2.

Criteria		Age 65 Years and Over (%)	95% Confidence Limits
Canadians (English-speaking)—1994	DSM-III-R/ICD-10	8.0	7.5–8.5
African-Americans—1995	ICD-10	8.24	7.09–9.40
Japanese-Americans (Honolulu) males only—1996	DSM-III-R	7.6	5.1–10.8
Japanese-Americans (Seattle)—1996	DSM-III-R	6.3	5.9–6.8

Table 51.6d-2 Age-Standarized Prevalence Rates for Dementia in Ethnic Groups in North America

LIFE SATISFACTION

The now-voluminous literature on life satisfaction, while having some contradictory findings, has one constant feature: elderly subjects generally report higher levels of life satisfaction than younger subjects. As life satisfaction is related to a number of socioeconomic as well as health indicators, it might be anticipated that the well-being of the elderly would be different in differing cultures. A unique, 13-nation international survey on human values and well-being involving both Western and non-Western countries reported that the elderly in all countries indicate more contentment and satisfaction with human relations, material needs, and religious

experience than did younger subjects. The reported level of life satisfaction by the elderly in all countries was remarkably similar regardless of the different economic status of the nations involved in the study. The only major differences between countries was that more non-Western than Western cultures reported homogeneity of satisfaction responses across age groups. They offered two possible explanations for this latter finding. First, Asian societies as opposed to occidental societies have relatively preserved extended-family systems and a greater commonality of religious beliefs and philosophies. Second, presumably because of perceived better opportunities, subjects in developed societies have higher aspirations, which may or may not be fulfilled whereas in less developed countries, such achievement motivation is less likely to occur and therefore satisfaction with the status quo may be more likely. The significance of extended-family relationships and religious involvement in tempering the effects of relatively low income and status on life satisfaction in minority elderly subjects in the United States has also been reported.

LATE-LIFE DEPRESSION

The value of conducting cross-national epidemiological studies in depression has recently been reinforced by the publication of the results of a major population-based international study involving 10 different countries and 38,000 community subjects aged 18 years and older using the DIS. Rates of major disorders between countries varied fifteenfold from 1.4 percent lifetime prevalence of depression in Taiwan to 19 percent lifetime prevalence of depression in Beirut; the latter figure is not surprising in view of the conditions in Beirut at the time of the study. These differences in rates suggest that cultural differences or variations in risk-factor profile could influence disease expression in depression. Unfortunately, the number of elderly subjects included in the study in many countries precluded a direct comparison of rates of late-life depression and few other such studies exist in the literature. However, there is reason to believe that differences in rates of depression in the elderly also exist between countries and that this area would be a fruitful one to explore. In a population-based study of major depressive disorder using the Geriatric Mental Schedule–Automated Geriatric Examination Computer Assisted Taxonomy (GMS-AGECAT) in Zaragoza, Spain, 1-year prevalence rates of 4.8 percent were reported. This contrasted with 3 percent prevalence rates of major depressive disorder reported from Liverpool, England, also using the GMS-AGECAT.

Rates of depression in elderly minority populations in the United States remain controversial. The Epidemiological Catchment Area (ECA) study suggested that 1-year prevalence rates for African-Americans (2.2 percent) were lower than for the white (2.8 percent) population and that Latinos had somewhat higher rates (3.3 percent). However, the ECA study had few elderly minority subjects on whom to base prevalence rates. In a larger population-based study in north Virginia, 1-year prevalence rates of 3.1 percent in elderly African-Americans (65 and older) comparable to the ECA rates in whites were found. Previous reports of varying frequencies of depressive symptoms in ethnic minority elderly populations may be due to differential responses of minority subjects to questionnaires such as the Center for Epidemiological Studies–Depression (CES–D) scale.

DEMENTING DISORDERS

Perhaps the greatest interest in cross-cultural studies in elucidating environmental and cultural risk factors in geriatric psychiatry is now in the area of the dementias and in dementia of the Alzheimer's type in particular. Rather paradoxically, this is at least partly the result of the findings from the recent genetic studies including the discovery of the powerful association between the possession of the e4 allele of apolipoprotein-e (APOE) and late-onset dementia of the Alzheimer's type. Epidemiologists are now able to combine the techniques of population genetics with risk factor research to explore the interaction between genetics and environment in the etiology of the disease. This ability to identify risk factors at the genetic level has other significant implications for epidemiological research. It may no longer be necessary to consider ambiguous and politically charged concepts such as race and ethnicity. A 1998 editorial in *Science* was entitled “DNA Studies Challenge the Meaning of Race.” Sophisticated etiological hypothesis involving specific genes and specific environmental factors can now be formulated to explain geographic or ethnic variations in disease rates.

In the National Advisory Council on Aging 1995 report, a major objective for research into this form of dementia was to “search for selective risk factors through cross-cultural epidemiological studies as a prelude for developing prevention strategies.” If populations with significantly differing rates of this dementia could be identified, risk factor research would be greatly expedited. A particularly fruitful area of research is studying migrant populations. A powerful argument for the presence of social and environmental risk factors could be made if varying rates of dementia are found in populations from the same ethnic group at different levels of development and from different environments. Conversely, different ethnic groups living in the same environment should have similar rates of illness. A few studies are now in progress looking at populations originating from Japan, India, and Africa. The results to date are intriguing but far from definitive. Recently, reported prevalence rates for dementia for Japanese living in Hawaii and in Seattle and African-Americans living in Indianapolis are very similar and remarkably close to the rates reported in a large Canadian study of English-speaking residents (Table 51.6d-3).

1. Identify cognitive and behavioral dimensions to be measured based on diagnostic criteria.
2. Select items for translation with indigenous investigators to make first draft.
3. Pretest first drafts for acceptability with small sample of target subject ($N = 10$).
4. Review and pretest revise for second drafts.
5. Pilot test on larger samples ($N = 50–100$).
6. Statistical analysis of pilot study and revise for final instruments. Each draft undergoes translation, independent back translation, and consensus harmonization before testing.

Table 51.6d-3 Steps to Construct a Culturally Harmonious Test

In a five-county, urban-rural area of North Carolina one study found no difference between African-Americans and whites in either prevalence or incidence rates for Alzheimer's disease. However, in a prospective, longitudinal study of subjects living in north Manhattan, the cumulative risk for Alzheimer's disease was four times higher for African-Americans and two times higher in Hispanics than in the white population for subjects who did not possess the e4 allele. These discrepant findings of Alzheimer's disease rates amongst African-Americans are perhaps not surprising. It is likely that there is a considerable genetic heterogeneity in African-Americans, based upon their country of origin or subsequent intermarriage. It is also likely that ethnic groups living in diverse geographic settings, even in the same country, are subject to different environmental and sociocultural influences. A recent study reported considerable variation in mortality rates due to cardiovascular disease within African-American populations depending on their place of birth. It is possible, therefore, that variations in rates of Alzheimer's disease for African-Americans in New York, Indianapolis, and North Carolina may be explained by a combination of genetic and site-specific environmental and sociocultural differences.

The prevalence rates of dementia in the Japanese-American studies are higher than those reported from Japan although the methodology in these studies is not identical. Whereas in Japan the most predominant form of dementia is vascular dementia, in both Japanese-American studies the predominant form of dementia was dementia of the Alzheimer's type. Age-adjusted prevalence rates of dementia (2.29 percent) and dementia of the Alzheimer's type (1.41 percent) in Ibadan, Nigeria, were significantly lower than the African-Americans in a study using identical methodology at both sites.

It is too early in the evolution of these studies to determine what might be the relevant interaction between genetic, environmental, social, and cultural factors that may increase or lessen the risk of developing Alzheimer's disease. A rather intriguing preliminary finding has been reported in the Seattle-based Japanese-American study where preservation of a Japanese lifestyle, including reading, writing and conversing in Japanese, was associated with low levels of cognitive decline and lower rates of dementia of the Alzheimer's type in that population. This is consistent with studies in the Cree in Northern Canada where the disorder also appeared to be relatively infrequent. The Cree attributed the apparent preservation of intellectual function to the role of the elderly. In this traditional, nonliterate, hunter-gatherer society, elderly Cree acted as the oral transmitters of cultural traditions from grandparents to grandchildren, thus ensuring a secure role for the elderly and ongoing intellectual and social stimulation. This role was still preserved at least in the reserves included in the study.

The importance of continued social activities was also highlighted in the Paquid study in France when regular participation in social and leisure activities such as traveling, odd jobs, knitting, or gardening was associated with a lower risk of subsequent dementia. Continuing intellectual stimulation has also been put forward as a possible explanation for the finding of the apparent protective effect of higher education in many (but not all) risk factor studies on dementia.

Sociocultural factors also have a considerable influence on the behavioral disorders associated with dementia and, in particular, to caregiver response to these disorders. These factors include the perception of the role of the elderly and the caregiver in society, the availability of a supportive social network, and the availability of nursing homes.

It is likely that sociocultural factors have a major influence on the etiology, diagnosis, and treatment of the psychiatric disorders of the elderly although the mechanisms explaining these influences are not always clear. The newer cross-cultural approaches offer great hope in elucidating these mechanisms and shedding light on possible social, environmental, and genetic interactions.

SUGGESTED CROSS-REFERENCES

All sections of Chapter 51, particularly Section 51.1b on the epidemiology of psychiatric disorders, are suggested for additional reading as well as Section 4.4 on cultural psychiatry.

51.6 SPECIAL AREAS OF INTEREST

51.6E MINORITY ISSUES

ZF. M. BAKER, M.D., M.P.H.

The population of older United States citizens who are people of color is rapidly changing. Among the four groups that constitute the ethnic elder population, persons age 80 and older are the fastest growing segment of the population. The term “ethnic elder” is used to describe persons age 65 and older who are of African-American, American Indian or Alaskan Native, Asian-American, or Hispanic-American. The United States government has designated these four population groups minorities. By 2010 the combined populations of all ages for these four groups will represent the majority of persons in the Unites States, outnumbering persons of European background. By the year 2030 the combined numbers of older persons in these four groups (ethnic elders) will represent 25 percent of persons age 65 and older in the United States (Fig. 51.6e-1). The term ethnic elder is used to reflect both the age and the unique role that many of these elders hold in their extended families and their communities of residence.

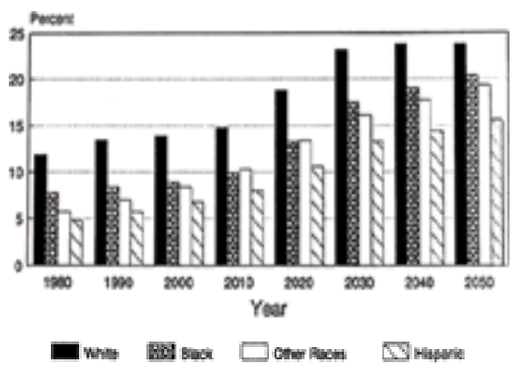

FIGURE 51.6e-1 Proportion of each race and ethnic group, age 65 and older. (Reprinted with permission from Angel JL, Hogan DP: The demography of minority aging populations. In *Minority Elders: Longevity, Economics, and Health*, L Harootyan, editor. Gerontological Society of America, Washington, DC, 1991.)

Preparing mental health professionals to work with an increasingly culturally diverse population of older Americans is an important task for the year 2000. Recent texts and the Glossary of Culture Bound Syndromes in the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) are helpful resources. This DSM-IV appendix provides an outline for the assessment of the patient's cultural identity and how it affects the person's perception of illness. The influence of culture on the therapeutic alliance between the patient and the therapist is also addressed. As an initial effort at incorporating the known information about the cultural context of mental illness, the material in Appendix I, coupled with specific cultural content associated with each disorder, provides a useful resource for those unfamiliar with a specific culture and its influence on psychiatric symptoms and the definition of unusual behavior. The references at the end of this chapter provide information on key resources in this field.

The four groups that constitute ethnic minority elders are not homogeneous. The black American population has become increasingly diverse with immigration from the Caribbean islands and Africa, specifically Ghana, Senegal, and Nigeria. The American Indian and Alaskan Native elders include over 400 recognized tribal communities with differing customs and over 250 languages. More than 20 specific Asian-American populations fit the descriptive term “Asian-American elder.” The diversity in language and customs influencing the definition of illness and treatment is seen, also, among Hispanic-American elders, who represent 21 different cultural groups.

Historical perspective experiences of ethnic elders are important because whether a specific patient did or did not directly experience these events, the clinician can determine whether they contributed to the psychiatric symptoms present and whether they influenced the way in which the ethnic elder was brought to treatment.

Although many ethnic elders of the four groups have had limited education, marginal employment, poor access to health care resulting in chronic medical problems, and the psychological stress of living in economically disadvantaged areas, many others have been teachers, successful business owners, lawyers, and doctors. The mental health professional who finds out about the unique history of the ethnic elder being treated will avoid making incorrect generalizations.

African-American and Hispanic-American elders obtain psychological comfort from religion and have an extensive social network deriving from their churches. Among many Native American people and Asian-Americans, men and women are seen as part of an interactive environment with nature. Psychological well-being is defined by these elders as maintenance of an appropriate harmony with the environment. The ying and yang conceptualization of complementary environmental components, a Chinese belief system, is more comparable to the belief systems of the American Indians than to the Judeo-Christian belief system.

One's definition of illness is influenced by one's culture. Understanding how symptoms are associated with specific conceptualizations of illness can facilitate establishment of the therapeutic alliance. The therapist's knowledge can avert drug-drug interactions between Western medicine and non-Western treatments; medicinal teas may include ingredients with psychoactive properties. Ethnic elders may arrive with their families to see a psychiatrist as the “last stop.” They have been to their native healer, their religious leader, and their family doctor, and come only then to a psychiatrist, because of the stigma associated with mental illness among many of these groups. Frequently, psychiatric care is sought because symptoms fail to resolve and the family members and social network of the ethnic elder has become increasingly concerned. The multiple medical problems of many ethnic elders (hypertension, diabetes mellitus, glaucoma) increase the risk for drug-drug interactions or a delirium due to an atropine psychosis.

AFRICAN-AMERICANS

Demographic Characteristics Persons of African origin in the United States are African, African-American, and African-Caribbean. Most are African-Americans. African-Americans are 12 percent of the total United States population, and persons age 65 and older are 11 percent of the total African-American population. Persons age 85 and older are the fastest-growing segment of the African-American population; 17 percent of persons age 65 and older in 2030 and 21 percent of persons age 65 and older in 2050 will be African-American elders (Fig. 51.6e-1). For persons age 65 to 74, there are 67 men for every 100 women. In the age group 85 and older, there are only 46 men for every 100 women. Most elderly women are single (divorced, widowed, or never married), and most elderly men are married.

Nineteen percent of African-American elders completed high school, 4 percent completed college, 11 percent had 5 years or less of formal education, and 24 percent had no formal education. One third of African-American elders are below the poverty level, and 26 percent of households are below the poverty level. The extended family and informal social networks of friends, neighbors, and church members continue to be important social, financial, and spiritual resources for African-American elders.

Immigration History and Patterns of Acculturation Africans arrived on the North American continent as a result of war and the trading of prisoners of war in Africa. Surviving the climate and the heavy toil, Africans became the focus of the slave trade and provided the labor that built America into a major agricultural nation. The rich cultural heritage and value system (Table 51.6e-1) of predominantly West African tribes was being lost until Africans from various tribal groups began to use a new language, English, to communicate. With the formal ending of the brutal system of chattel slavery, the current cohort of African elders learned the history of the Reconstruction Era from their grandparents and great-grandparents (Table 51.6e-2). The extended family and the adoption and absorption of nonrelated persons into the family characterized the structure of African-American families during Reconstruction, and that pattern continues today.

Table 51.6e-2 African-Americans: Significant Dates and Periods in History

Racial harassment and, following Reconstruction, economic recession, the development of the cotton gin, and the destruction of the cotton crop by the boll weevil stimulated the movement of African-Americans from the Southern states to the Midwest, the Northeast, and the West. Not until the migration to the North and the association of the alcohol abstinence movement with the Ku Klux Klan did many African-Americans begin to consume alcoholic beverages. The development of speakeasies and African-American involvement in entertainment and the arts contributed to the escalation in substance abuse by black Americans. The period of chattel slavery in the United States and the denigration of African-Americans by stereotyping contributed to the negative attitudes that characterized legalized segregation. The civil rights movement in the 1960s provided a rediscovery of the contributions of Africans to the development of the Western world. The specific contributions and strengths of the black community began to be summarized during that period in the literature of several fields.

The specific historical events that have formed the experience of African-American elders are summarized in Table 51.6e-2. The historical events are correlated with specific developmental stages in Table 51.6e-3.

Table 51.6e-3 Correlation of Historical Events With Developmental Stages: Cohort Experiences, African-American Elders

Medical Problems The rate of diabetes mellitus in African-Americans is five times higher than that in white Americans. The rates of hypertension and obesity are also significantly higher for African-Americans than for some ethnic elders and white Americans. The 5-year survival figures for black Americans with malignancies of the breast, cervix, uterus, prostate, and esophagus are only one third to one fourth the survival figures for white Americans. The rate of cerebrovascular disease among elderly African-Americans is three times higher than the rate among white Americans. In black elders alcohol is the substance of abuse, with significantly greater morbidity and mortality for black men than for black women. The rates of glaucoma are higher and the progression of the disease faster among African-American elders than among white Americans. Of the chronic diseases, arthritis is a particular concern for elderly African-Americans. The number of chronic medical problems increases the risk for major depressive disorders and episodes of delirium.

Psychiatric Disorders Various authors have questioned whether the rates of dementia differed in African-American elders. A higher than usual prevalence of vascular dementia was expected because of the high rates of hypertension. Recent data from a few investigators provide some support for that hypothesis. Although the prevalence of dementia of the Alzheimer's type, with late onset, was hypothesized to be the same as in white Americans, recent work by investigators at Duke University on a biracial subsample drawn from the Duke University longitudinal survey found a higher prevalence rate of the dementia among black elders. A cross-cultural study comparing African-American elders in Indianapolis, Indiana, with Africans in Ibadan, Nigeria, found that rates of dementia of the Alzheimer's type among African-American elders were similar to those of the total U.S. population, while lower rates of dementia were found among the Ibadan elders. Further studies are needed.

Epidemiological surveys that have screened elderly black Americans for psychiatric symptoms found rates of depressive symptoms that varied from 26 to 60 percent. Since ambulatory medical clinic patients and medical inpatients have rates of depressive illness that range from 29 to 33½ percent, it was hypothesized that because of their multiple chronic health problems, African-American elders would have higher rates of depressive disorder due to medical illness (secondary depression) than the 10 to 15 percent found in community resident elders. Recent studies have confirmed this hypothesis. Older medically ill, physically disabled, and hospitalized African-Americans who were depressed were found to have a remission of their depression at 6-month follow-up compared to elderly whites. This was a consistent finding with no change in the number of medical illnesses and the level of physical disability. Although the National Institute of Mental Health Epidemiologic

Catchment Area (ECA) Survey data reported above-average prevalence rates for phobic disorders among African-Americans in Baltimore, Maryland, and Durham, North Carolina, the prevalence of those disorders among elderly African-Americans awaits further investigation.

The Center for the Establishment of a Registry for Alzheimer's Disease (CERAD) has coordinated a national multicenter evaluation of the most frequently used screening tests to assess cognitive impairment. Norms for African-American elders for the specific neuropsychological tests of the CERAD screening battery were published in 1996.

Diagnosis The period of chattel slavery and Reconstruction resulted in a biased view of African-Americans that was reflected in psychiatric diagnoses. Blacks attempting to run to freedom were said to have the psychiatric disorder of “drapsomania.” In the early 1800s black Americans were reported to lack the intrapsychic structure to become depressed because of their “happy-go-lucky” nature. Although these psychiatric formulations reflected the societal bias of the investigators, misdiagnosis of psychiatric symptoms in African-American patients remains a concern today.

An African-American with a history of alcohol abuse beginning at age 14 may experience an episode of alcohol-induced psychotic disorder with hallucinations at age 24. If the psychotic symptoms were diagnosed as schizophrenia, that diagnostic label may continue for decades. A few authors have described bipolar disorder in poor black populations, a psychiatric disorder previously diagnosed mainly in middle-class white populations. An elderly African-American with a 30-year history of psychiatric illness requires a thorough record review and family interview to clarify the symptoms, the course of the disorder, and the presence or absence of alcohol use during the period of acute illness. Although the recent literature has emphasized the presence of psychotic symptoms in a variety of psychiatric disorders (alcohol hallucinosis, delusions, bipolar disorder), some psychiatrists view those symptoms as pathognomonic for schizophrenia. African-American elders of the 1990s with psychiatric illnesses with an onset in their 20s were diagnosed at a time when American psychiatrists made diagnoses of schizophrenia more often than did psychiatrists in Great Britain. A review of those diagnostic labels is essential.

Suicide Despite psychosocial stressors for poor African-American elders, their rates of completed suicide are significantly lower than those for elderly white Americans. Rates of completed suicide in the United States for 1990 and 1993 for white males ranged from 17.9 per 100 population (ages 65 to 74) to 22.8 per 100 population (ages 85 and older). In contrast, the rates of completed suicide for black men ranged from 14.7 (ages 65 to 74) to a rate too small to be calculated (age 85 and older). Rates of completed suicide for white women for 1990 and 1993 ranged from 7.2 per 100 population (age 65 to 74) to 5.4 per 100 population (age 85 and over). The rates of completed suicide among older black women were one third those of older white women, a rate of 2.6 (1990) and 2.2 (1993) for ages 65 to 74. Too few black women ages 75 to 84 and 85 and older completed suicides to calculate a rate of completed suicide in 1990 and in 1993. Religion and social support networks contribute to the maintenance of self-esteem by African-American elders. Their involvement in their churches and friendship networks give them multiple social roles in their retirement years.

Effects of Drugs Although 48 percent of African-Americans are slow acetylators, the importance of that fact in the metabolism of psychoactive medications is unclear. This fact may explain why older African-Americans elders treated with high dosages of antipsychotic medication may experience increasing confusion and increased severity of parkinsonian adverse effects. A few reports have indicated that African-American elders have been treated with high doses of antipsychotic medication to decrease or to prevent agitation. Further research is needed in older black patients to determine whether lower doses of antipsychotic medication are more effective than higher doses and result in fewer adverse effects.

African-American elders have been less likely to reside in nursing homes because of care provided by their children and extended family members. Those African-American elders in nursing home settings had similar rates of dementia (68 percent) compared to elderly white nursing home residents (70 percent). Rates of psychiatric disorders among elderly African-American nursing-home residents were as high as among white nursing-home residents, but the rates of behavioral disturbances were lower among African-Americans.

AMERICAN INDIANS AND ALASKAN NATIVES

Demographic Characteristics American Indians and Alaskan Natives (Eskimos and Aleuts) comprise more than 400 distinct tribal groups and speak more than 250 languages besides English. The Aleuts reside largely along the Aleutian chain, and various Indian groups reside in the interior and southeastern areas of Alaska. The term “Alaskan Native” also includes the Inuit Eskimos, who reside in north and northwest Alaska, and the Yupik Eskimos, who are found in southwest Alaska. These groups differ in culture, history, and language. Although data on American Indian and Alaskan Native populations are available from the Indian Health Service, less information is available from the U.S. Bureau of the Census.

American Indians and Alaska Native represent less than 1 percent of the total United States population, and persons age 65 and older represent 6 percent of the American Indian and Alaskan Native population. Nationally, 54 percent of American Indians live in predominantly urban areas; less than 24 percent live on reservations. In the 65-to-74 age group, there are 77 men for every 100 women; for age 85 and older, there are only 59 men for every 100 women. In those ages 65 to 74, 25 percent of American Indians and Alaskan Natives completed high school, 4 percent completed college, 11 percent completed the fifth or sixth grade, and 23 percent had no formal education. Twenty-five percent of urban-resident and 39 percent of rural-resident American Indian and Alaskan Native elderly persons live below the poverty level. The extended family or clan, as defined by some American Indian tribes, is an important psychosocial resource for the American Indian and Alaskan Native elder.

Immigration History and Patterns of Acculturation American Indians were the first Americans. Their adjustment and cultural accommodation with the varying populations of immigrants were sometimes accomplished without significant conflict but were more commonly associated with significant tensions that escalated to frank hostility.

Today's American Indian elders experienced the traumatic rupture of their familial and community bonds during their crucial adolescent years. The practice of moving American Indian children to boarding schools to facilitate their education and understanding of American culture ended only recently. The psychosocial stressors of attempting to bridge a dual identity (experienced by all groups of nonwhite Americans) were focused at a crucial developmental age for those American Indian adolescents and youths. The recent economic expansion resulting from oil exploration has produced a similar disruption of cultural continuity for young Alaskan Natives. The historical events that have formed the experience of American Indian elders are detailed in Table 51.6e-4.

Table 51.6e-4 American Indians and Alaska Natives: Significant Dates and Periods in Recent History

Medical Problems Several investigators have shown that an American Indian at age 55 has medical and psychosocial problems similar to those of a white American at age 65. The major health problems of American Indians and Alaskan Natives include non-insulin-dependent diabetes mellitus, hypertension, tuberculosis, heart disease, cancer, liver, and kidney disease.

Psychiatric Disorders Although the Center for Epidemiologic Studies Depression Scale (CES-D) has been used in a study of three tribes, a detailed study of screening instruments for all tribal groups of American Indian and Alaskan Native elders has not been completed. The CES-D was found to have good reliability and

validity, and an estimation of depressive disorder ranging from 30 to 50 percent was based on the evaluation of three tribal groups in the southwestern United States.

The CERAD project has developed a specific culture-fair battery to screen ethnic elder populations for cognitive impairment. That battery has not been applied to a population of community-resident American Indian and Alaskan Native elders to determine the prevalence of symptoms of cognitive impairment, an important area of future research.

The problem of alcohol dependence varies across tribal groups. A few authors have shown that depressive symptoms and mood disorders are associated with patterns of alcohol abuse in four American Indian tribes. Those studies assessed the presence of depressive symptoms after 6 to 8 weeks of alcohol abstinence.

Suicide The mortality caused by alcohol-related motor vehicle accidents among American Indians of all ages and by suicide among Alaskan Natives age 55 and younger underscores the importance of implementing effective primary and secondary preventive strategies. The rates of suicide among American Indian and Alaskan Native elders are significantly lower than those for elderly white Americans.

Effects of Drugs Lower dosages of antipsychotic and antidepressant medications may be indicated. Research to determine whether specific tribal groups of American Indians are slow acetylators needs to be completed.

ASIAN-AMERICANS AND PACIFIC ISLANDERS

Demographic Characteristics Asian-American and Pacific Islander elders comprise more than 20 different ethnicities. Their origins vary widely: East Asia, Southeast Asia, the Indian subcontinent, Polynesia, Melanesia, and Micronesia. Asian-Americans and Pacific Islanders constitute 1 percent of the total United States population. Six percent of the Asian-American and Pacific Islander population are age 65 and older. Sixty-four percent of these ethnic elders live in California, Hawaii, and Washington (in declining order of residence). Sixty-five percent were born outside the United States. The four largest groups are Filipino (26.7 percent), Chinese (26.6 percent), Japanese (24.7 percent), and Asian Indian (14.6 percent) (Fig. 51.6e-2). Ninety percent of Asian-Americans and Pacific Islanders live in urban areas. Thirty-seven percent of elderly Asian-Americans and Pacific Islanders completed high school, 10 percent completed college, 13 percent completed the fifth or sixth grade, and 21 percent had no formal education. Fourteen percent of Asian-American elders live below the poverty level, and 10 percent of rural-resident elders live below the poverty level.

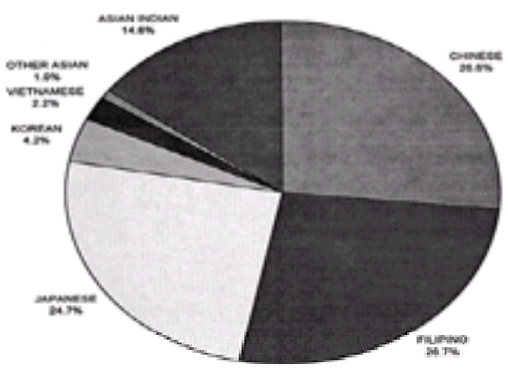

FIGURE 51.6e-2 Asian elderly population by nation of origin, 1980. (Reprinted with permission from Angel JL, Hogan DP: The demography of minority aging populations. In *Minority Elders: Longevity, Economics, and Health*, L Harootyan, editor. Gerontological Society of America, Washington, DC, 1991.)

Immigration History and Patterns of Acculturation A biphasic immigration pattern resulted from discriminatory legislation. In the late 1880s to 1924 often single, poorly educated immigrants from China, Japan, and the Philippines immigrated to the United States to provide cheap manual labor. Intending to make their fortunes before returning home or bringing their families to the United States, they could not fulfill those plans. With the Chinese Exclusion Act of 1882 and the Oriental Exclusion Act of 1924, immigration and naturalization of all Asian groups stopped. Because of legal sanctions and informal sanctions against intermarriage, those early, predominantly male immigrants became a bachelor society, with the exception of the Japanese who selected brides from pictures. Repeal of the Asian Exclusion Acts in 1965 resulted in a second wave of immigration that included many Asian women. Elderly wives who had been excluded in the past received preferential entry by the New Immigration Act of 1965. Key historical events for Chinese-Americans are summarized in Table 51.6e-5.

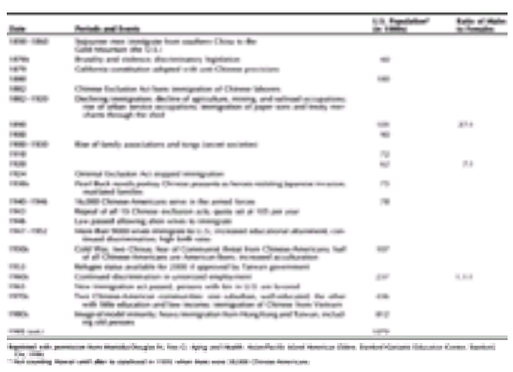

Table 51.6e-5 Chinese Americans: Significant Dates and Periods in Immigration and History

A few investigators have reported that of foreign-born Asian-Americans and Pacific Islanders age 65 and older in 1990, in decreasing order the greatest number was Japanese, followed by Filipino, Asian Indians, and Chinese. One study reported that of 100 low-income Asians age 55 and older in Asian communities in Los Angeles, 75 percent spoke only their native language, with 77 percent reporting that they had resided in the United States for more than 20 years.

Medical Problems Death rates are lower for Chinese, Japanese, and Filipinos (the only statistics on the various Asian and Pacific Islander groups kept by the National Center for Health Statistics) than for whites. Specific population-based studies have found low rates of mortality caused by coronary artery disease and acute myocardial infarction and a higher than average incidence of liver and esophageal cancers in Chinese populations. Second-generation (Nisei) Japanese-Americans were found to have three to six times more non-insulin-dependent diabetes mellitus than white American men, to have lower rates of kidney-related complications among diabetics, and to have a higher incidence of stomach cancer.

Psychiatric Disorders Depression A few investigators have studied the prevalence of depressive disorders among a random sample of Chinese, Filipino, Japanese, and Korean persons who lived in Seattle, Washington. Using the CES-D, they found that the mean score for the Asian-American sample combined was 9.38, in comparison with a mean score for whites that ranged from 7.96 to 9.25. Nineteen percent of Asian-Americans tested positive for depressive symptoms (a CES-D score of 16 or above). Koreans, the most recent immigrants, had the highest mean CES-D scores, followed by Filipinos, Japanese, and Chinese. Those differences were statistically significant. Recent immigrant status and resultant adjustments, low employment levels, and low socioeconomic status contributed to the high CES-D scores. The prevalence of depressive symptoms among these Asian-American residents of Seattle was at least as high as that in white Seattle residents and was consistent with community surveys of the mental health of Asian-Americans in California.

Posttraumatic Stress Disorder In a study of Southeast Asian refugee patients, a systematic reassessment of the population found significant rates of posttraumatic stress disorder. Patients' underreporting of symptoms, the failure of psychiatrists to explore a history of trauma in non-Cambodian groups, and the necessary unhurried, unobtrusive clinical approach to diagnosis and treatment required for working with the population contributed to the failure to identify posttraumatic stress

disorder. Among these refugees somatic complaints (headaches, stomachaches, poor sleep), were more commonly reported than depressive symptoms, which contributed to underdiagnosis of depression. The recent immigration of populations from Southeast Asia requires therapists to evaluate for the presence of posttraumatic stress disorder. Vietnam refugees resettled in cities throughout the United States are at risk.

Suicide The rates of completed suicides by Chinese and Japanese women more than 75 years old exceed the rates for white American women (Table 51.6e-6). Only in the old-old (persons 85 and older) do the rates of completed suicide by Asian-American men exceed the rates for white American men; Japanese men have a suicide rate of 139.76, Chinese men have a suicide rate of 64.10, and white American men have a suicide rate of 53.28. As shown in Table 51.6e-6, the total age-specific and age-adjusted suicide rates per 100,000 population are higher for Asian-American elders than for white Americans over age 65. Factors contributing to the high rates have been linked to the absence of spouses and families for the Asian men who immigrated to the United States to obtain better employment. As a result of the Asian exclusion laws, those Chinese, Japanese, and Filipino men never married, and these bachelor cohorts, resident in ethnic communities, are alone and have minimal social support. These elderly Japanese, Chinese, and Filipino men may be depressed, but they have not been studied for the prevalence of psychiatric disorders, particularly mood disorders. Some Japanese men in these cohorts brought brides to the United States and married before the Oriental Exclusion Act of 1924.

	Chinese			Japanese			White		
	Total	Male	Female	Total	Male	Female	Total	Male	Female

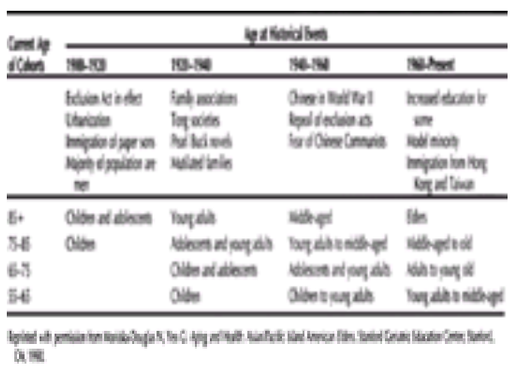
Table 51.6e-6 Average Annual Age-Specific and Age-Adjusted Suicide Rates per 100,000 United States Population for Specified Races, 1980 (Age 55 to Age 85)

Elderly Japanese and Chinese women immigrated to the United States in two waves: before the Asian exclusion acts and after those acts were rescinded in the 1960s. Some investigators suggest that these elderly women completed suicide because of their mutilated family experience, the absence of children, social isolation, and minimal involvement with the surrounding American culture. Although elderly Chinese and Japanese women may be at risk of mood disorders, no studies of those populations for the prevalence of psychiatric disorders have been completed to date. A correlation of specific developmental states with historical events for Chinese-Americans is presented in Table 51.6e-7.



Current Age of Cohorts	Age at Historical Events			
	1888–1920	1920–1940	1940–1960	1960–Present
	Exclusion Act in effect Urbanization Immigration of paper sons Majority of population are men	Family associations Tong societies Pearl Buck novels Mediated families	Chinese in World War II Repeal of exclusion acts Fear of Chinese Communists	Increased education for some Model minority Immigration from Hong Kong and Taiwan
85+	Children and adolescents	Young adults	Middle-aged	Elders
75–85	Children	Adolescents and young adults	Young adults to middle-aged	Middle-aged to old
65–75		Children and adolescents	Adolescents and young adults	Adults to young old

Table 51.6e-7 Correlation of Historical Events With Developmental Stages: Cohort Experiences, Chinese American Elders

Effects of Drugs Several studies found Asian-Americans to require one third to one half of the usual dosage of antidepressant and antipsychotic medications. Using lower-than-usual dosages in elderly patients and slowly titrating increases of psychoactive medications upward is particularly important for these ethnic elders.

HISPANIC-AMERICANS

Demographic Characteristics The earliest Hispanic immigrants to the continental United States were from Mexico and Puerto Rico. They were followed by Cuban immigrants who fled the Castro revolution and by Salvadorans, Nicaraguans, and Colombians. Hispanic-Americans represent 8 percent of the total United States population. They have a younger than average median age, higher fertility rates, and increasing immigration—factors that contribute to the rapid growth of the population in the nation. Among Hispanic-Americans (Fig. 51.6e-3), the percentage of persons age 65 and older varies: for Mexican-Americans, 47.6 percent; for Cuban-Americans, 18.7 percent; for Puerto Ricans, 10.9 percent; and for Central and South Americans, 8.4 percent. For Hispanic Americans age 65 to 74, there are 86 men for every 100 women. At age 85 there are 61 men for every 100 women. Of Hispanic-Americans who were ages 65 to 74 in 1990, 20 percent completed high school, 4 percent completed college, 18 percent completed the fifth or sixth grade, and 35 percent had no formal education. Twenty-six percent of Hispanic-Americans live below the poverty level.

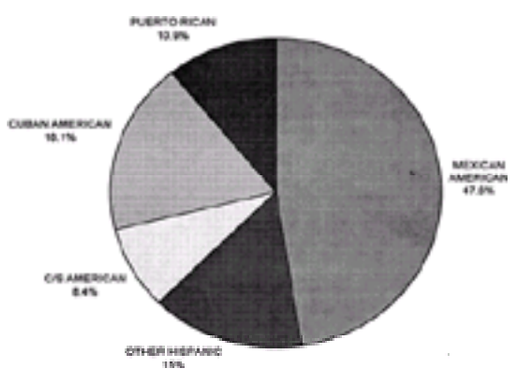

FIGURE 51.6e-3 Hispanic elderly population by nation of origin, 1989. C/S American, Central and South American. Gerontological Society of America, Washington, DC, 1991.)

Immigration History and Patterns of Acculturation Issues of exclusion based on ethnicity, level of acculturation, and language vary for each component of the Hispanic-American population. Mexican-Americans, who have a unique history in the development of the southwestern United States, include a population ranging from the original landowners and indigenous residents of Texas to the undocumented workers of the 1990s (Table 51.6e-8 and Table 51.6e-9).

Dates	Periods and Events	U.S. Population[1] (in 1000s)
Late 1500s–early 1600s	Gradual colonization of northern provinces of New Spain	
1821	Mexico obtains independence from Spain	
1845–1854	Conquest of northern Mexico by U.S. and annexation of territories of U.S. Southwest	80
	Increased immigration to California for gold rush and to Texas and Arizona ranchos and farms; anti-Mexican laws, rough discrimination, invalidation of land titles for many Mexican land-grant holders	
1850s–1900		
1900		381 to 562
1910	Mexican Revolution followed by political and economic chaos, spurring immigration to the U.S.	
	500,000 enter on permanent visas and thousands more enter informally; cause industry; establishment of the border patrol; increased employment in railroads and manufacturing, some in mid-west; development of urban barrios	
1920–1930	Immigration increases dramatically because of depression and dust bowl; forced repatriation of 500,000 residents to Mexico; family-oriented migrant farming; segregated housing and social organization, including labor unions	
1938–1942	350,000 Mexican-Americans serve in World War II; increased immigration to fill war-related industrial jobs; GI Forums programs anti-Mexican press coverage of conflict between zoot-suiters and Anglo servicemen and police	
1942–1947	Ex-GIs organize for civil rights, declining agricultural jobs, increasing urbanization and education in highly segregated communities; documented immigration of 273,000 in the 1950s; periodic raids and mass deportations of undocumented residents	
1947–1960		
1960s	Chicano movement; increased immigration of women	
	Immigration and Nationality Act sets 20,000 ceiling on annual immigration and issues family reunification of U.S. permanent residents	
1965		
	Bi-directional cultural migration from Texas to the Midwest and the West; greater political organization and passion; greater recognition of Mexican-Americans in U.S. Catholic Church; bilingual education; wide-scale deportation of undocumented workers	
1970s		6,000
	Emphasis on education, continuation of Mexican heritage and Spanish language through arts and the media; amnesty program; continued[2] deportations	
1980s		
1990	Increasing role in American media; increase in bilingual materials and advertising	11,000

Table 51.6e-9 Correlation of Historical Events With Developmental Stages: Cohort Experiences, Mexican-American Elders

Medical Problems Although most Hispanic-Americans have higher than average mortality rates—which have been related to the stress and wear and tear of raising large numbers of children—mortality and morbidity data are lacking because no large-scale studies have been done. Most existing studies are case reports or descriptive studies. The National Health and Nutrition Examination Survey that focused on Hispanic-Americans provided the first national data on Hispanic-Americans. United States census data did not separate Hispanics from whites until 1979.

Several investigators reported that arthritis, hypertension, circulation problems, and diabetes mellitus are the primary diseases of concern. Mexican-born persons had a rate of death caused by accidents that was twice that of Puerto Rican–born and Cuban-born populations. Mexican-born persons had the highest cerebrovascular disease mortality rates, and Cuban-born persons had the lowest. The mortality rates for chronic liver disease and cirrhosis in Puerto Ricans were twice those of Mexicans and three times those of Cubans. Mortality rates for homicide were high in all groups of Hispanic-Americans, but highest among Puerto Ricans.

Psychiatric Disorders Few studies have looked at psychiatric disorders in elderly Hispanic-Americans. One study used a regrouped set of Comprehensive Assessment and Referral Evaluation (CARE) items in an probability sample of 700 elderly Hispanics living in Los Angeles County to reflect criteria from the revised third edition of DSM (DSM-III-R). The authors found that more than 26 percent of the population had depression or dysphoria. Mood disorder correlated strongly with medical disability and dementia.

Mexican-American and Puerto Rican populations have been studied to a limited extent for the presence of psychiatric symptoms and disorders. High acculturation was associated with alcohol dependence and suicide among Mexican-American men. A study of a Puerto Rican community found higher-than-average rates of depressive disorders among persons who had little involvement with the American culture. Factors contributing to the rates of alcohol dependence and suicidal behavior were related to a failure of Puerto Rican persons to resolve the transition from rural Puerto Rico to urban centers.

Recent data from the CERAD investigators confirm the findings of ECA investigators that components of the Mini-Mental State Examination (serial sevens, retrograde spelling of *world*, and knowledge of one's county of residence) were more likely to be missed by nonwhite persons, particularly those with less than 8 years of education. In addition, the CERAD investigators identified specific culturally appropriate alternative questions that maintained the intent of the screens for cognitive impairment. Spanish translations of the revised instruments are available from CERAD investigators for the Mini-Mental State Examination and the Blessed Dementia Screen, an assessment of memory and functional level. Whether Hispanic-Americans have biological differences in the metabolism of psychoactive medications is unclear.

Suicide Among Hispanic elderly men the rates of suicide were the second highest among ethnic elders (Table 51.6e-10). Suicide was highest among Cuban and Puerto Rican men and lowest among women, particularly Mexican women.

Race	Number of Deaths	Rate per 100,000
White	6139	22.5
Black	164	6.6
American Indian and Alaskan Native	7	6.7
Asian	53	11.5
Hispanic (any race)	74	10.3

From National Center for Health Statistics. Unpublished data, 1990.

Table 51.6e-10 Completed Suicides by Ethnic Elders Age 65 and Older (1988 Data)

Effects of Drugs The effects of drugs are unknown.

FUTURE DIRECTIONS

Studies to identify factors contributing to the decreased suicide rates among ethnic elders have not been published to date. A few studies have addressed the adjustment of Asian elders in nursing home settings and have assessed the presence of depressive symptoms among ethnic elders. Studies differentiating between the presence of depressive symptoms and depressive illness among various populations of ethnic elders remain to be completed.

Areas of research among African-American elders include further assessment of the prevalence of Alzheimer's disease and vascular dementia in this population. It will be important to determine whether African-American elders have as high a prevalence rate of phobic disorders as African-Americans of younger age cohorts (ECA

survey data). The impact of slow acetylation among African-American elders and its impact on the metabolism of psychoactive medications remains unstudied.

Establishing effective dosage levels of antipsychotic and antidepressant medications is crucial to the effective management of all ethnic elders. Although there are some data for Asian-American populations, few if any published studies address the use of medications in African-American, American Indian and Alaskan Native, and Hispanic-American elders.

SUGGESTED CROSS-REFERENCES

Other pertinent parts of the chapter on geriatic psychiatry include Section 51.2 on assessment; Section 51.3 on psychiatric disorders of late life, (particularly Section 51.3e on Alzheimer's disease and other dementing disorders and Section 51.3d on mood disorders), and Section 51.4 on treatment. A general discussion of psychological sciences appears in Chapter 3, of sociocultural sciences in Chapter 4, of epidemiology in Section 5.1, of alcoholism in Section 11.2, of posttraumatic stress disorder in Section 51.3c, of suicide in Section 29.1, and of community psychiatry in Section 51.5d.

51.6 SPECIAL AREAS OF INTEREST

51.6F GENDER ISSUES

MARION ZUCKER GOLDSTEIN, M.D.

The later years of life constitute a considerably longer period of time than childhood, adolescence, young adulthood, or adulthood. Late life can span 40 years or more and start at 50, 55, 60, 62, or 65, depending on various organizational criteria. For example, eligibility to join the American Association of Retired Persons (AARP) starts at age 50, most airline and movie discounts start at age 62, Medicare eligibility starts at 65, eligibility to participate in studies on aging can start as early as 55, and admission to a geriatric unit at 60. Late life has a definitive cutoff (namely death) but not a definitive age of onset or end. Since the term *sex* has primarily biological connotations and *gender* refers to a broad spectrum of biopsychosocial attributes that can cross the stereotyped boundaries between male and female, the term “gender” will be used in this section. The gender ratio at onset of late life is about equal; however, with advancing years, women become an ever larger majority.

Both genders in our aging population are extremely heterogeneous in their life experiences. For example, at the turn of the century in the year 2000, the older population will include persons born around the turn of the previous century as well as those born after World War II. The late lifers will have experienced many societal changes including the rapid advances in information technologies. Adults over 50 are one of the fastest-growing segments of computer and Internet users, making up about 16 percent of the total, of which 42 percent are women and 58 percent men. Gender roles have changed from being primarily defined by men in power and authority to being less stereotyped and more self-determined. Communications, behaviors, and responsibilities within and between genders, families, and generations have changed markedly. Modifications in psychodynamic theory and psychotherapeutic approaches for both genders and for young and old are gradually reflecting these societal changes. Gender-specific life-cycle experiences, adaptations, and pathology during late life demand the same, if not more, psychiatric attention and study than earlier periods in life have had during most of the current century. Psychiatric studies of late life and the impact of earlier life on late life are in an early phase of development. However, because they are relatively recent, they have the benefit of the advances of the past three decades of studies on developmental gender differences in earlier life.

Many in our aging population have come to the United States during various immigration waves. Though unique for each gender, cultural heterogeneity is vast for both, and generalizations from one group to another are as flawed as generalizations from one gender to another or one ethnic group to another. By mandate, all federally funded research must now include both genders, be gender specific, and include ethnic variations. The Accreditation Council of Graduate Medical Education Psychiatric Residency Program Requirements mandate clinical experiences and didactics that include gender and ethnic variations in each age group. An increasing number of studies specific to women's health and health care are being funded. Most Veterans Affairs (VA) studies remain male specific, but universal conclusions can no longer be drawn from such studies. The Health and Human Services Department's Office on Women's Health envisions a nationwide network of integrated health care (including mental health care) for women from cradle to grave.

HISTORY OF DEMOGRAPHIC TRENDS AND THEIR SEQUELAE

In 1990 39 percent of births survived till age 65 and 12 percent to age 80. At the end of the century 86 percent of births are expected to survive to age 65 and 58 percent to age 80. Women constitute 63 percent of the population over 65, with 69 men for every 100 women at age 65 and 36 men for every 100 women at age 85. Elderly men who turn 65 can expect to live another 15 years; elderly women who turn 65 can expect to live an additional 19.4 years. At the turn of the century 67 percent of those age 30 will have a grandmother alive and 27 percent a grandfather. Ten percent of persons age 65 and over have living parents who can be great-great grandparents.

In the 1930s 50 percent of women had four or more children; in the 1980s, 25 percent of women had four or more children. Twenty percent of babyboomers have no children, and 25 percent have only one child. When the 76 million babyboomers born between 1946 and 1964 become senior boomers in 2010 to 2028, the network of family caregivers will have declined markedly in terms of numbers and availability. Primary caregivers continue to be predominantly women, be they wives, daughters, daughters-in-law, or paid service. More often, women in each generation will be in the workforce. Most sites of employment, unless owned and run by women with their own family responsibilities, continue to be unfriendly to family caregiving. Though more grandmothers, great-grandmothers, and great-great-grandmothers may be living, their roles will have changed. They may be physicians, professors, lawyers, corporate executives, or be otherwise employed in the next century, thus preventing the economic deprivations many elderly women experienced in the previous century and continue to experience.

Women make up 72 percent of poor elderly people, with twice as many African-American women experiencing poverty as Caucasian women. Women are half as likely to have pensions, and the amount of their pension is half as much as that of men. When men die they are three times as likely as women to leave an impoverished spouse.

Single, widowed, and divorced women often have to purchase the home care that married men get from their spouses. Women have more disabilities and more often live alone; thus they require the services of nursing homes more often than men. Seventy-five percent of nursing home residents are women age 65 and older. Women are four times more likely than men to use Medicaid for nursing home care because of their relatively indigent status. Because of relatively low Medicaid reimbursements to nursing homes, these women have little choice in the selection of a nursing home and must share a room, their beds can only be held for a limited period of time in case of hospitalization, and medications must be generic. Older men with spouses to look after them at home use more acute care hospital Medicare dollars than women. Medicare does not pay for nursing home care for more than 21 days and only following a hospitalization, it does not pay for prescriptions, and it pays only 50 percent of mental health outpatient care. The lure of paying for prescriptions and lower copay for outpatient mental health care by managed care companies often comes at great sacrifice of continuation of care and availability of specialists. Other health care economizing restrictions such as limited formularies are also common.

One of five illnesses with lowest out-of-pocket costs for treatment are most common among men (e.g., lung cancer); three of four illnesses with highest out-of-pocket cost for treatment are more common among women (e.g., arthritis). More women than men Medicare enrollees lack supplemental insurance policies.

Considerably more men than women have opportunities to participate in policy making as it pertains to Medicaid, Medicare, private insurance, or a combination thereof. As more women enter the research, financial, and political arenas, gender-specific health insurance in both the public and private sector is gradually evolving.

HEALTH AND HEALTH CARE OF WOMEN

Eighty percent of elderly persons 65 and over have at least one chronic condition, especially older women. These conditions most frequently include arthritis, hypertension, sensory impairment, heart disease, urinary incontinence, and depression. The prevalence of self-reported arthritis increases with age. Surveys show higher rates of arthritis-related consequences (e.g., limitation of activities) for women than for men. Higher rates are reported by overweight women, those with less than 11 years education, and those with incomes below $20,000.

Women have smaller hearts and heart vessels, more delayed onset of arteriosclerosis, a higher frequency of glucose intolerance and diabetes mellitus, and more-marked osteoporosis than men. Many studies have shown that gender bias prevails in diagnosis and treatment and inclusion of women in clinical studies and trials, which has contributed to long delays in determining these gender differences. Elderly women have more orthostatic hypotension than men and are at increased

risk for falling and subsequent hip fractures and their distressing sequelae. Postmenopausal hormone replacement therapy is now recommended for women to prevent osteoporosis and also because of the favorable effects of estrogen on serum lipids and brain function.

Research has shown that women with recurrent depression in their younger years are at higher risk for reduction of bone density in their postmenopausal years. The mechanism by which depression is associated with bone loss is unclear but may be related to higher urinary cortisol excretion in these women than in nondepressed controls. Decreased bone density is apparently not associated with taking antidepressants. On the other hand, women who have been treated with anticonvulsants such as valproic acid (Depakene) or carbamazepine (Tegretol) were found to be at high risk for lower bone density and were targeted as candidates for postmenopausal estrogen replacement.

New onset of mania has been described in late life in patients who were started on hormone replacement therapy, and awareness of this potential risk is needed in clinical practice. Estrogen replacement therapy has been shown to improve immediate and delayed verbal memory, maintain the ability to learn new material, and enhance mood in a dose-dependent manner. Estrogen replacement therapy has not been found to have any effect on general attention and visuospatial memory. The National Institutes of Health (NIH)-sponsored Multicenter Women's Health Initiative is well under way and will bring more scientific understanding to diagnosis and treatment of elderly women in terms of risk factors and prevention of osteoporosis, cardiovascular disease, and dementia. Because of the increased risk of breast cancer, regular mammograms are needed during the course of hormone replacement therapy. The increase in fibrocystic tissue during hormone replacement therapy makes mammograms by the current state-of-the art precision more difficult to read. Patients need to be warned of the risk they take, and insurance companies need to reimburse for every-half-year mammograms as medically indicated instead of insisting on the annual follow-up. This serious risk factor should limit any research with estrogen replacement therapy that does not include responsible, long-term follow-up of the participants. Because of the increased risk of uterine cancer for most women who have not had a hysterectomy, progesterone maintenance must be added. Synthetic progesterone dampens mood. Though risks and benefits of hormone replacement therapy are under ongoing investigation, the extensive use in clinical practice has surpassed the current knowledge base. The salutary effect of hormone replacement therapy on hot flashes, dry skin and mucous membranes, insomnia, and incontinence cannot be minimized, nor can the current epidemic of breast cancer. The optimal age for starting hormone replacement therapy has not yet been determined and depends on the conditions to be targeted and risks involved. Clinical guidelines for counseling postmenopausal women about preventive hormone replacement have been issued by the American College of Physicians and the American College of Obstetricians and Gynecologists and need to be under ongoing review.

DEPRESSION

The results of the Epidemiologic Catchment Area (ECA) Survey conducted in five different communities in North America have contributed to our knowledge of the gender differences in incidence and prevalence of mental disorders. All forms of depression appeared to occur approximately twice as often in women as in men throughout life. The more frequent occurrence of isolation, poverty, single status, lack of education, and poor health in older women must be considered as contributing to late-life depression. The prevailing underrecognition of depression in primary care practices is detrimental to the quality of life of more elderly women than men. This is compounded by the fact that research has shown that 50 percent of caregivers, most of whom are women, have symptoms of clinical depression and a higher rate of doctor visits than a matched group of noncaregivers. Older women with chronic nonlife-threatening painful conditions seek medical attention more frequently than older men. The range of symptoms with which elderly women exhibit their depression is a challenge to clinicians. Physical symptoms without pathological correlates are a common mask for depression. These masked depressions are more frequently seen in primary care practice than the criteria for depression listed in the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV). Though primary depressive disorders and secondary depressive disorder are listed in DSM-IV, presentation of a medical symptom with no pathological correlate is not mentioned. Research is investigating whether there is an association between depression, immune function, physical illness, and lack of estrogen in older women.

Older women suffer more from the adverse effects of their medications, which often include benzodiazepines and unnecessary polypharmacy. Ageism and sexism contribute to these practices. Gender-specific issues in patient-physician communications contribute to diagnostic and treatment decisions and need considerably more attention in outcome studies. Hormone replacement therapy and antidepressants together have been found effective in alleviating severe depression. This treatment modality needs further consideration for depressed postmenopausal women, with inclusion of contributions of estrogen to cognitive improvement as well as major attention to risk factors. Treatment of depression can improve cognitive functions; therefore, research on whether estrogen does so as well creates considerable ethical questions. Administering progesterone to the majority of postmenapausal women who have not had a hysterectomy creates an additional research challenge.

The incidence of suicide in the elderly is related to both the nature of the depression and gender. Divorced or widowed men over the age of 65 are four times more likely to commit suicide than other community-dwelling persons, including the younger population. The incidence of death in older men the year following divorce or widowhood is considerably higher than that of women. No evidence indicates that the death rate of women rises after they lose a partner, whereas the mortality rate in women increased after they lost a son in the war. Altogether, men accounted for 81 percent of suicides of persons age 65 and older in 1992, with considerable ethnic variation within this group. The suicide rate for men age 80 to 84 rose from 43.5 per 100,000 to 58.6 per 100,000 and for women from 4.7 per 100,000 to 6.4 per 100,000 between 1980 and 1992. One of the national health objectives for the year 2000 is to reduce the suicide rate of white men age 65 and over, who constitute the highest percentage. Preventive measures include peer-counseling programs, suicide prevention centers, and programs to increase awareness of risk factors. Bereavement has been shown to be a risk factor for increased alcohol consumption, more so in men than in women. Contributing risk factors for this behavior include a past history of major depression, a depressive episode beyond normal bereavement following a loss, high alcohol consumption prior to bereavement, and dissatisfaction with social supports following a loss. Women experience more anxiety than depression following bereavement. A form of separation anxiety manifested by feelings of panic, yearning, pining, sighing, restlessness, insomnia, shortness of breath, palpitations, and trembling has been observed 1 year after a death of a loved one in women with inadequate supports. It seems that many men and many women experience diminished quality of life with longevity, but not all. For example, the rare exceptions are those centenarian survivors who come to the attention of the media because of their sustained well-being. Each decade of elderly women has unique needs. One of the main problems remains inadequate resources, especially lack of transportation.

EVOLUTION OF GENDER-SPECIFIC DEVELOPMENTAL THEORIES

From 1932 to approximately 1972 psychoanalytic theory dictated the universality of male development. Girls and women were perceived as anatomically, morally, and emotionally deficient in male attributes, and their role in the life cycle of men was dedicated to enhancing expression of these male attributes for men. The qualities of adulthood, namely the capacity to think autonomously, make clear decisions, and take responsible actions, were associated with masculinity. The splitting of love and work *(lieben und arbeiten)* was out of balance between the genders, creating many injustices that became justified by this theoretical bias. Cumulative imbalance of economic relations between men and women prevailed throughout the life cycle, with women's work invisible, devalued, and poorly paid or unpaid. These prevailing norms went unquestioned and unchallenged. Men's relationships were (and are) subordinated to rules with male principles and concepts of justice. The emphasis on separation, individuation, hierarchy of authority, competition, and mentoring of other men superseded networking and collaboration between and within each gender with equal authority and reward. Like the situation observed in monkey colonies, individuals on top of the hierarchy have the liberty to perpetrate unretaliated aggression, and the subordinates in the hierarchy are more vulnerable, are at risk when they retaliate, and have fewer rights. These societal value systems have taken their toll on the current cohort of women in late life. These value systems and sexual stereotyping prevailed in the teachings of psychotherapy as long as theory blinded observation. For example, most women who wanted a role in the medical psychoanalytic establishment where these theories evolved and became firmly grounded joined the male ranks at lower levels than men and had to adopt the beliefs of the male establishment. Professional women who did not conform were asked to leave. For example, when Karen Horney evolved a feminist frame of reference of psychoanalytic thinking and later developmental theories for each gender, she had to separate from the male-dominated establishment and found the American Institute for Psychoanalysis. The evolution of gender-specific developmental theories empowered women of all ages. For example, Maggie Kuhn, founder of the Gray Panthers with six other women who had been forced to retire at the age of 65, pressed for innovative work concepts and intergenerational networking; health care systems to protect everyone, old, young, families, and children; and elimination of homelessness.

Among those who made major contributions to gender-specific observation and put them in a positive light for women in particular were Nancy Chodorow, Carol Gilligan, Jean Baker Miller, Alexandra Symonds, Matina Horner, and I. Broverman. The greater capacity for empathy, compassion, intimacy, and attachment in women, which lead to different priorities in decision making than those of most men, have been examined to enhance their appreciation and reward. The fear of adverse consequences of success, such as social rejection and loss of feminine attributes while entering into a male-dominated arena, was studied and found to be greatly ameliorated by support from other women, regardless of age. Mentoring and role modeling by older women in leadership roles has become desirable as has companionship between women throughout the life cycle, which is no longer considered second best. More men are aware that women's productivity and leadership can take place both inside and outside the home if men participate in both on a more egalitarian basis. These changed behaviors can reflect in their aging years. Only a few in the present cohort of elderly men can make such adaptations. The current generation of grandparents at times needs help to adapt to these changes, especially when intergenerational conflicts occur.

AGE AND GENDER-SPECIFIC PSYCHOTHERAPY

Challenges to the still prevailing ageist and sexist stereotyping in psychotherapy continue. Patients and many therapists are likely to be encumbered by sexist and ageist stereotypes. Renewal and generativity can be fostered at any age as long as it is appropriate to gender, mental, sensory, educational, and financial capacities and essential resources are made available.

Therapists must pay special attention to their own fears of aging, disabilities, losses, and death so they do not avoid these vital concerns during the aging process of their patients and can assist in optimal adaptation. Ageist and stereotyped views of elderly adults as shipwrecks at the end of their voyage—too slow, unproductive, and close to death—denies the many who are capable of ongoing growth, development, adaptation, friendships, and enjoyment the opportunity to get professional help in a respectful, reality-oriented, compassionate, and knowledgeable manner.

Elderly patients may need to adapt to greater dependency than they had earlier in life. Older women who were either independent during their adult lives or in a nurturant position that they equated with their worth, usually find dependency on others especially difficult. Excessive resistance to dependency can result in self-injurious or self-neglectful behaviors. Not wanting to be a burden to others (especially not one's own children) is a common concern, especially of older women, and can often be successfully addressed in psychotherapy by pointing out the vital contributions they have made to their family during their lifetimes. Unrealistic and excessive feelings of entitlement or dependency on others beyond actual need and capacity may also need to be addressed. The individual etiologies and meanings of such behaviors need to be explored and clarified to the patient in a gender-specific manner.

Family participation is a vital component of psychotherapy of dependent elderly persons. Again, more women in the advanced years live alone, have more chronic illness, and may need assistance from adult children. The readiness for emotional, physical, and at times financial committment to this parental caretaking task can vary widely among adult children in a family. The skilled and sensitive psychotherapist can assess and effectively distribute tasks and help families function as a quasi-multidisciplinary team while accessing appropriate community resources. By not assuming that the women in the family will take on all the household and caretaking responsibilities, gender barriers to participating in caregiving can at times be overcome. Medicare denials of reimbursement for these professional services is still all too common. Family involvement in medication management and compliance as well as many other activities of daily living for the elderly patient remains a professional standard in the therapeutic interventions for the dependent, frail elderly patient.

The developmental phase of being a grandparent needs attention in theory, research, teaching, clinical practice, and policy making. The stereotyped image of the grandmother as an unemployed or retired, babysitting, meal-preparing, cookie-baking, and ever-available individual becomes less and less of a reality. No such expectations are usually made of the grandfather, whose interest and assistance is often appreciated at whatever level he chooses. Grandfathers, when retired, may enjoy the new role of helper and caregiver. A therapist's role in a grandparent's life can include resolution of intergenerational conflicts and of facilitation of development of this new and challenging identity. Grandmothers who live alone and at a distance are less likely to have the financial resources to visit than grandfathers or both together. Clinical observations have revealed that depriving older women of the opportunity for regular visits with adult children and grandchildren can contribute to depression and considerable distress. Other clinical observations reveal that older men who have survived their alcoholism during younger years tend to get depressed when they are rejected by adult children who cannot forgive their abusive behaviors from earlier years. This rejection inadvertently leads to deprivation of the grandfather role. Gender-specific developmental theory for later life has not yet been established, though various modalities of psychotherapy including cognitive-behavioral approaches have been found quite effective for both men and women in late life.

GENDER- AND AGE-SENSITIVE MEDICATION MANAGEMENT

Medication management must be gender and age sensitive. Gender-related differences in efficacy safety, and dose recommendations have not been adequately researched. Physiological (e.g., 36 to 48 percent increase in adipose tissue in women as they age) and anatomical (e.g., organ size) differences between elderly women and men affect response to antidepressant, antipsychotic, and anxiolytic drugs. Research on gender differences in pharmacokinetics and pharmacodynamics is just beginning, and comparison data between men and women not uniformly available.

The relative lack of gender-sensitive drug studies in the elderly population affects more women than men. The 1993 Food and Drug Administration (FDA) recommendations include the need for data analysis by age, sex, and race; body weight; renal, cardiac, and hepatic status; concomitant illnesses and use of other drugs. The FDA guidelines support informed individualization of treatment while taking into account the needs of children, elderly adults, and each sex. Currently, drug studies with elderly patients usually take place after (rather than before) FDA approval.

MENTAL DISORDERS OTHER THAN DEPRESSION AND DEMENTIA

Except for sexual and gender identity disorders and conditions associated with the reproductive system, DSM-IV does not relate manifestations of disease to gender because of lack of information based on adequate research. Women are at higher risk than men for most disorders at all ages except alcohol and other substance use disorders (other than iatrogenic). Other parts of this section review diagnosis and treatment of psychopathology in the older population.

Anxiety disorders, such as panic disorder, phobias (especially agoraphobia), and obsessive-compulsive disorder, and somatoform disorders occur in more than 4 percent of the elderly community population. There is a higher incidence of agoraphobia in older women than men. Whether there is an association between the higher incidence of victimization of women and the higher incidence of disabilities in the advanced years has not been researched.

Excessive consumption of alcohol by elderly adults is a leading public health problem that originates from and leads to stressful life situations. A man's alcoholism often creates the problem for the woman he lives with. The ECA study revealed a 1-year prevalence of alcohol use disorder in persons age 65 and older of 3.1 percent in men and 0.4 percent in women. Though the prevalence in the older population is considerably lower than that in younger populations, alcohol-related hospitalizations are more frequent in older persons. The tolerance for alcohol diminishes with age, especially in women. Lower consumption than in younger persons can cause severe physical and psychosocial complications including cognitive deficits. Survey data reveal that alcoholism is frequently overlooked clinically in older women because it is not sought. Once detected and diagnosed, few age- and gender-appropriate treatment opportunities are readily available.

Sex and gender differences in psychosis (schizophrenia in particular) and population (bipolar I disorder in the elderly) require research attention in terms of differences in etiology, manifestations, course of illness, biopsychosocial consequences, and risks and benefits of treatment. More women than men have late-life onset of schizophrenia. No data are available to indicate that estrogen may have a protective function earlier in life or that it is effective in the treatment of psychosis—again, an ethical question in view of the advances in psychotropic medications. Women with psychotic disorders are at high risk of receiving less than optimal preventive care for disease. No studies of antipsychotic medication with and without hormone replacement therapy or hormone replacement therapy alone during late-life psychosis are available. Ethical and legal considerations may well delay such studies indefinitely. The fact that women are more apt to get tardive dyskinesia makes a gradual crossover to adequate dosages of the newer serotonin–dopamine antagonists such as risperidone (Risperdal) and olanzapine (Zyprexa) even more urgent than it is for elderly men.

FUTURE DIRECTIONS

Gender issues in mental health and aging require basic and health services research. Women's issues and men's issues have taken separate paths, and women's issues are lagging behind. For example, there is a biologic marker for prostate cancer but no reliable marker for breast cancer. Women can benefit from men's studies and men from women's studies, but women have much catching up to do in research and clinical service. Estrogen is not the panacea for all aging problems of women, though many can be symptomatically relieved and possibly prevented. A high research priority is to have women of all ages who take or have taken hormone replacement with varying frequency and doses and their medical care providers participate in a longitudinal epidemiological outcome study with minimal exclusion criteria. The group would include women on estrogen replacement therapy and hormone replacement therapy, with psychosis, depression, dementia, diminished bone density, breast cancer, uterine cancer, heart attacks and strokes, and hip fractures taking vitamin and mineral supplements and those who do not, and on high-fat, low-fat and other diets. The research population would be large enough and be studied long enough with regular assessment for data analysis to determine what women benefit substantially from replacement therapy and what women are at risk. Is this a gender issue or a women's issue? It is a societal issue that urgently needs attention. Practice patterns of care providers, their decision trees, and gender variations in communication with their patients can be studied simultaneously. Subgroups can be studied for immune and stress status with biologic markers and others for genetic vulnerabilities. In the era of information technologies a 20-year lag between research findings and practice is no longer acceptable. The busy practitioners who must see more and more patients in a shorter time and the patients who take time out of their busy day must be appropriately reimbursed for time spent in this research, regardless of gender so the research does not become yet

another gender issue.

Fragmentation of medical services must be stopped. Health care for both aging men and women, including mental health care, needs to be locally centralized and gender- and culture-sensitive. Centralization of all health care services would greatly facilitate clinical research in the aging population. Can women lead the way? Yes, of course, they may even be more motivated to do so than men if given the appropriate resources.

The effects of earlier life development, losses, and other traumas on late-life adaptations, coping mechanisms, and physiological and pathological responses require gender-based life-cycle studies. Erik Erikson and George Vaillant have been the pioneers. Appropriate application of information technologies will permit study of larger numbers in many subgroups to learn which past experiences enhance and which hinder physiological, interpersonal, and personal adaptation and coping in late life. Life-cycle studies of each gender should be simultaneous, not sequential.

SUGGESTED CROSS-REFERENCES

Section 2.6 discusses neuropsychiatric aspects of movement disorders; Section 3.1, perception and cognition; Section 3.4, biology of memory. Section 51.6g deals with elder abuse. Section 5.4 discusses animal research and its relevance to psychiatry, Chapter 6.3 discusses theories of personality and psychopathology and other psychodynamic schools, Chapter 12 discusses schizophrenia; Chapter 13, other psychotic disorders; Chapter 14, mood disorders; Chapter 15, anxiety disorders; Chapter 25, psychological factors affecting medical conditions; Chapter 28, psychiatry and other specialties. Section 29.1 deals with suicide; Chapter 30 with psychotherapies, and Chapter 31 with biological therapies. Dementia in the elderly and gender issues are covered in Section 51.3e and Section 51.6f; Section 51.3h is on drug and alcohol abuse.

51.6 SPECIAL AREAS OF INTEREST

51.6G ELDER ABUSE, NEGLECT, AND EXPLOITATION

MARION ZUCKER GOLDSTEIN, M.D.

The American Psychiatric Association (APA) has published a Position Statement on Elder Abuse, Neglect and Exploitation as recommended by the APA Council on Aging and approved by the APA Assembly and Board of Trustees in 1995. The content of this position paper is reflected in the following text and in Table 51.6g-1 and Table 51.6g-2. “Elder abuse, neglect, and exploitation have been identified as major public health problems. All 50 states have mandatory or voluntary reporting laws; however, problems remain.” Varying laws require specific professionals who have reason to suspect elder abuse or neglect to report their observations to designated public health agencies. Failure to report is considered a criminal offense in 42 states and the District of Columbia. Colorado, Illinois, New Jersey, New York, North Dakota, Pennsylvania, South Dakota and Wisconsin make reporting voluntary. Criminal enforcement of these laws which differ in nature from state to state is nonexistent. Clinical incentives to reporting, such as a comprehensive system of services to respond to such reports, providing appropriate follow-up services to victims and overstressed caregivers, and providing reporters with outcome of interventions, are lacking in most jurisdictions. This situation and the relative isolation of most abused elderly from society, have contributed to making mandatory reporting laws ineffective.

Emotional Abuses	Psychiatric Symptoms*
Threats	Resignation
Insults	Ambivalence
Harassment	Fear
Harsh orders	Anger
Infantilization	Cognitive impairment
Restrictions of social activities	Depressed mood
Restrictions of religious activities	Insomnia
Financial exploitation	Substance abuse
Physical abuse	Delirium
Excess stress	Agitation
	Lethargy
	Self-neglect

* Any or several of these symptoms can occur with any or several of these emotional abuses. Adapted from American Psychiatry Association Council on Aging: Position statement on elder abuse, neglect, and exploitation. Am J Psychiatry 152:5, 1995.

Table 51.6g-1 Elder Abuse, Neglect, and Exploitation: Emotional Abuses and Psychiatric Symptoms

- **Participate** in the formulation of protocols for the identification of elder abuse and exploitation.
- **Research** applicable laws concerning reporting of elder abuse.
- **Utilize** available resources in the APA Central Office and state societies to help in assessment and reporting of elder abuse and in interventions.
- **Collaborate** with government and private agencies that support the prevention, identification, and treatment of elder abuse.
- **Participate** actively in multidisciplinary research efforts on the incidence and prevalence of elder abuse and on outcome studies of specific interventions.
- **Develop** curricula for medical schools, residency training programs, and continuing medical education that teach the physician's role in the prevention, identification, and treatment of elder abuse.

Table 51.6g-2 Elder Abuse, Neglect, and Exploitation: APA Recommendations for Psychiatrists

Emotional abuses and psychiatric symptoms seen in abused elderly persons, as listed in the APA position paper, are reflected in Table 51.6g-1.

“The APA recommends that a comprehensive biopsychosocial assessment of the victimized elderly person and the perpetrator of the victimization be completed to facilitate effective interventions. These interventions should include utilization of legal, social, and financial resources.” APA encourages psychiatrists to participate in the activities outlined in Table 51.6g-2.

The presenting symptoms of elder abuse are some of the manifestations listed in the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) under a variety of diagnostic categories. Elder abuse as such is not listed in DSM-IV as a possible diagnosis for the symptom complexes noted here. A code for elderly victims of abuse, separate from that for children and adults, is necessary. The feeling of a foreshortened future as a consequence of trauma among elderly patients requires different interventions than those for children, adolescents, and adults. Child, partner, and elder maltreatment need to be clearly distinguished in domains such as prevention, detection, intervention, diagnosis, treatment, and legislative and judicial arenas. For example, the child abuse model for reporting elder abuse reflects the societal stereotype of infantilizing older persons and restricting self-determination and control of their own lives to the limit of capacity. Whereas child abuse was initially brought to public attention by physicians, elder abuse was brought to public and congressional attention by social workers and nurses. In 1996 3000 members of the American College of Emergency Physicians were surveyed about their practice characteristics, availability of elder maltreatment protocols, and their familiarity with local laws and reporting requirements. The results of the 24 percent who responded suggested that practicing emergency physicians are not confident in identifying or reporting the geriatric victims of abuse or neglect. Inadequacies in training, research, and continuing education with regard to mistreatment of older people were implied.

However, the APA Committee on Family Violence under the Council on Children and Adolescents did see to it that elder maltreatment was included in their Guide on Family Violence. The American Medical Association (AMA) has published diagnostic and treatment guidelines specific to elder abuse. The commitment of mainstream medicine to contribute to finding humane solutions to this increasing problem is growing steadily. Elder abuse should be included in medical school curricula, in postgraduate medical training, in Accreditation Council of Continuing Medical Education (ACCME) accredited forums of medical education, and in medical publications. Medical research in collaboration with social scientists and research nurses will enrich and broaden the knowledge base.

In 1991 a small amount of federal funds was specifically designated for the prevention and intervention of elder abuse and neglect in an amendment to the reauthorization of the 1965 Older American Act. These funds are subject to approval of annual renewal. The National Resource Center on Elder Abuse (NRCEA) was operated by a consortium of the American Public Welfare Association (now the American Public Human Services Association [APHSA]), the National Association of State Units on Aging (NASUA), the University of Delaware, and the National Committee for the Prevention of Elder Abuse (NCPEA) with funding from the Administration on Aging (AOA). This consortium has contributed to research in the epidemiology of elder abuse, neglect, and exploitation.

In 1998 the Department of Health and Human Services (DHHS) announced a new National Center on Elder Abuse (NCEA) for the promotion of understanding among

states and local networks of community workers, physicians, elder volunteers and others working to prevent elder abuse. The center is led by the National Association of State Units on Aging and is funded by a $1 million DHHS grant to expand its support of training activities of persons who work with older persons on a regular basis as well as medical and social service professionals to identify and respond appropriately to cases of elder abuse and neglect. The NCEA consists of a partnership of the National Association of State Units on Aging (NASUA), the American Bar Association (ABA) Commission on Legal Problems of the Elderly, Clearing House on Abuse and Neglect of the Elderly (CANE), the Goldman Institute on Aging San Francisco Consortium for Elder Abuse (GIOA), the National Association of Adult Protective Services Administrators (NAAPSA), and the National Committee for the Prevention of Elder Abuse (NCPEA). The NCEA has contributed to the 1996 National Elder Abuse Incidence Study (NEAIS) of domestic elder (age 60 and over) abuse, neglect, and self-neglect with a final report in 1998. This report confirmed the “iceberg theory” of the past 20 years, that for every reported and substantiated incident, at least five still go unreported.

EPIDEMIOLOGY

The true prevalence or incidence of elder abuse is not known because of underreporting and variability of reporting methods, instruments, sites, and reporters. The National Institute on Aging supported a survey of a random sample of 2020 elderly persons in the Boston community in 1985. While this study was being conducted the reported elder abuse prevalence of 32 per 1000 and incidence of 26 per 1000 was found. Nearly three fifths of the perpetrators were spouses, one fifth were adult children, and one fifth were other persons such as siblings, grandchildren, and boarders. Among the abusive adult children, sons outnumbered daughters 2 to 1.

During the same period of time as the study was conducted, the reported incidence of elder abuse in Massachusetts was 1.8 per 1000, indicating that only 1 in 14 cases came to public attention. This discrepency between survey results and reporting occurred in a state with a law that required (with penalty of $25–$1000 for noncompliance) immediate reporting of all physical abuse of persons age 60 and older.

A telephone interview study of 577 staff members in 31 long-term care facilities revealed a substantial rate of abusive behaviors among staff who also reported job dissatisfaction and the perception of elder persons as children. Surveys of elder maltreatment have been undertaken in many countries including Canada, the United Kingdom, Australia, the Scandinavian countries, France, Israel, South Africa, and others. Persons reporting include community dwellers, home health visitors, family caregivers, hospital patients and their families, and retrospective reviewers of maltreatment. International and cross-cultural perspectives have been described. National incidence and prevalence of institutional abuse is particularly difficult to determine. Ombudsmen (volunteers who visit nursing homes at least weekly) have been organized in many areas in each state by federal mandate since 1978. These ombudsmen report complaints by nursing home residents and their families and report their own observations about residents' care to state agencies. However, underdetection and underreporting continue. Ombudsmen are mandated to resolve only short-term situations. Overcrowding, understaffing, unappetizing dining rooms with one aide feeding five people at the same time, screams coming out of closed bathrooms, and insufficiently trained and supervised staff have not been targets for reports by ombudsmen. A 1990 study in six states of a total of 14,018 complaints divided in eight categories revealed a distribution as outlined in Table 51.6g-3.

Category	Percentage
Physical abuse, inadequate hygiene, neglect	42.6
Understaffing, discharge of Medicaid patients	18.1
Theft and loss of personal items, indignities	11.0
Unappetizing food, lack of assistance at meals	8.7
Lack of cleanliness, suitable ventilation, and temperature	7.3
Questionable charges and misuse of personal funds	6.5
Medications not given as ordered, overmedication	3.6
Physician services inaccessible for diagnosis and treatment	2.1

Table 51.6g-3 Categories of Abuses in Long-Term Care as Reported by Ombudsmen

Researchers also addressed elder abuse and neglect in the community. In 1991 NRCEA established reporting methods to and from state adult protective service (APS) agencies and state units on aging across the nation. NRCEA's analysis of existing state and federal definitions of elder abuse, neglect, and exploitation led to concise definitions of seven types of elder abuse: physical, sexual, emotional, and financial exploitation; and neglect, abandonment, and self-neglect. Once these reporting methods were implemented, the data collected revealed reporting of domestic elder abuse to have increased by 106 percent between 1986 and 1994 (117,000 to 241,000). Whereas the total increase in elder population from 1986 to 1996 was 10 percent, the NEAIS revealed an increase of 150 percent (117,000 in 1986 to 293,000 in 1996) of unduplicated Adult Protective Services–reported domestic abuse or neglect incidents during these 10 years. Whether new occurrences or reporting was higher remains to be researched.

Reporters of domestic elder abuse in the NRCEA study were: 21.6 percent physicians or other health care providers, 9.4 percent APS or other agency workers, and 14.9 percent family members and relatives; the remainder were friends and neighbors, law enforcement personnel, clergy, banks and business institutions, elder victims themselves, and others. Agencies that received and investigated reports were state and local APS, social service, and law enforcement agencies, police, and sheriff departments.

In 1994 physical abuse accounted for 15.7 percent, emotional abuse for 7.3 percent, financial and material exploitation for 12.3 percent, neglect for 58.5 percent, and unknown or other types of abuse for the remainder of the total abuse of elders. The median age for self-neglecting elders was 77.2 years and 76.5 years for the remainder of substantiated reports. Sixty-two percent were women, 38 percent were men; 65.4 percent of victims were white, 21.4 percent were black, 9.6 percent were Hispanic, and less than 1 percent were Native-Americans, Asian-American, or Pacific-Islanders. Characteristics of perpetrators were as follows for 1994: 50.6 percent were men and 49.3 percent were women; adult children were the most frequent abusers, spouses ranked next, and other family members were next in frequency.

ABUSED ELDERLY

The profile of an elderly person who is at high risk for abuse is complex and varied. This individual often lacks the opportunity or the physical and mental ability to report the abuse. When the perpetrators of abuses are the adult children, the elderly victims may desire to protect their children, be embarrassed about the situation, and even blame themselves. Common fears of disbelief, reprisal, abandonment, and institutionalization must be recognized and addressed by the professional provider of care who suspects victimization. Psychiatrists working in emergency rooms, acute-care inpatient units, consultation or liason services in general hospitals, and long–term care facilities need to question the possibility that they may be denying, minimizing, or rationalizing the occurrence of the abuse. Being alert to these findings can assist the professional provider of care to prevent recurrences by appropriate interventions in individual situations.

The following case vignettes demonstrate the complex situations reported to a local APS agency, how needs are being met by the APS, and how psychiatric assessment and treatment might have contributed to each situation had this been called upon or been available in a timely and expert fashion with participation of a multidisciplinary team.

Victim: Father (H.G.) 76, diagnosed with Parkinson's disease

Perpetrator: Son (J.G.) 30, diagnosed with schizophrenia

With H.G.'s consent, given with much encouragement from his neurologist, the neurologist was able to report abuse by H.G.'s son J.G., abuse that H.G. had been telling him about. J.G., who had been diagnosed with schizophrenia, had never left the parental home; his mother had died 2 years ago. The neurologist described H.G. as an intelligent and highly educated man whose Parkinson's disease had been exacerbated by the stress of household responsibilities and his son's threatening and uncontrolled behaviors. During a home visit, the APS worker observed that H.G. had been confined to two rooms by his son. APS recommended involuntary hospitalization for J.G. and an order of protection to prevent J.G. from returning home. He felt entitled to “possession” of the house but was unable to look after his own or his father's needs. No further assessment of his condition was described in their report.

J.G.'s phone contacts with his father were threatening both during and after discharge. Upon his return to the community, J.G. did not follow up on psychiatric outpatient treatment and lived in a motel with financial assistance from family members. H.G. sold his home and moved to a retirement home, where he reported feeling safe and contented. In this situation, involvement of mental health professionals would have been helpful for father and son. A more thorough history should have been obtained upon initial APS involvement. The current situation had arisen 2 years prior, after H.G.'s wife's death. She had been her son's advocate in the household and had educated herself on schizophrenia. According to family members, H.G. had disparaged J.G., favored J.G.'s older brother, and denied the diagnosis of schizophrenia. J.G. had been noncompliant with medication treatment because of extrapyramidal adverse effects. J.G. had never received disability income or insurance coverage.

A multidisciplinary mental health team could have provided evaluation and a treatment plan that could have included ongoing case management (with assistance with finances, insurance, and living situation) and medication management. The team could have offered education and support for H.G., as well as referral to community agencies such as the National Alliance for the Mentally Ill (NAMI), which his wife had participated in actively. Improved outcome could have included continuity of psychiatric treatment for J.G., maintenance of H.G. in the community, and belated understanding of his son's condition.

Victim: Wife (E.A.), 75, diagnosed with dementia

Perpetrator: Husband (C.A.), 78, diagnosed with bipolar I disorder

E.A. had been married to C.A. for 50 years. The couple had remained childless, outlived their siblings, and not maintained contact with nieces or nephews. E.A. had progressively become less able to take care of the household or her own physical care. C.A. had bipolar I disorder with grandiosity, delusions, excessive spending or giving money away, bouts of infidelity, and alcohol abuse. He had ignored his wife's needs during most of their married life but claimed “to love her.” He was now quite unable to deal with her ever-increasing dependency or to provide her with a safe home environment.

APS made attempts to provide personal care aids and nursing services for E.A. and even obtained guardianship of her person in order to make medical decisions on her behalf. One of the personal care aids alleged that C.A. had raped his disabled wife, a not unlikely event considering the hypersexuality during the acute phases of his now untreated bipolar I disorder. APS recommended involuntary psychiatric hospitalization of C.A. and hospitalization of E.A. for a delirium and dementia workup and nursing home placement. APS reported that the primary care physician would not “cooperate” with E.A.'s hospitalization, objecting to the potential expense of a prolonged hospitalization on an acute care unit. E.A. had to be admitted on an emergency basis. She died 2 weeks later in the hospital of causes that were not in the APS report. Following E.A.'s death, APS applied for guardianship of C.A.'s income and assests and transported him for psychiatric evaluation. He was hospitalized for several months and discharged to a supervised residence in the community. APS makes monthly visits and found him adapted to his surroundings but depressed. There was no further mention of the psychiatric management of his bipolar I disorder. There was speculation that he suffers from “chronic separation loss” and therefore was thought “to take no interest in life.” Appropriate psychiatric evaluation and treatment would most likely have stabilized his mood swings and improved the quality of his life.

Some areas' protective service agencies do a remarkable job in intervening and dealing with complex practical problems. However, mental health issues are rarely addressed because of lack of expertise, financial limitations, and perceived or actual unavailability of psychiatric consultations.

CHARACTERISTICS OF CAREGIVERS AT RISK FOR ABUSIVE BEHAVIORS

The perpetrators of elder maltreatment require as much attention as the victims. Stresses associated with caretaking are strong predictors of abuse. Separating victims from perpetrators can be very difficult in view of limited formal and informal supports available to the caregiver and alternative resources for the dependent elderly. The following major categories of abusive caregivers have been identified.

Criminals This category includes perpetrators of elder abuse whose activities are criminal in nature and who need to be dealt with by the criminal justice system while the victim is protected. Mental capacity of perpetrator, nature and severity of victimization, motivation, forethought, and malice must be determined. Abandonment, rape, and murder are examples of criminal activity by those who have assumed responsibility for the care of a dependent elderly.

Adult Children The pattern of abuse across generations, from child abuse to elder abuse, has been noted relatively infrequently whereas child abuse from generation to generation is common. In other words, parents who have been abused as children are more likely to abuse their own children than to abuse their frail elderly parents.

Spouses Spousal abuse can be a marital pattern of behavior of many years' duration preceding the disability that made one partner a caregiver of the other or that created increased dependence on each other. Unlike situations in which physical and verbal abuse arise out of stress secondary to resistance or lack of knowledge, access to, or availability of community or institutional resources, cases of long-term spousal abuse require different types of intervention. The relative frailty of the victim or the nature of the disability determines the nature of the protection required when modifications of the abuser's behavior is unlikely.

Persons With Mental Disorders Other perpetrators of abuse are those who because of their own limitations or disorders (e.g., developmental disabilities, schizophrenia, substance abuse) were previously taken care of and provided for by the now-dependent elderly parent. Physicians are in an optimal position to alert families with adult dependent children to plan well in advance for such an eventuality in late life. Situations in which role reversal is not possible need to be attended to in a timely manner.

Other Overstressed Caregivers Who Turn Into Abusers Another category of caregivers at risk for abusive behaviors are those whose behaviors have gradually become abusive or neglectful and whose elderly charge has become more and more dependent over the course of time. Community and family resources for such caregivers may be inadequate to begin with or may have become inadequate over time. Caregiver stresses may have become compounded by added responsibilities for more than one dependent person. Such a caregiver's behavior can most likely be modified with suitable interventions.

ASSESSMENT AND INTERVENTIONS

A multidisciplinary team is necessary to assess the situation when abuse, neglect, or exploitation is involved. Team members should include a geriatric psychiatrist, a geriatrician or other primary care physician who is well schooled in the problems of the elderly, a neuropsychologist, nurse, social worker, and a lawyer familiar with elder law. The team would provide medical and neuropsychiatric workups, information on community resources for caregiving, and for financial and forensic assistance. The primary task of such a team is crisis intervention. Other equally important functions are prevention, training of students and of less skilled workers, and education of the public.

Reporting to an adult protective service agency is effective if the local APS has the resources to provide protection and health care in a timely and ongoing manner. If the local protective service lacks resources, the multidisciplinary team can assume an educational and advocacy role to make sure that the reporting of abuse leads to effective intervention and follow-up. The multidisciplinary team can become a vital resource for a university, medical school, and the community. The team would evaluate the history, risk factors for abuse, medical and neuropsychiatric status, functional status, and psychosocial factors. With the backing of such a team the primary care physician need no longer feel overwhelmed by the complexity of most elder abuse, neglect, and exploitation situations that cannot be dealt with

effectively by any one health care provider.

A major problem workers in this field encounter is client rejection of and resistance to (noncompliance) the recommendations made. In order to establish a working alliance, a skilled and sensitive interviewer is needed who can include the elements outlined in Table 51.6g-4. Protocols and checklists can be of assistance to ensure comprehensive and factual information.

▶ **Assess** sensory and mobility deficits
▶ **Listen** with a nonjudgmental ear, without recoiling when atrocities are revealed
▶ **Assess** nature of physical and mental illnesses
▶ **Assess** suicidal or homicidal intent
▶ **Distinguish** realities from fantasies
▶ **Distinguish** fears from anxieties
▶ **Distinguish** denial from exaggerations
▶ **Assess** developmental disabilities
▶ **Distinguish** early-onset from late-onset mental disorders
▶ **Detect** mental stress secondary to physical abuse
▶ **Assess** perpetrator's psychopathology and other impairments
▶ **Be** culture and gender sensitive

Table 51.6g-4 Essentials for Inclusion in Assessment Interview

The psychiatrist brings to the team expertise in the diagnosis of major mental illness, in the interface between medical and psychiatric conditions, in the effects of nonpsychiatric medications on the elderly individual, and in the prescription of psychiatric medications. A psychodynamic understanding of individual, marital, and family situations can facilitate a working alliance and greatly diminish patient noncompliance.

SUGGESTED CROSS-REFERENCES

Section 51.3e discusses Alzheimer's disease and other dementing disorders, Section 51.6b discusses medical-legal issues that are relevant to the elderly, and Section 27.3 presents adult antisocial behavior and criminality. Section 28.5 deals with death, dying, and bereavement.

CHAPTER 52. HOSPITAL AND COMMUNITY PSYCHIATRY

52.1 PUBLIC PSYCHIATRY

JOHN RICHARD ELPERS, M.D.

Public psychiatry encompasses all mental health service systems that are primarily sponsored and funded by governments—federal, state, and local. It is no longer appropriate to conceptualize hospital and community services as separate treatment systems; they are integral components of the spectrum of services essential to any public mental health treatment system. Services may be provided directly by civil servants or contracted by government to either nonprofit or for-profit agencies. The essential feature is that the clientele are the responsibility of government because they do not have the means to provide for their own care.

HISTORY

The history of public psychiatry is the history of psychiatry until the beginning of the twentieth century. Before then there was no private psychiatry except for some small institutions practicing *moral treatment*, a philosophical movement that held that with humane care and close patient-staff interaction, patients could be restored to function. Moral treatment followed the reformations of Philippe Pinel, William Tuke, and Benjamin Rush at the beginning of the nineteenth century. While these small institutions were quite successful, many people with serious mental illness wandered through the towns and countryside; others were held in homes where keepers were paid for their care.

The dismal care of persons with serious mental illnesses led to a national movement in the United States to provide care and treatment for people with mental illness. The intent of the movement, led by Dorothea Dix (1802–1877), was to establish asylums for the insane. Congress passed a bill giving the federal government this responsibility; however, President Franklin Pierce vetoed that legislation in 1854. Thereafter, Dix and her followers convinced all of the existing states to establish such asylums, which marked the beginning of the state hospital systems and the tradition of state responsibility for persons with serious mental illness.

The cause of humane treatment was forgotten as the Civil War absorbed the nation's resources and energy. After the Civil War, apathy and therapeutic nihilism again prevailed. The insane asylums expanded as demand for their services increased. Unfortunately, staffing lagged far behind the patient population, and over the next 80 years, these once-promising facilities evolved into terrible custodial institutions, not unlike those that had been dismantled at the beginning of the nineteenth century.

Modern Public Psychiatry At the beginning of the twentieth century, psychodynamic psychiatry, catalyzed by Sigmund Freud and his many followers, again stirred hope that mental illness might be cured or prevented. The private practice of psychodynamic psychiatry sprang from this belief system and the child guidance movement based on the principle that early intervention in childhood prevents mental illness in the adult. While that movement never accomplished its prevention goals, it nevertheless stimulated interest in more ambitious efforts to apply psychodynamic and public health theories to a broad spectrum of mental illnesses.

Two other movements were taking place at that time, one professional and one lay. The emphasis on treatability and the successes of some progressive institutions again fed a sense of optimism and the idea that people could be treated outside institutions. By 1909, Adolph Meyer (1866–1950) proposed a visionary comprehensive community mental health approach that included geographically congruent service boundaries for human service agencies that serve similar populations; cooperation between psychiatrists, police, teachers, and social workers; and community programs of prevention and rehabilitation. Meyer, a major proponent of drawing the family physician into the care of people with mental illnesses, had many followers and became an acknowledged leader of American psychiatry. His ideas permeate much of the subsequent community mental health movement in America.

In 1905 Clifford W. Beers, a former mental patient, wrote *A Mind that Found Itself*, which exposed the awful conditions in mental hospitals. After its publication, Beers developed a coalition of lay and professional leaders and founded a new movement to improve the care of persons with mental illness. This movement was compatible with other reformist philosophies of the time and led first to the formation of the Connecticut Committee for Mental Hygiene in 1908 and subsequently to the formation of the National Committee for Mental Hygiene which became the National Mental Health Association, an organization that continues to be a leader in the fight for better care for people with mental illnesses.

Social Psychiatry Social psychiatry has been an effort to integrate the knowledge accumulated in clinical psychiatry with that of sociology. The diverse theoretical base of social psychiatry ranges from the interpersonal theories of Harry Stack Sullivan to Talcott Parsons' concept of social roles. Persons considering themselves social psychiatrists use theories and methods of the social scientists as well as clinical knowledge, leading to interests in family and extended family groups, group dynamics, dynamics of the workplace, a wide array of social support systems, and cross-cultural issues. The speculations of social psychiatry have contributed a great deal to the development of the community aspects of public psychiatry, leading psychiatry to address such areas as poverty, racial prejudice, war, and mass migrations. Unfortunately, social psychiatry's efforts were swallowed up by the magnitude of the problems addressed, with little or no impact; therefore, one cannot ascertain the correctness of the theories behind the interventions.

Role of the Federal Government Leaders of American psychiatry involved themselves early in the care of military personnel in World War II. A great deal was learned from mistakes in handling psychiatric casualties during World War I, which left many chronically ill veterans suffering from posttraumatic stress disorders. The treatment of acute stress reactions with sedation and support of the soldiers at the forward aid station and rapid restoration to their fighting units proved highly successful. After the war, this success further fueled the belief that mental illness could be successfully addressed. The National Institute of Mental Health (NIMH) was established in 1948, and the Joint Commission for Mental Illness and Health was convened by President Dwight D. Eisenhower in 1955.

The joint commission proved to be a major turning point in the interest and understanding of mental illness. It involved a tremendous number of persons from a wide array of interest groups and gathered many volumes of data. Its most significant findings and recommendations were condensed into a compact book, *Action for Mental Health*, which quickly became an important, widely read document when published in 1961, early in President John F. Kennedy's administration.

The NIMH leaders became the primary shapers of the federal response to the report of the joint commission. The major early decision was to develop an entirely new system of care rather than attempting reform of the existing state institutions. The belief at that time was that the available federal resources would be only a small fraction of the states' current expenditures in state hospitals; thus, if federal resources were to go to improve state hospitals, they would have little impact on the overall treatment of mental illness. The federal government was primarily interested in prevention, early intervention, and treatment of illnesses before they became chronic, not in assuming the cost of the states' care of those already institutionalized. The rationale was that institutions would disappear as chronic mental illnesses were eliminated. Unfortunately, that theory proved to be incorrect; once again the the lack of commitment of money doomed persons with serious mental illness to continuing suffering.

Community Mental Health Centers In January 1963, President Kennedy's message to Congress on mental health and retardation bore only slight resemblance to the recommendations of the joint commission after the input of the NIMH, but it formed the basis of the federal community mental health centers legislation that ensued. In October 1963, legislation to begin the construction of community mental health centers (Public Law 88-164) was signed into law, and in 1965, the construction act was extended and staffing grants were authorized (Public Law 89-105).

Local community governmental or nonprofit agencies were to be given grants to construct and operate community mental health centers. Technically, state governments were eligible and involved in the planning, but this involvement was more technicality than fact, and grants were directly negotiated between the

recipient agency and the NIMH. Centers had to ensure that a specified essential range of services would be provided—inpatient, outpatient, partial hospitalization, emergency services, and community consultation and education to a defined catchment area of 75,000 to 200,000 people. Constructed facilities were required to provide the essential services for 20 years and continue to be used for some type of public mental health services for 50 years. A multidisciplinary staffing pattern was required and links to welfare workers, clergy, family agencies, schools, and other human service agencies were to be maintained. After 1965, in addition to the essential services listed above, a long list of optional and supplementary services became eligible for staffing grants. Initially these staffing grants started at 80 percent of the projected budget and declined over 5 years to zero. Amendments to the original legislation allowed higher funding ratios for poverty areas and longer periods of support. In 1975 major revisions (PL 94-63) expanded the original five essential services to twelve, adding services for children and aged persons, alcoholism and drug abuse services, screening prior to state hospital admission, follow-up care for patients discharged from institutions, and transitional housing. Other requirements included a community governing board, quality assurance and utilization review, a relationship with any health maintenance organizations serving the catchment area, and services under Medicare and Medicaid. As grants declined and centers incurred financial difficulties, grants were made available for "distress," special programs, and new populations. Thus many programs received federal financial support far longer than 5 years.

By 1981, at the zenith of federal interest in mental health services, there were 758 community mental health centers serving catchment areas comprising over 52 percent of the country's population. At that time, President Carter's even more ambitious Mental Health Systems Act became effective. However, that act was short-lived; it was repealed in the early days of the Ronald Reagan administration in favor of block grants to the states to diminish the federal investment. Those block grants gradually decreased in relative size and importance.

The intent of the declining staffing grant was to help a community mental health center become established, develop local support, acquire multiple revenue sources—especially Medicaid and other third-party payments—and become ingrained into the local fabric of services to ensure its continued functioning after federal funds were withdrawn. This strategy seemed reasonable, since the per capita mental health services expenditures of the NIMH never exceeded 10 percent of the states' expenditures for public mental health services. Unfortunately, the strategy was largely a failure. While many formerly federally funded community mental health centers continue to exist, many operate as private agencies and have little or no influence on the availability of services to people with serious mental illness. Those centers that treat serious mental illness depend heavily on state government support and are either directly operated by or under contract to state mental health systems. The original vision of free-standing agencies that would treat all of the community's mental health problems and eliminate the need for state hospital care was not realized.

Serious mental disorders were neither preventable nor curable by early intervention. Detaching the new system from state mental health systems allowed many centers to avoid handling serious mental illness in favor of treating the "worried well." Much of the third-party money for the treatment of mental illness declined drastically in the late 1970s and 1980s. Medicaid, the federal-state health care financing system for persons in any of the federal financial aid categories, eroded through both fee and service restrictions. This was to have been the major source of revenue to allow the centers to serve people seriously disabled by mental illness. Simultaneously, private insurance coverage for mental illness was restricted as costs escalated. Limits were imposed on both treatment modalities and duration. In addition, the numbers of employees covered for mental health care through their employers' group plans declined. Thus, centers lost much of the revenue that had paid for care of the poor and the middle class.

Deinstitutionalization The community mental health movement was and is far greater than the federal community mental health center effort. Before 1963 a number of states had begun to adopt the philosophy of treating mentally ill persons outside of institutions. Many community mental health programs were established at the local level with state subsidies. Creative ways were found to allow people to use the available Aid to the Totally Disabled (ATD) program to support themselves in the community. Enactment of the Supplemental Security Income (SSI) legislation in 1972 provided more funds for community living, and the movement of seriously ill persons out of institutions accelerated. The reduction in state hospital populations preceded the availability of psychotropic medications; however, the availability of neuroleptic and antidepressant drugs expedited this depopulation of the state hospitals. The neuroleptic medications often were not taken after discharge because of their adverse effects; yet hospital administrators were reassured that their patients would behave well in the community. Eventually the success or failure of state community mental health programs came to be judged by their impact on state hospital populations. Deinstitutionalization superseded providing better services to people with mental illnesses.

Deinstitutionalization was more a civil rights goal than a psychiatric treatment goal. The 1960s were a time when American social systems were in great flux with strong momentum toward freedom, individual rights, and removal of governmental restrictions. These trends were best exemplified in the civil rights movement, the demands for sexual freedom, the rebellion of youth against the older social norms, and major riots caused by racial and economic inequalities. Even before the move to deinstitutionalize mentally ill patients, a major depopulation of the prison systems resulted from shorter sentencing, early release, and an emphasis on rehabilitation rather than punishment. Thus, philosophic trends regarding the care and treatment of the mentally ill continued to follow the social trends in the larger society.

The states' motivation to move patients to the community was not always altruistic. State hospitals required major expenditures. The opportunity to reduce hospital size and budgets by shifting some of the costs of caring for people to the federal subsidy programs was quite attractive. This shift of responsibility was abetted by mental health professionals who underestimated the cost of their new community programs to state legislatures and governors.

The apathy of patients in institutions was attributed to the institutionalization itself. With active rehabilitation, some of those removed from the institutions did become less apathetic. However, when left alone, their apathy returned. Similarly, as the availability of institutional care declined and more persons with severe mental disorders were treated in short-term hospitals and outpatient settings, many of them showed similar apathy. The apathy attributed to institutional care was instead a product of the illness itself—the passive, or negative, symptoms of schizophrenia.

TRANSINSTITUTIONALIZATION Making deinstitutionalization an end in itself was unfortunate. Although many long-term patients in state hospitals had been in those institutions far too long with little or no effort to rehabilitate them, shifting them to the community did not necessarily improve their fate. Their apathy made them easy to place in boarding facilities (or nursing homes if more care was required). However, no evidence shows that these patients were happier after placement than they were in the state institutions.

The shift of chronically and seriously ill patients out of state hospitals, although variable, has drastically reduced the populations of those hospitals since the peak levels of the late 1950s. By 1998 California, an extreme example, reduced its noncriminal, mentally ill, state hospital population to less than 3 percent of its 1957 level of 35,000 patients. Nationwide the state psychiatric hospital population decreased from 560,000 in 1955 to fewer than 88,000 public state and county beds in 1993. Unfortunately, many patients were merely shifted from state hospitals to other settings, most frequently nursing homes—an estimated 750,000 people—and board-and-care facilities. The real advantage of these community facilities was frequently fiscal. They were cheaper for state governments. Initially, the new institutions were often smaller and better than the state hospitals, but this is no longer the case. Care at many state hospitals improved as their staff-to-patient ratios improved, and there is less selectivity in the community facilities recruited with increased demand. Patient populations are more widely dispersed, and their care is more difficult to monitor than in the past.

Initially, as populations in state hospitals decreased, community hospital care increased. General hospital psychiatric beds rose from 7,000 to over 53,000 in 1990. Private, free-standing psychiatric hospitals peaked at 79,000 beds, and the Veterans Administration hospitals provided over 26,000 beds in 1988. The impact of limitations of insurance coverage, utilization review and control, and managed care has decreased the number of free-standing psychiatric hospital beds rapidly since that time; in 1993 there were approximately 43,000 beds. The differences between the severity of illness of patients treated in public and those treated in private institutions are far lower today because all hospitalized patients must demonstrate symptoms too severe to be treated in a less-intensive care setting. The availability of inpatient mental health services will be further complicated as the welfare reforms passed by Congress in 1996 are implemented by the states, modifying who is eligible for Medicaid.

The reduced utilization of hospitals has encouraged a more innovative range of alternative services. These range from good residential care settings to a wide array of outpatient services emphasizing case management, aggressive outreach, treatment of concurrent substance abuse, and a wide array of psychosocial rehabilitation services for persons with serious, persistent mental illnesses. Unfortunately, many jurisdictions cannot afford to provide a comprehensive, competent system of care; thus persons with serious illnesses become homeless or live in inappropriate settings, causing major annoyance to the community and their relatives and friends. These individuals would have been kept in state institutions in the past.

EVALUATION Deinstitutionalization as implemented seems to have been a failure. However, the concept of community care in preference to remote institutional care was not tested. The ability of state governments to reduce or shift the cost of treatment was tested and was quite successful. In spite of innovative treatment programs and new medications, many persons with mental illness now have far fewer treatment options because funds are not available. This lack of treatment coupled with the nationwide shortage of low-income housing leaves persons with severe mental illnesses in desperate straits, with few support systems. That unfortunate outcome illustrates the danger of undertaking a massive change in treatment policy without fully understanding the costs, the benefits, or the moral commitment of society to

the treatment of people with mental illness.

Mental health professionals share the responsibility for the plight of deinstitutionalized mentally ill persons. Many argued, without hard data, that they could treat seriously mentally ill people less expensively in the community than in state institutions. They assumed that through early intervention and judicial selection of the least-expensive alternatives they could perform as promised. Neither their performance nor the available funds measured up to expectations. States did save large sums of money. The people with mental illness remain in the community. Unfortunately many congregate in large numbers in our urban centers and in lesser numbers throughout the country, frequently lacking adequate services. Treatment is available in many parts of the country only when dangerous or disruptive behavior causes patients to be brought to emergency rooms and jails. Patients not on the streets may live in hovels with little hope of rehabilitation, alienated from families, and without support systems. At the end of the twentieth century, the conditions that led reformers to demand acceptable asylums for persons with mental illness at the beginning of the nineteenth century are seen again. The society at large is again turning to restrictive institutions to solve its problems. We have come full circle.

BASIC CONCEPTS

Responsibility Fixed responsibility for the mental health care of a specific individual or group of individuals is basic to public psychiatry. This responsibility must be for the individual, regardless of where the person is at any given time—in a treatment facility or in the community. Preferably that responsibility is assigned before a person's mental illness is detected, so a source of care can be designated at the earliest sign of illness. Thus patients would become the responsibility of a given physician because of their employment status, membership in a particular health insurance plan, or a contractual relationship with a particular provider group in this age of managed care. The payment for services might be wholly or partially guaranteed by membership in an age or disability category (e.g., Medicare or Medicaid), but there must still be a mechanism to ensure the availability of care.

Fixing responsibility for care of persons with severe mental illness is essential but difficult. They frequently leave hospitals, nursing homes, and residential facilities, either because their condition improves or because it deteriorates. Many cannot hold jobs long enough to enroll in health plans, and when they can, the managed care plans usually provide limited medical services without the essential psychosocial supports. Without these supports persons with severe mental illnesses frequently cannot avail themselves of medical care and are often excluded from managed care plans.

When the responsibility for care is not otherwise assigned, governmental jurisdictions tend to assign it geographically. The individual does not select the responsible person or agency; when someone first comes to the public mental health agency, it is already clear who must assume the responsibility for that patient. This fixed responsibility is intended to eliminate shunting away less desirable—meaning more difficult—patients or selecting only patients considered amenable to a particular type of treatment (e.g., psychotherapy).

A mental health agency with responsibility for the population of a defined geographical area must have a way to learn about that population. There should be an assessment of how its limited resources should be deployed to best meet the needs of the population served. This process, called *needs assessment*, can be accomplished directly by sampling treated and untreated populations in the area, gathering the opinions of knowledgeable persons about the area's needs, or inferring from what is known about similar populations. The complexity, cost, and specificity of the assessment will depend upon the approach or approaches chosen.

Community Participation Since the public mental health provider is carrying out some governmental functions, its legitimacy in the community must be established. This problem is generally addressed through the principle of *community participation*, that is, the community served must have a voice in the governance of the program, regardless of who is paying the bill. Defining and obtaining community participation is complex. Usually the elected political leaders of the community are expected to play a major role. They may be a public agency's governing board, appoint some or all of the agency's governing board, or serve in advisory capacities. They extend their authority over private agencies or individuals through contracts.

Indigenous leaders outside the political power structure form an important power structure in every community. These may be business leaders, leaders of the arts, civic crusaders, and, perhaps most importantly, leaders of the community's racial and ethnic groups. These leaders must all participate actively in defining the agency's mandate and approach to providing services.

Service systems need to have a process to develop a plan to serve their respective populations. The plan should evolve from the needs assessment, and if there is adequate community participation in its development, it will have wide public support as the best that can be done with available resources. Planning requires knowledgeable staff, but the plan itself depends on the broad range of inputs from the needs assessors, community participants, knowledgeable professionals, consultants expert in areas in which staff are not, and persons expert in organization, budgets, and management. Patients and their families are essential participants because they have unique knowledge of the needs of persons with mental illness. The process of developing the plan is frequently more important than the product. A successful process draws the diverse elements of the agency and its constituency together into a cooperative, functional relation that will allow efficient future problem solving. A wonderful plan developed without an effective process will not work.

A key element in bringing together the plan and ensuring a satisfying process is educating all participants in the art of the possible. The more the lay leadership knows about the restraints on the treatment system—legislative mandates, regulations, facilities, license requirements, existing contracts, budgets, and staff availability—the more helpful they can be in the planning process and the more realistic will be the final product. Mental health professionals must be willing to learn the values, customs, and expectations of the community. They often find that they know far less than they thought.

Outreach Outreach includes all the mechanisms that might be used to ensure that persons who need services know about their availability and priorities. The mechanisms range from listings in the Yellow Pages and community service advertising to cruising the streets enticing homeless persons with mental illness into treatment by offering them food, clothing, and shelter. In this process the community leadership enlisted in the participation and planning efforts can be valuable help. The outreach processes must reflect the service priorities established in the plan.

Outreach sometimes means that the agency must engage in more assertive social action. In the early days of the community mental health movement, social action was seen as a mechanism to change the negative forces of society and thus prevent mental illness. That objective is seldom raised today; instead, social action today is usually undertaken to improve the chances that people will receive necessary treatment. Reducing stigma is one form of social action. The effort to both eliminate the demeaning slurs and empathically present the plight of the patients and their families in the media can do a great deal to eliminate stigma. This allows patients to seek treatment and makes treatment programs more available. Social action may mean joining with other concerned parties to advocate better low-cost housing so people with mental illness will have a chance at decent shelter or better insurance coverage to allow more services. The social actions of a mental health agency should be judged by the impact the desired change will have on the lives of the people it serves.

System Balance Modern public mental health systems, especially in urban areas, tend to be complex. Every phase of a patient's illness requires a different type or intensity of service. If a service component is not available when the patient needs it, the patient must either be placed in a less appropriate treatment setting or have treatment delayed until the needed program is available. For a system to be balanced, each component of the treatment system must exist in balance with all other components. Bringing about this balance is extremely difficult because mental health professionals and lay persons tend to invest themselves in specific components of the system, fighting to develop their favorite component at the expense of others. When mentally ill persons are on the streets and emergency rooms are full, unsophisticated persons would solve the problem by simply acquiring more beds. When this is attempted, however, the new beds fill rapidly with long-stay patients if the needed community resources are not available to allow them to be discharged from those hospital beds. Thus, this most expensive element of the system again backs up, emergency rooms again become overcrowded, the initial problem has not been rectified, and resources that could have enhanced the community services have been absorbed by the bed costs. Had the system invested in fewer beds, more community placements, and extensive community support systems, the problem would have improved without the costly bottleneck.

To ensure a balanced treatment system, a central management must have authority over the entire integrated system and must have the ability to see that an appropriate plan is implemented to correct imbalances. Trust and respect for the central management are essential if such a complex system is to function as an integrated whole. When resources are limited, system elements tend to declare war on each other, severely taxing the skills of the integrating authority. When funding systems are tied to service components rather than to patient needs (as occurs in most noncapitated systems), fundable services tend to be available regardless of need while those not readily funded are in short supply. Many programs are severely distorted by what the federal Medicaid program does or does not support.

Continuity of Care In the ideal, continuity of care means that patients have the same therapists or caregivers throughout their illness. Thus the staff person who initiates treatment in the emergency room should follow the patient, whether hospitalized, returned home, or placed in an alternative setting. A small system may allow the staff this scheduling flexibility to permit staff to work with their patients wherever they might be. In the real world such continuity of care is rarely available,

regardless of how important it is for persons with serious mental illnesses. In the name of staff efficiency or convenience, service systems tend to become compartmentalized. Staff members are assigned to program units not to patients, an antiquated model difficult to eliminate. A positive aspect of some managed care plans is their insistence on continuity of care; they will not contract for services unless psychiatrists are available to follow their patients as both inpatients and outpatients.

Many paper transfer mechanisms are used to compensate for the lack of continuity of care in compartmentalized service systems. A great many use charts, forms, and documents. Some systems have charts that go with the patient even if the staff do not. Admission and referral forms are used to let newly assigned staff know what the patient has undergone previously. Similarly, discharge summaries and aftercare plans are designed to follow the patient from the hospital back to the community. In many settings computer networks are beginning to help transfer information about patients as they traverse the system. Telephone conversations and face-to-face discussions are very important adjuvants to the paper transfer of information. Unfortunately all of these mechanisms help the staff feel better but do little to reassure the patients.

Legal requirements for confidentiality can be major impediments to continuity of care when the same therapist is not responsible throughout all phases of a patient's illness. A patient's refusal to sign a release of information form when parts of the system are different agencies can be a powerful disincentive to continuity of care. However, confidentiality requirements can be an excuse for not doing all in the professional's power to ensure that essential information is transmitted. Although public stigma and the secrecy of psychotherapy motivate patients to be concerned about their confidentiality, staff members should help them see the greater good in information transfer. With the shift toward more biological treatment of serious mental illness and away from probing the unconscious, such concerns about confidentiality lose relevance.

Case management constitutes a more human effort to maintain continuity of care. Here a new class of providers is used to follow the patient throughout treatment. Their role is a mixture of advocacy, system management, patient support, and sometimes therapy. If the elements of the mental health system are not available or do not cooperate, the role of case manager can be frustrating. To be effective, case managers must have small case loads and wide latitude to meet the patient's needs. When these objectives are met, it is hard to distinguish the case manager from the primary therapist for the person with serious mental illness. Merging the roles of case managers and primary therapists to eliminate unnecessary redundancy may accomplish the original goal of continuity of care—the patient has the same primary therapist throughout the duration treatment. The case manager described here is not to be confused with the case managers working for managed care companies who have minimal patient contact and are better described as cost managers.

Least Restrictive Alternatives The well-accepted concept of *least restrictive alternatives* means that mentally ill persons should be treated in settings that least interfere with their civil rights and freedom to participate in society. Patients should not be hospitalized (especially against their will in locked facilities) if their illness can be treated in a more open setting. Most states now have legislation protecting the rights of patients, and treatment in the least restrictive setting is usually one of those rights.

How far the concept of least restrictive care should be carried remains controversial. Patient rights advocates argue that this is the overriding principle, even if the therapeutic potential of the least restrictive facility is seriously compromised. Clinicians argue that therapeutic efficacy is the greatest concern and that the least restrictive principle can be compromised in the interest of better treatment. One must consider carefully whether any restriction on a patient is for the convenience of the psychiatrist and staff or for the protection of the patient.

Rehabilitation Interest in rehabilitation is enjoying major resurgence in public mental health programs for two reasons. First, deinstitutionalization placed many more persons with serious mental illness in the community under the care of public mental health systems. Without continuous attention to their psychosocial rehabilitation these individuals deteriorate over time and cost the mental health programs great sums of money. Second, the new generation of neuroleptics alleviates the negative aspects of schizophrenia and facilitates rehabilitation. Unfortunately few psychiatrists are available to lead psychosocial rehabilitation efforts. Most of the traditional mental health training programs offer little, if any, training in the techniques of rehabilitation. Disease or illness paradigms used in medical and psychiatric training do not encourage interest in or pursuit of rehabilitation. When one focuses on finding and identifying symptoms and syndromes, one does not concurrently learn to see the patient's strengths or potential. The professions closely allied to psychiatry and medicine have generally adopted views of the patient similar to those of psychiatry. A second problem is that the vast majority of those professionals interested in rehabilitation—in medicine as well other disciplines—are interested in physical rehabilitation and have little knowledge of the needs of persons with mental illness. Not being trained in managing the emotional problems of persons with serious mental illnesses, they have little tolerance for their idiosyncrasies. Similar behaviors in persons not labeled as mentally ill are often better tolerated. Finally, it is very difficult for professionals to agree on the goals of rehabilitation and unfortunately they are reluctant to consult the patients.

Psychosocial rehabilitation goals can range from complete restoration of functioning to limited improvement in the patient's ability to handle self-care. Before rehabilitation can begin, such basics as food, clothing, and shelter must be available to the patient. Thereafter each patient's needs must be individually ascertained. Work is an extremely important component of any individual's sense of self-worth and participation in society. Professionals often underestimate a person's ability to work, seeing symptoms rather than specific functional capacities. That realization has evoked increased interest in work-oriented rehabilitation in recent years, with good results. Many persons with mental illness require continuous rather than short-term efforts to achieve and maintain improved functioning. Some professionals find this frustrating. The concept that once attained, improved functional abilities may erode if continuing professional attention is not available is incompatible with traditional medicine's desire for a cure. In reality, this situation does not differ from that in many other chronic medical conditions, and the outcome is frequently far better.

SYSTEM COMPONENTS

Prevention Mental health programs have traditionally used the public health nomenclature of primary, secondary, and tertiary prevention. However, when applied to mental illnesses, this system has problems.

Primary Prevention *Primary prevention*—avoiding the occurrence of an illness—is elusive in psychiatry. In the past a lot of social engineering was tried in the name of preventing mental illnesses, but there is no evidence that it was successful and so it is now out of favor. The social breakdown syndrome was to be prevented through deinstitutionalization; however, the loss of social skills in persons who have never been in long-term institutions is now considered to be a component of the primary mental illness. Currently, some professionals believe that behaviors such as child abuse are learned in childhood and can be prevented through reeducation; this theory remains unproved. As human genetics becomes better understood, genetic counseling may become much more relevant. Presently it is important in such disorders as Huntington's disease and of some value in advising prospective parents with a strong family history of schizophrenia or other major mental illnesses. Primary prevention of the mental disorders that psychiatry struggles with today awaits better delineation of their causes.

The primary prevention of disorders that used to fill mental hospitals is being practiced every day. Tertiary syphilis is prevented by treatment of the primary infection. Many organic brain disorders are now prevented by making proper vitamins available in foods, especially for high-risk persons, such as those with alcoholism. Serious mental and emotional damage can be prevented in many children by eliminating the use of cocaine and other drugs during pregnancy. Education about acquired immune deficiency syndrome (AIDS) can prevent both the physical and psychiatric aspects of this disease. When primary prevention works, the illnesses are soon forgotten or the responsibility for their prevention is no longer the purview of psychiatry.

Secondary Prevention *Secondary prevention* is the early detection and prompt treatment of a disorder to avoid or reduce permanent damage. In psychiatry this is a major responsibility of children's services. The current best model to accomplish effective secondary prevention is the federal Children's Mental Health Services Initiative and its many permutations in the states. These systems attempt early identification of emotionally disturbed children and carefully target wraparound services to meet a broad spectrum of needs and mitigate their illnesses. This is done through the careful coordination of the work of agencies most likely to come into contact with high-risk children. Once children with various behavioral disorders are identified, these multiagency systems of care bring all of their resources to bear on the needs of the child and family. The effort is to reinforce the family and create the best possible environment to mitigate further deterioration in the child's emotional state. Family structures are preserved, and out-of-home placements are avoided to allow more-normal social development. A large percentage of children with behavioral disorders of childhood demonstrate major mental illnesses as adults. Whether these early interventions will prevent continuing disability or deterioration as the child matures is not yet known.

On a broader scale, secondary prevention is embodied in the work of most psychiatrists and other mental health professionals. All try to initiate treatment and alleviate suffering at the earliest possible moment. Crisis intervention theories and services are important attempts at secondary prevention. Efforts to educate the public and reduce stigma to allow persons to seek treatment earlier is also secondary prevention.

Tertiary Prevention *Tertiary prevention*—reducing the functional impairments caused by disease in persons in the population—in its broadest sense encompasses all forms of treatment of persistent mental illnesses. In its more restrictive and useful sense, tertiary prevention is interpreted to mean reducing the residual defects left after the disease itself has been addressed. In this case the primary thrust of tertiary prevention is rehabilitation. Because most serious mental illnesses follow a long and relapsing course, it is not appropriate to delay rehabilitation until treatment is complete. Consequently secondary and tertiary prevention are often concurrent processes in psychiatry. Indeed, it is often difficult to ascertain how much of the patient's apathy and anhedonia is a symptom of the active disease and how much is residual.

Tertiary prevention or rehabilitation in psychiatry nearly always addresses patients suffering from the most severe and debilitating illnesses—schizophrenia, the most severe affective disorders, and the most disabling personality disorders. All of these illnesses, especially schizophrenia, tend to strike in late adolescence and young adulthood. These individuals are effectively removed from society during those years when most people complete their education, learn trades, establish careers, begin families, and develop social support systems in the community. Consequently, even if the illness were completely cured without any residual functional deficits, these people would still need extensive social rehabilitation. Unfortunately the illness leaves residuals in many cases. These people can have a wide range of psychological deficits that impair their ability to interact with others, handle the usual stresses of daily life, and achieve their potential. Therefore, psychiatric rehabilitation involves a complex process in which the professional attempts to address the psychological, social, and often the medical needs of the patient simultaneously. Obviously, the better the patient's functioning in society can be maintained during the acute exacerbations of illness, the less psychosocial rehabilitation will be necessary. This is why modern public psychiatry attempts to limit the lengths of hospitalizations by rapid interventions and to maintain social support systems even when patients are acutely ill.

Institute of Medicine Prevention Model Because many people find the primary, secondary, tertiary prevention terminology confusing, a new definition of prevention, recommended by the Institute of Medicine's Committee on Prevention of Mental Disorders, is gaining acceptance. Under this system, the term “prevention” would be used only for interventions that occur before the onset of a disorder. Secondary and tertiary prevention would be dropped in favor of the more accepted terms *“treatment”* and *“rehabilitation.’* That system further breaks down prevention into three categories. Universal interventions are targeted to the general public, independent of risk factors. Selective interventions are targeted to individuals or groups thought to have a higher-than-average risk of developing mental illnesses. Indicated interventions are targeted to high-risk individuals with biological markers or early signs of illness who do not yet meet the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) diagnostic criteria.

Crisis and Emergency Services Crisis and emergency services are mechanisms through which patients in need reach the system. In some programs these are the same service, in others they are separate operations. Emergency services are generally the entry point for patients with psychobiological problems who need hospitalization or a similar level of short-term care. Crisis services are for people whose difficulties are psychosocial and require immediate intervention but not hospitalization. The difficulty with this differentiation is the inability of patients to determine which service they need. Those persons and agencies in the community commonly referred to as *gatekeepers* (meaning police, social agencies, families, and others having first contact with individuals in trouble) also have difficulty differentiating an emergency from a crisis. Therefore a public mental health system that separates its emergency and crisis services must educate both the public and the gatekeepers about who should be referred where and provide for rapid transfer of inappropriate referrals to the other entry point. One alternative is to have a single entry point that provides both emergency and crisis services. Another is to have mobile crisis-emergency teams that screen people in the community, determine which services are necessary, and institute the appropriate responses. Mobile teams are most effective when they function integrally with local police agencies.

Crisis services are designed to help someone decompensating under acute psychological stress to reintegrate rapidly, marshal any available environmental resources, and return to function in the community as soon as possible, usually in hours to a few days. To accomplish that task experts in crisis intervention, short-term psychotherapy, psychotropic medications, family intervention, and community resources must be readily available.

Emergency services on the other hand are intended to serve patients decompensating in the course of a major mental illness deemed likely to require hospitalization or a similar intervention. Emergency services should be able to admit patients to the hospital or other appropriate facility without having the patient undergo further screening; otherwise there are intolerable backups of patients in the emergency setting. Both crisis and emergency services must make rapid but accurate diagnoses, rule out medical conditions that might be wholly or partially responsible for the patient's psychiatric symptoms, obtain the necessary laboratory and X-ray studies, and initiate treatment. To ensure the availability of medical care when possible organic causes are suspected, emergency and crisis services are best located in or near a general hospital with a good emergency room. A close working relationship between the psychiatric and medical emergency rooms is essential.

Well-functioning emergency-crisis programs greatly improve the effectiveness and efficiency of the overall system. By limiting access they avoid wasting resources on persons who do not need or cannot benefit from mental health services. When services are in short supply, as they tend to be in many jurisdictions, these programs play an essential rationing function. By assigning patients to the most effective, least restrictive, and least expensive service available, they ensure efficient use of available services, which is helpful to both the patient and the system.

Short-Term Hospital Services After the emergency service, the person in need of intensive treatment is usually admitted to an acute inpatient service in a general or free-standing psychiatric hospital. Licensing definitions and names may vary from state to state, but these services are expected to be well staffed with a full diagnostic and treatment armamentarium. Average stays are usually short, 1 or 2 weeks. After careful diagnosis, the patient's treatment in the acute hospital should be intense and involve psychotropic medications, education about the illness, group and individual psychotherapy, and activity therapies as appropriate. Work with family members and early discharge planning are critical. True continuity of care in an integrated service system will shorten the hospital stay by allowing continued development of the professional relationships, education, and treatment plan after the patient leaves the hospital. Patients clearly benefit from more rapid return to home, community, and jobs if the proper support systems are in place.

Long-Term Services Persons with severe, persistent mental illnesses have continuing service needs. These needs can be broken down into several components: treatment, housing, rehabilitation, social support, and financial support. While these components are discussed separately, they should be provided as parts of an integrated service plan with a single treatment team.

Treatment Patients with severe, persistent illnesses should have a number of alternatives available in a well-functioning public mental health system. Patients who can live in the community but would benefit from intensive treatment should have a full array of services available as intense or more intense than those in the hospital. Included are education about their illness and the effects, adverse effects, risks, and benefits of psychotropic medications; psychotherapy, especially of a supportive nature; group therapy; social activities; and assistance with housing, income maintenance, and transportation. This array of services can be organized into a day hospitalization program, which can be quite effective if it is truly intensive. However, today it is considered more efficient to have these services as front-end components of an integrated psychosocial rehabilitation system.

Patients who cannot live in the community because they remain dangers to themselves or others or who are gravely disabled but no longer need or can tolerate intensive treatment are cared for in state hospitals, skilled nursing facilities with psychiatric treatment staff available, and a variety of residential treatment programs. These programs must be individually assessed in any public mental health system because they vary greatly in intensity and quality of treatment and environment. With the advent of the newer neuroleptics and the success of psychosocial rehabilitation programs it is a mistake to assume that any patients must spend long periods of their lives in these long-term care institutions.

Some long-term programs—both residential and outpatient—are designed to address special problems of persons with serious mental illness and coexisting drug and alcohol dependence. The various forms of substance abuse are major problems for many mentally ill persons; up to 40 percent of persons with severe mental illnesses have coexisting substance abuse problems. Every public mental health system must have resources to treat dual diagnosis patients, preferably integrated with their comprehensive mental health care.

The vast majority of the severely mentally ill persons treated in public mental health systems today can live in the community. However, some will never achieve that goal or will do so only after long periods of illness. These persons require long-term or custodial care, which is still the role of state hospitals in most jurisdictions. With the reduction of state hospital populations, the quality of custodial care in most state institutions has improved greatly. What used to be very oppressive back wards are now usually humane, tolerant settings for people whose illness is severe, persistent, and unresponsive to modern psychiatric care. Skilled nursing homes in the community serve a similar population, especially those with concurrent medical problems and organic mental disorders. Those community facilities are varied and must be monitored individually. Licensing standards and quality-control mechanisms vary among the states.

Housing Securing and maintaining appropriate living situations is a major problem for persons with mental illness. Treatment is impossible if adequate housing, food,

and clothing are not available. Many patients have alienated their families of origin. They are unlikely to have developed supportive relationships with mates or peers; thus they must manage on their own with little help. Their problem is compounded by both the decline in the amount of government-subsidized low-cost housing over the past 25 years and by the disappearance of single-room occupancy hotels caused by urban redevelopment. When they were cared for in institutions, housing was provided. With deinstitutionalization, SSI was supposed to cover basic living costs; however, with the rising cost of even inexpensive apartments and limited or interrupted SSI support, many people with mental illness are forced to live on the streets or in board-and-care facilities that are often dirty and noisy and provide inadequate food and services.

Multiple solutions to the housing problems must be considered. Some mentally ill persons do remain at home. This is a cheap (and therefore desirable) solution for public mental health systems, but remaining at home undermines the self-esteem of young and middle-aged adults and places undue burdens on families who have already suffered a great deal. The presence of a mentally ill son or daughter can raise emotional tensions in the best of homes. Thus other mechanisms must be sought to house people whose illness forces dependency.

A wide array of facilities throughout the country fall under the general rubric of half-way houses. These programs have one thing in common—they are designed to ease the transition from hospital to the community. Most are designed to serve specific types of patients, have unique philosophies, and place specific demands or expectations on their patients. They tend to be selective and hence unavailable to many of the most seriously ill persons. Because no universal funding mechanism covers care in half-way houses, there are not a lot of them, and many cater to people with private means of payment. When available, a well-structured half-way house can be helpful for selected patients.

A major mechanism used in most states is a licensed facility that provides room, board, and some supportive care for chronically mentally ill persons. Some are for-profit, some nonprofit; some are large, some have six or fewer beds; some are very good, some are awful. Most depend upon what SSI pays in their respective states, taking most of the monthly check and giving the patient a small amount of spending money for personal needs. Most board-and-care facilities keep and dispense medications prescribed by the patient's doctor. Some insist that patients be medicated, sometimes heavily, to control behavior. These facilities tend to have little privacy, with shared bathrooms and bedrooms. For persons who have difficulty tolerating others encroaching on their space, as do persons with mental illness, board-and-care facilities may be very unpleasant settings.

One of the peculiarities of most current public mental health systems is that the housing needs of seriously mentally ill persons are tightly linked to their treatment needs. When hospitalized, the patient loses the bed in the board-and-care because the facility is no longer being paid. In the hospital facility they must accommodate to a whole new set of peers and staff members. When the illness recedes, the patient is transferred to another, less intensive facility with another collection of strangers. If patients again improve, they must again move, deal with new people, and try once more to establish some sense of continuity. Those forced moves are designed for the convenience and economic stability of the treating staff and institutions, not for frightened people for whom developing satisfying interpersonal relationships is a problem.

It is better for people with mental illness to live in permanent, stable housing, not linked to their treatment needs, as early as possible in their rehabilitation. Thereafter, should they need services, they go out for them—rehabilitation, socialization programs, work readiness training, supported employment, and psychiatric sessions. Should they need hospitalization, their homes remain, and they can return to a familiar environment on discharge and continue existing relationships. These homes might be an apartment by themselves, apartments with roommates, or apartment buildings for the disabled built with assistance from the federal Department of Housing and Urban Development. The essential features are that persons may remain there as long as they desire, they have privacy and space of their own, they own the furniture and appointments, and they can regulate their own schedules. Many people considered quite ill do much better in such settings than when they are shunted around. They have a secure base from which they can move out and take modest risks in dealing with other people, which reduces their fright. Some patients do require education and support to maintain their own apartments, but that support is usually less than is expected.

Rehabilitation Services With the advent of the serotonin-dopamine antagonists (atypical antipsychotics) many more persons with severe illnesses have had their symptoms controlled enough to make them candidates for rehabilitation. Indeed, today one must assume that all persons with schizophrenia and major mood disorders do or will need rehabilitation services. Therefore rehabilitation is an essential component of the continuum of services necessary for persons served by the public sector.

Rehabilitation focuses on the patient's remaining capacities not the residual symptoms. It emphasizes individual responsibility and self-reliance rather than illness and dependency. Once the acute symptoms are under control, rehabilitation should begin immediately. There is no single approach to all patients. Instead, one uses whatever means are necessary to help recovering patients adapt to their specific environments. One does not help a patient develop skills for no purpose. The rehabilitation needs of patients must be individually assessed within the context of what they wish to do with their life. Patients should expect to improve, but the expectations should be compatible with their capacities.

An essential ingredient in rehabilitation is hope. Staff must believe that improvement is possible and communicate that belief to the patient. Many mental health professionals see symptoms rather than potential and underestimate the patient's capacity for rehabilitation. Usually they think of work when they think of rehabilitation. In our society, work contributes a great deal to one's identity and self-esteem and is thus important. Yet competitive, mainstream, and full employment need not always be sought. If the job stretches the client's capacities, it might be part time, noncompetitive, or even volunteer and still build self-esteem.

Rehabilitation also addresses other skills necessary for survival in the community. These skills may include tolerating others in near proximity, the ability to dress appropriately, polite social interactions, keeping appointments, preparing one's own food, and grooming. The development of any one of these skills may seem mundane, but acquisition of a few may completely change a person's life. Being able to exist in the community without being shunned or appearing bizarre is essential to rehabilitation.

Integrated Services Combining all treatment, rehabilitation, case management, and support services into one agency, so that patients have a single source for all of their needs, is now considered the most efficient way to serve persons with severe mental illnesses. Successful programs are driven by patients' needs. That means that the patients define their needs rather than the staff, although staff do assist in the process. Any treatment goal not shared by the patient is doomed to failure. An integrated service agency must also have the flexibility in the use of its resources to provide what the patient needs rather than some predetermined product. Integrated service programs care for their patients regardless of the level of service they require, ensuring continuity of staff relationships and services. They maintain close relationships with the patients' families, residential facilities, and even employers if appropriate. Employment readiness training, job-finding assistance, housing assistance, ensuring that patients receive their appropriate benefits, and social and recreational opportunities are all key elements of an integrated service program. Because these are costly programs, they are usually reserved for persons with severe illnesses. They function best if provided under a capitated funding system that allows the agency complete freedom in the use of its resources and evaluates the agency on patient outcomes.

Administration Administration is the most essential but least loved component of a public mental health system. It includes establishing the vision, goals, objectives, and implementing plans of the mental health service program, nearly always through complex interactions with a wide array of individuals and agencies with competing interests. Administration requires individuals with strong clinical backgrounds, a vision of what the service should be, strong leadership skills, and a working knowledge of such technical aspects of administration as personnel, budget, fiscal and supply operations, and information systems.

Maintaining public support for mental health services is essential because they depend on public money; thus the public must be continuously educated about mental illness and the importance of public mental health services to the general well-being of the community. Less sophisticated citizens may be concerned only with public safety and decorum, not easy items to ensure. More altruistic citizens will also expect humane care and rehabilitation. Knowledgeable persons who have friends, children, and other relatives in the system have specific demands, some of which are unique. The mental health professional community, both within and outside of the system, also has specific ideas about what the system should be doing for which patients. Reconciling these usually competing demands, especially in the face of limited resources, is a Herculean task. It demands leadership, tact, diplomacy, and the ability to conceptualize and sell an integrated, comprehensive program to a large, skeptical audience. Such skills are in short supply in any one individual, so a team effort is essential.

PSYCHIATRIST REQUIREMENTS

Training An effective psychiatrist in the public mental health system must first be competent and well trained. No area of basic training can be neglected because patients in all diagnostic categories, all age groups, and in a wide array of predicaments will be encountered in any public mental health system. The patients require sophisticated interventions ranging from somatic therapies to insight-oriented psychotherapy. A thorough knowledge of both psychopharmacology and establishing

trusting relationships with patients that allows them to accept one's medication recommendations is critical.

Persons interested in working in public systems should observe the workings of the institutions in which they are trained. How the programs function affects both the patient care provided and the training. Observing the complex interactions of the various professionals in different administrative layers can be highly educational and requires little of the trainee's time. Hospitals, where one spends a great deal of time during residency training, are microcosms of the far more complex social and administrative system one enters in public psychiatry.

Special Interests and Knowledge The most important attribute of a good public system psychiatrist is a deep empathy for and interest in persons with severe mental illness. Intellectual fascination with the complexities of schizophrenia, including research interests, is important for the public psychiatrist's dedication to that difficult population. One should also have similar interests in the major mood disorders and the most disabling personality disorders.

Public mental health systems today must handle the treatment of substance abuse, both primary illnesses and those secondary to other mental disorders, and thus require personnel (including psychiatrists) who are skilled in dealing with these problems. Substance abuse is complex and multidetermined and different patients require different types of interventions. Psychiatrists are now required to have greater sophistication regarding all types of substance abuse, regardless of their practice settings. Because many traditional substance abuse programs abhor the use of any drugs, including psychotropics, they may not be appropriate for patients with both mental illness and substance abuse problems. Thus psychiatrists in public mental health systems may be called upon to help design special programs for these dual-diagnosis patients.

Since psychosocial rehabilitation must now be an integral part of any public mental health system, psychiatrists must be knowledgeable in this area. The public psychiatrist may not be a direct participant in many of the psychosocial rehabilitation activities, but knowledge of their importance to the patient's recovery is essential. When psychiatrists do participate directly in rehabilitation programs, they invariably see patients from a new and valued perspective. Every opportunity to observe patients in real work situations should be seized. Willingness to leave the office, meet patients in their workplace, and help with mundane problems give valuable assistance to the rehabilitation process.

Family and Social Systems An effective public psychiatrist must be willing to work with the families of mentally ill persons in a caring, nonjudgmental manner. Decades of having been blamed inappropriately for the illnesses of their children cause parents to be wary of psychiatrists and other mental health professionals. Yet they are frequently the strongest support systems that patients have in the community. Seeing the deterioration in their children and siblings has caused families excruciating pain. Many have done, and will continue to do, all in their power to help the ill member of the family. At times, those efforts may seem overly intrusive and even counterproductive. Yet the psychiatrist must recognize the basic good intentions and help all members of the family cope with a difficult situation. Parents generally wish to be allies in the treatment of their children and are willing to accept advice about how best to cope with their difficult children. Blaming parents for the illness of their children is totally inappropriate.

Families are hungry for information about the diseases that affect their members. A psychiatrist must be willing to educate family groups in any way possible–speeches, individual meetings, written materials, or telephone conversations. No opportunity should be missed. Families seek information not only about the diseases, but also about community resources and current research in the field. The Alliance for the Mentally Ill, a national association of families, is a sophisticated organization that plays a vital role in the education of both families and professionals and is a strong advocacy body for persons with severe mental disorders.

A working knowledge of social systems and their effects on persons with mental illness is necessary. An understanding of how school systems deal with deviant behavior is particularly important. School systems, like all such social agencies, are variable and unique to their specific region or community. A psychiatrist must be willing to look at each system individually and ascertain how that particular system will affect young patients. As patients age, the number of social agencies with which psychiatrists interact expands exponentially. They include welfare agencies, housing authorities, landlords, police, courts, probation systems, and even transportation and urban renewal. Some public psychiatrists work with many of these agencies to change their methods of doing business to ease the interactions of all mentally ill persons. Others intercede only when their patients have difficulty interacting with the social system. In either case the public psychiatrist must know the functions of interacting community agencies and the attitudes of their personnel. Offering consultation services to social agencies in one's community is an excellent way to gain an understanding of the social services available in one's community. There is helpful literature in the area of community consultation, and experience rapidly brings confidence. Most rewarding is the fact that the consultant nearly always learns as much or more than the consultees.

A psychiatrist who wishes to be a leader of a public mental health program needs a view of social systems beyond that of specific social agencies. This view comes best from being an astute observer of social and political trends and understanding the impact these trends have on attitudes toward mental illness. For example, shifts in attitudes about the treatment of criminals are usually echoed in attitudes toward people with mental illness. Economic conditions and policies certainly affect the availability of mental health and other services essential to patients. The country continuously undergoes shifts in political philosophy; psychiatrists may not be able to affect them, but they must understand them to protect their programs and patients.

Epidemiology Epidemiology has taught us a great deal about the distribution of mental illnesses in communities; that information can be of valuable assistance in planning public mental health service systems. Epidemiological data gathered by the NIMH Epidemiologic Catchment Area studies and the National Comorbity Survey are used to determine the need for public mental health treatment resources in various populations. The interaction of those data with specific communities' particular ethnic and socioeconomic makeup is very complex. A psychiatrist familiar with the psychiatric syndromes, the screening instruments used to identify those syndromes in the population, and the effectiveness of those instruments when used in various ethnic and socioeconomic populations can be helpful in their application to a program or community.

Psychiatrists must know the communities in which they work. That knowledge can be gained through careful inspection of census and other demographic data and by spending time in its neighborhoods. With this knowledge, one can quickly determine whether projections of need made from epidemiological data are correct. The community at large or special populations are frequently surveyed to assist in the planning of local mental health services. Since these surveys are often undertaken with small budgets and limited expertise, one must appreciate both their limitations and their usefulness. A psychiatrist should understand the basics of the application (and misapplication) of statistics and questionnaires.

Leadership The knowledge and skills needed to carry out the functions defined under administration are many and varied. No discipline has a monopoly on high-level management positions; indeed, some are held by lay administrators. However, the vast majority of directors of public mental health programs are members of the major mental health professions. For any discipline, special skills are required to achieve high-level management and leadership positions. Some of these skills are best gained by additional training, some can only be acquired by experience under the tutelage of a good mentor, and others require a combination of experience and education. One can gain the necessary education without pursuing further degrees in public administration or management, but such degrees can be helpful. It is often more efficient to undertake an appropriate reading program and avail oneself of the many short courses on specific topics that are available in most communities.

Public mental health services must be collaborative efforts because of the nature and size of their treatment populations. Modern psychiatric training should take place in institutions where those in other disciplines are also being trained. Shared training experiences help the disciplines work together, but mutual respect is essential. Breadth of technical knowledge does not ensure any professional a particular role in a mental health treatment program beyond those responsibilities defined by training and licensure. Other roles must be earned. Certainly psychiatrists have a distinct advantage, since theirs is the only discipline trained in all aspects of diagnosing and treating mental illness. However, to achieve leadership, they must demonstrate their competence like anyone else. That competence must go beyond the technical areas to encompass interpersonal relations, empathy with patients, the ability to teach, and a willingness to help with whatever needs to be done.

Psychiatrists do not allow themselves to be relegated to only a psychopharmacologist role. Because of the relative cost of psychiatrists and the critical function of psychotropic medications in the treatment of severe mental illness, some systems try to use psychiatrists only for medication management. However, one cannot be a good psychopharmacologist without understanding the patient's functioning in all aspects of life. That knowledge cannot be gained in a 15-minute interview in an office. The psychiatrist must learn to use broader interactions with both patients and colleagues to determine the effects of medications and other interventions on the patients. Whether or not patients take prescribed medications is greatly affected by their relationship with the prescribing psychiatrist.

Management Skills A number of other skills required to manage public mental health systems are rarely discussed or taught. To be a successful public mental health administrator, one must understand how communities are organized, how they choose their leadership, and how the formal and informal power structures work. Clinicians who are administrators must be able to frame their programs to be acceptable to the powers that be. Without that acceptance, the finest program

conceptualizations will go for naught. One must be aware of prevailing public attitudes, where support can be found, the opinions of key community leaders, and when one is wasting time. Public speaking and salesmanship skills are helpful, and neither is learned in most psychiatric training programs.

The ability to work with and respect lay leaders is essential. One must communicate without technical jargon and respect all political philosophies. In public systems politicians change, and administrators must remain nonpartisan to provide continuity of programs in the face of changing political control. Unfortunately, some elected officials feel that all managers, like themselves, are or should be partisan. This attitude can lead to disruptive management changes when political control changes. A leader must know when to resign for the good of the program.

Technical Skills Political skills and agility may be hard to learn in a formal manner, but the skills that concern public administration and management are not. They deal with budget, personnel management, organization, control, and leadership. To manage a public mental health program one must learn both the budget process and how to read and manage the final product. The budget is where all plans for the program come to fruition or fail; planning and budgeting are inseparable. Every governmental jurisdiction has its own budgeting process, but they are in fact quite similar and are easily understood if one simply gets to know the major players and participates actively in the process. A rapidly evolving technical area that requires management attention is the use of computers and information systems. A manager must be able to use the full potential of the information system and know whether that system is state of the art.

Managers must understand and devote time and energy to personnel matters. Careful selection of the management team is essential. Top administrators must recognize their own shortcomings and choose staff that complement them. Insecure administrators tend to choose weak, nonthreatening managers. Strong administrators tend to choose the most competent managers they can find, but they must also fit the organization. The working climate must be open so that all staff can carry out their functions and speak what they believe to be the truth without fear of reprisals. Those who raise the difficult questions about the organization are most likely the strongest members of the management team; however, those who only raise questions and never offer solutions may be less than helpful.

Leadership is a critical quality but it is very difficult to define or teach. It involves both the knowledge of what needs to be done and the ability to communicate that knowledge to a wide array of people. It includes the ability to see how what happens in one part of the organization will eventually affect all other parts, so one can balance competing interests. The ability to see the big picture and act accordingly has been described as the ability to think in general systems theory. Unfortunately this ability may be inborn rather than learned.

EXTERNAL FORCES

Shifting Governmental Roles Mental health services are expensive and are not politically popular in many jurisdictions. In the United States there is a continuous effort by the federal government, the states, and local governments to pass costs to each other. This battle is clearly evident in many of the Medicaid and Medicare rules, exceptions, and distortions; welfare reform; the passing of service responsibilities with or without funds to local governments; and attempts to cut taxes at the federal level by funding fewer state and local programs. These shifts represent both danger and opportunity. Often a shift in funding sources lets one update programs by getting out from under onerous regulations and fiscal strings. On the other hand there is the grave danger of getting new responsibilities without the resources to meet these obligations.

The care of persons with mental illness is not uniform throughout the United States, and persons with chronic mental illness are a highly mobile population. They cannot expect the same or even similar services in various parts of the country. Even financial eligibility for service varies widely. Whether these factors affect patient's choices of where to live has not been determined.

Economic Forces The community's willingness to support mental health and social services is directly related to the health of the general economy. When the national economy is poor, tax revenues fall and are diverted to other projects. In those times public mental health programs are often cut back even though the demand for service increases. In many jurisdictions mental health services are soft priorities for funding, that is, the general public considers them desirable services but, because the taxpayer does not expect to use them, they will not be funded in stiff competition with other priorities. New mental health services can only be funded in good economic times.

The private sector has a major impact on the public sector. Here two issues are involved—the availability of private-sector services and the means to pay for them. The unique services (especially rehabilitative ones) needed by persons with serious mental illness are often unavailable in the private sector, and even persons with the means to pay must come to the public sector. More important is the availability of third-party coverage. The tremendous expenditures necessary to care for someone with schizophrenia are often unmanageable, even for upper-middle-class families, if they are not covered by insurance. Insurance coverage for mental health services has been one of the casualties of the rapid rise in health care costs in the United States. The stringent limits on insurance coverage for mental illness has brought about the current demand for parity of coverage with that for illnesses of other body systems. While some small moves toward parity were made at the federal level, the real battles are being fought at the state level with very mixed results. Should real parity come about, demands on public mental health systems may be lessened.

Managed Care The nation's response to the intolerable escalation of health care costs has been managed care. Under managed care a number of mechanisms are used to limit services to those the payer considers absolutely necessary. In addition, costs are lowered by negotiating lower rates and capitation contracts with selected providers and even by limiting the availability of certain services. Managed care has had a massive impact on both parties and providers in the private sector, forcing many patients to turn to the public sector for longer-term care and rehabilitative services not offered by many managed care entities.

While managed care has had a remarkable impact on the costs of health care in the private sector, its impact on quality and outcomes is quite controversial. Many leaders of mental health managed care companies came from the public sector, and they applied rationing techniques that have been prevalent in the public sector for ages. With the looming saturation of the private managed care market, a number of managed care companies are now looking to contract with states and local governments to manage the health care services to the poor (predominantly the Medicaid population) under recent health care reform legislation.

Leaders of public mental health care systems are concerned about managed care entities taking over the mental health needs of the Medicaid population for a number of reasons. Even though most contracts have differential rates, there is great concern that healthy patients will be skimmed and sicker patients left to a residual, largely unfunded, public sector. Managers of public mental health services have been distributing limited resources to the public patient population for a long time, and they know that there are not enough resources available to service people properly. Thus, they are alarmed about what will be left after management fees, profits, and stockholder dividends are taken out. Perhaps the greatest fear is that these private companies will make attractive offers to local governments to manage their mental health services, replace the existing local mental health management team and at least some providers, and then discover that under the fiscal and administrative restraints of governmental programs, there are no profits to be made. They would then pull out of their contracts, leaving chaos and a service vacuum in their wake. Many experiments in public sector managed care are currently under way. They must be watched very carefully.

Social Attitudes Mental health professionals can do little to influence social attitudes that depend on economic conditions, political leadership, and world affairs. Yet, social attitudes have a greater impact on the delivery of public mental health services than most people realize.

They dictate whether institutional or community programs are supported, determine who is to be cared for in the public mental health systems, and influence the amount of freedom allowed to the clientele. The public's attitude toward criminals and other social deviants is strongly correlated with their attitude about persons with severe mental illnesses. While it is important to try and separate mental illness from other types of social deviancy in the minds of the public, public mental health programs and their leaders probably cannot affect major social attitude changes. Instead, they must attempt to adapt, while preserving their service mission and humanity. Fortunately, humane and effective mental health services can be provided in many different settings if the needs of the patients are kept foremost in the minds of the professional staff.

Mental health professionals must constantly guard against having their patient care responsibilities corrupted by political demands or social fads. It is often difficult to know when the program is appropriately adapting to changing social needs or values and when it is neglecting its responsibilities to its patients in service to an alien ideology.

Human Resources Psychiatrists with the training, aptitude, and interests for the public sector are in short supply in most regions of the country. Many of our psychiatric training programs use public facilities, but little is done to help the resident psychiatrist appreciate a future in the public system. Instead, training is often seen as a period of indentured servitude in public hospitals, a rite of passage to the private sector. This attitude, unfair to both the public systems and the trainees, is often perpetuated by their role models in academic psychiatry. Failing to understand the larger system causes the trainees to get a distorted picture of chronic mental

illness (e.g., during most of their lives, patients with schizophrenia are not as dysfunctional as when they are hospitalized) and of the programs that can profoundly affect the lives of patients outside the hospital. The impressions that trainees gain from dealing with only the most frustrating, difficult patients understandably blunt their interest in public service later in their careers.

One benefit of the current move toward managed care in the private sector is an increased interest in positions in the public sector by young psychiatrists. That increased interest has generated greater demands for training experiences in psychosocial rehabilitation, in correctional facilities, and with seriously ill populations.

CURRENT ISSUES

Homeless People The homeless population is a heterogeneous group with multiple diagnoses; a high percentage suffer from substance-related disorders. They can be categorized into three groups: (1) persistently homeless persons who have a combination of schizophrenia and substance-related disorders, a history of psychiatric hospitalization, and multiple health problems; (2) episodic homeless persons whose psychiatric diagnoses are more likely to be serious personality disorders or mood disorders with a complex treatment history; and (3) situationally homeless persons who suffer from stress rather than a primary psychiatric or substance-related disorder. Persistently homeless persons resist all treatment settings that force them into congregate living or limit their behaviors. Therefore getting or keeping them in traditional treatment settings is usually not possible. Instead, reaching them in their natural settings with medications and support to develop trust and make their lives on the streets more tolerable is a better strategy. Episodic homeless persons present the most complex treatment challenge. They require wraparound services—psychosocial rehabilitation, psychiatric care, community living support—with aggressive case management. Situationally homeless persons require primary social service intervention with secondary psychiatric support.

Underserved People Members of minority populations, especially those who speak English as a second language or who do not speak English at all, require special consideration. Bilingual and bicultural staff are essential to relate to those populations. This is not an easy requirement to meet, since few such professionals have been trained, and this problem may be exacerbated by the recent trend of limiting minority quotas and affirmative action programs in educational institutions. Recent immigrants from underdeveloped countries find mental health services an alien concept. In their homelands they depended on support systems that are frequently not available in the United States. Better understanding by mental health professionals of cultural and familial styles and values is essential to remove these obstacles to their getting care.

Others who are underserved include elderly adults and persons residing in rural areas that offer few mental health services. Both of these groups tend to suffer quietly; their mental illness does not come readily to the attention of others. To reach them, mental health programs will have to work more with other practitioners of medicine—gerontologists, family practitioners, and internists.

Outpatient Commitment The recognition that some persons require medications to remain peacefully in the community has led to a number of proposals for laws to allow involuntary outpatient care. Some might say that the concept is an oxymoron; others feel that it should be tried. It is true that persons on probation or parole who must be in psychiatric care as a condition of their release are more likely to stay in treatment. However, these individuals face the very real threat of being returned to prison or jail to serve out a sentence for a crime they committed.

In the case of persons with mental illness, the situation is different. The strongest threat one would have is returning the patient to a hospital, something all parties are trying to avoid. Furthermore, it might be unconstitutional to detain individuals who are not at that time gravely disabled or a danger to themselves or others, even if they are not complying with treatment. Rehospitalizing an individual for not complying with treatment is equivalent to making noncompliance with treatment a crime. Many feel that such a policy would further criminalize mental illness—something to be avoided.

An alternative to outpatient commitment, conservatorship, is used in many states. Conservators—usually not part of the treatment system and often family members—are given responsibility for the patients' well-being and varying amounts of authority over their life, up to and including the ability to place them in a locked facility if their condition demands such placement. Of course, treatment staff must agree that the patient needs to be admitted for medical care before that individual can be admitted. Thus these patients are being admitted because of their condition, not as punishment for not complying with treatment.

Self-Help Rehabilitation has proceeded hand in hand with other patient empowerment efforts—the self-help and client movements. Patients usually see self-help programs as adjuncts to traditional treatment programs that support the use of psychotropic drugs and regular treatment contacts. Often they are organized by traditional agencies such as mental health associations, although the clients are expected to govern the programs to the extent possible. These programs are valuable in the psychosocial rehabilitation of persons with chronic mental illnesses. They give patients an opportunity to test social skills and experiment with control of their own lives in an accepting environment not available in regular society.

The client movement is difficult to define and characterize. It ranges from self-help groups to organizations of former patients with radically antipsychiatric belief systems. Most client organizations have been constructive and have performed invaluable services in sensitizing professionals to the inhumanities inherent in some treatment programs. Those on the radical fringe, however, have often impeded services to patients in dire need of care. Often the leaders of these more radical groups have themselves been mistreated; they were labeled psychotic and treated with antipsychotics when their problems were primarily personality disorders. They then perceive all patients to be like themselves, a tragic and destructive assumption. In any case, mental health professionals should do their best to help all of the client movements play a constructive role in improving the system and their own members' rehabilitation.

Working With Families Many families remain wary of involvement with the mental health system regardless of mental health professionals' efforts to rectify past errors. In addition, many patients have severed relationships with their families, and because of the trauma they suffered, parents and children are reluctant to reestablish relationships. Reestablishing family relationships is often critical to treatment and rehabilitation.

Families who are involved with their children are tremendous assets to rehabilitation. They provide a wealth of knowledge regarding the patient's treatment history, including what works and what does not. They are an invaluable support system for the patient that is difficult or impossible to replicate. Although it is frequently unwise for the patient to continue to live at home beyond an age when young people usually leave, a concerned family is still an asset.

Psychiatrists must recognize that families have borne a tremendous burden for years with little or no support. That support must now be provided on an ongoing basis. Families who are involved with their children deserve to have readily available professional backup. The love and emotional support that parents can offer their child is far more important than playing the role of caretakers.

Parents have a right to know everything possible about the illness—the prognosis, realistic expectations, and its most optimistic potential resolution. In addition they need to be kept informed about current research and possible implications for their children. The success of the Alliance for the Mentally III shows that well-informed parents constitute one of the strongest forces for improvement in the system of treatment for serious mental illnesses and research to seek cures.

Resources Continuous underfunding is the curse of public mental health systems. The situation ebbs and flows, subject to external economic and political pressures, the ability of the systems to use available resources efficiently, and the pressure brought by organized constituency groups for greater resources. Lobbying is critically important. Successful lobbying requires a coalition of all advocacy groups and professional associations that have a stake in the outcome. Petty differences must be put aside to allow agreement on a single national agenda.

The National Mental Health Association has been a major force for the improvement of care for people with mental illness and the protection of their rights for decades. It is organized with chapters in states and metropolitan areas and is active at all levels where people need support and protection. Its primary function is advocacy for the rights of patients, both civil and treatment; however, its chapters frequently provide social and work programs and housing and other support services for people with mental illnesses.

Much of the effort to improve funding for both services and research is necessarily undertaken by professionals in the field. Most public mental health leaders spend disproportionate amounts of time fighting to obtain an adequate budget, as do the managers of their various program divisions and contract agencies. However, many of these efforts are undermined by the accusation by funding bodies that managers and employees of the provider agencies are simply feathering their own nests. For that reason the agency personnel must work with advocates, professional organizations, the Alliance for the Mentally Ill, patient networks, and any other support groups to present a united front to the decision makers. History shows that programs prosper only when such coalitions are present.

COLLABORATION OF PUBLIC AND ACADEMIC INSTITUTIONS

Academic institutions and public mental health programs are mutually dependent on each other. Public mental health programs need well-trained psychiatrists and other mental health professionals; academic institutions need clinical training facilities and research populations. However, issues of money and control have strained this relation. Public programs fear that the academic institutions are only interested in them for their money and other resources; academic institutions feel that they must exercise control over programs in which either research or training is conducted. In addition, public institutions fear that research projects will jeopardize their reputation or their patients.

Academic institutions have been important in the evolution of public psychiatry. They have undertaken monumental epidemiological studies, operated some outstanding community mental health centers, trained some personnel with unique skills for public psychiatric work, and researched service delivery methods. Yet many argue that academic institutions frequently shirk service delivery that does not directly feed their needs and fail to give their trainees the skills and motivations necessary to work in the public sector.

Doing more training in well-developed public programs would give trainees more of the needed skills and interests. The benefits to the universities beyond training sites and research materials are less tangible but perhaps more important. They can be summarized as image and relevance. Publicly funded institutions must be seen as having special value to the community beyond the benefits to their students and faculty to maintain their levels of support. Public services can enhance that image as readily as research. Similarly, active involvement in public mental health services is one sure way to keep the university relevant to the needs of the community.

The shift of research interests toward the biological and away from psychosocial areas has diminished academic institutions' interest in public mental health programs. This trend should not be allowed to continue. The advance of organized systems of health care has made the interdependence of public mental health systems and training institutions greater than ever.

FUTURE DIRECTIONS

Public mental health systems will exist until schizophrenia, the severe mood disorders, and the more disruptive personality disorders can be prevented or easily cured. Society reluctantly accepts its responsibility to people with mental illness and will continue to address the problem. Current trends indicate that in the next decade much more mental health service will be provided in correctional institutions because of the increasing propensity of society to jail mentally ill persons committing crimes, the lack of adequate mental health treatment facilities in many urban areas, substance abuse by mentally ill persons, and the demand for psychiatric care for persons with severe personality disorders. Prisons are one of the great growth industries of our society, and their mentally ill inmates will increase concomitantly. A fascinating aspect of public psychiatry is its constant evolution.

SUGGESTED CROSS-REFERENCES

The other sections in this chapter on economics, the role of the psychiatric hospital, and psychiatric rehabilitation are of obvious importance to persons interested in public psychiatry. In addition, all of Chapter 12 on schizophrenia is of special interest, especially Section 12.9 on its psychosocial treatment. Chapter 13, Chapter 14, and Chapter 24 dealing with other psychotic disorders, mood disorders, and personality disorders, respectively, are also important since these disorders provide many of the public sector's patients. Section 5.1 discusses epidemiology. Finally, anyone involved in public psychiatry will be interested in the comprehensive coverage of managed care in Section 52.2.

52.2 MANAGED CARE

ROBERT JEAN CAMPBELL, III, M.D.

DEFINITION

Managed care is an organized system of health care providers whose goal is to deliver needed services in an effective, responsible, and cost-efficient manner. It is generally assumed that any such system will also provide increased access to appropriate primary health care. Managed care differs significantly from what most people understand as health insurance, that is, the indemnity fee-for-service system in which a person buys an insurance policy to protect against the unforeseen cost of falling sick and needing care. Managed care organizations consist of networks of providers, such as physicians, hospitals, clinics, and day programs, that often share the financial risks associated with providing care to all of those enrolled in the plan whenever they need it.

Managed care includes an evolving array of cost-containment mechanisms that combined with different types of provider networks, reimbursement systems, provider incentives, plan sponsorship, and gatekeeping design that can create a diversity of plans tailored to employer characteristics and employee demographics. The managed care systems that now predominate are health maintenance organizations (HMOs) and preferred provider organizations (PPOs). Individual HMOs may offer more than 400 different health, mental health, and substance abuse benefit structures, based in part on the specific needs and requests of the individual employer groups.

HISTORICAL DEVELOPMENT

The basic elements of managed care—capitation and integration—had developed in the United States by the 1800s, in the funeral and benevolent societies founded by immigrants to cover their death expenses. Those early models of managed care organizations were developed as a way to fill unmet health needs, not as a way of containing costs, dominating a market, or turning a profit. Since then, the situation has changed radically, in part because the U.S. government, through health programs introduced in the 1960s, became the single most important purchaser of health care.

Only 5 years after Medicare was introduced in 1966, the Nixon administration became alarmed by an unanticipated rise in its cost. Despite mounting health care costs, the rate of uninsured individuals continued to swell, threatening to topple a fragile health care delivery infrastructure. Even for many with insurance, coverage was inadequate to pay the costs of a serious illness. Less money is coming into Medicare, and it is estimated that the fund's reserves will be exhausted by 2001. Without some sort of change, the system may be unable to support the scope of coverage currently allowed.

COSTS OF HEALTH CARE

Development of the managed care system was part of the response to seemingly uncontrollable rises in health care costs. In 1993 business alone was spending over $279 billion yearly ($3781 per employee) on health insurance premiums and payroll tax contributions to the Medicare Hospital Insurance Trust Fund. Arguably, American medicine has become the world's largest business.

In 1970 the government introduced the concept of a health maintenance strategy that allowed beneficiaries to choose between HMO and traditional fee-for-service systems. Not long after, employer purchasers began to encourage their employees to join health plans, whose attractions to the consumer were lower out-of-pocket costs and ease of use.

HMOs were designed to be of two forms: prepaid group practices (such as the Kaiser Permanente Health Plan) and independent practice associations. As of July 1, 1994, there were 593 HMOs in the United States. Nearly three fourths of all enrollees were in independent practice associations, in which physicians, hospitals, and other entities contract with a health plan, or in mixed models that involve more than one structure.

In the current era of managed care, the players on the health care field are not necessarily the willing partners they once were; they are just as likely to be the product of health care power politics, each competing for dominance, control, and ultimately as much profit as can be squeezed out of the system.

PHASES IN THE DEVELOPMENT OF MANAGED CARE ORGANIZATIONS

In the early stages when there is little or no managed care in the area, the medical system is “overbedded” and relies heavily on the use of specialists. Managed care first tries to control costs by limiting the delivery of health care services in inappropriately costly settings. In the next phase, health plan administrators adopt more comprehensive utilization management techniques, and physicians become more fully integrated into managed care plans. As managed care begins to penetrate, discounted fee-for-service is initiated, and plans for consolidation of health services develop.

In these generations of managed care, the emphasis is on managing the utilization of health care services, not on managing the care itself. Any cost savings achieved come primarily from providing care in less costly settings or by rationing services. Taken to the extreme, this approach might indiscriminately reduce both appropriate and inappropriate care.

By the time managed care penetration achieves 30 to 40 percent in an area, reimbursement within a given market declines significantly. Consolidation among hospitals, physician groups, and other large health care entities becomes more prominent. Redundant beds are closed, and there is increasing effort to end duplication in administrative and clinical systems. Then the health care system must find the capital necessary to acquire primary care or other essential groups.

Development of managed care organizations has not been a unified national movement. Different parts of the country are at very different stages of managed care organization development. Because of their variety, their continuing evolution into new forms, their different phases of development in different parts of the country, and the role they play as potentially large contributors to the profit side of big business, managed care organizations are not best understood through the peer-reviewed journals with which most physicians are familiar. They change so rapidly and involve such large amounts of money that their modifications and development are more likely to be reported in the business sections of newspapers and trade journals of the hospital and managed care industries than in professional medical publications.

MAJOR CHARACTERISTICS OF MANAGED CARE ORGANIZATIONS

As noted, no single model can describe the rapid changes in the field. Nonetheless, some models are used more than others, and some common strategies can be identified. Mainstream managed care organization features include (1) a claims payment system; (2) competition; (3) provider networks, particularly medical care systems that strictly control resource consumption; (4) gatekeepers; (5) shifting economic risk from payer to patient and provider; (6) an enrolled population; (7) management and information systems; (8) monitoring provider performance; and (9) influencing patient-care decision making.

Provider Networks The first step in implementing a managed care organization plan is to assemble a network of providers. Networks must be large enough not only in terms of the actual number of hospitals and physicians—primary care physicians and specialists—but also in their willingness to use midlevel practitioners to expand the primary care base. A typical rule of thumb calls for one primary care physician for every 2000 enrollees (and, often, one psychiatrist for every 10,000 covered lives), with primary care physicians making up 50 percent of the total medical staff. The ratio varies according to the characteristics of the population served.

Organization of Providers Once the providers have been selected, they must be organized along some kind of functional model. There are many different possibilities.

In the *staff model*, the professionals are either employed or exclusively retained by the HMO, managed care organization, or network.

In the *assessment and referral model*, assessors are employed or retained by the managed care organization. They provide initial diagnoses and treatment plans, which necessarily reflect their own theoretical orientation.

In the *central access network*, the patient contacts a central point. The managed care organization verifies eligibility, assigns the patient to a primary care physician in its network, and authorizes treatment. All care, including assessment, is rendered by community providers. Many self-insured employers use this model, and most *managed mental health care* or *alcohol, drug, and mental health* companies and insurers operate this type of network.

In *open access* provider panels, the patient may go to any approved provider at any time. The provider must review the case with the managed care organization and obtain continuing authorization after either an assessment or a set number of visits. (The participating provider should be certain to note which company requires what.)

In *opt-out* systems, patients may choose participating providers (in-network) or nonparticipating providers (out-of-network). If they choose the latter, certain increases in deductibles or copayments or reductions in benefits may apply. The financial penalties in an opt-out system may be so great that most enrollees cannot afford to remain outside the network.

Closed networks are those that accept no more providers into their panels. Within a network, the number of selected providers is typically much smaller than the actual number of providers in a given area, especially in metropolitan centers. A managed mental health care or alcohol, drug, and mental disease firm wants a relatively short list of providers. That allows the firm to reward its own providers with more referrals, thereby making it more likely that the providers will remain within the network of discounted fees. (The “any willing provider” laws under consideration in many states would eliminate this advantage.)

PHYSICIAN HOSPITAL ORGANIZATION Formal alliance between physicians and hospitals, usually created to contract for managed care and to increase the physician hospital organization's market share, physician hospital organizations often require capital investment by participating physicians, usually through some kind of arrangement that allows physicians to pay back their share of the initial capitalization over time.

Inherent in the physician hospital organization concept is the assumption that physicians and the hospital will share decision making. Leadership cannot be left in the hands of the hospital's administrative personnel, nor can it be shared by them with handpicked physician representatives who do not command the trust and respect of the medical staff.

PREFERRED PROVIDER ORGANIZATIONS Also called select provider organizations, PPOs are providers who have agreed to discount their fees to enrollees of the plan, meaning lower out-of-pocket expenses for people who choose them. It is the least restrictive form of managed care. The impetus for managed care organizations to contract with mental health providers presupposes the willingness of the providers to share in the company's vision of managed health care.

HEALTH MAINTENANCE ORGANIZATIONS HMOs are the most restrictive type of managed care organization and currently the most popular. HMOs developed early in the twentieth century as prepaid group practice plans. There are many forms, but they have some characteristics in common: assuming contractual responsibility to provide an integrated and comprehensive range of health and mental health services to a voluntarily enrolled population on a prepaid contractual basis. Until recently, it was believed that all HMOs eventually would be acquired by leading indemnity insurance companies. But it now looks as if HMOs will dominate the business, perhaps replacing insurance carriers entirely. *Point of service* plans are similar to HMOs but allow some reimbursement if a patient opts to receive care outside the provider network.

INDEPENDENT PRACTICE ASSOCIATIONS In this model, providers deliver ambulatory services in their own offices and maintain their own staffs; their fees are either discounted or capitated (paid in advance, based on the number of enrollees in the program). Independent practice associations are contracting networks of solo practitioners. HMOs capture their market share by offering a wide choice of physicians, and independent practice associations are a quick and inexpensive way to assemble a large network. Many multispecialty groups and hospitals form independent practice associations to expand their geographical coverage without expending large amounts in capital funds (it can cost tens to hundreds of thousands of dollars for a hospital to acquire a physician's practice).

The HMO contracts for inpatient care from community hospitals in its service area. An HMO may create an independent practice association to serve it and only it (a “married” independent practice association). Or independent practice associations may be formed to capture the business of many HMO and PPO products developed by the insurance industry; these “unmarried” associations can enter into relationships with many organizations simultaneously.

The essential task of this model is to preserve the desirable elements of autonomy of traditional practice and yet give the independent practice association the necessary authority for organizational change and governance. The independent practice association organizes the delivery of care. It contracts with HMOs and PPOs; it assembles, credentials, and inspects the network of provider physicians, institutions, and services; it constructs authorization and referral processes; it establishes gatekeeper and specialist responsibilities, sometimes including treatment protocols; it disburses payment to physicians and ancillary services; it conducts utilization and quality assurance reviews; and it ensures the fiscal integrity of the enterprise. No entity in medicine has ever before had so much power over independently practicing physicians.

Hospitals, because of their financial and organizational resources and their interest in generating admissions, were central to the initial formation of independent practice associations in California, an advanced managed care market with high HMO penetration. There have been exceptions, however, and throughout the country more and more independent practice associations are now owned and managed by physicians.

NETWORK MODEL Also known as an *integrated delivery system*, a network is an organization of primary care, specialty care, and hospital care services under one umbrella. In many respects, the organization of networks mirror that of HMOs except that inpatient facilities are a full partner with ambulatory components in ensuring quality services. Without such integration, inpatient facilities are often in a competitive bidding process to attract managed care dollars by discounting their charges. As an integrated, full partner with ambulatory resources in a network plan, inpatient providers no longer have filling beds as their primary goal but shift instead to appropriate utilization of inpatient and ambulatory capacities.

PROVIDER-SPONSORED NETWORKS Employers seek to extract additional savings by cutting out managed care organizations and turning to provider-sponsored networks, hoping that by dealing directly with providers they will manage healthcare benefits more cost-effectively and will trim the administrative expense of an intermediary. Some provider-sponsored networks are beginning to accept downstream risk from HMOs: the HMO bears full risk for a group of patients and pays the provider-sponsored network on a capitated or percent-of-premium basis to provide certain services.

DISEASE MANAGEMENT *Disease management*, or *disease state management*, is a newer clinical model that integrates, both clinically and fiscally, all health care services for a specific health problem. Its primary purpose is to identify and manage the 20 percent of patients who use 80 percent of total health resources.

The hospital, physicians and other professionals, and intensive case management are integrated into a single program. In behavioral health, disease management programs have been developed for depression and schizophrenia. Disease management gives the flexibility needed for early intervention, prevention programs, integration of clinical services and psychopharmacology, and improvement of outcomes.

MANAGEMENT SERVICE ORGANIZATION Not another integration model, management service organizations provide contract management or practice management services to physician organizations, and they add substantial capital to the group. Some management service organizations purchase the equipment, furniture, and supplies of medical practices and employ the office staff and physicians. The key component missing in most physician organizations has been the administrative component, and management service organizations provide a stong administrative infrastructure.

Primary Care Managers or Gatekeepers Both HMOs and point of service plans rely on gatekeepers, who are usually primary care physicians or, in the case of mental health and substance abuse, a specialty care firm. The gatekeeper is responsible for a longitudinal approach to patient care, integrating the clinical and psychosocial aspects, as well as subspecialty care, health promotion, and disease prevention.

The gatekeeper screens all patients and decides if referral to a specialist is needed; often, this includes a decision about what kind of specialist is appropriate (e.g., psychiatrist, psychologist, psychiatric social worker, or psychiatric nurse practitioner). Many plans carve out mental illness and substance abuse, using a managed mental health care or alcohol, drug, and mental health firm to handle them. The firm sets up a provider network and authorizes needed services. The companies are staffed by mental health professionals, usually nurses and social workers, who use written sets of criteria to determine what services are needed and for how long.

Shifting Economic Risk Benefit design and pricing strategies shift the economic risk from payer to patient and provider. In managed care organizations the contract is between the provider and the payer. If the patient complies with the restrictions imposed by the managed care organization, the cost of medical care will be less than that incurred outside the network of contracted providers that the firm has set up.

Pricing strategies include incentives to enrollees to use the plan's providers, and incentives to providers to be cost-effective in giving care, often using risk and reward options (sometimes called bonus funds).

Reimbursement of the Practitioner Managed care organizations use several methods to reimburse physicians for services. The provider contract should identify the method used and provide detailed information. The most common mechanisms are fixed-fee schedules, discounted fees, and capitation.

In a *fixed-fee schedule*, all physicians receive the same payment for the same procedures, based on either an average of fees in the area or a relative value scale. In a *discounted fee-for-service* arrangement, physicians in the plan agree to discount a certain percentage (usually 10 to 20 percent off their regular charge). In *capitation*, physicians are paid a certain amount per number of enrollees in the plan per month or per year, regardless of the amount of service provided.

Capitation is an incentive-based system of health care in which providers are paid a negotiated sum in advance to cover all required medical and mental health services for each enrolled member over a defined period of time. Under capitation, hospitals are not only financially responsible for their own services; they may also be responsible for services they do not provide themselves, such as tertiary hospitalization, skilled nursing care, home health care, and ambulance services—even though some of those services may be delivered by their competitors.

Many capitation contracts include a *withhold*—a percentage (often in the neighborhood of 10 percent) of the physician's fees are reserved until the nd of the contract or are paid only if the business is profitable. While a capitation system encourages providers to render medically necessary services, it also removes incentives to overuse health care resources. It creates a precarious situation for the risk-bearing provider, who receives a fixed sum for each person covered each month, regardless of whether any services are used. Capitation pits hospitals, specialists, and primary care physicians against each other in reaching a decision about what portion of the original capitation amount each one will get (the “split of the cap” problem).

Meantime, capitation continues to grow, and provider-managed capitated systems may ultimately replace fee-for-service medicine. In the independent practice association model, the managed care organization makes capitated payments to the independent practice association, which decides how and what to pay each physician and assumes some responsibility for managing the costs and quality of care provided by its physician members. Some independent practice associations control use by *contact capitation*—specialists are paid a standard rate for each patient seen, regardless of the number of follow up visits or procedures.

How the total bonus dollars are apportioned among the primary care physicians at the end of the year varies from one independent practice association to another. They may be divided equally among all the primary care physicians; or the referral costs generated by each primary care physician may be tracked, and those with lower referral costs are rewarded with bigger bonuses than the primary care physicians with high referral costs. In December 1996 the government moved to stricter control over bonus payments that could be seen as rewards to physicians for withholding or limiting care.

Specialty capitation is also growing; it reduces the specialist's incentive to provide more care, and by limiting the payout to specialists, it reduces pressure on the primary care physician not to refer. It reduces the risk for primary care physicians, but it also reduces their potential profit. In a system that includes specialty capitation, it is essential to delineate which services will be paid for by the capitated fee and which services are paid for separately by the managed care organization or independent practice association.

If the current trend away from hospital use toward less intensive levels of care continues, the flow chart of premium dollars within a capitated managed care organization might look as shown in Table 52.2-1.

$100 premium, allocated to		
HMO		$17
Administration	$9	
Out of area services	$3	
Profit and reserves (incl. withhold)	$5	
Provider group	$11	$83
Administration: quality assurance, reinsurance, contracting, marketing, information systems		
Hospital, including outpatient surgery, clinics	$29	
Medical group	$43	
Emergency services	$ 4.25	
Primary care physicians	$20.50	
All specialists	$18.25	
Total	$100	

Table 52.2-1 Example of Distribution of Funds in a Capitated Managed Care Organization

Enrolled Population Geographical accessibility to the population served often means using primary care physicians not on the medical staff of the hospitals who refer to specialists on the hospital staff. Some of these referring physicians may hold admitting privileges elsewhere; if so, they must meet preestablished quality standards and demonstrate a commitment to the concepts of managed care.

Management and Information Systems Management and information systems must be sophisticated enough to handle simultaneously the use and other clinical data of the system, financial functions (billing, collection, and distribution of funds), and measurement of performance outcomes. They must have access to current membership information and to services provided by both participating and nonparticipating providers and subcontracted providers. They should be able to coordinate elements of care, conduct population-based risk analysis, monitor changes over time in disease rates, track individual patients rather than procedures, and provide other information for clinical decision making. Current computerized systems primarily collect data on procedures, use, and costs; they are generally ineffective in handling nonhospital data.

Providers also need automated information systems to provide adequate information to subscribers and to managed care organizations on the basis of real-time data

on the treatments they are providing. Practitioners need concise and immediate information about treatments, including guidelines, disease management strategies, and the costs of different diagnostic strategies and medications. A primary care physician in a managed care organization must have information about the complication rate and the experience of the surgeon or other specialist to whom the patient is being referred. The physician also needs data about outcomes at hospitals.

MANAGED CARE ORGANIZATION STRATEGIES

Once the provider network is in place, the next concern of a managed care organization is how to influence the patterns of practice of its providers. The most direct approach is to limit the choices that providers can make in treating their patients. They may restrict the ability of physicians to perform certain procedures or to order certain medications or tests.

Other levers for restricting clinical choices focus on limiting the use of specialists or specialty services. Gatekeepers in one sense serve a rationing function, and that may convert the doctor-patient relationship into an adversarial one.

Monitoring Provider Performance The managed care organization must know how well its providers are functioning. In compiling data about the quality, outcomes, and quantity of treatment provided, the managed care organization constructs a profile of the care delivered by each treatment provider and each facility.

Different purposes are served by different profiling systems. Profiling can be used to analyze the strengths of each provider; it can show the treatments and diagnoses that a provider handles most effectively. This information can be used to match a patient with the provider who has had the greatest success in treating the patient's condition. Ensuring that the skills of the providers match the needs of patients within the system is an important component of network management. A profiling system can also be designed to find the providers who need the most scrutiny or have the greatest difficulty working within a managed care organization.

Assembling providers' profiles begins with a review of their credentials, their malpractice histories, their training, and their own reports on the treatments they provide and the patients they prefer. The convenience of the provider's geographical location, the ease of access for handicapped patients, the waiting time for appointments—all these features of a practice are weighed in establishing the provider profile. The managed care organization may perform a site visit to examine the program and offices where patients are treated.

The willingness of the provider to cooperate with the review process and the quality of treatment reports submitted also contribute significantly to the provider's profile. The profile may also incorporate case managers' evaluations of their interactions with the provider, and patient satisfaction may be tracked.

Utilization Review Utilization review is a specific subset of managed care and the strategy with the most immediate impact on patient care. A third party, interposed between patient and provider, judges the necessity, appropriateness, and adequacy of care and thus becomes the final arbiter of treatment. Utilization review consists of a set of techniques used to manage health care costs by influencing patient care decision making; an important technique is case-by-case assessment of the appropriateness of care before its provision. Utilization review is the most explicit effort to regulate physicians by modifying their treatment decisions; it is a direct intrusion on professional autonomy and judgment.

Under capitation, utilization management involves all the elements of the continuum of care, from the primary care physician's office, specialists' offices, the hospital, skilled nursing facility, and the patient's home. The goal is to control utilization before hospitalization is required; if admission is necessary, appropriate and cost-effective care must be implemented as soon as possible to minimize the probability of readmission. Utilization management must, therefore, be integrated with the medical protocols being followed by physicians who deliver outpatient care and aftercare once patients are discharged. Managed care organizations do not merely deny inappropriate admissions; instead, they direct the patient to the most appropriate level of care.

Prior Review Also known as *prior authorization* or *precertification, prior review* is an assessment of the need for the medical services being proposed for a patient, before they are provided. In the past, prior review was most frequently required for inpatient care; it is now being used more and more for ambulatory care, where it may be required in advance of treatment or after a specified number of visits.

Prior review typically consists of a telephone call between the treating physician and the first-level reviewer (e.g., psychiatric nurse or social worker). A few managed care organizations prefer written prior review requests. Prior review usually authorizes the initial procedures and the initial amount, duration, and scope of service required to evaluate the patient and generate an initial treatment plan.

How It Works Although hundreds of variations are possible, a managed care organization usually works in the following way. The patient calls a toll-free number and requests care. The system addresses emergencies immediately, while most callers follow a more routine path. The computer plays a central role in eligibility verification, data entry, utilization review, provider relations, treatment authorization, and provider assignment.

While the patient is on the telephone, eligibility is verified. The more sophisticated systems review basic demographic data on the patient, the patient's employer, the patient's group number and location, benefit descriptors, benefits used versus benefits available, availability of past treatment history, name of previous or current provider or providers, any “red flag” situations such as impending complaints or previous suicide attempts.

If the record shows that the patient has a therapist, the patient will be allowed to remain with that practitioner if the patient wishes to do so, if the therapist is a participating provider, and if, in the estimation of the reviewer or operator who is at the other end of the line, the provider's services are most appropriate for the patient.

If the patient has no therapist or record, the utilization review nurse, even with no knowledge of the patient's local area, can identify providers rapidly by scrolling down the list of participating providers in the patient's area. The computer thus introduces an element of randomness into provider assignment. The computer system creates a patient file, allowing for direct entry of notes about the patient's condition, requests, and disposition. The operator can either accept an existing provider or request a search for other providers if the therapist of record does not meet the company's requirements.

Initial screening is usually by zip code, because the company is obliged to provide care that is available within 30 minutes of driving time from the patient's home or workplace. Providers within a given zip code are generally displayed alphabetically, but they may be subtyped into particular clinical competencies. Once the reviewer has found a provider acceptable to the patient, the assignment is made and the system moves on to authorization for treatment. Most managed care organizations will not authorize treatment until a provider has been assigned.

In the case of self-referred patients, the psychiatrist is ordinarily responsible for both verifying the patient's eligibility to receive services and obtaining utilization review approval for the course of treatment being recommended. It is often wise to verify eligibility before the patient arrives and then obtain utilization review approval after the initial interview for the course of treatment being recommended.

Patients referred to the psychiatrist directly by the managed care organization usually (but not always) have been checked for their eligibility to receive services. The provider must check back at the end of the authorized period to update the record and to request additional care if necessary. If assessment has not already been done (by the primary care physician, for instance), the psychiatrist must get back to the managed care organization after assessing the patient, to obtain utilization review approval for the treatment planned.

Concurrent Review Concurrent review evaluates the appropriateness of the initial authorization for treatment, the need for the services outlined in the treatment plan, the consistency of the different treatment interventions with the measurable goals of treatment, and the adequacy of discharge planning. Requests for continued inpatient or outpatient treatment beyond the initial amount authorized (rarely more than 1 week in the hospital) trigger additional reviews, which may be required in any event at specified intervals. The psychiatrist is asked to provide updated treatment plans, progress notes, and treatment summaries.

The actual process of obtaining authorization for continued treatment through treatment summaries is much more involved than the foregoing would indicate. In one state, for example, approximately 175 managed care organizations are in operation. Most of them require written treatment summaries, and most have developed their own forms. The protocols associated with each form differ from the others. Providers are required by some managed care organizations to send the information after the assessment; by others, after a set number of visits; and by still others, with each request for continued authorization. Some may be faxed, others can only be

mailed. Several companies require use of their form; others will accept the provider's form.

Discharge Planning Discharge planning begins at the time of prior review. Goals for discharge and follow-up care (or termination, in the case of outpatients) should be contained in the initial treatment plan. Discharge planning may require arranging for additional follow-up medical and nonmedical services; case management may be of great assistance in such instances.

Case Management Also referred to as high-cost case management, case management targets the relatively few beneficiaries who generate (or are likely to generate) large expenditures or need a large number of providers or services. It determines whether extra assistance in planning, arranging, and coordinating a specialized treatment plan will permit appropriate and less costly care. Unlike utilization review, case management is voluntary and may permit coverage not specified in the benefit plan, such as residential treatment or partial hospitalization.

Retrospective Review Retrospective review is the final evaluation of utilization, designed to ensure consistency of the treatment plan, progress report, and medical records. The usual review is a medical record audit performed on-site for a random sample of patients. The results are used to analyze patterns of practitioner or institutional care for use in provider education, profiling, and selective contracting arrangements.

EFFECTS OF MANAGED CARE ORGANIZATIONS ON PHYSICIANS

Physicians in managed care organizations find themselves trying to balance three sides of patient care: patient compliance and lifestyle issues on one side, government regulation and requirements on another, and the cost (to both patient and physician) of the treatment chosen on the third side.

If managed care does in fact work, it will significantly affect the physician workforce requirement. It has been estimated that by the end of the century the surplus of physicians will be one third of the projected requirement. The surplus is particularly marked in the specialties, which account for 85 percent of the total surplus (an extra 139,000 specialists) (Table 52.2-2).

	Number of Enrollees in Plan		
	60,000	300,000	300 million
Primary care physicians	30.0	150.0	150,000
Psychiatrists	6.0	30.0	30,000*
Hospital beds	120	600	600,000

* In the private sector; not included are those needed in the public sector (also unknown are the ultimate effects of shifting costs and patients to the public sector). In 1996, there were more than 40,000 psychiatrists in the United States.

Table 52.2-2 Estimated Number of Full-Time Equivalent Primary Care Physicians, Hospital Beds, and Psychiatrists by Size of Plan

In recent years, the level of clinical autonomy has decreased for all physicians, including self-employed solo practitioners, not only because of the growth of managed care, but also because of concerns about professional liability, the implementation of certain clinical guidelines, and the activities of peer-review organizations.

Continued efforts to slow the growth of health care expenditures have furthered a trend toward large group practices. If current trends persist, most physicians in future years will be employees who are likely to have relatively little clinical autonomy, the hallmark of medical professionalism, with their practices subject to increasing bureaucratic rationalization.

EFFECT OF MANAGED CARE ON HOSPITALS

Like physicians, hospitals face major changes in a managed care organization environment. In the past, 10 patients requiring hospitalization might have received 2 to 3 weeks of inpatient care for a total of 210 patient days. Under a managed care organization only 3 to 5 of those patients will be admitted in the first place, and their average length of stay will range from 10 to 12 days, for a total of 60 inpatient days. In capitation contracts the hospital is committed to reducing the number of services provided, not to increasing the number of admissions.

PUBLIC HOSPITALS

Of all the pressures facing public hospitals, perhaps the greatest is the potentially devastating loss of revenue due to the growth of Medicaid managed care. Public hospitals have relied on fee-for-service Medicaid for as much as 40 percent of their total revenue. In recent years, however, states have begun to turn over their Medicaid programs to private managed care plans. These plans frequently sign up low-cost Medicaid enrollees (most often, women and children), depriving public hospitals of revenue while leaving them with the burden of caring for higher-cost Medicaid patients such as the chronically ill as well as uninsured patients.

MEDICARE AND MEDICAID MANAGED CARE

Because of a legal quirk in the new Medicare Plus Choice law, more and more health plans are pulling out of the Medicare risk-contracting business. In October 1998, 119 health plans notified the Health Care Financing Administration (HCFA) that they were either leaving Medicare completely or reducing their service areas. More than 500,000 beneficiaries were affected. Payment cutbacks and increasingly onerous, and often unreasonable, regulations may prompt a wave of health plans to depart Medicaid, similar to the documented defections in Medicare coverage. Payment cuts have already caused some Medicaid plans to lose millions and have driven others, often large commercial HMOs, from the market.

Some health systems believe the best strategy is to merge with smaller plans, adding fuel to the already existing fires of merger mania. If too many commercial plans leave the market, it could jeopardize competition and raise concern that a two-tiered health system is forming.

The prevailing philosophy in many states is that managed care is an adequate replacement for all public health services, and money is being diverted from categorical programs to managed care without adequate provisions for community health measures. Children constitute more than half the Medicaid population, and they highlight the multiplicity of factors that contribute to poor health, particularly in urban areas: poverty, parental and social neglect, and maldistribution of resources. While managed care can potentially reduce service fragmentation, increase access to individual care, and stimulate the development of more appropriate and less restrictive services in community settings, at the same time capitated payment arrangements inherently provide incentives to limit care. Children with special health care needs—chronic and handicapping conditions—may constitute between 20 and 30 percent of all children, and such medically complex children are the most likely to receive inadequate care or be extruded administratively from the system.

CHANGES IN MEDICAL CARE DELIVERY

The emergence of managed care as the predominant force in the practice of medicine is virtually ensured in the United States. Predictions using reasonable rates of growth indicate that 40 to 65 percent of the U.S. population will be enrolled in managed care plans within the next 5 years. What are the implications for the practice of medicine of the shift from patient-based to population-based medicine? As resources directed to health care are reduced, how will the trade-off between cost and quality be altered? Will quality even remain on the agenda? Who defines the appropriateness of interventions? How will managed care organization physicians make decisions about allocation of scarce resources, and what efforts should be made in tracking the population in terms of mental, physical, and social functioning? Should resources be allocated to assessing and improving the functional status of depressed patients who do not take their antidepressant medications? Should resources be reserved for those who participate in the medical system? Should certain groups (e.g., the chronically ill, the mentally ill, the elderly, children) be given

special resources for prevention and rehabilitation? If managed care organization demands reduce the contact-time between patient and physician, will the quality of the interaction be altered, and will the physician be able to gather enough information to make the correct clinical decision? Are the data now being made available to the public valid enough to guide the consumer in making health care choices?

Today, the typical hospital is 65 percent occupied. In Minneapolis, one of the pioneers of managed care, the number of hospital beds has dropped from 9000 to 4000. Nationally, the number of hospital beds has declined from 1,200,000 in 1989 to 980,000 in 1994, and it will probably dip to 870,000 by 1999.

California is the nation's most competitive market for managed health care services. HMOs there targeted hospitals as the principal locus of preventable health care utilization and expenditure. As a result, rates of admission and lengths of stay have plummeted. Hospitals are merging, reducing bed capacity, or closing. More and more medical and surgical procedures are being shifted to outpatient, subacute, and home health settings.

Between 1983 and 1993, the number of hospitals declined by 19 percent, acute care discharges declined by 11 percent, average length of stay by 17 percent, inpatient days by 30 percent (but to as low as 48 percent in areas of high HMO penetration), and inpatient surgical procedures by 35 percent. Patient visits to hospital-based ambulatory care facilities increased by 69 percent, and outpatient surgical procedures performed in hospital facilities increased by 132 percent.

SHIFT TOWARD CONSOLIDATION

Because their role as facilities for inpatient services is declining, probably irreversibly, hospitals are pursuing a strategy of “vertical integration” to gain control of the full continuum of care in their communities. Some observers predict that competition will drive providers in some major markets to consolidate into two or three systems by the turn of the century and that stand-alone hospitals and sole practitioners will disappear.

In 1994, 87 hospital mergers were publicly announced; in 1995, 126. All of 1995's transactions were eclipsed by MedPartners/Mullikin's $2.5 billion acquisition of Caremark, announced in April 1996. Aetna, a $13.3 billion company, acquired US Healthcare for $8.18 billion in April 1996 and Prudential Health Care for $1 billion in December 1998.

Health care merger and acquisition activity reached a record high in 1997 of 1183 transactions—an increase of 19 percent over the 997 mergers of 1996 and 87 percent over the 633 deals of 1995. The mergers included 56 HMOs, 127 units in the home health sector, 181 hospitals, 108 laboratories and dialysis centers, 108 long-term care facilities, 278 physician medical groups, 59 in the psychiatric sector, 74 rehabilitation facilities, and 192 in all other categories. In 1998, transactions decreased 9 percent to 198 deals, but the number of hospitals involved rose almost 10 percent to 687. The 1998 declines were particularly marked in physician groups, physician practice management companies, and the home health market.

The relations between managed care organizations and integrated delivery systems are still adversarial, and the megamergers may make them more so. The directions taken by the recent mergers have cast some doubt on the future of integrated delivery systems. Vertical and horizontal integration may be a transition phase, rather than the end result. Joint ventures, alliances, and “virtual” integration—consolidations involving less than full-asset mergers—are becoming more common. Rather than consolidate all their facilities at one location, managed care organization executives realize that they must provide multiple access sites.

Although HMOs prospered at first by taking advantage of easy one-time savings, their large profits are shrinking in the face of rising medical and administrative costs. Since 1996, many HMOs have experienced huge losses. Oxford lost $291 million in 1997 and a staggering $553 million in the first half of 1998. Even profitable plans lagged behind past performance. Humana's net income fell 97 percent from 1995 to 1996, Aetna's profits dropped 79 percent, and Cigna's net income fell 11 percent.

In 1997 HMOs accumulated nearly $800 million in losses, on average $1 million each, compared with an average profit of $5.4 million each in 1996. Administrative costs have also risen (8 percent, to $21.95 per enrollee per month in 1998 from $19.53 in 1997). Inpatient costs rose 4.9 percent per day, even though inpatient days per 1000 enrollees dropped 3.2 percent. Most Blue's plans also reported operational losses in 1998.

HMO losses translated into a large increase in premiums in 1998. Consumers who pay for their own care faced especially steep increases. The alternative was to pray for good health and go without insurance. The pool of uninsured people continued to rise by more than one million annually, to 43.1 million in 1997 (the latest information available). Small businesses that cannot self-insure, largely because they have so little leverage with health plans, are also hit hard by insurance rate increases.

MEASURING EFFECTS OF MANAGED CARE ORGANIZATIONS

Despite the dire predictions about its threats to the quality of health care and the occasional horror story reported in the press, managed care has yet to produce unequivocally negative results detectable by the measures so far applied. There is concern that necessary care will be delayed or eliminated, but few data support the position that managed care denies necessary care. What has changed are the ways many physicians and hospitals had practiced medicine under a fee-for-service system; whether that has an adverse effect on the quality of medical care remains to be demonstrated.

Almost all studies since 1980 have found that while HMO members generally had somewhat lower hospital admission rates, shorter lengths of stay, less use of expensive procedures and tests, and more use of preventive procedures and examinations than enrollees in indemnity plans, the HMOs provided a roughly comparable quality of care based on outcomes and process measures. Hospital costs in high managed-care markets are about 11 percent below the national average. Managed care does not give higher mortality rates or complication rates. In fact, the risk-adjusted mortality rates in high managed-care markets are 5.25 percent below the national average. Overall, HMOs are approximately 18 percent more cost-efficient than indemnity plans, and their cost-effectiveness is strongly correlated with the level of HMO penetration in the region. This finding contradicts the common argument that HMOs have only been cost-effective because they cover the best risks.

A study comparing changes in physical and mental health status between fee-for-service and HMO patients over 4 years found no distinguishable changes on average between patients in the two systems. Patients who were elderly, poor, or chronically ill, however, were more than twice as likely to decline in health in an HMO than in a fee-for-service plan.

A survey of New York City Medicaid beneficiaries found that managed care enrollees consistently rated their care better than, or at least as good as, conventional Medicaid beneficiaries. Beneficiaries in managed care and nonmanaged care systems did not differ on measures of use, nor did managed care decrease the use of more expensive settings to obtain care; inpatient stays and emergency department visits were essentially the same in both groups.

More-recent studies have been less positive, however. More and more public opinion surveys report that more than half the American public feel their health system has deteriorated with the advent of managed care. In Montana, HCFA investigated utilization rates for mental health services provided in the Medicaid program after the introduction of for-profit managed care delivery. Authorized inpatient days dropped 96 percent; residential services, 85 percent; authorized partial hospitalization visits, 45 percent; intensive outpatient services, 25 percent; and authorized outpatient visits, 76 percent. In addition, the number of patients being readmitted within 30 days after discharge increased 147 percent in fiscal year 1997 over previous years. The reductions in health care utilization are in no way matched by reductions in cost. Some critics argue that managed care does little more than transfer resources from those who are vulnerable because of illness and who need treatment (to which they are entitled under the Medicaid program) to venture capitalists who run managed care organizations.

Although quality-of-care reporting systems are in an early phase of development, the quality of both processes and outcomes of care can be evaluated. *Process measures* (what is done to a patient) are more sensitive measures of quality of care because poor *outcomes* (what happens to a patient) may not occur each time something is done incorrectly. *Efficacy* (the outcome of a procedure performed under ideal circumstances) may not predict *effectiveness* (the outcome of a procedure performed under usual circumstances).

Outcomes are multidimensional; a complete assessment of the outcome of care requires measuring general, physiological, mental, physical, and social health and patient satisfaction. Disease-specific outcome data must be collected, and patient preferences should be incorporated into these assessments. Patient satisfaction surveys alone are not always valid, however. Treating a patient in a pleasant and respectful manner (i.e., a good bedside manner) can mask poor technical care.

NEXT GENERATION OF MANAGED CARE

HMOs have long talked about introducing information technologies to track and reduce health costs, along with new models to manage and prevent disease. But few HMOs got past being able to market themselves, process claims, and cut checks each month. Health plans had trouble raising rates because big employers and purchasing groups beat them down. In recent years, however, 16 of the nation's 25 biggest HMOs were swallowed by other companies, which are now so big that they call the shots and find it easier to raise prices.

In addition to their need to raise premiums, health insurers and managed care companies are struggling with an aging population, expensive drugs, new medical technologies, the growth of services to patients outside hospitals, disaffected providers, the growing perception among consumers and policymakers that HMOs have put profits over patients, the complexities and unanticipated expenses of outcome research, the need for population-based prevention services, and the possibility of huge losses related to the various patient protection laws that have been passed or are under consideration by Congress and many state legislatures.

Currently, managed care organizations and payers have little incentive to invest dollars saved through short-term interventions in long-term preventive medicine programs. In the next generation of managed care, it is likely that disease management will overtake complications management and that managed care organizations will reinvest the short-term savings realized through their current strategies into a long-range strategy that promotes health, lowers disability, reduces morbidity and mortality, and ultimately achieves long-term savings.

HMO REFORM

The latest version of Rep. Charlie Norwood's bill, the Access to Quality Care Act of 1999, would amend the Employee Retirement Income Security Act (ERISA)—often used as a shield by HMOs against lawsuits brought in state courts by enrollees who claim that their decisions contributed to a patient's injury—to allow malpractice suits to be brought against HMOs and let states impose stricter standards on health plans than ERISA itself imposes. The bill (1) ensures access—plans must have adequate capacity to offer a broad range of services in a reasonable time at a reasonable location; (2) ensures emergency room care (if a “prudent layperson” believes the visit was necessary, the plan must cover it); (3) prohibits gag clauses; (4) regulates cost-control incentives by requiring that the plan disclose coverage, cost structure, provider mix, utilization review requirements, financial arrangement, and grievance procedures; and (5) allows enrollees to sue when they are injured by a plan's decision to deny coverage of health care services.

Managed care companies are beginning to embrace the external review and independent appeals processes they once scorned, in an effort to stave off reforms that will require them to justify their health care decisions to judges and juries. In some states, however, they were too slow to act (Table 52.2-3). In Texas, for example, HMOs can be held liable for malpractice if they make negligent benefits decisions affecting care. The first case under the new law involved a psychiatric patient, whose family claims that a managed care firm had negligently forced his discharge, despite the protests of his treating psychiatrist, by denying benefits. Following his discharge, the patient committed suicide by ingesting a half-gallon of antifreeze.

Table 52.2-3 HMO Consumer Bill of Rights

LEGAL ISSUES

Problems arise because many services have moved from hospital to primary care offices, gatekeepers are allowed limited flexibility yet are pressured to expand their scope of services, the information (and promises) given to the public by managed care organizations is not always reliable, and the choices provided patients in obtaining medical care may be restricted. Managed care limits a patient's freedom of choice, and it is thus inevitable that there will be more lawsuits against providers.

The main dangers for the physician and in particular the gatekeeper in managed care risk contracts are:

- Limits on care: Accepting utilization review denials without objection or delaying care while waiting for authorization, leading to “loss of opportunity for cure.” The physician's contract with the managed care organization should spell out how the physician and the patient can appeal the denial, delay, or location of patient care decisions. Managed care organizations often fail to give the public (and physicians) adequate or accurate information; some also intimate in that the care they will provide is more extensive than it actually is. In both cases, the physician is left holding the bag, because the patient tends to blame the physician rather than the managed care organization. Physicians are expected to provide services that would meet the community's standards of care, whether or not they are authorized by the plan. Lawsuits alleging negligence under managed care have been growing steadily over the last 5 years, and the claims are increasingly targeting physician groups rather than HMOs. Health care plans have been criticized particularly for withholding needed care by excluding or limiting coverage for chronic conditions such as human immunodeficiency virus (HIV) disease or mental illness, by denying reimbursement for experimental procedures, or by setting limits on the duration of inpatient hospital care for certain conditions.
- Financial incentives, as in capitation and bonuses that may lead to conflicts of interest. Many managed care organizations include “gag rules” in their contracts with physicians; they prohibit physicians from doing or saying anything that might undermine the confidence of enrollees in the plan. Yet the doctrine of informed consent requires disclosure by the physician. The enrollee may not lose confidence in the plan; instead, trust in the physician is undermined.
- Expanded scope of practice. The specialist's standard of care will apply even when the special care is rendered by the gatekeeper; this may lead to liability for failure to diagnose as well as failure to perform. Furthermore, even though the panel of specialists may be limited in a plan, gatekeepers are nonetheless expected to ascertain the qualifications of those to whom they refer, and they may be vicariously liable for specialist care.
- Coordination of care, such as failing to follow up on patients who are referred.
- Health screenings, often promised when a plan is being marketed as part of its focus on wellness. The physician who does not follow through could be held responsible.
- Plan exemptions. ERISA limits the types of damage that can be awarded a claimant. A managed care plan cannot be held liable for the consequences of a benefit determination, although it can be held liable for the consequences of a treatment decision. Physicians, however, are always held to their professional responsibilities to the patient. Whether a judgment made by a managed care organization is a benefit determination or a treatment decision has been the subject of many court cases. It is not clear if ERISA preempts state tort actions based on the medical malpractice of physicians or if managed care organizations, as employers, can be held vicariously liable for the physician's negligence. Some managed care organizations have tried to avoid the courts' uncertainty through indemnification (hold-harmless) clauses in their contracts with physicians. Such clauses require the physician to indemnify the managed care organization not only for physician negligence but also for all patient care liability, even denial of care by the managed care organization. Obviously federal law has not yet solved the problems of access and equity in health care, and it may even obstruct states' efforts to do so. ERISA preempts state action to ensure access and nondiscrimination, while the financial disincentives imposed by the managed care organization to provide fewer costly medical interventions, emergency department visits, and specialist referrals are potential threats to the patient-physician relationship and the quality of care provided.
- Termination. The termination policy in the contract between the physician and the managed care organization must clearly spell out the mechanisms for notification of patients and the transfer of patient care responsibilities when the physician resigns or is terminated; otherwise the patient may claim abandonment.
- Antitrust liability. Peer review and credentialing activities may expose the reviewer to antitrust action by a physician who is not admitted to the plan or one who is

dropped from a plan. In many areas, physicians and hospitals lack the immunity from antitrust actions that HMOs enjoy and are in fact proscribed from joining together and working collectively in ways that might benefit their patients. Under the 1994 guidelines to the antitrust enforcement policies of the Federal Trade Commission (FTC) and the Department of Justice (DOJ), physicians in solo practice or in small groups were allowed to negotiate discounted fee-for-service contracts directly with employers only under a cumbersome “messenger model.” In such a model, the physicians had to appoint a third party to be their messenger, who solicited offers from payers and then informed each physician separately (and without disclosing the range of fees that any other physician had said would be acceptable) about the payers' decisions. Any attempts to modify the messenger model were seen as per se violations of antitrust law—meaning they were considered violations merely because they had occurred and not because they were shown to harm competition. Clearly, it would be better for physicians if a rule of reason applied instead, requiring demonstration on a case-by-case basis that antitrust laws were violated and harmed competition. In August 1996 the antitrust guidelines were revised so that physician and multiprovider networks can escape automatic charges of price fixing. They can still be examined and challenged, of course, but it will be on a rule-of-reason basis rather than per se.

Many states are trying to increase control over managed care organizations (Table 52.2-3). Mandated maternity length of stay was the most widespread law in 1996, propelled by media reports that plans were requiring new mothers to be discharged from the hospital in as few as 6 hours after delivery. Next in frequency were laws requiring plans to provide patients with information about terms and conditions, anti–gag clause legislation, “fairness” laws (e.g., requiring plans to credential providers based on quality), standards and safeguards in utilization review, and requiring plans to allow patients to use nonnetwork providers.

Other issues that have come under legislative review in different states include complaint procedures, methods for opting out of a plan, marketing abuses, regulation of emergency services through the “prudent layperson” standard of what is a serious health problem, ensuring the chronically ill direct access to specialists, outside review of coverage decisions, provider due process for termination including the opportunity for a hearing, disclosing information on policies for referral, prior authorization, provider compensation, standards for drug coverage, establishment of a grievance procedure for denials and setting deadlines for resolving grievances, and maintaining confidentiality by establishing security procedures.

ETHICAL ISSUES

Whether health care should be subjected to the values of the marketplace is a fundamental question, because market-driven care tends to alienate physicians and undermine patients' trust of physicians.

Conflict of Interest Beneficence is central to medicine, but it is an impediment to the operation of competition and market forces. Beneficence toward individual patients frustrates the physician's obligatory role as gatekeeper in a managed care plan, which may encourage some gatekeepers to try to manage cases longer than they should, to keep patients at the primary level of care. Within capitated managed care organizations, physicians are expected to provide a wide range of services while keeping expenses to a minimum, typically by limiting use of services, increasing efficiency, shortening the time spent with each patient, and sparing use of specialists.

Managed care involves other conflicting loyalties. Within a managed care organization physicians have a responsibility to the patients they treat, but they also have a responsibility to all the other members of the capitated population. At times, that involves setting limited goals for particular patients in the interest of preserving access to appropriate care for all other patients in the group. It sometimes means drawing a careful distinction between what the patient wants and what the patient needs, between what is the best of all possible treatments in a particular situation and which one will be adequate and acceptable.

Managed care can pit patient needs against the financial interests of their physicians. Managed care organizations may pay bonuses to physicians, with the bonus increasing as expenditures for patient care decrease. Possible results are that some physicians will not provide all the services they should and that some will not always be adequate advocates for their patients in dealing with the managed care system. Under incentives to cut corners, even though there is no actual patient harm, physicians may lose their patients' trust that all necessary care is being provided.

Confidentiality Because health care depends on ready access to data, absolute privacy is unattainable in any kind of health data system. This raises the vexing question of the proper balance between data collection and privacy protection and the best means of achieving it. Justifications for privacy are based primarily on respect for the individual; justifications for using health information are based on the societal or collective good.

At present, data banks exist for specific kinds of data (e.g., genetic databases) and diseases (e.g., acquired immune deficiency syndrome [AIDS], tuberculosis, cancer). Systematic acquisition of a broad range of personal health data automatically results in loss of privacy. Health information can reveal intimate aspects of a person's or a family's life; it may affect one's ability to hold a job, maintain custody of children, secure immigration status, or obtain access to insurance or public benefits. In growing recognition of the effects of behavior on personal health, health agencies now collect and analyze behavioral information regarding, for instance, alcohol and other drug use, seat-belt and bicycle helmet use, smoking, exercise, and sexual practices.

Many forms of surveillance require disclosure of patient information to health departments. Patients, often rendered physically and mentally vulnerable by their illnesses, divulge intimate details of their lives to their physicians. Assurance that such information remains confidential is central to a trusting physician-patient relationship. It promotes patient candor about health and disease risks; uncertainty about confidentiality favors decreased disclosure, less frankness, or worse, reluctance to seek care. Finally, unauthorized disclosure of information can result in embarrassment, stigma, and discrimination.

Most states have nominal safeguards of public health privacy, but they are often incomplete or inadequate. Statutes are often silent about secondary uses of information (i.e., disclosure of data for purposes beyond those used to justify the original collection). Patients are not told whether, or to what extent, data collected for one purpose may be used for an unrelated purpose.

Many states have enacted disease-specific statutes. Some laws rigorously protect certain disease-specific data (e.g., HIV/AIDS) but are silent about guarding information on other conditions (e.g., noncommunicable diseases). As a result, different parts of the same health record may receive different degrees of protection under separate disease-specific statutes.

Electronic Records The change from fee-for-service to managed care has greatly expanded the use of electronic patient records. Manual records per se are by no means a guarantee of privacy. The major differences between the two kinds of records are that electronic records can more easily store much more information, can transmit it rapidly and simultaneously to large numbers of viewers (thousands, or even millions, rather than one or two), can readily link data that would otherwise remain separated indefinitely, and can store data indefinitely. The electronic record offers so many advantages that no credible suggestion of control has ever proposed its elimination. In view of the strengths and desirability of electronic records, what can be done to protect the patient's confidentiality? Among the basic elements of security strategy are the following: (1) data confidentiality, (2) identification and authentication of transmission sources and destinations, (3) data integrity, (4) ability to trace the message to a specific sender and receiver, and (5) access control.

Electronic systems can support selective restrictions on access to data, maintain extensive audit trails of who has seen or modified data, and transmit data in encrypted form. A message can be tagged so the sender cannot deny having sent it and the recipient cannot deny having received it. Digital signatures—unique numerical codes—are used to check the authenticity of sender and receiver. They can also be used for the physician's approval of record summaries and medical orders. The signature identifies location, privileges, and other essentials of secure electronic message exchange.

The *firewall* is a sophisticated software/hardware combination that stops unauthorized messages from the outside, accepting only those approved in advance. It also keeps insiders from using the Internet for unauthorized purposes.

A *message authentication code* (also called a *check sum*) extracts a unique summary of the message, compresses it, and compares it with the actual message. It recognizes any bit that has been changed and exposes the corrupted file.

No perfect system of confidentiality protection (if there be one) has yet been devised. Breaches of security can occur at all levels of communication, and information can be intercepted at different points. The human layer of confidentiality is the hardest to regulate. Hackers who attempt to break security systems invariably do so by duping people into giving out their passwords. They might claim they are system maintainers, impressing the unwary with technical jargon. Another hacker technique is “dumpster diving,” that is, looking through trash cans for paper memos containing the scribbled passwords that computer users write to themselves to help remember how to access their systems.

Informatics specialists strive for a balance, using technical and administrative safeguards to balance efficient access with confidentiality. A further step is to enact laws that impose severe sanctions on those who contribute to the misuse of confidential medical information. Finally, the sanctions must be enforced rigorously (not haphazardly) against all violators, not only a few token scapegoats.

SUGGESTED CROSS-REFERENCES

Primary care psychiatry is covered in Section 28.1. Health care delivery systems are discussed in Section 51.5 which covers Medicare, Medicaid, veterans affairs and community issues for the elderly. Legal issues in psychiatry and ethics in psychiatry are covered in Chapter 54. The future of psychiatry is discussed in Section 55.3. For the editors' view of managed care in psychiatry, see the Preface.

52.3 ROLE OF THE PSYCHIATRIC HOSPITAL IN THE TREATMENT OF MENTAL ILLNESS

W. WALTER MENNINGER, M.D.

DEFINITION

Efforts to control escalating health care costs in the 1990s have focused on the most expensive locus of treatment, the hospital. This has been true for medical and surgical hospitalization as well as psychiatric hospitalization. Nonetheless, the psychiatric hospital represents a significant modality in the treatment of severe mental illness. It is a structured, therapeutic setting that simultaneously provides care, protection, and control while allowing the patient respite from a stressful situation.

From 1970 to 1992 the number of mental health organizations in the United States with inpatient or residential treatment services doubled, but the actual number of psychiatric beds provided by these organizations diminished by nearly half, from 524,878 in 1970 to 270,867 in 1992. Most striking has been the decrease in state hospitals, both in numbers and in beds. In 1990, while the total number of beds was lowered, the number of private psychiatric hospitals had increased threefold over the previous two decades from 150 to 462, with somewhat more than half owned by for-profit multihospital corporations. This same period saw more than a doubling of general hospital psychiatric units from 664 to 1571.

As tracked by the National Institute of Mental Health and National Center for Mental Health Services, patient care episodes in all mental health organizations increased fivefold between the first collection of these data in 1955 (1.7 million episodes) and 1992 (8.8 million episodes). In 1955, the inpatient episodes (1.3 million) represented more than three fourths of the total patient care episodes; the balance was outpatient. Consistent with their relative dominance in 1955, state and county hospitals accounted for 63 percent of those inpatient treatment episodes. By 1992, while inpatient episodes were somewhat increased (to 2.3 million), they accounted for only one fourth of all treatment episodes. Outpatient episodes then accounted for 69 percent of all treatment episodes, and partial care accounted for the remaining 6 percent. By 1992 only 15 percent of the inpatient episodes occurred in state and county hospital facilities. An increased number of psychiatric units in nonfederal general hospitals served 43 percent of the inpatient episodes in 1992 (up from 21 percent in 1955), while the proportion of 1992 inpatient episodes in private hospitals jumped to 24 percent (from 9 percent in 1955). Veterans Administration medical centers provided 9 percent of the inpatient episodes in 1992 (7 percent in 1955), and multiservice centers, not in existence in 1955, accounted for 9 percent of the inpatient episodes in 1992.

Paralleling the overall decrease in hospital beds, the average length of inpatient stay has been halved since the early 1980s. In one university hospital psychiatric service, the length of stay dropped 64 percent between 1985 (39 days) and 1993 (13 days). For Medicare admissions in 1992, the average length of stay was between 16 and 19 days. In short–term-care private hospitals, the average inpatient stay in 1993 ranged from 10 to 28 days, and this downward trend has continued in the years since. In general hospital units, the average stay now is 4 to 6 days. Whatever their governance, all hospital programs are expanding to provide a full continuum of care, ranging from crisis respite to intensive inpatient treatment to partial hospital care and sometimes residential programs for aftercare.

HISTORY

Sanctuaries for the physically and mentally ill date back to sixth century BC Greece. The earliest institutions devoted just to the care of the mentally ill were in the fourth century AD, in Byzantium and in Jerusalem. Over the next 1000 years, various religious orders, both Christian and Mohammedan, established places of refuge for the mentally ill. In Baghdad, the mentally ill were brought from all parts of Persia in 1173 to a House of Grace, where they received medical care until they recovered. Bethlehem Hospital in London, founded in 1247, began to accept “lunatics” in 1377. In Spain, mental hospitals date from 1410; mental patients were designated by the term une innocente (one without malice, easily fooled), and the mental hospital was identified as *hospital de innocentes*. The institutional care of the mentally ill in Europe in the late eighteenth and early nineteenth century was largely one of abuse, neglect, and restraint, with patients poorly clothed and fed, chained in hovels and dungeons, at times exhibited for the amusement of the public. For many years, keepers at London's Bedlam (Bethlehem Hospital) displayed patients like animals in a side show.

Philippe Pinel (1745–1826) is credited with revolutionizing the institutional care of the mentally ill when he liberated over 50 patients from chains and dungeons at the Bicetre hospital in Paris in 1793; his subsequent publication of *Traite Medico-Philosophique Sur L'alienation Mentale* (1801) outlined a humane approach to the care of these patients. In that same era, in England, William Tuke (1732–1819) proposed to the Society of Friends that they establish an institution “where a milder and more appropriate system of treatment than that usually practiced might be adopted.” In 1796 this led to the York Retreat, where abuse and restraint were replaced by kindness, tolerance, gentle exercise, work in the garden, and light recreation.

In early America, patients were cared for in their own or their relatives' homes, allowed to roam the countryside, or locked up in jails. The first institution to provide a specific unit for the mentally ill was the Pennsylvania Hospital, founded in 1752; its charter specifically provided for “the relief of the sick and the reception and cure of lunatics.” The first public facility exclusively for the mentally ill was opened in 1773 in Williamsburg, Virginia, based on the Bedlam Hospital in England. Both these institutions initially treated the mentally ill with procedures similar to the practices in Europe: bodies were chained, scalps were shaved, and bowels were purged. At the time of the American Revolution when Benjamin Rush (1745–1813) was on the staff of the Pennsylvania Hospital patients were being treated with venesection (blood letting), low-salt diets, purges, and emetics.

Early in the nineteenth century, “moral treatment” reached the United States. Modeled after the principles espoused by Tuke at the York Retreat, this treatment emphasized open wards, pleasant surroundings, minimal restraints, regular activity, and a familial relationship between the superintendent and the patients. Several private institutions committed to this humane therapeutic approach were opened: the Friends Asylum at Philadelphia (1817); the McLean Asylum outside Boston (1818), the Bloomingdale Asylum in White Plains (1821), and the Hartford Retreat (1824). Extraordinary treatment outcomes were claimed for this new treatment, with “cure” rates of 40 to 100 percent.

Except for a few early public mental hospitals—Eastern State Hospital in Lexington, Kentucky (1824); Manhattan State Hospital in New York City (1825); Western State Hospital in Staunton, Virginia (1828)—care for the indigent mentally ill was provided in jails. Dorothea Lynde Dix (1802–1887), a school teacher retired because of recurring tuberculosis, encountered the appalling conditions of the mentally ill when she was teaching Sunday School to female prisoners in Boston in 1841. She embarked on a crusade to get the mentally ill out of the jails and into suitable hospitals. By 1850 almost all the northeastern and midwestern states accepted her concept of a state-funded mental hospital; by 1860, 28 of the 33 states had at least one such hospital.

These state hospitals were originally designed to provide moral treatment in rural settings well removed from population centers because the “evils” of urban life were presumed to be a major cause of mental illness. They became large institutions, isolated from patients' families, increasingly impersonal and inhumane. The moral treatment emphasis on silence, orderliness, and regular routines gradually turned into regimentation and control. The initial expectation for treatment success was not achieved, optimism faded, populations began to rise, and hospitals became overcrowded.

In the late nineteenth century in Europe and the United States, special psychiatric hospitals were established for scientific study and treatment of mental illness—psychopathic hospitals. Bellevue Hospital in New York City, completed in 1879, was the first in this country, emphasizing examination, short-term observation, and treatment of acutely ill patients. Subsequent psychopathic hospitals were established in Boston (1912), Baltimore (Phipps Clinic, 1913), and Denver (Colorado, 1923), affiliated with medical schools to facilitate psychiatric education and research.

Modern Hospital Psychiatry The first biological era of modern hospital psychiatry was ushered in by the discovery of an organic etiology for some mental disorders early in the twentieth century, particularly syphilis, and the encephalitis associated with the 1917 influenza epidemic. Physicians prescribed specific medications—bromides, hypnotics, amphetamines, thyroid extract—in the treatment of mental illness in the 1930s. In 1933, coma induced by giving insulin to schizophrenia patients was touted as a new cure for the disorder. In 1934, Hungarian psychiatrist Ladislau von Meduna (1896–1964) reported positive results from chemically induced seizures in schizophrenia patients with severe psychosis. In 1938, Ugo Cerletti (1877–1963) and Lucio Bini (1908–1964) introduced electroconvulsive therapy (ECT). Initially employed for schizophrenia patients, it became recognized as an effective treatment for certain depressions, acute mania, and catatonic excitement. By the 1950s ECT had become the most used organic treatment in hospital psychiatry.

During the 1930s psychoanalytic ideas also were applied to the psychiatric hospital, most notably in the work of William Menninger (1899–1966) at the Menninger Clinic and Harry Stack Sullivan (1892–1949) and Frieda Fromm Reichmann (1889–1957) at Chestnut Lodge. Menninger designed an individualized treatment approach addressing the patient's needs through prescribed staff attitudes and therapeutic activities, activities that helped patients develop more appropriate outlets for the internal conflicts and psychological needs that previously found expression in the illness.

Following World War II, hospital programs were profoundly influenced by concepts of social and community psychiatry. In 1947 Maxwell Jones (1907–1990) established what came to be known as a therapeutic community. Rather than operating in the traditional, hierarchical manner of most hospital programs, he emphasized democratic, egalitarian values, encouraging everyone in the community to maximize their therapeutic potential through community meetings and ward activities. Meanwhile, the explosion of antipsychotic and antidepressant medications prompted the second biological era of hospital psychiatry. The availability of medications to diminish psychotic disorganization and facilitate patients' recovery changed the character of hospital units and reduced hospital stays.

In the 1950s, prompted by writings in the lay press, there was a renewed focus on the scandalously poor care provided in most public mental hospitals. Social psychologists were also criticizing the “institutionalization” associated with care in such facilities. Congressional action in 1955 established a Joint Commission on Mental Illness and Health, which produced a report in 1961, *Action for Mental Health*. This report laid the groundwork for the widespread establishment of community mental health centers. Concomitant with these developments and the introduction of psychiatric medications, there was a steady decrease in the public mental hospital census—a decrease that has continued to the present day.

The day or partial hospital is a modern development. The first reported day hospital was established in Moscow by M. A. Dzhagarov in 1933 because of a bed shortage and inadequate funds; it consisted mostly of work therapy. The first program in the Western Hemisphere was established by Ewen Cameron at the Allen Memorial Institute in Montreal, Canada, in 1947. A partial hospital program was established at Yale in 1948, the Menninger Clinic in 1949, and the Massachusetts Mental Health Center in 1952. The growth of partial hospital programs was stimulated by the deinstitutionalization of the public mental hospitals and the creation of community mental health centers.

The role of the psychiatric hospital in the treatment of mental illness has been maligned in recent years, with criticism stemming from several quarters. As a byproduct of the civil right's movement in the 1960s, civil libertarians challenged the restriction of patient movement and activity that accompanies most psychiatric hospitalization. Legislators viewed hospitals as expensive and outdated, needing replacement by less costly alternatives. Professionals, policy makers, and the public all looked at the community mental health movement as a less expensive, more effective, and more humane treatment alternative.

Meanwhile, when psychiatric hospital services were granted an exemption from the cost controls dictated by prospective reimbursement for hospitalized patients based on diagnosis-related groups, many general and psychiatric hospitals expanded capacity. A resulting dramatic increase in mental health care costs in the 1980s prompted third-party payers for psychiatric services to institute independent utilization review and to challenge the justification for hospital treatment. Following the proliferation of private psychiatric hospital beds in the late 1980s, some for-profit psychiatric hospitals engaged in unethical practices to fill those beds—paying for patient admissions, charging for services not rendered, using fraudulent diagnosis data, waiving the patient's deductible, and overcharging the insurance company.

THEORETICAL ISSUES

Traditionally, the functions of the psychiatric hospital have been: (1) the protection of the patients against their possible destruction of themselves, or harm to their homes, their work, or others; (2) the simplification of existence for patients by affording them protection from factors in the environment that precipitated and aggravated their illness; and (3) the provision of supportive care, personal contacts, and opportunities for expression and psychiatric counsel. To facilitate “healing” and recovery from mental illness, the hospital functions as a holding environment—secure, safe, predictable, warm, caring, and nurturing. Limits are clearly defined, particularly with respect to interpersonal boundaries. As a general rule, if these functions can be provided in a less restrictive treatment alternative, a patient should not be hospitalized.

These traditional functions and utilization of the hospital in psychiatric treatment have been challenged in recent years, primarily because of the greater expense of hospital care. In today's managed-care environment, one approach to reducing cost has been to limit psychiatric hospital treatment to patients who meet the criteria for “medical necessity”—suicidal behavior, aggressive behavior, or symptoms or behaviors that impair the person's ability to function outside an inpatient unit. Intervention is warranted only when the patient's life is in jeopardy or if the patient's behavior threatens to harm others. Critics of hospital treatment have also cited the limited data regarding the efficacy of inpatient treatment over alternative care. Indeed, experimental studies of hospital versus alternative treatment for mental disorders during the 1970s prompted a conclusion that outcomes of hospitalization were no more positive than the outcomes of alternative treatment.

Under pressure to reduce the cost of treatment, largely by reducing the length of hospitalization, the goal of hospital treatment has been significantly modified—to resolve the crisis that prompted the hospitalization. In the past, extended hospitalization provided an “in vitro” setting in which patients play out the symptomatic conflicts that they had manifested in everyday life “in vivo,” prior to hospitalization. In the milieu of the treatment setting, patients recreate their internal object world and problematic relationship patterns. Through the process of projective identification, staff members replicate important figures from the patient's past and current relationships. Careful examination of transference and countertranference developments in the patient's relationships with staff members reveals the dynamic conflictual issues in relationships that were a source of distress and malfunction in the patient's everyday life. Thus, the hospital is an artificial environment where the patient's unconscious conflicts can be expressed and perhaps resolved.

The therapeutic milieu in the hospital seeks to address patients' needs by containment, structure, involvement, support, and validation. As outlined by John Gunderson, *containment* sustains the physical well-being of patients and removes the unaccepted burdens of self-control or feelings of omnipotence, that is, it prevents patients from damaging themselves or others. *Structure* encompasses all aspects of the setting that provide a predictable organization of time, place, and person, allowing patients to feel safely attached without being overcontrolled or alone. *Involvement* in group activities and meetings with staff and other patients force patients to utilize and strengthen their ego and modify aversive interpersonal patterns as they interact with the therapeutic environment. *Support* is provided by the conscious efforts of the treatment team to make patients feel better and to enhance their self-esteem. *Validation* occurs when the therapeutic encounters and individualized treatment plan affirm the patient's individuality.

From the perspective of ego psychology, which regards mental illness as an ego disruption and disorganization, John and Elaine Cumming suggest that the hospital

> milieu must offer to the patient a clear, organized, and unambiguous social structure, problems to solve in protected situations, and a variety of settings in which to solve these problems. It should also offer him a peer group and a helpful staff to encourage and assist him to live more effectively. The program should aim at equipping the patient to act in clearly defined roles powered by a variety of motivating forces and governed by different cultural values.

In 1972 D. L. Rosenhan exposed some of the weaknesses and limitations of psychiatric hospitalization after arranging for pseudopatients to be admitted to twelve psychiatric hospitals in five different states. While there were significant methodological shortcomings in his study, his observations are nonetheless reflective of the criticism of the psychiatric hospital unit. He concluded:

> The hospital itself imposes a special environment in which the meanings of behavior can be easily misunderstood. The consequences to patients hospitalized in such an environment—the powerlessness, depersonalization, segregation, mortification, and self-labeling—seem undoubtedly counter-therapeutic.

TECHNIQUES

Hospital treatment characteristically involves a multidisciplinary group of mental health professionals. Each team member addresses different elements of the patient's difficulty: psychiatrist (medical or psychiatric, medication, psychotherapy), nurse and mental health technician (personal care and interaction), psychologist (diagnostic assessment of cognitive strengths and weaknesses, psychotherapy), social worker (relations with family), activity therapist—occupational, recreational, music (avocational and vocational skills). The diagnostic assessment and treatment of the patient are enhanced by the collaboration and integration of these multidisciplinary perspectives.

The phases of hospital treatment include (1) admission, (2) immediate assessment and intervention, (3) continued diagnostic evaluation and refinement of treatment, (4) clarification of treatment goals and discharge criteria, (5) progress toward and achievement of goals, (6) discharge, and (7) appropriate aftercare or follow-up. The impact of managed care review has shortened the time allotted for these phases. When the hospital has a full continuum of care, ranging from intensive inpatient treatment to partial hospital programs for aftercare, the phases will continue into the partial hospital period.

Each patient should have a well-defined master treatment plan that addresses the reason for admission and the need for hospitalization, an assessment of patient problems, patient's strengths and assets, formal diagnoses, discharge criteria, and anticipated placement and posthospital treatment. Further, the treatment plan should identify problems to be focused on by the members of the treatment team, particularly problems that reflect the primary reason for hospitalization. Generally, the problems will be evident in one or more of the following areas: self-concept, interpersonal relationships, thinking and cognition, emotional functioning, impulse regulation or addiction, adaptive skills, or family. Goals should be articulated in measurable terms so that the patient's progress can be readily observed by all members of the treatment team. Prescribed diagnostic and treatment modalities should be recorded, as well as which staff members are responsible for carrying out these tasks (Table 52.3-1).

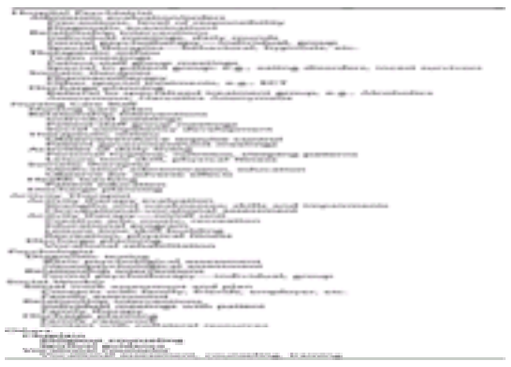

Table 52.3-1 Hospital Treatment—Responsible Staff and Modalities

Hospital treatment programs may be characterized by their length of stay, primary treatment modality, and treatment goals. Inpatient programs are generally categorized as (1) short-term, crisis intervention (1 to 4 weeks); or (2) extended treatment (greater than 4 weeks). Partial hospitalization programs are generally open-ended, and may serve as a transition from inpatient to outpatient care, or they may be entered directly. These programs include various combinations of day hospital supervision and activities and night accommodations—night hospital, halfway house, family care, cooperative housing, and independent living.

Short-Term Inpatient Programs Short-term or brief hospitalization seeks to arrest and reverse an emotional decompensation, alleviate an acute mental illness, reduce symptoms, restore defenses, and facilitate a readjustment of the patient to the prior environment. These goals are achieved through the separation of the patient from the environment by admission to the hospital, administration of appropriate psychiatric medication, exploration, and negotiation with significant others in the patient's life, and supportive and exploratory psychotherapeutic intervention with the patient. Sometimes specialized treatment procedures like ECT may be indicated. Short-term hospitalization may also be utilized for an in-depth diagnostic patient evaluation. Short-term stays are possible when no untoward treatment complications arise and when posthospital resources or support systems are available, accessible, or rapidly developed.

Specialized or focused programs have been developed for a wide range of mental illnesses, such as alcohol or other substance abuse, eating disorders, and dissociative disorders. In the 1970s the prototype of these programs was developed for the treatment of alcohol use disorders, with a time-limited treatment program consisting of patient education about all facets of the condition, group confession and confrontation, self-help groups (Alcoholics Anonymous), and social work with family. Now, these programs may utilize the controlled environment of the hospital to control the patient's impulse to pursue symptomatic behavior while providing psychotherapeutic, educational, social work, and rehabilitative support.

Extended-Treatment Programs Extended-treatment programs remain necessary for difficult-to-treat illnesses that do not respond to brief intervention or short-term treatment. Lloyd Sederer and Paul Summergrad note that longer-term treatment may be indicated when briefer treatments have failed, treatment complications are severe, a treatment alliance is absent or resisted, life stressors are so profound or persistent that they impair recompensation, or an extended period of treatment is needed to achieve any beneficial effect. Extended-treatment programs may be modeled after a psychoanalytic psychotherapeutic model, a therapeutic community model, a token economy behavioral treatment model, or a moral treatment custodial care model.

The psychoanalytic perspective views symptoms as a product of unconscious psychic conflict within the patient, a compromise formation that expresses both the unconscious drive derivative and the ego's defense against the impulse. Further, it is assumed that all behavior is determined and has meaning. The psychoanalytic model of hospital treatment seeks to identify and resolve the conflicts and symptomatic ego defenses of the individual as they are played out in the interactions with other staff and patients in the hospital. As articulated by William Menninger:

> It is our hates and our mismanaged loves that account for most if not all of our emotional sickness. In other words, our reactions to the people about us and their reactions to us result in adjustment or in varying degrees of maladjustment. Similarly, within the hospital, it is the relationships with other human beings—with other patients and with the hospital personnel—and the understanding of these relationships which lead the patient back to emotional health. The hospital must provide a variety of opportunities for resolution of the patient's conflicts through his expressing his hate in appropriate or constructive ways, in his learning to find new or renewed satisfactions in his activities, in his learning to love and be loved.

The therapeutic community was originally introduced in England, conceived by T. F. Main and popularized by Maxwell Jones. This model looks at the hospital unit as a social system. It seeks to optimize the patient's healthy functioning in a setting that levels the hierarchy of the hospital and involves patients in decision-making on the unit. It places responsibility on the patients to serve as agents of change, having a significant role in the rehabilitation of other patients on the unit. This model depends upon older patients transmitting to newer patients the norms, skills, and values essential for meaningful participation in the therapeutic community. Jones' treatment program was primarily designed for the treatment of patients with personality disorders. Therapeutic community approaches are more difficult to implement in units that treat a large number of psychotically disturbed patients because groups may be overstimulating to them.

The token economy model applies principles derived from experimental psychology and operant conditioning, with token rewards used as positive reinforcement for desired behaviors. These programs are used with more regressed, lower-functioning chronically ill patients. As the patients receive rewards for the preferred, adaptive behavior, they can exchange the tokens for desired privileges and activities.

In all models of inpatient hospital treatment, psychiatric nursing plays an essential role. Nursing personnel provide the direct supervision of the patients and administer prescribed medication. They also provide for basic needs of the patient, offer organization and structure, give support and aid intrapsychic growth, assist the patient with interpersonal and interactional skills, and promote coping skills in a teaching and learning environment.

Partial Hospitalization Partial hospitalization offers an alternative to 24-hour hospitalization, with some structured treatment programs that represent a transitional care setting between hospital and community. For some chronically ill patients the partial hospitalization may continue for an extended period. Most programs provide an informal, clublike setting that facilitates social interaction, features therapeutic activities, and diminishes dependency and isolation. Patients have a case manager or treatment coordinator who functions as an advocate and facilitator for the patient. Rehabilitation and vocational programs include assistance with daily living skills,

recreational activity, and job training. Other services provided are medication review, group therapy, family treatment, and crisis treatment.

CLINICAL ISSUES

Indications for Hospitalization Indications for hospital treatment are determined by factors within the individual patient—severity of the illness, level of awareness or insight regarding the illness, and the capacity to contain impulsive, destructive behavior—and factors in the environment such as presence or absence of support and intensity of ongoing stressors. As a general rule hospital treatment is indicated when the patient is so severely disturbed that it is necessary for someone else to step in and protect the patient from harming self or others, and the patient's environment is not in a position to provide this protection (Table 52.3-2). In recent years various checklists of admission criteria have been published; essentially, a patient merits hospitalization when there are serious problems in three parameters: the degree of dangerousness, the adequacy of the support system, and the ability to cooperate with care.

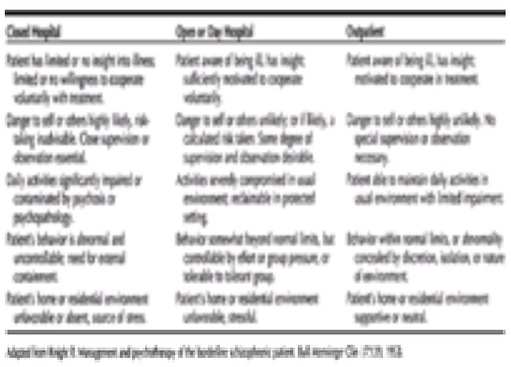

Table 52.3-2 Criteria for Hospitalization

Glen Gabbard has outlined comparative indications for brief and extended hospitalization according to a grid of (1) severity of illness factors, (2) treatment factors, and (3) environmental factors. Severity of illness factors include the danger to self or others, the degree to which symptoms interfere with functioning in work of family and are unresponsive to outpatient treatment, impulsive or noncompliant behavior, and dual diagnosis with substance abuse complicated by another psychiatric disorder. Relevant treatment factors are the history of any previous hospitalization and the response to any prior treatment, the presence of any treatment complications, and the goals of treatment. Environmental factors are the family system, the posthospital support system, and the existence of clear precipitating stressors (Table 52.3-3).

Table 52.3-3 Indications for Brief Hospitalization and Extended Hospitalization

With regard to criteria for hospitalization for children, a review of 375 children seen at the Western Psychiatric Institute and Clinic at the University of Pittsburgh identified six items that discriminated between those children who were hospitalized and those who were not:

1. Aggressive outburst toward other people.
2. Aggressive outbursts toward animals or objects.
3. Patient's condition was deteriorating rapidly or failing to improve despite adequate outpatient treatment.
4. Physical or neurological conditions or a psychotic, disorganized state requires hospitalization to initiate treatment or to establish a diagnosis.
5. A pathological or noxious situation exists among the patient's family or associates that makes treatment without hospitalization impossible; or the patient's disordered state creates such difficulties for the family that the patient has to be hospitalized.
6. Evaluation of the patient's condition requires 24-hour observation and evaluation which only a hospital can provide, including stabilization or reevaluation of medication or treatment of drug or alcohol dependence.

Complications of Hospitalization Complications of hospital treatment—inpatient or partial hospital—are in large part a function of the multidisciplinary treatment team interacting with patients' pathology. Many forces impinge on the work of this team, reflecting group dynamics, patients' transference reactions, and staff countertransference. In their classic study of Chestnut Lodge, Alfred Stanton and Morris Schwartz review “institutional participation in psychiatric illness and treatment,” and they identify breakdowns in staff communication and splitting, which resulted in treatment complications. Gabbard identifies four features of the process of splitting in hospital treatment:

> (1) The process occurs at an unconscious level. (2) The patient perceives different staff members in dramatically different ways, based on projections of the patient's internal object representations, and treats each staff member differently according to those projections. (3) Staff members react to the patient, through projective identification, as though they actually were the projected aspects of the patient. (4) As a result, treaters assume highly polarized positions in staff discussions about the patient and defend those positions with extraordinary vehemence.

T.F. Main has described troublesome countertransference reactions when patients fail to respond to earnest treatment efforts. Treatment staff “tend to become more passionate, to be reinforced by aggression and then to deteriorate in maturity, with sadism invading the situation, together with its concomitants of anxiety, guilt, depression and compulsive reparative wishes, until ultimate despair can ensue.” Other countertransference phenomena include rejection of the unresponsive or difficult patient, benign neglect of undemanding patients, and inappropriate acting out by staff through expression of anger or romantic involvement with provocative patients. These countertransference patterns are best managed by creating a climate and expectation that permits treatment staff working in the milieu to openly express countertransference feelings in staff meetings. Clear communication of disagreements between staff members on the team is essential to cope successfully with the complications that result from splitting and projective identification enactments. Finally, ongoing staff education about splitting and projective identification is important to help staff members recognize these phenomena when they occur.

Patient's Family The family both influences and is influenced by hospitalization of a family member. Rather than focus on a pathological interaction between patient and family, modern hospital treatment attempts to engage the family as a caring and concerned resource in the treatment process. Models have been developed for inpatient family intervention, initiating family therapy with the patient's hospitalization. This approach does not assume that the etiology of the major psychotic disorders lies in family functioning or communication, but rather that the present-day functioning of a family with which the patient is living or is in frequent contact can be a major source of stress or support. The intervention seeks to help the family to understand, live with, and deal with the patient and the patient's illness. Psychoeducational workshops and multiple family group meetings are especially helpful to families of patients who are chronically mentally ill.

CONTEMPORARY ISSUES

Access to Treatment It has become increasingly evident that economic forces determine which patients gain admission to public hospitals, general hospitals, or private psychiatric hospitals. Rather than a specific diagnosis, the driving factor behind admission to a particular hospital is the patient's source of funding. A review of sample surveys from the National Institute of Mental Health for 1975, 1980, and 1986 found state hospitals increasingly admitting patients with no source of payment. Although there was an overall decline in patients with private insurance across all diagnostic and racial groups, patients with mood and mild mental disorders were more likely to have private insurance or access to Medicare or Medicaid dollars and to gain admission to either private general hospitals or private psychiatric hospitals.

What happens with fewer and fewer state hospital beds? Richard Lamb and Roderick Shaner reviewed the experience in California, which had only 8.3 state hospital beds per 100,000 population in 1993, compared to the national average of 40 per 100,000 (in 1955 the national average was 339 beds per 100,000 population). They cite a relatively small but important minority of patients for whom the most effective ongoing psychosocial and psychopharmacological interventions are not enough. They identify four major effects: (1) The new generation of chronically and severely mentally ill persons pose the most difficult problems in community treatment and do not readily benefit from brief hospitalization. (2) In the absence of intermediate and long-stay psychiatric beds, there is a revolving door syndrome, leaving many persons untreated or inadequately treated. (3) The homeless mentally ill population has increased, forcing many to live lives of danger and deprivation on the streets. (4) Society's limited tolerance of mentally disordered behavior results in pressure to institutionalize persons; in the absence of hospital beds, these persons behave such that they are arrested, incarcerated, and transferred to the criminal justice system.

For-Profit Versus Nonprofit Hospitals In 1988 over 64 percent of the inpatient psychiatric facilities were privately owned, with a substantial increase in the number of hospitals in multifacility for-profit corporations. Since the financial goal of these facilities is to maximize the wealth of the stockholders, there are clear incentives for these institutions to have higher prices, lower expenses, and more profitable patients than the nonprofit facilities. With a careful analysis of data from the Health Care Financing Administration's Minimum Cost Data tapes for 1986 to 1990, Michael McCue and Jan Clement compared operational performance and productivity of matched pairs of nonprofit and for-profit psychiatric hospitals. They found significant differences in length of stay (for-profit average stay was 5 days longer, 23.71 days versus 18.44 days nonprofit average stay), number of discharges per bed (for-profit average was 4 fewer, 10.53 versus 15.11 nonprofit average), and full-time employees per adjusted census (for-profit 1 less full-time employee, 2.53 versus 3.65 nonprofit). This resulted in nonprofit hospitals averaging 46 percent lower total profit margin and a 14 percent lower return on total assets that the for-profit, investor-owned group.

The for-profit hospitals had significantly higher net revenue and lower salary expenses per patient day, presumably achieved through reduced staffing levels. The for-profit and nonprofit hospitals did not differ significantly in expenses for routine care and ancillary services; they did differ in their capital structure. The system size and reputation provided the for-profit hospitals greater access to debt capital and newer facilities, with higher depreciation.

Patient Violence With a narrowing of criteria for hospitalization, which emphasizes danger to self or others, the threat of violent behavior by patients in hospitals has received greater attention. It is of note that there were practically no articles on violence and assault in the psychiatric literature and no references in leading textbooks until the mid to late 1960s. That was a period of increasing violence in American society, and the problem has continued to increase, with the Surgeon-General and the U.S. Public Health Service officially identifying violence as a public health concern.

Violent patients present a challenge to staff and patients in hospital units. One prospective study in a large managed mental health program in the metropolitan Chicago area looked at 270 consecutive admissions to seven participating hospitals. It was found that 14.8 percent of those admissions (40 patients) had engaged in a behavior in the 30 days prior to admission that threatened great bodily harm to another and 15.2 percent (41 patients) had engaged in violent or threatening behavior at some point in the previous year. These patients were more disruptive during their hospital stays, engaged in more outbursts and more verbally threatening behavior than the other patients who ranked low on a scale that measured danger toward others. Acute symptom severity and prior dangerousness were the most useful predictors of disruption on the unit. Eileen Morrison studied nine units in four hospitals—private, state, federal, and county—and found that over half of the patient sample was violent toward others on admission. From a series of studies, Morrison has identified a different view of violence from the traditional idea of the violent patient being a schizophrenia patient who is out of control. Rather, the violence in patients in the 1990s parallels the violence in society in the 1990s, reflecting issues of power and control. Predictors of violence in hospital patients are a history of violence; a coercive or exploitative style with others, that is, using others for self-gain; and length of hospital stay. Schizophrenia patients are less likely to be violent than substance abusers and antisocial patients.

Clearly, hospital staff must be prepared to deal with conflict that goes with an aggressive population, and the hospital should have clear policies and guidelines for dealing with outbursts and emergency situations in the least restrictive but most efficient manner. To minimize violence in the hospital, staff needs to be trained in communication skills of negotiation and conflict resolution, and to use creative interventions aimed at preventing aggression and violence before it starts.

Impact of Managed Care Utilization review by outside, managed-care entities has intruded into hospital treatment in a profound manner, but few careful studies have documented the impact of this development. The data on 2265 utilization management reviews conducted during a 3-year period (1989–1992) for patients insured by a single large commercial insurance company were analyzed and it was found that managed care clearly restricted inpatient care, primarily through limiting length of stay. The insurance company reviewers initially approved inpatient psychiatric treatment for nearly all (98.8 percent) of the patients, but authorized, on average, only one third of the days requested (6.9 versus 19). The utilization management relied on standardized treatment protocols that do not include consideration of individual patient or clinical factors and the continuous review and approval placed a considerable burden on the clinician.

Partial Hospital Care and Wraparound Services With the pressure to reduce hospital inpatient utilization, there has been a surge in partial hospital programs and elaboration of a new concept of “wraparound” services developed in the community with the initial assistance and supervision of hospital staff. In 1982 the American Association for Partial Hospitalization published a set of standards to narrow the concept and restrict the term to comprehensive, multidisciplinary programs with medical, psychiatric, psychosocial, and prevocational components, targeted toward patients with serious mental disorders. Despite concerns that the majority of persons traditionally referred to inpatient settings could not get better outside of the hospital, repeated studies have demonstrated that day treatment as an alternative modality is as effective or more so in facilitating adjustment and reintegration of patients into the community. Despite this evidence, partial hospital care has not replaced inpatient treatment for a number of reasons, not the least of which is the entrenched professional commitment to the hospital as a locus of treatment. Also, insurers have been reluctant to cover the costs, for fear the new costs would simply explode in magnitude while hospital costs continue unabated.

This resistance is likely to change as more studies point to the cost effectiveness of partial hospital treatment programs. William Sledge and his colleagues at Yale followed 197 patients in an experimental program designed as an alternative to initial, short-term inpatient hospitalization. The clinical, functional, social adjustment, quality of life, and satisfaction outcome measures were as effective as acute hospital care for these urban, poor, acutely ill voluntary patients with severe mental illness. Further, the alternative care cost roughly 20 percent less in total direct costs, on average, than the inpatient hospitalization. The two programs had roughly equal direct service staff and capital costs, but the day hospital and crisis respite operating costs were 51 percent of the inpatient hospital costs. This study demonstrated again that many people with major mental illnesses, especially voluntary patients, can be treated safely, effectively, and less expensively in alternative settings but this program requires an effective triage and crisis service as well as back-up from a hospital. The authors of the experimental program observed:

> There are times when the structure of a hospital is quite necessary; alternatives to hospitalization do not entirely replace the need for psychiatric hospitals. Essential hospital-based specialty functions are the provision of safety and security in the management of patients who are out of control and quick access to skilled medical nursing care of patients with mental complications.

RESEARCH AND EVALUATION

Concern about the increasing costs associated with hospitalization has prompted a search for reliable data regarding treatment outcomes. Such studies are difficult to design and execute. Traditionally, outcome studies have focused on changes in a patient's clinical status. Equally important is the level of the patient's interpersonal and occupational functioning in daily life.

Researchers in Israel sought to identify variables associated with improved functioning after psychiatric hospitalization, reviewing 25 clinical and demographic variables, improvements and functioning at discharge of 309 consecutive patients in an open psychiatric ward over a 2-year period. Of particular note, they found that diagnosis had little value in predicting which patients would improve during hospitalization. The best predictors of a return to a preadmission level of functioning were psychotherapy, a hospital stay of less than 4 months, and attendance at occupational therapy.

There are an increasing number of significant long-term outcome studies of mental illness like Thomas McGlashan's Chestnut Lodge follow-up study and Michael Stone's follow-up of patients with borderline personality disorder treated at the New York State Psychiatric Institute. Findings reported from controlled studies comparing short-term and long-term hospital treatment have been equivocal. A major finding is that aftercare arrangements are more important in the patient's outcome than the actual length of hospital stay.

A recent study explored the outcomes of nursing home residents admitted to the Houston Veterans Medical Center geropsychiatric inpatient unit. In general, the hospitalization resulted in improvement in overall psychiatric function and problem behaviors of nursing home residents with and without dementia. Of the hospitalized nursing home patients, 10 percent were able to be discharged to less restrictive settings than those from which they were admitted. However, the investigators acknowledged that their 37-day average length of stay was longer than most current health insurance companies allow.

Early studies surveyed attitudes of patients and doctors regarding what was most helpful about hospitalization. One survey at the UCLA neuropsychiatric Institute found that patients ranked the most helpful treatment modality to be (1) being in a new environment, (2) interaction with nurses, (3) interaction with patients, (4) individual psychotherapy, and (5) medication. The doctors ranked medication first, followed by being in a new environment, individual psychotherapy, interaction with nurses, and nursing care programs (Table 52.3-4).

Patients' Ranking		Doctors' Ranking
1	Being in new environment	2
2	Interaction with nurses	4
3	Interaction with patients	6
4	Individual psychotherapy	3
5	Medication	1
6	Recreational therapy	10
7	Work therapy	8
8	Nursing care program	5
9	Group therapy	9
10	Occupational therapy	11
11	Ward social activities	7
12	Psychodrama	12

Adapted from Leonard CV: What helps most about hospitalization? Compr Psychiatr 15:363, 1973.

Table 52.3-4 What Helps in Hospitalization (Rank Order)

Outcome studies of partial hospital treatment programs have found equivalent outcomes in symptom improvement, relapse reduction, and family adjustment for patients who could be treated safely in partial hospital settings. In some studies, better social functioning was achieved in partial hospital treatment. Several programs, like the Massachusetts Mental Health Center day hospital, have demonstrated effective treatment for patients who would otherwise have been admitted to an inpatient unit but these programs typically have high staff-to-patient ratios, highly structured programming, and the capacity to handle clinical emergencies.

One randomized controlled trial of day patient versus inpatient psychiatric treatment in the United Kingdom concluded: “Roughly 40 percent of all acutely ill patients presenting for admission to a psychiatric unit may be treated satisfactorily in a well-staffed day hospital.” At 3 months' follow-up, the only significant difference was a greater improvement in social role performance of inpatients. By the 1-year follow up, there was no significant difference between day patients and inpatients in mental state, social role performance, burden or behavior.

A number of outcome studies prompted by deinstitutionalization in the public sector in the United States, United Kingdom, and Italy conclude that a new long-stay group is replacing the old long-stay group. The residual patients are older, mostly with organic syndromes, who are difficult to accommodate in the community. A follow up study of Rhode Island patients with chronic mental illness and long histories of hospitalization found that 55 percent did require at least one hospital readmission. At the 7-year follow up, 57 percent were functioning effectively in structured, community residential settings; 28 percent had moved on to independent living; and 16 percent had returned to an institutional setting.

In the United States there also appears to be a transinstitutionalization phenomenon, with an increasing number of mentally ill persons being processed by the criminal justice system and incarcerated in correctional facilities rather than mental hospitals.

SUGGESTED CROSS-REFERENCES

Additional perspective on the history and future of psychiatry are found in Section 55.1 and Section 55.3. The role of the structure and protection of patients from destructive consequences of their illness is addressed in the treatment sections for specific diagnoses as well as in Section 29.1 on suicide. Section 48.8 addresses day treatment and residential and inpatient treatment of children and adolescents; Section 52.3 discusses treatment settings for geriatric patients.

52.4 PSYCHIATRIC REHABILITATION

ROBERT PAUL LIBERMAN, M.D., ALEX KOPELOWICZ, M.D. AND THOMAS E. SMITH, M.D.

The growing recognition that a large proportion of persons with schizophrenic and mood disorders experience a poor quality of life with long-term disability, persisting symptoms, or a relapsing course of illness has given birth to the field of psychiatric rehabilitation. Early intervention and effective treatment of acute episodes of symptom exacerbations are important for minimizing long-term disability. On the other hand, workers in psychiatric rehabilitation emphasize continuous, comprehensive, coordinated, and indefinite treatment of lifelong mental disorders to maintain symptom control, prevent or reduce relapses, and optimize psychosocial performance. The goal of psychiatric rehabilitation is to teach skills and provide community supports so that individuals with mental disabilities can function in social, vocational, educational, and familial roles with the least amount of supervision from the helping professions.

Treatment and rehabilitation are interconnected seamlessly, as are the full range of biopsychosocial services, in a continuous and comprehensive effort to reduce impairment, disability, and handicap among the mentally disabled. In addition, a major goal of psychiatric rehabilitation is enabling the mentally disabled person and family members to be actively involved in treatment decisions and to achieve the highest feasible quality of life in the community.

An enormous population of mentally disabled persons needs psychiatric rehabilitation to bolster their quality of life. For example, the National Plan for the Chronically Mentally Ill used the triad of diagnosis, disability, and duration to identify persons who suffer from persistent or recurrent organic, schizophrenic, mood, anxiety, and other disorders that become chronic and erode or prevent the development of their functional capacities in relation to three or more primary aspects of daily life. These functional areas of daily life include personal hygiene and self-care, self-direction, interpersonal relationships, social transactions, learning, recreation, and economic self-sufficiency.

Since many childhood developmental, psychotic, and mood disorders that persist for many years and impede normal psychosocial development are included in the target population, the total number of persons in the United States who need psychiatric rehabilitation in any 6 month period may exceed 10 million, based on data compiled by the National Institute of Mental Health (NIMH) Epidemiologic Catchment Areas study.

The terms “chronically,” “severely,” or “seriously mentally ill” have been used interchangeably to identify persons with long-term disabilities resulting from schizophrenia, persisting depressions, and bipolar disorder, delusional disorders, borderline personality disorders, and dementias. Estimates of the prevalence of persisting mental disabilities, such as those shown in Table 52.4-1, are now considered gross underestimates, given more recent data from the NIMH Epidemiologic Catchment Area and Co-morbidity studies, the difficulty of counting homeless and jailed mentally ill persons, and the number of persons with dual diagnoses as well as those disabled by serious mood and anxiety disorders. Although this section focuses on rehabilitation of persons with psychotic disorders, persons with disabling mood, anxiety, substance abuse, and personality disorders can also benefit from many of the same structured and skills-training modalities. Behavioral rehabilitation can also slow the functional deterioration of persons with dementias, using modalities found effective with younger, mentally disabled persons.

Prevalence estimates for chronic mentally ill (2.1–2.6%)	4,000,000–5,000,000
Community estimates of chronic mentally ill	2,800,000–3,500,000*
Treated prevalence of chronic mentally ill patients	
In mental hospitals	50,000–60,000
In other specialty facilities†	250,000
In nursing homes	1,000,000–1,100,000
In prisons and jails	100,000

* Excluding 1.2–1.5 million living in institutes.
† Includes halfway houses and other large community residential facilities not covered in community survey.
Data from Barker PR, Manderscheid RW, Hendershot GE, Jack SS, Schoenborn CA, Goldstrom ID: *Serious Mental Illness and Disability in the Adult Household Population of the United States, 1989.* Center for Mental Health Services, Rockville, MD, 1992.

Table 52.4-1 Point Prevalence of Persisting, Long-Term Mental Illness and Disability in the United States

The challenge to psychiatric rehabilitation is amplified by the inadequate resources and poor organization of service delivery for the target population, which results in thousands of homeless, mentally ill persons in urban centers of the United States and a concentration of mentally disabled persons in state and local prisons. With over 5000 mentally ill prisoners, the Los Angeles County Jail is said to be the largest psychiatric institution in the United States. The transinstitutionalization of the seriously mentally ill from state hospitals to jails, custodial board-and-care homes, and inner city streets is a condemnation of our society's humane values. Our failure to provide high-quality, continuous psychiatric treatment is made more tragic by the availability of new rehabilitative technologies that, when systematically organized and delivered, have the potential to reduce morbidity, disability, and handicaps among serious and chronic mentally ill persons.

Organization and delivery of therapeutic and rehabilitative interventions for persons experiencing serious mental disorders requires a longitudinal, informed, mutually respectful and collaborative therapeutic alliance between the patient and caregiver. Whether the care-giving function is fulfilled by a psychiatrist, allied mental health professional, or paraprofessional case manager, the qualities inherent in a supportive, empathic, individually tailored relationship must be present. Given the primary role of the family and other natural caregivers (e.g., operators of residential care homes) in maintaining treatment and compliance, plus the enormity of the family burden experienced by relatives, professionals must also involve families in treatment planning and implementation. Rehabilitation is a labor-intensive and person-to-person venture. Even the pharmacotherapy that must accompany psychiatric rehabilitation is effective only to the extent that the doctor-patient relationship contains trust, problem solving, and shared goals. Medication is never prescribed, ingested, or metabolized in a socioenvironmental vacuum; both drug and psychosocial treatments depend upon a working alliance between treater and treated.

The terminology used to refer to an individual receiving mental health services can vary depending on the site at which the individual is being treated. For example, *patient* may be a suitable term for inpatients in a hospital; *client* may be appropriate in mental health centers; and *consumers* or *members* may be useful in outpatient programs or vocational and residential settings. The term *patient* is used in this chapter for consistency with other chapters in this book. However, readers need to be mindful of the appropriate terminology when developing and implementing rehabilitation programs.

CONCEPTUAL FRAMEWORK FOR REHABILITATION

Studies in Europe, the United States, and Japan that followed up persons who experienced disabling forms of schizophrenia during early adulthood found, 20 to 40 years later, a remarkable 50 to 66 percent functioning actively in their communities with few symptoms, a reasonably good subjective quality of life, and only limited dependence on professional caregivers. These findings have spurred interest in psychiatric rehabilitation as a way to facilitate social and symptomatic recovery of seriously mentally ill persons. With an attachment to data-based empiricism and hypothesis testing, an interdisciplinary cadre of specialists in psychiatric rehabilitation derived new assessment and intervention methods from the vulnerability-stress-protective factors model of psychiatric impairment, disability, and handicap (Fig.

52.4-1). The course and outcome of major mental disorders are defined by:

1. *Impairments*, the characteristic positive and negative symptoms and associated cognitive and affective abnormalities of disorders such as schizophrenia, autistic disorder, and bipolar disorder
2. *Disabilities*, the restrictions impairments impose on such functional life domains as personal hygiene, medication self-management, recreation for leisure, and family and social relationships
3. *Handicap*, the disadvantage experienced by an individual with impairments and disabilities that limits or prevents the fulfillment of normal roles, such as worker, student, friend, citizen, and family member

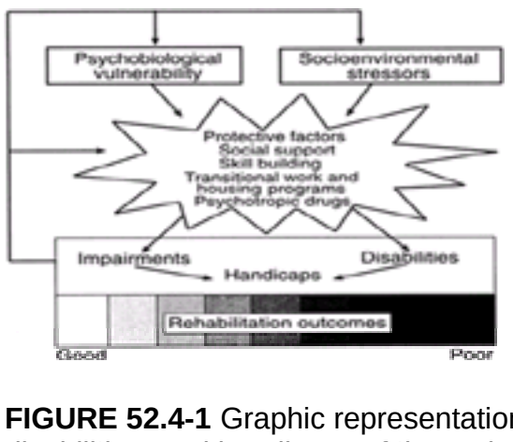

FIGURE 52.4-1 Graphic representation of the vulnerability-stress-protective factors framework for understanding the determinants of symptom impairments, disabilities, and handicaps of the major mental disorders. Protective factors buffer or filter the noxious effects of stressors superimposed on enduring vulnerability in producing psychopathology. There is a feedback loop from impairments and disabilities back to vulnerability and stress; for example, improved social skills and coping capacity can mitigate stressors and may even modify neurobiological vulnerability.

Moving mentally disabled persons along the spectrum of impairment, disability, and handicap from poor to good outcomes requires orchestration of protective factors in treatment and community support services. As long as the psychobiological vulnerability factors responsible for the specific syndrome are unknown, interventions cannot directly modify them. Those vulnerability factors (most likely genetic and neurodevelopmental) endure. They likely exist before the symptoms of the disorder emerge as well as during periods of symptom remission and relapse. Similarly, as long as the principles of community care of the mentally ill are adhered to, vulnerable individuals cannot be isolated from socioenvironmental stressors. Stressors, whether drugs of abuse or social overstimulation, are a fact of life for mentally ill persons, even in the so-called asylums, where privacy is absent and violence is omnipresent. Even in the absence of major life events or the noxious effects of illicit drugs and alcohol, vulnerable persons can succumb to tension or conflict in their environments or to microstressors and daily hassles if they lack the protection conferred by medication, coping abilities, and social support.

Psychiatric rehabilitation must harness the protective factors in both the treatment and natural environments to offset and buffer the adverse effects of stress superimposed upon vulnerability. Those protective factors include optimal psychopharmacological interventions that can raise the threshold at which environmental stressors precipitate symptoms in an individual with a given level of vulnerability to a serious mental disorder. But even prescribing pharmacotherapy with attention to the highest possible benefit to risk ratio (i.e., using atypical antipsychotic drugs to maximize therapeutic effects while minimizing side effects) does not ensure protection against relapse. Medications must be supplemented by psychosocial interventions that (1) equip patients with personal, social, and vocational coping and competence and (2) galvanize necessary social support services to compensate for the intrusion of symptoms, deficits, and disabilities that even the best system of care cannot remediate.

MULTIDIMENSIONAL REHABILITATION KEYED TO DISORDER STAGE

The clinical practice of psychiatric rehabilitation joins three major sets of factors that protect against stress and vulnerability: (1) pharmacotherapy tailored to the type and severity of psychopathology at dosages that do not produce sedation or adverse effects that interfere with positive engagement in rehabilitation; (2) development of skills so the patient can meet the challenge of stressors and life situations that demand adaptation and independence; and (3) a range of supportive social services, including housing, transitional and supported employment, financial support, and case management to sustain a mentally disabled person in the community. Psychiatric rehabilitation assumes that disabled persons need maintenance medication, social and independent living skills, and environmental resources and supports to fulfill the role demands of community life.

The organization of truly comprehensive psychiatric rehabilitation is diagramed in Figure 52.4-2. One dimension of the cube represents the stage of the disorder, ranging from prodromal, to acute, to residual phases. The second dimension contains treatment and rehabilitation modalities, such as drug therapy, family and cognitive therapies, social skills training, and vocational rehabilitation. The third dimension holds requisite support programs aimed at compensating for disability and minimizing handicap (e.g., family education and support, social service entitlements, case management, housing, and psychosocial clubs). The psychiatric rehabilitation practitioner or team following a person for many years through various phases of a disorder should be able to use this multidimensional framework to match treatments and support services to the changing needs of the patients as dictated by their impairments, disabilities, and handicap at any point in time.

FIGURE 52.4-2 Complex cube of psychiatric rehabilitation.

Rehabilitation of individuals with chronic and serious mental disorders had to respond to the transition in locus and focus of care from institution to community and from custodial care to functioning in society. Community support programs, psychosocial self-help clubs, and community mental health centers are now the hubs of psychiatric rehabilitation services where new modes of intervention are coordinated and delivered by case managers in league with multidisciplinary teams of clinicians who assume long-term responsibility for sustaining seriously mentally ill patients in the community. As is shown in Figure 52.4-3, the tripartite roles and competencies of case managers are the key to comprehensive and continuous rehabilitation.

FIGURE 52.4-3 Case management functions for serving the comprehensive needs of seriously mentally ill persons.

Engagement The successful engagement of a patient in a therapeutic relationship is the first step in psychiatric treatment and rehabilitation, no matter what the venue for service delivery. The clinician or clinical team attempting to engage seriously mentally ill persons in treatment must build a collaborative relationship with patients and their families. Professionals and patients must recognize each other's agenda and seek some common ground in developing a comprehensive treatment plan. Engaging homeless, mentally ill persons often requires active outreach, with mental health practitioners meeting prospective consumers of services on their own turf, frequently the streets and back alleys of urban centers.

The process of engagement is contemporaneous with the setting of overall rehabilitation goals. Helping individuals define their desired life roles can be a vehicle for engaging and motivating them to participate in a lengthy rehabilitation process. Patients who actively participate in goal setting are more likely to abandon denial of their illness, acknowledge ownership of their goals, seek reinforcement from significant others when they work toward their goals, and customize or modify their goals as their rehabilitation proceeds. Successful engagement of the patient and family or other natural caregivers in rehabilitation often requires not only active outreach by the professional, but also a nonjudgmental and nonauthoritarian approach and even toleration of nonadherence to medication for periods of time. Engagement, a long-term effort, is often challenged by obstacles in service delivery, reflected in the current terms supplanting “patient” such as “consumer” or “customer.” The following case vignette illustrates engagement.

Mark was a 23-year-old man who experienced the onset of schizophrenia during his last year in college. He was referred to the rehabilitation team after efforts to engage him in treatment had previously failed. He was found to be severely psychotic, evidencing disorganized thinking, paranoid delusions, auditory hallucinations, and bizarre behavior. He had refused earlier efforts to have him take antipsychotic medications because of adverse effects he experienced. The information about his psychotic symptoms gathered by using the Brief Psychiatric Rating Scale (BPRS), particularly that relating to disorganized thinking and the hallucinations, was shared with Mark. He was specifically told about the impact the symptoms had on his daily functioning and was shown the ratings for his symptoms. He was told that his ability to use his social and independent living skills was limited as a result of his psychosis. He agreed to a trial of antipsychotic medication, during which time he would self-monitor his psychotic symptoms using a scale similar to that used in the BPRS. He and his parents were sent home with this scale, and were asked to complete the Independent Living Skills Survey (Fig. 52.4-4), a self-report assessment of daily functioning.

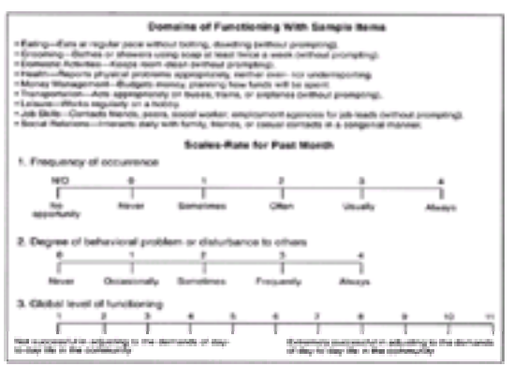

FIGURE 52.4-4 Independent Living Skills Survey.

When Mark returned, his psychotic symptoms had decreased from the extremely severe level to mild and moderate levels. He reported enhanced self-efficacy since taking the medication and especially noted his improved attention and concentration, which allowed him again to read for reasonably long periods of time. That effect was important to Mark because it allowed him to pursue his longer-term rehabilitation goal of completing his college education. Close examination of the Independent Living Skills Survey revealed difficulties in grooming and self-care and basic conversational skills. He and the rehabilitation team agreed to target those deficiencies during their initial skills-training efforts.

Community Reentry Program Ideally, engagement should begin when patients first encounter mental health services, regardless of treatment setting. For instance, inpatient treatment for individuals with serious and persistent mental illness should be seamlessly integrated with community services so that hospitalization is brief and minimally disruptive and the community's rehabilitation services can be implemented as quickly as possible. Unfortunately, this ideal is often not achieved, and many psychiatric inpatients do not follow through with community care after discharge. Often, the result is a cycle of relapse and rehospitalization, known as the “revolving door” phenomenon.

The poor rates of transition to community-based treatments are likely to be both system and patient related. Efforts to alter the structure and function of mental health systems to make them more cohesive and accessible (e.g., the Program for Assertive Community Treatment) have had some success in reducing recidivism, but model programs have not been widely adopted and are unavailable to most patients who might benefit. Fewer efforts have targeted the other half of the aftercare equation, namely, the patient. The Community Re-entry Program—a 16-session modularized, skills-training program—was designed to teach inpatients how to actively collaborate with the mental health system in creating and implementing their own tailor-made aftercare plans. Once engaged in this fashion, educated patients might acknowledge the need for continuing care and actively participate in treatment, discharge, and rehabilitation planning. Studies at New York Hospital–Cornell Medical Center and UCLA/Olive View Medical Center have shown that inpatients who participated in this program improved their knowledge and performance of the skills presented in the program, had significantly higher rates of engagement with aftercare services after discharge, and had improved levels of community functioning 2 months after discharge. These results suggest that engaging patients in psychiatric rehabilitation procedures such as skills training can begin in the hospital and continue without interruption into the community, linking inpatient and outpatient facilities in a common treatment philosophy and a matching set of treatment techniques.

ASSESSMENT

If engagement is the first (albeit continuing) step on the road to successful psychiatric rehabilitation, then assessment is the roadmap for the journey. A thoroughgoing, carefully conducted assessment pinpoints the areas for rehabilitation and provides a baseline for monitoring its effects. Furthermore, assessment within the framework of psychiatric rehabilitation, with its emphasis on positive goals and functioning linked to the current phase of illness and symptoms, fosters a collaborative relationship between patient and practitioner that greatly facilitates treatment.

Assessment is part and parcel of any therapeutic interaction, and some might argue that the clinical sensitivity of an experienced mental health practitioner is all that is needed to conduct an adequate assessment. Indeed, only minimal sensitivity may be needed to detect certain problems such as assaultiveness, which if present must be a target of treatment. Comprehensive assessment not only reveals factors that subtly influence even the most obvious problems, it also establishes both the baseline for monitoring the effects of treatment and the collaborative relation that sustains it. This comprehensive assessment process is illustrated by a recently

developed, integrated and coordinated assessment and treatment-planning instrument, Client Assessment of Strengths, Impairments, and Goals (CASIG).

Client Assessment of Strengths, Impairments, and Goals CASIG is a multidimensional assessment tool that helps practitioners plan, document, and evaluate psychiatric rehabilitation. The acronym of this instrument takes into account the empowerment of the client or consumer in identifying service needs, while following the World Health Organization's International Classification of Impairments, Disabilities [the reciprocal of capabilities or “Strengths”], and Handicaps [the reciprocal of participation in setting interests and goals]. CASIG is based on the model of psychiatric rehabilitation outcomes presented above, with the additional assumption that the plan for services must solicit the active participation and integrate the goals, assets, deficits, needs, resources, and constraints of all the relevant stakeholders. Stakeholders include client or patient and significant others including family members and other caregivers and those paying for the services.

As shown depicted in Figure 52.4-5, CASIG assesses performance in 10 areas of functional living skills, subjective quality-of-life in 11 areas, presence of 5 symptoms, 20 medication adverse effects, compliance with medication, and performance of 10 unacceptable community behaviors. The information is collected from the patient during a 60- to 90-minute interview, with corroborating information collected from the patient's significant others and treatment personnel who know the client well. Additionally, the patient's preferences to change his/her behavior in each area are elicited.

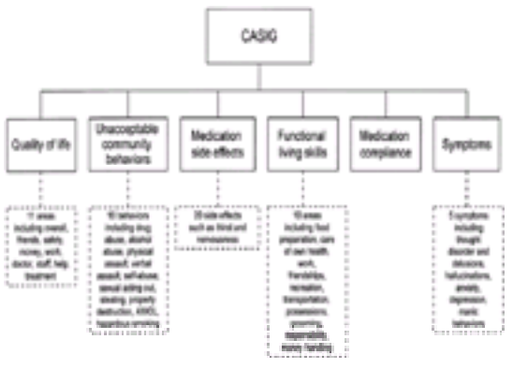

FIGURE 52.4-5 Areas assessed by Client Assessment of Strengths, Impairments, and Goals (CASIG).

Regardless of the area being assessed or the source of the assessment information, CASIG items have all been designed to achieve several objectives:

to be reliably administered by any of the paraprofessional and professional staff who typically provide services for patients (even high-functioning consumers can reliably administer CASIG to other patients)

to be easily incorporated into programs with diverse staffing patterns, resources, locations, and clinical responsibilities

to include multiple sources of information about particular social deficits or symptoms of the patient so that any disagreements can be resolved to plan services better

to bridge the many facilities in which patients are served

to monitor (with repeated administration) the progress of individual patients in their treatment and rehabilitation programs and in the aggregate monitor the effectiveness and changing characteristics of programs

Two clinical examples for the CASIG—one assessing a symptom (depression), and the other assessing a functional living skill (money management)—are presented in Figure 52.4-6 and Figure 52.4-7, respectively.

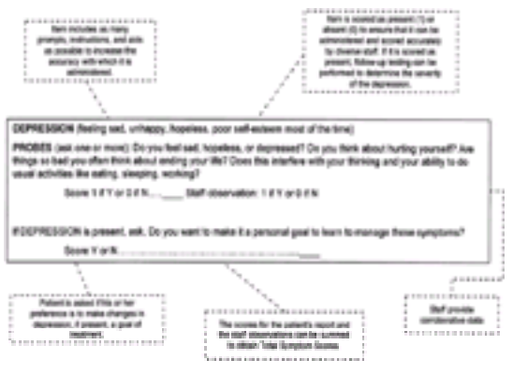

FIGURE 52.4-6 Example of a symptom—depression—assessed by CASIG.

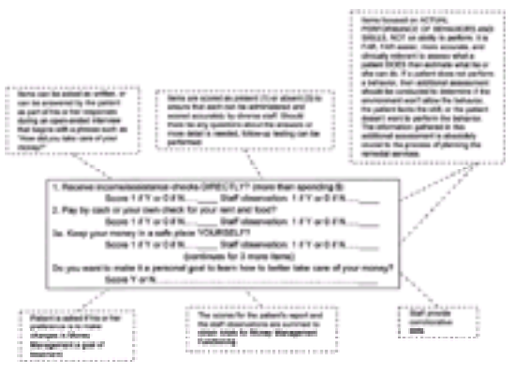

FIGURE 52.4-7 Example of functional living skills: three items from the money management section of the CASIG.

The assessment results are summarized and then interpreted by comparing them with norms developed from other patients and with the requirements for successful functioning in various environments. As indicated in Figure 52.4-8 these comparisons, combined with the expectations of the stakeholders, provide the basis for treatment planning.

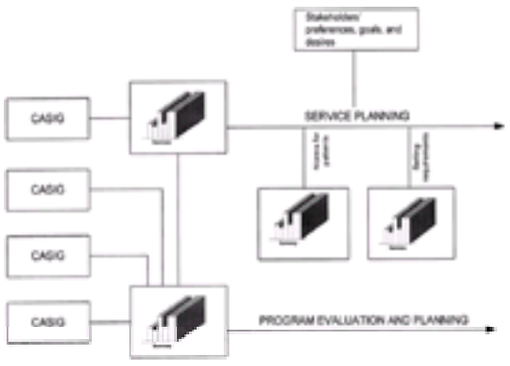

FIGURE 52.4-8 Output of CASIG. Service planning, and program evaluation and planning.

SHORT- AND LONG-TERM GOALS

To guard against deviating from the rehabilitation pathway, both the engagement and assessment processes emphasize the importance of focusing on the rehabilitation goals endorsed and validated by the individual. However, making the patient a full and equal partner in the treatment and rehabilitation process is not always easy. Negative symptoms, disabilities, intrusive hallucinations, institutionalization, and cognitive dysfunction may impede the patient's ability to participate actively and helpfully in this crucial endeavor. The setting and resetting of short- and long-term goals provides the road markers by which clinician and patient can judge whether (or not) they are traveling in the same desired direction.

Within a few months, Mark had noticeably improved his grooming and self-care habits. However, he still had trouble initiating and maintaining conversations. Because of this persistent deficit, the rehabilitation team encouraged Mark to reformulate his goal of pursuing a college education into a long-term plan with several intermediate steps. The team helped Mark identify a series of short-term tasks that would build toward his matriculation at a local community college. Mark began by attending a daily group focused on basic conversation skills at the mental health center. Within a few months, his progress led the rehabilitation team to offer Mark the opportunity to colead the skills-training group, which Mark readily accepted. Within a few weeks Mark was not only cofacilitating the group but also conducting ad hoc tutorial sessions for patients who lagged behind. At a subsequent meeting with the rehabilitation team Mark announced that rather than go to college, he wanted to be hired by the mental health center as a peer advocate. Once again, Mark and the team designed a step-by-step approach that allowed him to work toward this new goal.

The clinician and patient are guided by the continuous interaction of the patient's overall rehabilitation goals with the current stage of the disorder. During the acute, florid stage of the illness, the task for the clinician may be to help the patient move from grandiose, unrealistic fantasies to articulating the more proximal and immediate realistic changes and steps that must be accomplished before the longer-term goals can be reached. As symptoms stabilize and (hopefully) ameliorate, the focus shifts to helping patients define their goals in terms of occupational, student, friendship, familial, and residential roles. Another shift occurs during the late rehabilitation and recovery phase, when individuals begin to look for goals which transcend their status as patients qua patients. In this phase, the goal is to develop and nurture the wellness factors (e.g., hope, courage, self-esteem) that enable patients not only to manage but sometimes to overcome the illness.

Logistically, an individual's preferences, desires, and motivations should be operationalized in behavioral terms and divided into long- and short-term goals. Long-term goals involve months to years and should correlate with overall rehabilitation goals to progress toward functional life roles. Long-term goals should be comprehensive in subserving progress in all relevant domains of life functioning (Social/Interpersonal, Familial, Financial, Recreational, Medical/Psychiatric, Activities of Daily Living/Independent Living Skills, Vocational/Educational, Spiritual, and Housing/Residential). Short-term goals involve days, weeks, or months and should articulate with long-term goals as stepping stones, or subgoals. Short-term goals also must be prioritized and endorsed by all parties participating in the rehabilitation. To facilitate accomplishment, individuals should prioritize their goals and, when possible, have them endorsed by the family, caregivers, and responsible clinicians.

Keith was a 26-year-old man recently diagnosed as having paranoid schizophrenia. When psychotic symptoms were controlled with antipsychotic medications, he engaged in a rehabilitation planning effort with an occupational therapist who was a member of a community mental health center treatment team. When first asked to identify his goals, he said he wanted to enter college and complete his bachelor's degree. He hadn't been in school for 6 years, yet he said he wanted to matriculate as a full-time engineering student in a prestigious school. The clinician thought that goal was unrealistic. On further exploration it was learned that Keith had felt happiest when he was in school, and he now thought this would be the best way to realize his goal of being “happy and independent.”

Once this goal of becoming independent and more pleased with himself was identified, Keith was helped by his therapist to set as a long-term goal resumption of his schooling at a local trade school. He then began to work with his therapist to target skills and deficits in the areas of time management, organizing scheduled activities, and self-assertion. He saw those as essential to prepare for his goal of entering school. He had been an organized person with good study habits prior to developing his illness, so those were seen as potential assets. His basic conversational skills were more than adequate, but he needed training in speaking up to obtain his needs in the classroom, with teachers and with peers. He had the prerequisite resources to engage in the recommended training sessions (i.e., time, a car, and the availability of social skills training services in his local community support program). Six months later, after benefiting from structured and systematic skills training to improve his self-advocacy, he entered a course in automotive mechanics at a vocational school.

MONITORING THE QUALITY OF INTERVENTIONS AND CLINICAL PROGRESS

Biopsychosocial assessment and intervention is an ongoing process requiring the psychiatrist to titrate medications and psychosocial services on the basis of an individual's fluctuating need. In fact, the effectiveness of drug treatment depends on the clinician's ability to elicit, rate, and monitor symptoms, leading to appropriate adjustments (or maintenance) of treatment (e.g., medications, crisis services, skills training). Instruments such as the BPRS have been used by a wide variety of practitioners as sensitive indicators of impending psychotic relapse. Behavioral observations (e.g. time sampling or experience sampling) can be even more sensitive indicators of the need for psychiatric intervention than interview-based ratings, but these are more demanding to implement.

The CASIG evaluation system was designed with the presumption that treatment planning does not end with the collaborative development of the patient's service plan. As shown in Figure 52.4-9, treatment consists of recurring cycles of assessment, planning, and service delivery. These cycles reflect the ever-changing nature of treatment; as the services achieve their effects, all of the stakeholders change. In such a fluid environment, treatment cannot be successful unless assessment and services are intertwined in the on-going process. New information obtained from an updated assessment engenders new treatment plans designed to make the information obsolete and hence require yet another assessment. This pattern proceeds through the patient's journey from acute episode to stabilization, rehabilitation, and (if successful) recovery.

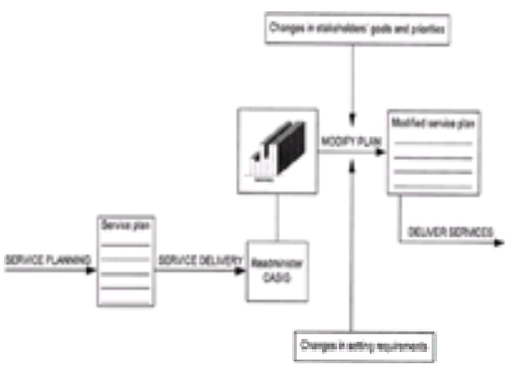

FIGURE 52.4-9 Cycle of service plan, evaluation, and new service plan. This cycle is repeated as often as needed to fulfill service goals.

According to his parents, Matt had been unable to “fit in” since his early teenage years. Now 35 years old, Matt's daily routine consisted of eating at fast food restaurants, working as a stock boy at a local retailer, and spending most of his time alone in his apartment. During the CASIG interview, Matt stated that he had no friends, attended no social gatherings, and was bored most of the time that he was not at work. His parents complained that Matt failed to groom himself regularly and was being threatened with eviction from his apartment for not cleaning properly.

The initial treatment goal derived from the CASIG interview focused on increasing Matt's opportunities for social engagement. He was initially given a homework assignment to count the number of chances he had each day to interact briefly with someone. It quickly became clear to Matt that he had 15 to 25 opportunities each day to say “Hello” to other employees or residents at the apartment building. Consequently, Matt and his therapist updated the CASIG plan, adding social skills training to increase his ability to interact appropriately when the opportunity presented itself.

After learning some brief conversation skills and when to apply them, Matt was next assigned to count the number of times each day that he actually engaged people in brief conversations as well as the percentage of these engagement attempts that were successful. As his percentage of successful engagements increased, he developed more confidence in his ability to “fit in” and thus modified his CASIG plan once again to include attendance and participation in social gatherings. He told his therapist that he wanted to invite a few coworkers to his apartment to watch television after work. This idea required adding goals that he had not considered in his original CASIG plan, such as improved grooming and better housekeeping. Using the recurrent, interconnected technique of the CASIG evaluations allowed Matt to see how his self-identified goal of increased social relationships could be facilitated by improvement in self-care and daily living skills.

FITTING TREATMENT AND REHABILITATION INTERVENTIONS INTO THE GOALS

One must move from the identification of symptoms and functional deficits and formulation of positive goals to the delivery of the appropriate biopsychosocial treatment modalities. Although setting specific, concrete interpersonal goals is perhaps the most challenging step in a patient's rehabilitation, the failure to reinforce these goals with consistent, yet modest accomplishments may lead to discouragement, frustration, and ultimately treatment discontinuation. The clinician choosing and using the needed intervention must encourage patients to reach just beyond their grasp and help facilitate the success of their efforts.

In preparation for his “party,” Matt rehearsed with his therapist each conversation he was to have with his coworkers. Matt had little difficulty in the role play with his therapist, but he reported several failures when he tried to invite his peers to his apartment. This was useful information for Matt's therapist who, rather than simplifying the goal increased his level of intervention by accompanying Matt into the field to provide closer prompts and feedback during the peer contacts. The in vivo support provided by his therapist enabled Matt to make the invitations and successfully host his party. Soon thereafter, Matt began to receive and accept invitations to social gatherings hosted by others, including members of his family.

REHABILITATION SERVICES

Case management services are required to coordinate a wide range of entitlements, community support, and rehabilitation services now available to mentally disabled persons. Specific rehabilitation services include social skills training, family psychoeducation, cognitive remediation, vocational rehabilitation, and self-help programs. The effectiveness of these and other services has been established, and their importance is highlighted by recent notable changes in the nature and organization of care for severely mentally ill persons. For example, introduction of the atypical antipsychotic medications including clozapine (Clozaril), risperidone (Risperdal), and olanzapine (Zyprexa) has led to hypotheses regarding potential enhancement of cognitive and learning capacities that underlie individuals' abilities to benefit from rehabilitation interventions. A wide range of social factors have highlighted the importance of rehabilitation in effecting community reintegration and functioning, including the dramatic reorganization of health care services and funding over the past decade, the growing problem of homelessness and criminalization of the mentally ill, and the Americans With Disabilities Act. The utility and effectiveness of rehabilitation strategies have been recognized, and they are prominently included in a number of treatment guidelines for schizophrenia published by organizations such as the American Psychiatric Association.

As illustrated by the Practice Guidelines for Treatment of Schizophrenia by the American Psychiatric Association:

> [P]sychiatric rehabilitation aims to optimize the recovery of individuals with schizophrenia and other disabling mental disorders. This is accomplished through the use of the full array of biopsychosocial interventions, strengthening the supports and resources available for the person in the community, a collaborative approach with the patients and the natural caregivers, and an emphasis on function rather than symptoms. There is an attempt to improve the patient's performance in social, vocational, educational, and familial roles to achieve the highest quality of life and productivity attainable.

Social Skills Training Social skills training involves behavioral techniques or learning activities that enable patients to acquire instrumental and affiliative skills in domains required to meet the interpersonal, self-care, and coping demands of community living. While skills training can be done with individuals and families, the typical skills-training session is conducted as a group or class with one or two cotherapists as trainers and 5 to 10 mentally ill patients. Sessions last from 45 to 90 minutes, depending on the patients' level of concentration and symptom control, and meet one to five times a week. Since most mentally disabled persons have pervasive deficits in social functioning, skills training should become a central element in their long-term rehabilitation. It is not unusual for skills training to be offered for years, as the person's abilities, goals, and values ascend a hierarchy of community adaptation. Trainers draw on learning activities like those listed in Figure 52.4-10 to help patients master each skill area.

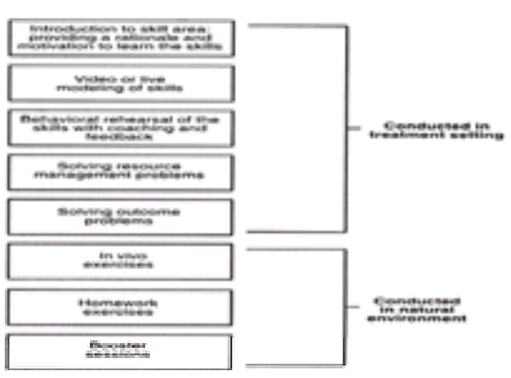

FIGURE 52.4-10 Learning activities used to teach social skills.

In conducting social skills training, therapists engage patients in goal setting and motivational enhancement. Patients are given an understanding of how the skills to be learned can help them achieve their own personal needs and desires. For example, in generating motivation to participate in a conversation skills group, patients are given examples of how conversation can mediate friendships, dating, and job success. The component skills in the skill area are next presented to the patients as learning targets. For example, a trainer leading a basic conversational skills session aimed at teaching patients how to start a friendly chat would say:

> In this skill area, you'll learn three skills that you need to start a friendly conversation. First, you'll learn how to find places where there are people to talk to. Second, you'll learn how to find people who are willing to talk to you. Finally, you'll learn how to find topics of conversation. For example, one way to find a topic is by observing what another person is doing and use that activity as your topic to start a friendly conversation.

Modeling is used next to give patients an opportunity for vicarious learning. Using prearranged situations or situations taken from participants' everyday lives, the

skills are demonstrated by the trainer or by peers in the group. Modeling can be provided by video samplers as well as by role playing by the trainer or another group member. Generalization can be enhanced by having the model or trainer annotate or speak aloud what steps are involved in successfully completing the skills:

> Wow, I'm supposed to go up and start a conversation with that girl. But I'm scared she might turn me down. Wait a minute. I remember in class that it is a good idea to start a conversation about what another person is doing. Let's see, she's sitting over there knitting a sweater so I could start by talking to her about knitting.

Thus modeling and other steps in social skills training combine cognitive techniques with more-overt behavioral techniques into a cognitive-behavior therapy.

Patients are then provided opportunity to try the new skills in guided behavioral rehearsal, or role play. Specifically, patients practice interpersonal situations from their lives that involve the targeted skills and role play a scenario using those skills. Trainers provide active coaching during the role playing and give generous positive feedback afterward by rewarding approximations to the targeted behaviors. Critical feedback can be counterproductive and should generally either be avoided or be couched in constructive terms. One particularly effective training technique involves videotaping the patient's role playing and replaying the video, highlighting the positive signs of progress by the patient.

After patients have demonstrated some mastery of skills in the supportive context of role playing, they are given in vivo homework assignments to facilitate transfer of newly acquired skills into the community. Homework assignments are more likely to be successful when patients are given specific tasks to do in their community (e.g., “Go home tonight and ask your roommate to play cards with you for 10 minutes”) and when they are helped, in advance, to anticipate obstacles to success and to engage in problem-solving exercises to overcome these obstacles (e.g., “Let's anticipate some of the things that might interfere with your inviting your roommate to play cards and what you might do about them.”). Trainers can also accompany patients into their real-life settings to provide coaching in vivo as well as liaison with the patients' natural caregivers to ensure opportunities and encouragement to use the skills. Subsequently, patients need to be reinforced for homework-related efforts. One advantage of doing social skills training in groups is the amplified reinforcement that occurs when patients give their peers positive feedback for implementing their skills in real-life situations.

Variants of Social Skills Training Social skills training can be conducted in the context of individual, family, or group therapy. Goals can be individualized to fit the functional and symptomatic needs of each patient or can follow a prescriptive format in which preset goals are pursued that have general relevance for a large proportion of the patient population. Most patients with chronic schizophrenia can benefit from educational curricula that teach medication and symptom self-management, grooming, social conversation, self-directed recreation, management of personal finances, and family communication. Four variations on the standard skills-training approach have been used effectively to remediate the deficits of persons with severe mental disorders: training of verbal and nonverbal expressive skills in response to specific situational expectations and personal needs; training to improve the accuracy of social perception; training in problem-solving skills; and enhancement of skill generalization via environmental intervention.

Behavioral Response Training In behavioral response training, a task analysis is conducted of the interpersonal situation that is problematic, and socially acceptable responses are targeted as goals for the patient. Each situation is assumed to call for a set of discrete verbal, paralinguistic, and nonverbal skills that combine to form a competent social response. For example, to be a proficient conversational partner, an individual needs to use appropriate forms and amounts of eye contact, facial expression, voice intonation, and interpersonal distance as well as judicious amounts of self-disclosure and social curiosity. Helping patients learn to combine these specific behaviors closes the gaps in their social ineptness.

Abundant research has shown the efficacy of this variant of skills training in reducing deficits in expressive behavior. In addition, the importance of conducting individualized task analyses linked to the phase of a patient's disorder merits emphasis. For example, inpatients struggling with persistent psychotic symptoms who have difficulty finding adequate housing have different behavioral training goals than stable outpatients who wish to improve their vocational functioning. On the other hand, behavioral response training has been criticized for its unidimensional, limited view of social interactions. Impaired processing of social information has been proposed as a more comprehensive model for understanding the social deficiencies of patients with chronic mental disorders. Thus, diminished sensitivity to social cues, inability to comprehend interpersonal problems and generate relevant solutions, poor comprehension of rule-governed social behavior, and deficits at the discourse level of linguistics have been implicated as core limitations in the social behavior of persons with schizophrenia and other chronic mental disorders.

Training in Social Perception Skills Recently efforts have been made to develop strategies for training patients in affect and social cue recognition. Patients with chronic psychotic disorders often have difficulty in accurately perceiving and interpreting the subtle affective and cognitive cues that are critical elements of communication. Social perception abilities are considered the first step in effective interpersonal problem solving; difficulties in this area are likely to lead to a cascade of deficits in social behavior. Training skills in social perception address these deficits and help provide a foundation for developing more-specific social and coping skills.

> Despite attending several social gatherings, Matt felt apart from the rest of the group. He reported that he experienced these events like “a jumble of sights and sounds.” His therapist, recognizing Matt's difficulty with social perception, provided him with a series of questions designed to help organize and give meaning to the social stimuli he encountered. For example, when Matt was confused about a conversation someone was having with him, he would ask himself, “What is this person's short-term goal? At what level of disclosure should I be? Should I be talking now or listening?” Identifying the rules and goals of a particular social interaction provided a template for Matt to recognize and react to a greater variety of social cues, thus enhancing his behavioral repertoire.

Information-Processing Model of Training Methods of training that follow a cognitive perspective teach patients to use a set of generative rules that can be adapted for use in various situations. For example, a six-step problem-solving strategy has developed as an outline for helping patients overcome interpersonal dilemmas: (1) adopt a problem-solving attitude; (2) identify the problem; (3) brainstorm alternative solutions; (4) evaluate solutions and pick one to implement; (5) plan the implementation and carry it out; (6) evaluate the efficacy of the effort and, if ineffective, choose another alternative.

While the step-wise, structured, linear process of problem solving occurs more intuitively and without conscious awareness in normal persons, it can be viewed as a useful interpersonal crutch to help cognitively impaired mental patients cope with the information needed to fill their social and personal needs.

Skill Enhancement via Environmental Organization Skills training is most effective if the patient's environment allows repeated opportunities and encouragement to practice newly learned skills. One example is in vivo amplified skills training. Here the patient's case manager or treatment team, together with the patient, makes direct and repeated efforts to create opportunities, encouragement, and reinforcement for using the acquired skills in the patient's living, working, and social environments. These efforts involve contacts with family, employers, agency officials, peers, and other persons who can facilitate the patient's use of specific skills in the environments where they are most relevant.

A related strategy involves teaching individuals to modify their home environment to incorporate specific cognitive and behavioral cues for skills. Reminder cards, notes, schedules, prompting devices (e.g., remotely activated beepers), and other concrete cues can be systematically used to augment skills learned in training programs.

Modules for Training Social and Independent Living Skills Based on the cognitive model of social skills training, a set of psychoeducational modules was developed at the University of California at Los Angeles (UCLA) Clinical Research Center for Schizophrenia and Psychiatric Rehabilitation for use by interdisciplinary professionals and paraprofessionals in a wide array of mental health facilities and natural environments to teach patients the social and instrumental competencies of key domains of community functioning. The domains include self-management of antipsychotic medication, identifying warning signs of relapse, coping with psychotic symptoms, grooming and personal hygiene, recreation for leisure, interpersonal problem solving, job finding, community reentry, safe and satisfying sex, family coping, street smarts, and engaging in friendly conversations. Those domains were chosen because competency in them has been associated with better social adjustment, longer community tenure, and lowered risk for relapse and rehospitalization.

Each module uses the same highly structured and thoroughly specified instructional techniques, so even paraprofessionals can use them with a minimum of training and consultation. The techniques also compensate for patients' cognitive dysfunctions by using overlearning, visual as well as auditory instruction, and in vivo training. Each module is a self-contained package that can be used alone or in combination with other modules in comprehensive rehabilitation programs.

The training modules were constructed to teach patients specific functional skills, to solve problems they might encounter while attempting to use newly learned skills, and to practice the skills in the natural environment. That model of social skills training offers considerable promise for patients who have the cognitive capacity for

learning social skills in small groups. Each module is divided into separate skill areas, and each area has specific behaviors taught to achieve personal effectiveness and competence. For example, as shown in Figure 52.4-11, the Medication Management Module contains skill areas for (1) understanding the benefits of antipsychotic medication, (2) mastering medication self-administration, (3) coping with the adverse effects of medication, and (4) negotiating medication issues with health care providers. Similarly, the Symptom Management Module comprises four specific skill areas: (1) identifying the early warning signs of relapse; (2) managing a prodrome and developing a relapse prevention plan; (3) coping with persistent symptoms; and (4) avoiding street drugs and alcohol.

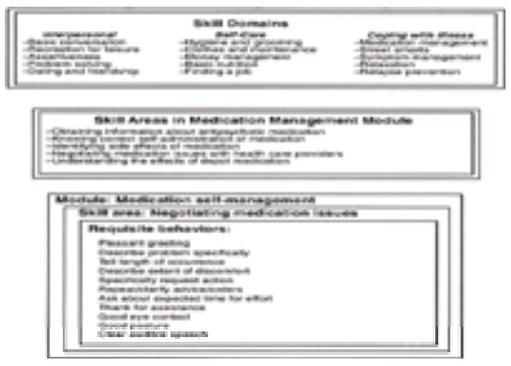

FIGURE 52.4-11 Domains of skills training with skill areas in the Medication Management Module. The fourth skill area comprises specific verbal and nonverbal behaviors that are the educational objectives taught in this skill area.

Each module contains a prescriptive clinician's manual or guide, a videotape demonstrating the skills to be learned, and a patient's workbook containing practice exercises and monitoring forms. Skills are trained by using a combination of focused instructions, videotaped demonstrations, role-playing rehearsals, social and videotape feedback, problem solving, and practice in the natural environment through in vivo exercises and homework assignments. Patients proceed through each skill area in a specific sequence of learning exercises and activities, starting with an introduction that explains the values and advantages of the module. The training procedure emphasizes discovery learning rather than expository or didactic teaching.

INTRODUCTION TO THE MODULE The objective of the first learning activity in the module is to help patients identify the goals of the module, the consequences of achieving the goals, and the steps needed to achieve each goal. Patients are also introduced to the language used in various aspects of training. The introductory exercise consists of a brief description of the module and the topics and goals to be covered in each skill area. Questions such as the following are asked until all patients can answer them correctly:

1. What is the goal of this module?
2. What problems are addressed by this module?
3. If you achieve the goal, what will happen?
4. Do you have time, money, skills, and people to help?
5. What steps are required to achieve the goal?

The purpose of the introduction is to inculcate realistic and favorable expectations and motivation to continue module training. The major goal at this stage is to encourage the patients to think and talk about the material they are about to learn. The therapist concentrates on establishing a highly reinforcing environment rather than on the correctness of patients' responses. However, if patients respond incorrectly to any question, the trainer asks an additional set of ever-more-leading questions designed to prompt patients to give the correct answer.

TRAINING SKILLS Following the introduction, training progresses through the various skills that comprise each domain or area of the module. Training involves two basic sets of procedures. First, patients view a videotaped demonstration of the correct performance of the skills they are about to learn. The tape is stopped periodically, and patients are asked questions to assess their attentiveness and comprehension of the information presented in the videotape demonstration. Incorrect answers result in replay of the videotape and highlighting of the information needed to answer the question correctly when it is repeated.

Next, patients use a role-playing exercise to practice the skills they have just learned. This performance is videotaped for subsequent review by patients and the therapist. The therapist evaluates the performance and provides positive feedback and suggestions for improvement. Role playing with video feedback is depicted in Figure 52.4-12. The role playing is then reenacted, and the process is repeated until the patient exhibits mastery.

PROBLEM SOLVING The training protocol recognizes that patients may encounter obstacles that make it difficult for them to achieve expected outcomes as they perform their newly acquired skills. Training in problem-solving skills is designed to teach patients methods they can use to overcome the obstacles. The problem-solving model used is a five-step procedure: defining the problem, generating alternative solutions to it, evaluating the alternatives in terms of their potential positive and negative consequences, choosing an alternative based on the evaluation, and implementing the chosen alternative. Patients are taught how to overcome two types of obstacles: resource management problems and outcome problems.

The training in solving resource management problems is designed to teach patients how to gather the resources necessary to implement a particular medication or symptom management skill. For example, even if training in the Symptom Management Module has taught an individual the skills needed to request an appointment with the psychiatrist to evaluate a prodrome, the patient must have access to certain resources such as a telephone to make an appointment and transportation to visit the doctor. A set of resource management problems is presented during the training in each skill area in each of the modules. The therapist describes a skill and asks the following questions:

1. What is your goal in using this skill?
2. What resources must you have to carry out the skill?
3. How would you obtain the resources?
4. If you were to obtain these resources, what positive consequences would happen?
5. If you were to obtain these resources, what negative consequences might happen?
6. Do the positive consequences outweigh the negative consequences? If yes, the method generated by patient is role played; if not, the patient is asked what else

he or she would do.

The training in solving outcome problems teaches patients how to respond when the environment fails to provide the expected outcome following the performance of a particular skill. For example, if an individual arrives for an appointment with the doctor and finds that the doctor has been called away to an emergency, what must the patient do to solve the problem? The training methods are similar to those used during the training in resource management problems.

Training begins as the therapist describes an obstacle that might be encountered as patients attempt to use their skills. Patients are then asked a series of questions that engage them in the problem-solving model.

1. What is the problem?
2. Do you have the time, money, skills, and people to help?
3. What can you do to solve the problem?
4. Is the chosen method feasible?
5. If you use the chosen method, are you likely to achieve your goals?
6. If you were to use that method, what positive consequences would happen?
7. If you were to use that method, what negative consequences would happen?
8. Do the positive consequences outweigh the negative consequences? If yes, role play the alternative generated by the patient; if no, what else would you do?

PROMOTING GENERALIZATION Patients must have the opportunity to practice newly learned skills in the natural environment as an additional step toward programing for generalization. Skills that can only be used in the context of the clinic or hospital are of little use to the patient. In vivo exercises are used to facilitate the transfer of training. Essentially, patients perform the skills in their own world. However, a therapist accompanies the patient to prompt and reinforce the patient's performance and to provide corrective feedback. The exercises are arranged to present increasingly difficult situations that require extending skills beyond the training provided in the clinic. An example in the Medication Management Module is an exercise in which the patient (and therapist) generate questions regarding the patient's antipsychotic medication, after which the patient questions a nurse on his or her treatment team to get the answers. Following that, patients may be encouraged to ask the same or similar questions of their physician or a local pharmacist. In each in vivo exercise the therapist helps patients fine-tune their performance while identifying needed resources and anticipating obstacles that may be encountered during the exercise.

Homework gives patients an opportunity for performance independent of the skills they have learned. Because the module's goal is to teach patients to function independently, homework represents the ultimate step in training. Wherever possible, patients are asked to return from the assignment with tangible evidence that the assignment was completed. For example, if the assignment is to obtain information from a pharmacist about one's medication, the patient can verbally report the information to the therapist and bring back the pharmacist's business card. The role of the therapist in the exercises is to provide feedback to patients regarding their performance.

Validation Meta-analyses and reviews of the more than 50 controlled studies of social skills training have shown that individuals with schizophrenia can acquire and retain skills, and that training results in significant favorable effects on social adjustment, symptoms, relapse, and rehospitalization rates. The most recent skills training studies showed significant methodological advances, including the use of control or comparison groups, increased reliability of assessments, and a better understanding of the cognitive psychology of schizophrenia and the distortions in learning processes commonly encountered. Skills training has consistently led to diminished symptom levels and improved social and interpersonal skills. Strong evidence indicates that skills training leads to skill acquisition and maintenance in schizophrenia, especially if training is intensive (more than two sessions per week) and of sufficient duration (at least 6 months). While schizophrenic patients with even high levels of hallucinations and delusions can acquire skills through systematic training, cognitive disorganization (e.g., severe distractibility and thought disorder) and the deficit syndrome (i.e., primary negative symptoms) appear to interfere markedly with the training process.

Recent advances in rehabilitation include the integration of skills training programs with other standard treatment interventions for schizophrenia. One program combines modular skills training with low-dose antipsychotic medication. This therapeutic strategy is aimed at minimizing neuroleptic adverse effects that can intrude on social functioning while equipping patients with the knowledge and skills to do a better job of managing their illness. Patients participating in this skills training program demonstrated significant skill acquisition and also showed gains in social activities, personal well-being, and overall adjustment. When patients learn through skills training to identify the early warning signs (prodromes) of relapse and to seek early intervention to avert relapse, outcomes are markedly improved, especially with lower doses of medication in patients who had an early onset of their illness.

Other recent developments in skills training involve the use of briefer, highly focused training protocols for commonly encountered clinical situations. In one program, the Community Re-Entry Module, hospitalized patients are taught the skills necessary to collaborate in their discharge planning. These skills are a critical aspect of treatment, given the obstacles in engaging with community-based treatment programs and the increased pressure on clinicians to keep inpatient treatment as brief as possible. A training protocol for chronically mentally ill individuals with comorbid substance abuse problems aims to teach skills necessary to manage the cravings, high-risk situations, and stressors contributing to substance abuse.

The impact and utility of social skills training can also be documented through professional validation, that is, the extent to which it is being implemented by practitioners and mental health facilities. The modules for training social and independent living skills developed at the UCLA Clinical Research Center for Schizophrenia and Psychiatric Rehabilitation have been implemented in 48 of the United States by over 1000 private and public hospitals, community support programs, mental health centers, and practitioners in private practice. A survey of module users found that 61 percent of the respondents used the modules regularly, and another 36 percent planned to institute or reinstitute the modules when administrative and logistical obstacles were overcome. In addition, the modules have been translated into 15 languages and are in use in Asia, Europe, South America, and Africa. Controlled studies have validated the efficacy of the modules in Quebec, France, Switzerland, Germany, Finland, Bulgaria, Poland, and Japan. The growing use of skills training methods around the world and their adaptation to local culture and conditions heightens the value of this modality as a major technique in psychiatric rehabilitation.

Three types of rehabilitative interventions overlap with social skills training in terms of treatment goals and behavioral learning principles: (1) family skills training and psychoeducation, (2) token economy and social learning programs, and (3) cognitive remediation. The choice of a particular rehabilitative modality depends on the needs of an individual as determined through symptomatic and functional assessment; the phase of illness; level of incapacity, structure, and supervision required; and the availability of resources to deliver the services. Thus, individuals with serious cognitive, functional, and symptomatic problems who need frequent prompting and reinforcement to learn basic life skills will benefit from a token economy. Patients who have contact with their family members will benefit from a psychoeducational and skill-building program aimed at improving communication and problem solving. Cognitive therapies and remediation, newer treatment modalities that have yet to prove their clinical validity, represent the cutting edge of treatment development for the attentional, memory, symptomatic, and executive dysfunctions of persons with schizophrenia that endure, limit rehabilitation, and are refractory to pharmacotherapy.

Family Psychoeducation and Behavioral Management Removing the barriers to the generalization of social and independent living skills can be facilitated by involving both the family and the patient in a collective enterprise of (1) education about the patient's particular mental disorder and the ways to obtain professional and community services for it, (2) training in communication skills, and (3) using the communication skills in systematic application of problem solving with the stressors and daily hassles that inevitably accompany mental disability. Because the family comprises an important part of the patient's natural support system and living environment (even chronic mentally ill patients living apart from their relatives may maintain significant personal and phone contact with them), improving the family's attitudes, knowledge, and coping skills regarding serious mental illness can be rapidly translated into better opportunities, encouragement, and reinforcement for using skills learned in the family therapy arena and other rehabilitation settings.

Many international studies have replicated the findings that family stress—reflected in criticism of and emotional overinvolvement with the mentally ill relative—is the most powerful predictor of relapse in schizophrenia and mood disorders. Therefore, several modes of family intervention were designed and empirically validated for the ability to equip relatives with coping skills and thereby change the emotional climate of the family and reduce the incidence of relapses and rehospitalizations. From the vantage point of the vulnerability-stress-protective factors model of serious mental illness, families are viewed as struggling with the stress of positive and negative symptoms and disability of their severely mentally ill relatives. In an interactive process the stress load produces demoralization, tension, and emotional and financial burdens on the family, while it can precipitate relapse in the index patient with fragile coping capacity and significant psychobiological vulnerability to stress.

Disavowing the anachronistic and antitherapeutic theories of the past that implicated family interaction in the etiology of schizophrenia, clinicians now engage relatives as essential allies in treatment and rehabilitation. The psychoeducational model has five basic aims. First, the treatment team must develop collegial relationships with family members and other support persons. Since many mentally disabled persons live apart from their families in group homes or half-way houses, the operators and staff of these facilities in psychoeducation must also be involved. Family members and support persons need coping skills and social support, and

active engagement in the educational process is encouraged by involving them at all stages as colleagues and collaborators in the patient's treatment. Secondly, a specific psychoeducational program is used to teach what is known scientifically about the patient's mental disorder and direct the family and other caregivers to locally available treatment and rehabilitation services. Topics might include information about positive and negative symptoms, effects of psychotropic medications, relapse prevention, crisis management, and treatment options for psychiatric rehabilitation. As much as possible, empirically validated treatment principles drawn from the clinical psychiatric literature are used in the psychoeducation, carefully translated to a layperson's level of comprehension.

Factual material is typically presented during the first half of an education session followed by a guided discussion in which families are helped to personalize their learning with comments or questions regarding their own experiences. A third principle underlying the psychoeducational approach is critical at this point, the assumption of least pathology. Problems understanding or managing a family member's illness are assumed to be a consequence of ignorance or the lack of necessary skills for managing specific situations, not of family dysfunction. Family members are assumed to be doing the best they can and acting in the interests of the patient and family, given their coping capacities and biobehavioral vulnerabilities. With this approach, setbacks are considered to result from lack of knowledge, treatment services, or skills, and the demoralization and extreme self-criticism that severely inhibit the family's efforts to help are minimized. Instead, treatment alliances are strengthened, and families can successfully pursue the next step, which involves developing step-by-step communication and problem-solving skills, the fourth major aim of the psychoeducational approach.

To produce durable clinical effects, family interventions must go beyond education and train family members in such necessary coping skills as basic communication and contingency management. Examples of communication skills that form the basis for effective problem solving include active listening, giving positive feedback, and making positive requests. With these skills, families can better address recurring difficulties associated with patients' symptoms and disabilities and the stressors of everyday life. Skills training strategies similar to those reviewed above are used to help individual families learn to interact in more constructive and goal-oriented ways. Thus, family psychoeducation is a specific form of social skills training, using the family system as the vehicle for targeting goals and skills. For example, the six steps of problem solving are taught using real-life problems faced by the family. Often one family member is chosen as leader of a problem-solving session who guides the family through a process, as shown by the family group in Figure 52.4-13.

FIGURE 52.4-13 A family participating in a problem-solving session of behavioral family management, led by a therapist. (Photograph courtesy of Thomas Smith, M.D.)

Most of the members of the Hanrahan family had been concerned about John's smoking in his room at night. His parents, Jackie and George, were particularly worried that John might fall asleep smoking in bed and start a fire. Using the problem-solving steps they learned in the family skills training sessions, the parents decided to call a meeting to discuss the matter. The Hanrahan family rotated leadership of the meeting each session; today it was John's sister Beth's turn to review the steps.

Although John first saw the problem as his parents' nagging him about his smoking habits, with gentle pressure from Jackie and Beth, John soon agreed with the others that he had a problem with smoking in his room at night. Beth then encouraged everyone to generate solutions to the problem. Jackie said that John should be encouraged to learn new ways to stop smoking and thought he should be rewarded $1.00 each day he went without smoking in his room. George did not like the idea because he thought this would only coddle his son. Beth reminded George that the family should only evaluate the solutions after several had been generated and challenged him instead to come up with a solution. George retorted that they should take away John's smoking privileges altogether.

After listing six solutions, the group reviewed the pros and cons of each alternative. Family members were then asked to vote on the worth of each solution. Four of the five agreed that “finding John another place to smoke at night” would be a good alternative. To implement the solution, Beth volunteered to help John walk through the house after the meeting to find a safe and quiet place to smoke between 8:00 and 10:00 PM. They agreed that the basement family room would be just such a place. The plan was to start the next night, and a week later the group would reconvene and discuss progress.

Next week it was George's turn to lead the family meeting. Under his guidance, the group discussed whether the frequency of John's bedroom smoking had decreased. John reported that he had smoked in his room at night only once the preceding week, which pleased everyone. Jackie, however, said she now found watching TV in the family room a bit unpleasant at night because of John's smoke. Because the original target of bedroom smoking had decreased markedly, the family decided to wait a week before deciding whether and how to tackle the smoke problem in the family room.

The last basic aim of psychoeducation programs involves developing a network of like-thinking people. Chronic mental illness presents substantial burden, stigma, and isolation to families, and a network of involved, understanding support persons and resources is of tremendous help. Psychoeducational programs encourage not only collaboration regarding the treatment process, but also active socialization and the development of lasting, personal relationships among families and treatment staff. Relationships are also encouraged with self-help groups like the affiliates of the National Alliance of Mentally Ill or local mental health associations.

Validation Over two dozen well-controlled studies in the past decade from several countries have examined the effects of family psychoeducation and coping skills training on patients and their families. Results showed that the rate of relapse and subsequent hospitalization for patients who participated in that type of treatment was significantly lower than for patients who completed various comparison treatments. In one study, only 6 percent of patients who participated in behavioral family management's problem-solving treatment with their families relapsed in a 9-month period following treatment, while 44 percent of the contrast group receiving individual supportive therapy relapsed. Over 2 years, only 11 percent relapsed in the family program, versus 78 percent of those who received supportive therapy. Moreover, the patients who participated in behavioral family management also gained significantly more in social adjustment and required less overall neuroleptic medication.

Recent studies show that family psychoeducation programs have significant benefits in areas other than symptom and relapse management for the family member with a chronic psychiatric disorder. When psychoeducation and skills training are conducted in a multiple family group format, family burden is lowered, and relatives' sense of self-efficacy regarding their ill family member improves. Participating in a multiple family group can reduce stress, isolation, and stigma experienced by family members; the burden of care no longer seems unique, and families can exchange helpful suggestions and coping techniques with each other. Evaluation of the clinical effects of multiple family groups suggests that the format may be at least as effective as single-family psychoeducation in reducing relapse while also offering special advantages in case management and vocational rehabilitation. The components of behavioral family management, now replicated in two subsequent studies, are listed in Table 52.4-2.

Behavioral analysis of all members of the family
Defining individual and familywide problems
Setting goals for each individual and family system
Identifying reinforcers
Education of all family members on nature of schizophrenia and currently available treatment and rehabilitation modalities
Training in communication skills
Expressing positive feelings to others and acknowledging when others do or say something positive toward you
Active, reflective listening
Making positive requests and asking for what you want
Expressing negative feelings in constructive ways
Training in problem-solving skills
Be specific and objective in describing the problem
Express how you feel directly and subjectively about the problem
Listen to each other actively and reflectively as the problem is described and feelings are expressed
Help each other generate alternatives and options in dealing with the problem
Weigh the potential consequences or outcomes (risks and benefits, pros and cons) of each alternative
Choose a reasonable alternative
Decide how to implement the alternative
Behavioral interventions for specific problems
Contingency management for negative symptoms
Job-finding skills training
Friendship skills training
Independent living skills training
Realistic and incremental expectations for performance
Reinforcing process through successive approximations (shaping)

Table 52.4-2 Component Interventions of Behavioral Family Management

Research on various forms of family intervention suggests that training in communication and problem-solving skills may be necessary to reduce family burden and stress-induced relapse as well as being prerequisite for achieving gains in social functioning. Family psychoeducation and skills training can be conducted with success in the clinic or in the family home. Recent work suggests that the modality may be as applicable for bipolar disorder and recurrent depressions as for schizophrenia. Studies have not yet isolated the specific, effective ingredients of behavioral family intervention or determined how much of the therapeutic effect results from the nonspecific social support that ensues from discussing common problems.

Cognitive Remediation The cognitive disorganization and neuropsychological deficits commonly seen in schizophrenia play a major role in determining the success of psychiatric rehabilitation strategies. Enduring thought disorder, short-term memory, and verbal learning deficits are more predictive of skill acquisition than psychotic symptoms. In addition, deficits in vigilance, memory, and executive functioning have been repeatedly associated with social skill and overall social adjustment. Further evidence of the importance of neurocognitive deficits in determining social adjustment in schizophrenia comes from studies of antipsychotic medications, especially the novel medication clozapine. Clozapine has greater efficacy than typical antipsychotic medications, which has been attributed in part to improved neurocognitive capacities that mediate the development and use of social skills. Recent studies suggest that clozapine and newer antipsychotics such as risperidone and olanzapine exert a beneficial effect on executive functioning, short-term memory, and attention systems mediated by basal ganglia function.

While many clinicians have assumed that the cognitive deficits of schizophrenia represent an irreversible, enduring form of dementia that cannot be mitigated by rehabilitation, evidence is accumulating to justify strategies for remediation of these basic cognitive deficits. Two types of cognitive remediation strategies have been developed that differ in the behavioral targets for remediation and the nature of the intervention. Both strategies aim to elevate the individual's capacity to learn a wide variety of social and independent living skills, thereby permitting psychiatric rehabilitation to begin at a higher plateau of rehabilitation readiness.

Direct Remediation of Basic Cognitive Deficits Individuals with schizophrenia have pervasive cognitive deficits that are substantially independent of psychotic symptoms. In addition to treating psychotic symptoms with traditional methods, programs have been developed to address these more basic information-processing deficits. Demonstrations have shown that laboratory-based measures of cognitive dysfunctions (e.g., reaction time, memory, card sorting, span of apprehension, and vigilance) can improve significantly with behavioral training. A variety of remediation strategies can be used, including repeated practice, instructional modification such as providing ongoing detailed instructions with cues and immediate feedback throughout a training session, positive reinforcement in the form of money or points that can be redeemed for desired incentives, and errorless learning that teaches discrimination and problem solving in small steps that maximize success and minimizes trial-and-error learning. As shown in Figure 52.4-14, the patient participating in this form of cognitive remediation is typically seated in front of a computer screen and instructed to repeat multiple trials on vigilance, memory, reaction time, discrimination, or concept tasks. As a rehabilitation instrument, the computer provides consistent and repeated trials, while monitoring patients' responses and adjusting test stimuli and consequences to shape gradually improving performance on the cognitive task.

FIGURE 52.4-14 Computer-assisted cognitive remediation. A patient is viewing the video monitor during a abstract reasoning task. (Photograph courtesy of Robert Kern, Ph.D.)

Recent efforts have incorporated more complex models of social cognition into remediation protocols for schizophrenia. In one approach, patients are involved in a hierarchical series of training subprograms, beginning with cognitive differentiation and proceeding through social perception exercises to verbal communication, social skills, and interpersonal problem-solving phases. A modification of this strategy involves methods for assessing discrete cognitive styles (e.g., reality distorters, impoverished, or disorganized), with the subsequent training program designed to address deficits in social cognition hypothesized to underlie the specific cognitive style. Data from these and other similar studies will help elucidate the nature of social cognition and the most appropriate interventions. Another approach adds vocational relevance to the cognitive training by having patients maintain a focus on concentration while performing quasi-job tasks such as folding, cutting, stapling, and sorting papers.

Empirical evaluation of the efficacy of these direct approaches to cognitive training suggests that striking improvements—approaching normalization of some functions—are possible in the cognitive tasks, but the links between improvements in laboratory-based molecular levels and in molar social and clinical status remain to be documented. Current research aims to promote clinical generalization of direct cognitive remediation by identifying and strengthening the cognitive, behavioral, and social processes that mediate learning of adaptive skills. For example, short-term verbal memory and sustained attention are possibly rate-limiting in the acquisition of social and instrumental skills. Vocational outcomes are predicted much more accurately by the patients' attentional capacities than by their symptoms of disorder; hence, current cognitive remediation efforts are directed at normalizing those deficits of attention, concentration, memory, and problem solving that appear to be the core obstacles to a person's responsiveness to rehabilitation. However, the ecological validity of laboratory-based remediation of cognitive dysfunctions awaits demonstration.

Cognitive-Behavioral Therapy of Psychotic Symptoms Another remediation strategy ameliorates psychotic symptoms through cognitive restructuring and behavioral learning principles. To date, strategies have been developed for treating delusions, hallucinations, and negative symptoms. Sometimes referred to as cognitive strategy enhancement, these approaches involve identifying specific symptoms and subsequent training in the use of cognitive coping strategies. Commonly used strategies include distraction (e.g., listening to music or humming when auditory hallucinations occur) or methods such as reframing, self-reinforcement, reality testing, and verbal challenging, all of which have the patient use cognitive protocols to test the logic of specific delusional beliefs. For example, delusional beliefs can be altered by collaborative, reframing methods with an investigative style that leads the patient to discover and test the dysfunctional quality of the irrational beliefs.

Mr. Smith believed he was being poisoned by his father. As a result he was anxious and paranoid during home visits. Rather than confronting the patient's delusion with reality testing, Mr. Smith's therapist engaged him in an examination of how these beliefs had an adverse impact. For example, harboring the persecutory ideas prevented him from feeling close to his father and from enjoying his home visits. The therapist helped Mr. Smith identify times when he felt safe and secure in the presence of his father, such as when they watched a football game together on TV and had some spirited conversation. The contradiction between happy times and fearful times became the opening wedge for questions about the validity of the patient's delusional beliefs.

Self-instruction and self-reinforcement can be used to counter delusions and hallucinations and to improve concentration.

A lawyer with a paranoid delusional disorder was chronically fearful that his colleagues were trying to extrude him from the firm. He was constantly on guard, vigilant, and tense when interacting with them. He was taught to take a more proactive stance at the firm and, instead of waiting for someone to say something, instructed himself to approach his colleagues each day, smile, and exchange some pleasantries. When these social initiatives had succeeded in disarming them, he was given practice in rewarding himself by saying, “That was a good gambit!”

A final therapeutic variant in this category is the use of cognitive-behavioral modification techniques to increase adaptive behavior and reduce the frequency and preoccupation of thought disorder, delusions, and hallucinations that are refractory to antipsychotic medication. Contingent reinforcement, reinforcer sampling, discrimination training, fading procedures, and discrete trials learning have all been effective, at least during short-term follow-up in hospital and clinic settings. Much of the emphasis is on increasing adaptive behavior that is incompatible with the symptoms and that, used frequently, will displace the psychotic symptoms. For example, in the attention-focusing procedure, repeated prompting, modeling, and reinforcement of appropriate verbalizations during many conversational learning trials enhances acquisition of verbal skills and reduces incoherence. The high density of prompts, modeling, and reinforcement makes it almost impossible for a thought-disordered patient to make incorrect responses.

Token Economy While systematic, planned provision of social and tangible reinforcers for patient's participation and progress is an indispensable element of social skills training, family psychoeducation, cognitive remediation, and vocational rehabilitation, contingent use of reinforcement becomes a round-the-clock necessity in token economy and social learning programs for the most seriously mentally disabled patients. If the pervasive positive and negative symptoms, instrumental role deficits, and intolerable, acting-out, and bizarre behaviors of treatment-refractory patients are to be remediated, the entire therapeutic milieu and its staff cadre must be united and consistently deliver systematic positive and negative consequences to patients' behaviors and encourage adaptive and prosocial behaviors from them.

The use of tokens, points, or credits as secondary or generalized reinforcers can be seen as normalizing a mental hospital or day hospital environment with a program mimicking society's use of money to meet instrumental needs. Token economies establish the rules and culture of a hospital inpatient unit or partial hospitalization program, offering coherence and consistency to the interdisciplinary team as it struggles to promote therapeutic progress in difficult patients. These programs are challenging to establish, however, and their widespread dissemination has suffered because of the organizational prerequisites and the additional resources and rewards needed to create a truly positively reinforcing environment.

Elements The first step in designing a token economy is targeting specific behaviors to be increased or decreased in frequency. For example, self-care and appropriate social participation in therapeutic activities would be targets for positive reinforcement, while aggressive and intrusive behaviors might result in token fines. Each behavior needs to be described well enough to be recognized reliably by patients and staff. For example, showering includes gathering soap, shampoo, towel, and clean clothes; preparing the shower area; washing the body; shampooing the hair; rinsing and drying the body; and cleaning up the area after use. Without extreme specificity, patients and staff may not reliably agree upon what behaviors justified token rewards.

After identification of token economy targets, contingencies need to be created that govern the consequences of those behaviors. Contingencies describe if-then rules connecting a target behavior with a reinforcer. Staff specify payoffs much like the contingencies in Table 52.4-3, with the size of the payoff differing across behaviors and proportional to the difficulty of changing that behavior. As the token economy progresses, specific contingencies can be adjusted depending on the frequency with which individual behaviors are performed by the patient group and the fluctuating rate of commodity purchases.

Token earnings	
Morning rising from bed and getting dressed on time	3
Satisfactory completion of morning activities of daily living	3
Satisfactory participation in a social skills training group or recreational therapy activity	10
Satisfactory participation in individual behavioral therapy session	10
Satisfactory participation in leisure time activities (per activity)	5
Meets criteria for dress and grooming checks during day (per check)	3
Showers satisfactorily	3
Completes assigned jobs or tasks on unit (per job or task)	4
Participates in off-unit vocational rehabilitation or adult education activity (per half-day)	10
Token fines	
Smoking rule violation	5
Lying on floor	5
Stealing	10
Forgery of token credit card	10
Assault or property destruction	20
Late return from grounds privileges	20
Reinforcers available for tokens	
Cigarettes	4
Drinks (coffee, tea, sodas, hot chocolate)	10
Snacks (potato chips, pretzels, ice cream, candy)	10
Grounds privileges (per half-hour)	4
Music time (per half-hour)	4
Private room time (per half-hour)	4
Nintendo, Walkman stereo, private TV (per half-hour)	4

* This token economy uses a card that can be punched with holes to document token earnings and purchases. The token economy has three levels, which differ in the flexibility and type of reinforcers and privileges. At the highest level of performance, the patient carries a “credit card” and has full access to all unit privileges and rewards without having to pay with tokens.

Table 52.4-3 Contingencies of Reinforcement in the Token Economy Used at the Camarillo-UCLA Clinical Research Unit*

Frequently, behavioral contingencies are confounded by opportunity. Staff must be able to observe the patient perform the skill so the patient can be reinforced. Hygiene activities are easily scheduled into the daily routine so that staff know when to observe patients perform the target. However, other skills like social behaviors are performed continually throughout the day. Staff may miss a learning opportunity if they do not observe the skill or behavior being exhibited.

Patients must also have the opportunity to perform the targeted skill. Patients cannot be reinforced for leisure activities with peers if they do not have access to games or other recreational activities. Similarly, if the goal in a medication management program is to increase the rate of appropriate drug self-administration, then patients need to be given independent access to their drugs.

After targets are fully defined and reinforcers are in place, rules must be developed to designate how patients receive and return tokens. Administrators of token economies need to define where and when tokens can be exchanged for commodities and other reinforcers. Typically, treatment units dedicate one small room to store cigarettes, decaffeinated coffee, candy, pop, personal radios, videos, and magazines. The store needs to open at least every 2 to 3 hours during waking hours so that patients have ample opportunities throughout the day to exchange tokens for reinforcers.

The prices for commodities are listed at the token store and vary depending on the demand for the item and the cost of purchasing the item from outside retailers. Thus, prices of frequently purchased items may be periodically inflated to maintain the attractiveness of all items in the store.

Empirical Findings Token economies are among the best replicated modality in the treatment of chronically ill psychiatric patients. Studies have shown that symptoms, bizarre behaviors, aggression, and self-care skills of psychiatric patients in token economies have improved significantly even after other treatments were ineffective. Many early studies of token economies focused on chronically institutionalized psychiatric patients and found that many patients in token economies were discharged from the institutions with positive effects that were maintained for up to 2 years. While token economies remain widely used in long-term inpatient programs, recent research shows that these strategies can also be used effectively on acute inpatient psychiatric units and in community-based residential and rehabilitation programs. Token economies are also useful treatment programs for geriatric, chronically aggressive, and dual-diagnosis patient populations.

An exemplary token economy, embedded in a comprehensive social learning program that included skills training, reinforcer sampling, and individualized goal setting, was studied in a rigorous experimental design by Gordon Paul and Robert Lentz. The absolute efficacy of this social learning program (in contrast to milieu therapy or custodial care) was documented in the realms of adaptive functioning, psychotic symptoms, bizarre behaviors, aggression, and cost-effectiveness. For example, the average social-learning patient increased interpersonal and communicative skills by over 1200 percent of entry level. Twenty-five percent of these severely disabled patients improved enough to be indistinguishable from the normal population on a blind, time-sampled behavioral checklist. Over 97 percent of the social-learning patients were successfully discharged to the community with tenure exceeding 120 days, compared with 71 percent of the milieu therapy group and 29 percent of the

custodial patients.

A token economy operated continuously for 26 years at the Camarillo State Hospital, cosponsored by the California Department of Mental Health and the UCLA Clinical Research Center for Schizophrenia and Psychiatric Rehabilitation. Patients were recruited from among the most impaired, treatment-refractory population in the hospital. An integrated pharmacological and behavioral program of interventions was applied. Table 52.4-4 shows the results of a cumulative empirical evaluation of the program, based on direct observation of problem behaviors during patients' baseline assessments and the frequency of the same behaviors in the month prior to discharge. A wide array of positive and negative symptoms, psychosocial deficits, and bizarre and intolerable behaviors were successfully modified in this exemplary model of public-academic liaison. More importantly, follow-up evaluations found that over 80 percent of gains were maintained, and half of the patients discharged from the unit maintained residence in the community.

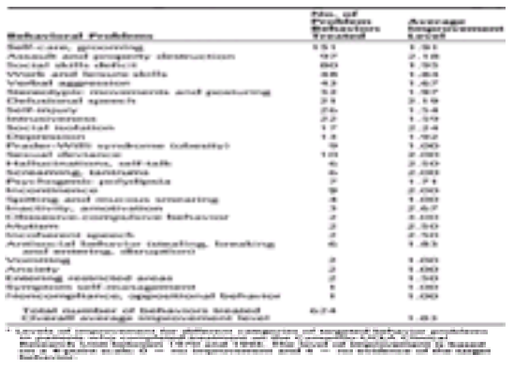

Table 52.4-4 Behavioral Outcomes*

For the increasing reservoir of treatment-refractory psychotic patients living in state hospitals, forensic institutions, or community residential facilities, the token economy is the psychosocial treatment of choice. To ensure a high-quality, ethical token economy (1) staff must be well trained in providing positive reinforcement and shaping successive approximations to adaptive behavior, (2) competent supervision by a behavioral psychologist is essential, (3) administration must provide extra support so that the environment is enriched with reinforcers rather than resorting to behavioral control through deprivation and response costs, (4) the token contingencies should be supplemented with approximately 30 hours per week of planned and scheduled rehabilitation activities consistent with social learning methods, and (5) maintenance and generalization of clinical improvements must be promoted through well-planned aftercare programs and gradual fading of the structure and frequency of the contingencies. As an example of the principle of fading, patients being readied for discharge can be shifted from daily receipt of tokens to a credit card level in which they have free access to all the rewards and privileges of the unit noncontingently as long as they maintain a reasonable level of performance of self-care, social skills, and instrumental skills.

While a faithfully designed and implemented token economy has predictable and salutary effects on chronic and refractory schizophrenia patients, few ideal programs exist. Administrative support is essential for a token economy to succeed. Other variables contributing to patients' benefiting from a token economy include higher intelligence quotient, female sex, and involvement of patients more actively with staff in determining the specific tasks and goals of the program. Patients who negotiate aspects of their contingencies are more likely to comply with the behavior therapy program.

Psychosocial Clubhouses and Self-Help Programs Fellowship clubs of formerly hospitalized patients were developed in the early years of deinstitutionalization. Many psychosocial clubs now exist in most large cities in the United States. The most influential organizations that spearheaded the clubhouse movement include Portals in Los Angeles, Fountain House in New York City, Horizon House in Philadelphia, Center Club in Boston, and Thresholds in Chicago. Clubhouses help satisfy their members' basic needs for acceptance, friendship, advocacy, housing, destigmatization, social and recreational activities, and emotional support. Through the years, the goal of those programs has gone from stabilizing individuals in a normalizing environment by providing peer support to offering opportunities for people to participate actively in planning their own rehabilitation program, including the chance to engage in meaningful and gainful work. Although the psychosocial clubhouse movement developed separately from the more medically oriented community mental health centers, in the past few years an increasing number of community mental health centers have converted their traditional day-treatment programs to the clubhouse model.

Central to the psychosocial self-help philosophy is the belief that individuals with mental disabilities have a fundamental right to work, socialization, and a home and that these basic needs, when satisfied, generate self-esteem and the positive identity necessary for community adjustment. Thus, psychosocial clubhouses focus on developing employment opportunities, peer support, and housing programs tailored to the capabilities of their members. Recently, the increasing influence of consumer empowerment as a philosophy, with its emphasis on patients as consumers of services as well as choice vis-à-vis mental health planning and service delivery, has spurred the growth and popularity of psychosocial self-help programs. The success of those programs, including those operated by patients themselves (so-called consumer-run agencies), is reflected by reimbursement of the services by Medicaid and Medicare and state departments of mental health and rehabilitation, by their certification by accreditation agencies, and by the vitality of the International Association of Psychosocial Rehabilitation Services, an organization spawned by the clubhouse network. Increasingly, the psychosocial self-help programs are evolving toward full-service enterprises with assertive community management, pharmacotherapy, and community support.

Validation For the most part, research on the psychosocial clubhouse model has been impeded by the regrettable barriers between academia and the clubhouses, resulting in studies that lack diagnostic rigor, random assignment of subjects, and reports of subjects' medication status. The outcome research that has been published provides supportive evidence for increased community tenure, increased adaptation, and enhanced satisfaction of members, compared with traditional approaches. However, there is a relative lack of empirical research about the effectiveness of the clubhouse model, in spite of the recognition and acceptance that it has received.

Fountain House, the prototypical clubhouse, was also the first to evaluate outcome systematically. The outcome measures selected were consistent with clubhouse goals, namely, to create a restorative environment within which individuals disabled by mental illness could be helped to lead vocationally productive and socially satisfying lives. Thus, early studies focused on preventing hospitalizations. For example, a 2-year study found that individuals randomly assigned to receive peer outreach services from Fountain House members had a 37 percent rehospitalization rate, compared with the 77 percent recidivism rate of their counterparts who did not receive peer outreach services. Other clubhouses have achieved similar outcomes in randomized, controlled studies aimed at decreasing rehospitalization rates.

The establishment of a Rehabilitation Research and Training Center at the Thresholds Psychosocial Clubhouse has permitted the study of a broader variety of outcome measures. For example, a number of programs that focused on different aspects of psychosocial functioning have been successfully implemented at Thresholds including assertive community treatment, supported education, supported housing, and human immune deficiency virus (HIV) risk reduction. However, studies of transitional employment have found that this prolongs artificial work settings and impedes eventual gainful employment.

Vocational Rehabilitation Vocational rehabilitation has traversed three distinct eras in the pursuit of improved employment outcomes for seriously mentally ill persons. The first was institution bound, with community- or hospital-based, sheltered work programs as the mainstay of intervention. Sheltered approaches were found counterproductive; their dead-end jobs offered no future hope for real jobs and taught few marketable work skills.

The second era was ushered in by the community mental health movement of the 1960s and by the psychosocial rehabilitation clubs. While the community mental health movement set the necessary conditions for building gainful vocational programs, its potential was never realized because most vocational efforts were sponsored by state departments of rehabilitation whose rehabilitation counselors' activities took place outside the main body of the mental health treatment sector. State-sponsored vocational rehabilitation programs tended to focus their efforts on physically disabled and on less seriously mentally ill persons.

Transitional employment programs, such as those in the Fountain House type of psychosocial clubs, evolved independently and often without much input from mental health professionals. Transitional employment involved prevocational work activities or work enclaves in industrial settings with the philosophy of train-then-place in a real job. A job in the competitive work sector was considered stressful, requiring gradual work hardening through jobs intrinsic to the psychosocial clubhouses: clerical services, food preparation, janitorial services, and other maintenance tasks. Research has shown that lengthy periods of work hardening in transitional employment

actually reduce the likelihood of competitive employment and that accelerated placement—as occurs in supported employment—yields better outcomes. That isolation unfortunately still exists today, and most psychiatric treatment systems neglect the area of vocational rehabilitation.

A renaissance in vocational rehabilitation, sparked by emergence of the supported employment movement, may be developing in the 1990s. The federally sponsored supported employment initiative springs from the understanding that persons with psychiatric disabilities require ongoing services, such as training in the skills necessary to maintain employment, once they secure competitive employment. It deemphasizes the importance of what has been labeled prevocational training, advocating instead a place-then-train approach. Based on their interests, skills, experience, and deficits, clients are placed in employment settings and then offered the training and supports necessary to maintain their positions. In its fully applied form, persons are offered services indefinitely, with job coaches visiting them at their workplaces to help them learn and retain the technical, interpersonal, and problem-solving skills they need to sustain employment. Supported employment requires close collaboration and communication among the client in the job, the vocational specialist (or job coach), and the community-based, interdisciplinary treatment team responsible for medication management and case management.

For example, the vocational specialist or job coach assesses a client's stamina, emergent psychopathology, medication adverse effects, and interpersonal relations directly on the job site. In league with the other members of the community mental health team, the job coach or case manager ensures that interventions are delivered to strengthen stamina, nip relapses in the bud, consult with concerned employers, control adverse effects, and improve social skills. In mastering the technical aspects of a job, the job coach carries out a task analysis of the requisite work and subdivides the training process into component, incremental steps. In contrast with the supported employment of mentally retarded persons, in which hands-on, coach-client contact is important, job coaching for mentally ill individuals demands more crisis intervention and liaison with psychiatrists who provide medication to promote clients' tenure on the job.

What are the determinants of successful vocational rehabilitation? The following factors make independent contributions to an individual's prospects for obtaining and retaining a job: psychiatric diagnosis and severity of psychopathology (especially conceptual disorganization and negative symptoms), stress in the family (expressed emotion), neurocognitive functioning, being on a disability pension (disincentive to work), poor premorbid social and work adjustment, no recent work experience, age and gender (older individuals and males are less likely to find jobs), interest and desire to work, and availability of supported employment imbedded in a comprehensive array of community-based psychiatric services.

The Individual Placement and Support (IPS) Program, developed at the New Hampshire–Dartmouth Psychiatric Research Center, is a model of supported employment for individuals with long-term impairments due to severe mental illness. The essence of this model is integrating employment specialists into case management or mental health teams to provide clients with practical assistance in finding and maintaining competitive employment. A critical component of this model is that it is time-unlimited; follow-along support from the mental health team, rather than closure of services by a state's vocational rehabilitation department, is often necessary to sustain employment. Controlled evaluations of the IPS model of supported employment have revealed successful job placements in competitive, community-based work for over 50 percent of the seriously mentally ill persons who participate in the program—more than twice as many as achieved these outcomes through transitional employment.

To minimize stress-induced relapses that can defeat the best-intentioned forms of vocational rehabilitation, practitioners and service systems must ensure that (1) occupational goals are realistically linked to patients' assets and deficits, (2) progress is promoted incrementally with abundant supports and reinforcement, (3) social skills training is made available to help the worker develop social support inside and outside the workplace, and (4) pharmacotherapy and crisis intervention services are kept accessible.

Sex and AIDS Education Sexual issues have been neglected in most work with seriously mentally ill persons. That neglect has historical roots and reflects a tendency of psychiatric practitioners to avoid exploration of sexual problems or to assume that seriously mentally ill persons do not have active sex lives. The sexual behavior of persons with schizophrenia differs from that of the general population, especially male patients, whose predominant sexual activity is autoerotic, with few sexual partners. Their median number of lifetime sexual partners is below normative profiles. However, schizophrenic individuals are at increased risk for HIV infection, perhaps related to their infrequent use of condoms; number of anonymous sexual partners; hypersexuality during psychotic episodes; poor ability to decline sexual overtures; and male homosexual activity, which may be more prevalent than in their counterparts without schizophrenia. Most antipsychotic and antidepressant medications influence sexual drive and activity adversely. Known adverse effects (which undoubtedly influence compliance) include ejaculatory difficulties, erectile dysfunction, decreased libido, orgasmic dysfunction, and priapism.

Education programs on sex and acquired immunodeficiency syndrome (AIDS) have been designed with the following goals: increasing patients' knowledge and comfort about sexuality, helping patients identify and clarify their values and attitudes about sexuality, helping patients acquire decision-making skills regarding sexual activity, overcoming medication-related sexual dysfunction, preventing deterioration of sexual functioning, improving intimacy skills, providing basic AIDS education, and teaching proper condom use. To compensate for patients' attentional and cognitive difficulties, materials were kept graphic and simple. Videotaped presentations were used, as were behavioral techniques such as role playing and structured problem-solving methods. Although careful design of such programs compensates for the cognitive and motivational deficits of chronically mentally ill persons, data are not available to guide future efforts in sex education.

Clinical Case Manager as the Linchpin of the Service Delivery System Successful coordination of the elements and modalities of any service delivery system depends on effective case management. Soon after the onset of the deinstitutionalization movement, many clinicians realized that ensuring continuity of care for seriously mentally ill persons in a system that is complex, fragmented, and frequently inaccessible would require professionals trained to navigate the murky waters of social services. Successful service delivery models with a case-management framework have increased the community tenure of previously institutionalized patients in a variety of settings.

Effective case management can integrate psychiatric treatment and rehabilitation services, incorporating the elements listed in Table 52.4-5. Most individuals with schizophrenia, as part of the nature of their enduring symptomatology, do not readily travel for medical and psychiatric appointments nor do they eagerly embrace the social contact that is offered by therapeutic services. It is often necessary to deliver services through a mobile, outreach form of clinical case management.

The client or patient is the central focus for the case manager, who works collaboratively with the client to formulate long- and short-term goals and create opportunities for treatment, rehabilitation and support
Caseloads for assertive-outreach, intensive, clinical case managers must be limited to less than 20 clients or patients per manager
Case management services should be delivered primarily in the client's community and natural habitat; thus, transportation, mobile communications, and in vivo work are key requisites
Case managers are expected to be accessible, either directly by being on call or indirectly through rotation with other case managers on the team; they often provide crisis intervention, either directly or indirectly
Case managers serve as advocates or brokers developing medical, psychiatric, dental, medication, financial, housing, and social support for clients or patients
Case managers serve as teachers, guides, role models and problem solvers
Case management services are not time limited; thus, long-term nonprofessional supports must be developed by case managers within informal and natural support networks to relieve themselves of cumulative stress and strain from increasing caseload demands

Table 52.4-5 Elements of Clinical Case Managers' Functions and Role

As experience with case management has grown, its prototype has changed from a broker of services to an intensive clinical service provider and advocate. Intensive case managers attempt to wrap needed services for community function and adaptation around each patient, with the type and amount of services matched to an individual's clinical status, values, and phase of illness. The Training in Community Living or the Program of Assertive Community Treatment (PACT) developed in Madison, Wisconsin, is a model of broad-spectrum case management organized in round-the-clock continuous-treatment teams. The program has been replicated throughout the United States and abroad in both rural and urban settings.

The PACT model has been adopted in several areas where funding for public psychiatric services faces greater constraints by state governments that are cutting back on budget support for human services. For example, in Los Angeles County, 7 percent of the mental health budget of $400 million has been funneled into agencies providing PACT-like services to recidivistic mentally disabled persons. These individuals, who are the highest users of hospitalization and costly crisis services, expend 15 percent of the mental health budget and yet make up only 1 percent of the population served in the county (averaging $50,000 per year). By providing the

service agency with a capitated budget (usually between $15,000 and 20,000 per patient a year) the funding agency (in this case the Mental Health Department of Los Angeles County) can maintain fiscal solvency through its ability to assess annual expenses more accurately while allowing the treatment provider maximum flexibility in the use of resources and selection of services such as housing, crisis intervention, vocational rehabilitation, medications, and continuous case management.

Although it is generally agreed that case management is a desired service for individuals with serious, persistent mental illness, there is little consensus about which elements of case management are most clinically useful. A case manager in a psychiatric rehabilitation setting has several specific tasks to perform including assisting patients in building social networks; facilitating procurement of housing and employment; helping patients interact with the various service organizations to meet ongoing needs; teaching patients the skills they require for illness self-management; monitoring the clinical progress of the patients; and, when necessary, undertaking timely clinical interventions. Each of these tasks requires specific competencies, illustrated in Figure 52.4-15. By acting as the fixed point of responsibility within a continuum of care, case managers have influenced patient outcomes toward improved vocational functioning, less social isolation, and more independent living.

FIGURE 52.4-15 Clinical competencies of assertive, outreach case managers.

Validation The current state of research inquiry into case-management services includes several well-designed, randomized, controlled studies with clearly operationalized and faithfully delivered models of case management and careful examination of outcomes such as symptomatic status, relapses, acquisition and generalization of social and independent living skills, vocational outcomes, quality of life, and service utilization. These studies showed that different models of case management may be more effective with system outcomes (e.g., reducing the number and length of hospitalizations and consequently cost-effectiveness) than with clinical outcomes (e.g., symptoms, social functioning, and quality of life). For example, a 2-year study conducted at Department of Veteran Affairs (VA) medical centers found that high users of inpatient services who were randomly assigned to receive intensive psychiatric community care (IPCC) had 33 percent fewer inpatient hospitalization days than their counterparts assigned to standard VA care. The impact of the IPCC intervention was greatest at long-term hospitals, with older patients, and with patients with higher levels of preintervention inpatient service usage.

Despite its proven cost-effectiveness, case management as a clinical intervention cannot be justified solely by decreased service use and increased cost containment. For example, a case-management system that increases service use by homeless, mentally ill persons by moving them from bus stations, shelters, and alleys to hospitals and housing, should be seen as a success, not a failure. Unhappily, current concerns with cost savings have led statewide mental health systems to abandon clinical markers of success in favor of the least-expensive alternative—often leading to transinstitutionalization of mentally disabled persons to prisons and jails.

Ultimately, the success of any case-management approach depends on whether or not patients receive the appropriate services to meet their needs. The problems encountered in attempting to draw conclusions from the current generation of case-management studies include a failure to assess the needs of the individuals receiving the services, inadequate definition of the activities in a given model of case management, and little consideration given to the relation between process and outcome measures (i.e., how a particular intervention leads to a salutary result). Improvements in the yield from empirical evaluations of case management require better specification of case-management methods and objectives, characterization of the symptomatic impairments and psychosocial deficits of the study population, use of multiple outcome measures, and longer studies that follow clients over 3- and 5-year periods.

One such study began in the early 1990s when the California legislature created two pilot integrated service agencies (ISAs), The Village, located in urban Long Beach, and the Stanislaus County ISA, located in a small city within a rural county. The ISAs received a fixed payment for each enrolled patient to cover all mental health services (approximately $15,000 per year). The treatment program incorporated the components of the PACT model, with interdisciplinary teams providing core services and assuming responsibility for each client, offering 24-hour coverage from a single service source for a 3-year period. Individualized treatment was based on a personal services plan developed jointly by patients, family members, and staff.

At each site a team of state, county, and ISA clinicians screened referrals to the programs. The authorizing legislation required that participants in the ISAs have a serious and persistent mental illness, demonstrated by a revised third edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III-R) diagnosis other than a primary substance use disorder, substantial functional impairment due to the mental disorder, and eligibility for public assistance because of the functional impairment. Eligible patients at each site were randomly assigned to receive ISA services or a comparison group. Patients in the comparison groups continued to receive usual county mental health services, such as outpatient, day treatment, case management, inpatient, and minimal rehabilitative services.

After 12 months of the 36-month program a total 426 patients were assessed on a variety of outcome variables using subjective information from patient interviews and objective data from patients' records. Patients in both ISAs were more likely to remain in treatment, were less likely to use psychiatric hospital care, and were more likely to work for pay. However, much of the employment activity was part time or temporary, and no outcome differences were observed in several other socially and clinically important domains such as rates of long-term hospitalization, arrest, or conviction; symptomatology; substance abuse; homelessness; or quality of life. Data for the full 36 months will be important in either confirming these results or showing the increased impact of mature programs.

In summary, most studies of case management undertaken thus far have been first-generation studies concerned with comparing case management with more traditional models of service delivery. While helpful, this type of research often provides unwieldy comparisons of different models of clinical case management in markedly different care systems, with poorly defined or heterogeneous patient populations. The second-generation of case-management research will compare different models of case management or specific interventions within case-management services to determine which service elements are responsible for the various outcome domains. One hypothesis supported with data from case-management teams that incorporated specific expertise in supported employment and social skills training holds that reaching specified treatment outcomes (e.g., improvements in independent living skills) requires specific therapeutic intervention in that domain (e.g., training in independent living). In the larger perspective, researchers must determine whether adding competency in symptomatic and functional assessment, vocational rehabilitation, social skills training, and family psychoeducation to the repertoire of case managers is translated into superior, long-term improvement in the person's symptomatic and functional status.

Community Support Programs The signing of the Community Mental Health Centers Act by President Kennedy in 1963, and the extension of Social Security disability benefits to mentally ill individuals 10 years later, set the stage for the transition of care of seriously mentally ill patients from large state hospitals to less-restrictive settings. However, by the mid-1970s, the fragmentation and complexity of deinstitutionalization-oriented services and supports were apparent. The prevailing psychotherapeutic paradigms were ill equipped to help individuals with serious and persistent mental illness cope with life in community settings. Most programs were facility or office based; and they expected people to come in to seek services and to negotiate a great deal of red tape. Thus, while the locus of care had shifted, no complementary shift in treatment focus had occurred, nor had new and appropriate modes of care been articulated and implemented.

An overarching conceptual framework was needed to counteract the pervasive fragmentation in the mental health field. The Community Support Program (CSP) was developed as a national model by the NIMH in 1976, with the input of field-based knowledge from practitioners, families, policymakers, and patients. According to this model, interventions were to be delivered in a coordinated fashion by multidisciplinary teams of clinicians who assumed long-term responsibility for the care of the seriously mentally ill patients across the spectrum of mental health services including inpatient units, outpatient programs, partial hospitals, and psychosocial

rehabilitation centers. The community support system had several essential functions or components, listed in Table 52.4-6.

Outreach and engagement
Support of basic needs
Mental health care and treatment
Crisis and emergency services
Comprehensive psychosocial services
Range of housing options
Support and education for provides and families
Development of natural supports
Advocacy and protection
Case management

Table 52.4-6 Elements of a Community Support System

Several principles were to guide the development of local community support programs. People with disabling mental disorders were to be treated with dignity and their privacy and right to confidentiality respected. Services were to be adapted to the changing needs and preferences of each person on the basis of self-determined goals. The service system was to provide comprehensive, accessible services for as long as, and whenever, a person needed them, in settings that were the least restrictive and most normalized.

The impact of the CSP model, though difficult to quantify, has been extensive. Through national working conferences and a focused program of planning and demonstration grants directed to the states, the CSP model has been incorporated into a wide variety of successful community-based programs. One example of the success of the CSP initiative is with young adults diagnosed with both severe mental illness and substance abuse disorder. The results of 13 demonstration projects funded by the CSP branch of the Center for Mental Health Services showed that substance abuse treatments could be integrated with components of outpatient mental health services and that motivational interventions were fundamental. Patients could be engaged in integrated, community-based treatment, with the possibility of concomitant reduced hospital use, improved severity of substance abuse, and enhanced quality of life. These CSP-driven service demonstrations and related program evaluations provided a watershed in the development of dual-disorder services and research.

With the passage of Public Law 99-660, the Americans with Disabilities Act, states were required to incorporate CSP principles into their plans for providing vocational services to persons with serious and persistent mental illness. The act outlaws discrimination against persons with disabilities in nearly every domain of public life: employment, transportation, communication, and recreational activities. With respect to employment, the most important definition of discrimination is an employer's refusal to make a reasonable accommodation. When requested by a qualified applicant or employee with a disability, an employer must provide a reasonable accommodation unless doing so would impose undue hardship. A common example of a reasonable accommodation is building a ramp for an individual confined to a wheelchair. Similarly, individuals with psychiatric disabilities may require accommodations to address their functional limitations. For example, an individual who has difficulty concentrating may ask the employer to provide a private space for work, to limit interruptions and noise. Other possible accommodations for such an individual include maintaining a structured schedule with well-defined daily tasks, eliminating nonessential or secondary tasks that might be distracting, and minimizing supervisor or coworker interruptions of the employee. By invoking the principles of the Americans with Disabilities Act, many communities have been able to secure the mandate and resources needed to design and implement comprehensive, continuous systems of mental health care.

Housing Safe, acceptable housing is a critical element in the complex array of basic and extended services that persons with serious, disabling mental illnesses require to establish and maintain themselves in the community. In fact, rehabilitative efforts are doomed to failure unless affordable, adequate housing is available. Some of the most time-honored needs met in past eras by psychiatric hospitals—offering protection, social support, nutrition, security, supervision, and sanctuary for the mentally disabled—are now provided by the spectrum of community-based housing options. While most psychiatric patients desire such housing, obstacles prevent them from securing and maintaining satisfactory shelter.

Impairments related to the patients' illnesses, such as deficits in social and independent living skills, severe psychotic and affective symptoms, and cognitive dysfunctions; environmental barriers such as stigma, poverty, and discrimination; and service system inadequacies such as inattention to patients' need for support in their vocational and independent living endeavors, have compounded the problem. Consequences of that inattention include homelessness, inappropriate use of intensive psychiatric and general hospital services, family burden, and increased involvement of mentally disordered persons with the legal and penal systems.

Efforts to redress these problems have taken many forms over the past decade. Attention has been given to examining the level of support needed for seriously mentally ill persons to secure and maintain housing. Initially this involved developing comprehensive arrays of transitional living arrangements, so that patients could move from more- to less-supervised, supportive settings. Such elements as quarterway, halfway, and three-quarterway houses; board-and-care and other group living arrangements; crisis and homeless shelters; foster family settings; and supported apartment programs were popularized. The best efforts allowed consumer choice, easy access, and free movement among the service elements depending on patients' needs for supervision and support. However, many efforts suffered from the tendency for clinicians and systems to attend to their own needs, leading to fixed lengths of stay in each of the housing elements, with patients moving to meet systems' needs rather than having services flexibly tailored to their own waxing and waning impairments and personal resources.

Over the past several years, partnership between mental health and public housing agencies have become more common. What has been lacking are approaches that attend to patients' individualized desires for housing. Service providers and policymakers have not implemented systems that actively ask patients what their housing preferences are and then teach them the skills they need to find adequate, acceptable housing. Future efforts will seek to solicit patients' goals for shelter and basic needs, identify their personal resources and deficits in the pursuit of those aims, and help them acquire the coping skills and competencies they require to attain their housing goals.

A shift in conceptual framework has already begun with the increased availability of supported housing. One element of the supported housing movement is a change from reliance on a facility-based residential treatment setting or a series of such specialized settings as the focus for treatment and rehabilitation to the need for a safe, secure home of one's own as a basis for a stable life in the community. In this new paradigm, professionals no longer select the setting or determine what type of placement is best for the patient, nor do they place a person on the basis of open beds or slots in the residential service system. Rather, the person is helped to choose an appropriate living situation on the basis of personal criteria, preferences, resources, and needs. As such, the patient assumes the role of tenant, householder, neighbor, and mainstream community member, working together with staff on mutually agreed on goals and tasks geared toward the individual's success and stability in the home chosen. Additionally, social support, case management, crisis intervention, in-home skills training, and accessible psychiatric consultation are flexibly wrapped around the changing needs of the patient. Financial assistance is available through subsidized rental vouchers (Section 8 grants) provided by the United States Department of Housing and Urban Development.

Two large research efforts have provided some information on the value of the supported housing approach. The Program for Chronic Mental Illness was sponsored by the Robert Wood Johnson Foundation in concert with the United States Department of Housing and Urban Development. The program was targeted toward overcoming fragmentation in the mental health system so that homeless persons with psychiatric disabilities were better housed and served. The nine cities selected developed comprehensive housing plans and designated a single mental health authority with defined, continuous responsibility for those in the target population. This single mental health authority had budgetary control, responsibility for targeting services and supports, and access to rental subsidies.

The demonstration program showed that comprehensive supports and housing subsidies had a major impact on the lives of persons who would otherwise be homeless, including decreased hospitalization and improved quality of life. However, these results were predicated on the patients receiving ongoing, intensive case management and practical help. Normalized housing with intermittent support from visiting case managers did not suffice to buffer the stressors attendant on living independently.

The second demonstration project was a joint venture of the United States Department of Health and Human Services and the Department of Housing and Urban Development. The McKinney Research Demonstration Program for Homeless Mentally Ill Adults consisted of five longitudinal, experimentally designed studies

serving a total of nearly 900 participants. These sites tested a variety of methods of reaching, housing, and serving the target population. In general, the studies demonstrated that homeless persons with serious, persistent mental illness can be engaged, will accept the services that meet their needs, and can successfully become stabilized in community-based housing with appropriate help. Participants displayed significant decline in symptoms of mental disorder and use of psychiatric hospitalization and a slight improvement in social and role functioning. Moreover, individuals' perception of their quality-of-life improved significantly. However, for a large minority of the participants, continuing substance abuse, social isolation, boredom, and overall difficulty adjusting to living alone negatively affected the stability of their lives.

Taken together, these demonstration projects indicate that innovative supportive housing programs do seem to allow many persons with long-term psychiatric disorders to develop a stable home in the community. However, an ambitious policy of independent housing—without consideration of such factors as substance abuse, an individual's social network, poverty, quality of housing, criminal activity in the neighborhood, and the amount and quality of ongoing, personalized support and assistance from community-based mental health teams—is not likely to maintain long-term residential stability.

Combined Psychosocial and Drug Therapies The biopsychosocial approach to comprehensive care including training in social and independent living skills, family psychoeducation, self-management of medication and symptoms, assertive clinical case management, and supported housing and employment can amplify the impact of medication in fostering better outcomes and higher levels of personal functioning. Optimal psychiatric treatment and rehabilitation offered in a coordinated, comprehensive, and continuous fashion can clearly facilitate symptomatic and social recovery from schizophrenia and other disabling mental disorders in many more individuals than are currently helped. Clinicians must teach patients the skills they need to be effective collaborators in the treatment planning process. The following case vignette illustrates this point.

Bill was a 23-year-old man with a 5-year history of schizophrenia. He had been resistant to taking medication due to the adverse effects he had experienced, including severe akathisia, tremors, and muscle stiffness. He acknowledged that these medications had diminished his psychotic symptoms and improved his attention and concentration but resisted efforts to become more compliant with prescribed regimens. He also related that some of his psychotic symptoms, particularly auditory hallucinations, persisted at a low level despite altered dosages and types of medications. Bill had been hospitalized an average of three times a year for psychotic exacerbations since the onset of his illness. He said that all efforts to treat him “missed the boat” and that staff had not attended to his own goals and ambitions.

At this point, staff engaged Bill in a goal-setting process, in which he identified targets of living independently without being hospitalized, taking little or no medication, and eventually getting a job. His psychiatrist and social worker accepted these goals as laudable and set out to establish clear and measurable landmarks to gauge his success in pursuing these aims. They then worked with Bill to identify his personal resources and the obstacles he faced in attaining his goals. Bill said that the most frustrating problem was his lack of understanding about his illness and its treatment, because this led to frequent relapses and concomitant life disruption.

Bill's psychiatrist and social worker next enrolled him in a class designed to increase his understanding of his illness and the medications used to treat it. He gained a good working knowledge of how these medications caused the adverse effects he found so intolerable, and he learned communication skills that would help him effectively negotiate the type and dosage of his medication. Following this, he worked with his psychiatrist and agreed to a trial of an atypical antipsychotic. He noticed that the new medication resulted in much less discomfort from extrapyramidal adverse effects. Finally, he was taught coping methods—such as humming and reducing social stimulation—to manage the persisting auditory hallucinations he experienced. This gave Bill a sense of mastery over his illness, and he adhered to his medication regimen. During the next year, he experienced two minor relapses but sought help from treatment personnel early in the prodromes of these relapses and did not require rehospitalization.

The key features of the foregoing example were that Bill's goals and personal desires were solicited, respected, and incorporated into the treatment plan; his resistance to medication was confronted in a straightforward, nonjudgmental, problem-solving manner; and he was taught skills he needed for effective collaboration in his own treatment and rehabilitation. Treatment occurred in a multidisciplinary team context, and Bill was seen continuously by the same group of treatment providers.

The new generation of antipsychotic medications offers distinct advantages over conventional antipsychotics in facilitating rehabilitation. These agents, which include clozapine, risperidone, olanzapine, quetiapine (Seroquel), and sertindole (Serlect), are superior to traditional antipsychotics in ameliorating negative symptoms such as social withdrawal and anhedonia and are less likely to produce extrapyramidal adverse effects, thus minimizing the use of anticholinergic agents that tend to impair attention and memory capabilities. They may also have direct salutary effects on information processing and attentional capacities in the central nervous system. For all of these reasons, increased use of these newer agents offers hope of greater recovery from the illness if continuous access to treatment and rehabilitation is provided.

Findings to date indicate that comprehensive treatment programs for persons with serious mental disorders should combine drug and behavioral, learning-based interventions. The following principles, distilled from the results of many studies and practice guidelines, summarizes current clinical wisdom regarding drug-psychosocial treatment interactions.

1. Psychosocial treatment is most helpful for patients in reasonably good partial or full remission from florid symptoms who have reached stable levels of maintenance medication. Psychosocial treatment during acute flare-ups of symptoms should be aimed at calming the patient, reducing levels of social and physical stimulation, and helping the patient integrate and understand the symptoms as part of an illness process.
2. The most effective psychosocial treatment—whether provided by individual, group, or family therapy; day hospital; or inpatient milieu therapy—contains elements of practicality, concrete problem solving for everyday challenges, low-key socialization and recreation, engagement of attainable tasks, and specific goal orientation.
3. A continuing positive relationship is central in the overall strategy for treating the patient with schizophrenia, no matter how much drug or psychosocial treatment contributes. That relationship may be with the prescribing psychiatrist or with a paraprofessional case manager.
4. The critical time to offer psychosocial treatment is during the aftercare period, when the patient can absorb rehabilitation and needs assistance in surmounting the problems and stresses of readjusting to family and community.
5. Psychosocial treatment should be long term; benefits rarely become apparent before 12 months and are even greater after 2 years. Indefinite, if not lifelong, psychosocial support, guidance, and training are probably optimal for most patients with chronic schizophrenia. As antipsychotic drugs are most effective in maintaining symptomatic improvements when continued indefinitely, it is not surprising that psychosocial rehabilitation efforts are similarly optimized by continuity.
6. Psychosocial treatment should focus on stressors in the environment and deficits in personal characteristics that seem to play specific roles in relapse and community maladjustment. Schizophrenic relapse is common, even when drug compliance is firmly established. No evidence suggests that a patient's level of manifest psychopathology at hospitalization or discharge predicts subsequent relapse. The best explanation, based on converging lines of evidence from empirical studies, is that the patient's personal assets and deficits, the social environment, and the type of psychosocial therapy are the most powerful influences on relapse, even in the face of reliably administered maintenance medication. Medication is never prescribed, ingested, metabolized, or excreted in a socioenvironmental vacuum.

FUTURE DIRECTIONS

With improved and more reliable methods of diagnosis, symptom assessment, and functional assessment, the population and needs of patients requiring psychiatric rehabilitation are becoming better defined. Because of its growing technology and its conceptual and empirical base, psychiatric rehabilitation has attracted an interdisciplinary group of practitioners and investigators whose work has contributed to its evolving scope and stature as a subspecialty of the mental health and rehabilitation professions. The challenges to community-based care for seriously and chronically mentally ill persons have been met by new initiatives at the clinical and policymaking levels, for example, social skills training, case-management models for coordinating continuing care, supported housing and employment services, greater advocacy and involvement by families, and the Americans with Disabilities Act.

Despite advances in assessment and treatment, implementation of psychiatric rehabilitation in the public sector has been frustrated by inadequate funding and resources, lack of trained personnel, limited dissemination of the new technology, insufficient affordable housing, unattractiveness of voluntary treatment, and a lack of administrative and financial integration of state and local community mental health and substance abuse services. The consequences of those systemwide problems have meant that too few mentally disabled individuals are actually receiving state-of-the-art services, and too many thousands are living on the streets of our

cities and in jails and prisons.

Innovations for the Twenty-First Century How might the future of psychiatric rehabilitation be charted? Will the field continue to flourish or merely become a historical footnote along with deinstitutionalization and community mental health centers? Some ideas for clinicians and researchers emphasizing domains of rehabilitative activity are currently taking root.

Illness Self-Management Techniques Skills training modules, such as those in the UCLA Social and Independent Living Skills series, will enable an increasing array of practitioners help patients acquire the abilities to monitor their psychopathologic and functional progress, to identify stress through changes in skin conductance and prodromal symptoms, and to seek early, flexible levels of intervention from professionals and caregivers. With patients also more knowledgeable about the benefits and adverse effects of their medication, a true partnership in managing pharmacotherapy will yield improved adherence and self-efficacy and fewer relapses, and more individuals will achieve symptomatic and functional recovery.

Cognitive Remediation As researchers learn more about the cognitive substrates and mediators of psychopathology and social dysfunction, techniques will be developed from applied behavior analysis and amplified by a new generation of atypical antipsychotic drugs that can effectively remediate and overcome the attentional, memory, and information-processing deficits. The brain is a plastic organ with many compensatory mechanisms that can be activated by structured, systematic environmental intervention; thus, the biopsychosocial nature of serious mental disorders will illuminate the bidirectional pathways among brain-behavior-environment interactions.

Assessment Technology Functional and symptom assessment will become better integrated, with mathematical models derived from large-scale research studies showing how personal, social, and psychopathological variables interrelate. One study of over 400 mentally ill persons showed that long-term employment outcomes were determined by a confluence of psychiatric symptoms, social competence, work capacity, and pension disincentives. When practitioners adopt quantifiable and repeated measurements of symptoms and functioning in their patients, interventions will be selected more judiciously and their effects monitored more precisely. Improving the quality of care ultimately depends on reliable and clinically relevant assessment instruments that give informational feedback and guide decision making.

Integration of Social Learning With Assertive Community Treatment Proponents of intensive forms of outreach case management and clinical intervention will adopt behavioral therapy techniques to promote greater gains in psychosocial functioning and independence of patients. Life adjustment teams will use structured skills-training techniques—which themselves will have been infused with new principles from research on cognitive science—while engaging patients in naturalistic settings in the community. Demonstration studies of this type of integrated mental health care have already accelerated and broadened the symptomatic and social recovery of persons with serious mental disorders.

Normalization of the lives of long-term mentally ill individuals will improve with a wider array of supported employment, housing options, and access to educational, social, and recreational opportunities that promote community adaptation. The anticipated contraction in the work force because of lowered birth rates, continuing growth of the economy, and the impact of the Americans with Disabilities Act will make jobs more accessible to disabled persons. The type and frequency of follow-along psychiatric services will be tailored to the individual's symptom patterns, work tolerance, stress vulnerability, and social disabilities. Volunteers, students, and retired persons will take on a greater role in providing social support, friendship, and community linkages for mentally ill individuals. Telephones, answering machines, beepers, and informatics made possible by fiber optics, television, and computers will reduce the isolation and stigma of mental illness.

Family and Patient Participation With the growing size and political impact of the National Alliance for the Mentally Ill, the National Alliance for Research on Schizophrenia and Depression, the National Depression and Manic-Depression Association, and the consumer self-help movement, patients and family members will become more effective advocates for needed services and partners in treatment planning and intervention.

Financial Integration of Mental Services New initiatives will flow from the various states and from demonstration projects sponsored by the federal government to improve the cost-effectiveness of mental health services. With pressures to reform the nation's health delivery systems and the advocacy of the National Alliance for the Mentally Ill, efficient and efficacious psychiatric services will be reimbursed at levels commensurate with other medical and surgical services. Incentives will be offered to encourage community-based continuity of care through such mechanisms as capitation, health maintenance organizations, regional consortia of service providers, performance contracts, clinical information systems, and patient registers.

SUGGESTED CROSS-REFERENCES

Public psychiatry is the focus of Section 52.1, and the role of the psychiatric hospital in the treatment of mental illness is the subject of Section 52.3. The individual psychotherapy of schizophrenia is discussed in Section 12.10, and the psychosocial treatment of schizophrenia is discussed in Section 12.9.

CHAPTER 53. PSYCHIATRIC EDUCATION

53.1 GRADUATE PSYCHIATRIC EDUCATION

STEPHEN C. SCHEIBER, M.D.

The goal of the American Board of Psychiatry and Neurology (ABPN) is to enhance the quality of psychiatric and neurological care through the voluntary certification process and thereby serve the public interest. To accomplish this goal, the ABPN works closely with the Residency Review Committees for both Psychiatry and Neurology, the two bodies that accredit programs for general residencies and subspecialties. The ABPN also works closely with the chairmen of departments of psychiatry and neurology as well as residency and postresidency training directors of both disciplines. By issuing time-limited certificates rather than lifetime certificates, the ABPN is forging closer relationships with the appropriate specialty and subspecialty societies to encourage these organizations to develop continuing education programs for their constituents. The advances in the biological and social sciences, the advent of new technologies, and the dramatic economic changes in the health care delivery system, particularly as they affect the patient care, contribute to the complexities of maintaining standards of excellence and confidence in the practice of medicine. The history of the specialty boards parallels the expansion of new knowledge and technology.

HISTORY

The need to establish standards of competence in the field of psychiatry was first publicized by Adolf Meyer during his presidential address at the 1928 annual meeting of the American Psychiatric Association (APA). He urged establishing a system of standardization of education similar to the British system. The APA, through its Committee on Medical Services, took a leadership role in 1929 by urging that the field establish formal requirements for the practice of psychiatry. The committee supported the initiation of a plan to sanction competent psychiatrists. Edward Strecker presented the committee report at the 1929 APA annual meeting. The Committee on Graduate Education was formed and given the responsibility of investigating such a plan. Meyer chaired the committee, and Edward Strecker and George Kirby were appointed as members. Despite numerous reports and a name change to the Committee on Psychiatry and Graduate Education, no action was taken.

In 1931, the American Medical Association (AMA), through its Section on Nervous and Mental Diseases, also called attention to the need for a certification process for psychiatrists and suggested involving the National Board of Medical Examiners in establishing such a process.

At the 1933 annual meeting of the APA, the National Committee on Mental Hygiene held a national conference at which the 28 participants urged the formation of an examining board of the APA. The Council of the APA adopted this suggestion and appointed a board of examiners. The appointees were Meyer, William White, C. Macfie Campbell, and Franklin Ebaugh. They were charged with preparing a plan for certification of psychiatrists.

In 1933, the AMA also adopted a plan for the certification of neuropsychiatrists. The AMA appointed Walter Freeman as chairman and Lloyd Ziegler, Edwin Zabriskie, J. Allen Jackson, and George W. Hall as members of its committee.

To avoid duplication of effort, a third group, the American Neurological Association (ANA), was invited to join the AMA and the APA to participate forming an examining body. The ANA Committee consisted of J. Ramsey Hunt, I. S. Wechsler, and H. A. Riley.

At a 1933 meeting the following was established: (1) each of the two specialties would choose four members, and the AMA would choose two from each specialty; (2) each discipline would establish separate qualifications; (3) a separate examination would be administered for each discipline; and (4) to achieve certification in both disciplines, a candidate would need to pass both examinations.

In 1934, the following training requirements for psychiatry were established: (1) the applicant needed to graduate from an approved medical school and possess a license to practice medicine; (2) basic training in psychiatry would include 3 years of study of psychiatry after the internship, with at least 18 months in a clinical setting in an approved hospital, clinic, or laboratory; and (3) 2 years of practice in a hospital or 1 year largely limited to psychiatry would be required.

In October, 1934, the first organizational meeting of the board was held with Meyer as chairman. He, along with Clarence O. Cheney, Campbell, and Ebaugh were APA appointees; Louis Casamajor, Lewis J. Pollock, H. Douglas Singer, and Zabriskie were ANA appointees; and Hall, Jackson, Freeman, and Ziegler were AMA appointees. They became the first directors of the board. The board was incorporated under a Delaware charter and bylaws were adopted. Singer was elected president, Campbell was elected vice president, and Freeman was elected secretary-treasurer. Standing committees were established, and directors were assigned to these committees.

At the December, 1934 meeting, issues of fees, classes of applicants, a “grandfather clause,” and the name of the Board were decided. The name engendered a great deal of controversy over whether neurology or psychiatry should appear first. Psychiatry, with a larger constituency, prevailed over the alphabet.

The first certifying meeting was held in February 1935, and on June 7, 1935, the board issued its first certificates: 22 in psychiatry and neurology and 12 solely in psychiatry. The first 11 went to the founding directors though Pollock refused to apply for or accept a diploma.

In 1974, the number of directors increased from 12 to 16 with the addition of two representatives from each discipline. Sixteen directors currently serve the board (Table 53.1-1). The American Academy of Neurology (AAN) became the fourth sponsoring society. In 1981, the board voted to no longer recognize the AMA as a sponsoring society for neurology directors. Currently the APA provides nominations for five psychiatry directors, the AMA for the remaining three. The ANA and the AAN each nominate four neurology directors. The directors of the board review the nominees of the sponsoring societies and conduct their own election of new directors. The usual period of service is a 4-year term, and a director cannot serve more than two terms. The autonomous functioning of the Board was stated by Henry W. Brosin in 1962 when he wrote:

Darryl C. De Vivo, M.D., President
Sheldon I. Miller, M.D., Vice President
John E. Schowalter, M.D., Secretary
Rosalie A. Burns, M.D., Treasurer
José Biller, M.D., Member-At-Large
Harold P. Adams, Jr., M.D.
Glenn C. Davis, M.D.
Michael H. Ebert, M.D.
Larry R. Faulkner, M.D.
H. Royden Jones, M.D.
Edgar J. Kenton III, M.D.
Alan K. Percy, M.D.
Pedro Ruiz, M.D.
James H. Scully, Jr., M.D.
Nicholas A. Vick, M.D.
Elizabeth B. Weller, M.D.

Table 53.1-1 ABPN Directors—1999

Although the ABPN is composed of representatives from three (now four) constituent societies to whom they report and are responsible, it is a working principle that the Directors vote solely in the best interest of the Board. In the final analysis, they are responsible only to themselves.

American Board of Medical Specialties The ABPN is one of 24 specialty boards. The other boards are Allergy and Immunology, Anesthesiology, Colon and Rectal Surgery, Dermatology, Emergency Medicine, Family Practice, Internal Medicine, Medical Genetics, Neurological Surgery, Nuclear Medicine, Obstetrics and Gynecology, Ophthalmology, Orthopaedic Surgery, Otolaryngology, Pathology, Pediatrics, Physical Medicine and Rehabilitation, Plastic Surgery, Preventive Medicine, Radiology, Surgery, Thoracic Surgery, and Urology. In 1970, the American Board of Medical Specialties (ABMS) was founded as the umbrella organization for all of the boards. It is responsible for reviewing and approving applications for any new boards and for any new certificates of specialization and of special qualifications and added qualifications for subspecialty certification. It also maintains standards of organization and operation for all specialty boards. The executive vice president of the ABMS is J. Lee Dockery, who replaced Donald G. Langsley, in 1991. Dockery has announced his retirement effective December 1997. Langsley, a psychiatrist who had served as a director of the ABPN and as president of the APA, was the executive officer of the ABMS for 10 years. M. J. Martin, a former vice president and director of the ABPN, was elected president-elect of the ABMS in 1992, assumed the presidency in 1994, and completed his term in 1996. Barbara Schneidman, a psychiatrist from Seattle, Washington, was appointed first deputy executive vice president of the ABMS in 1993. She had previously served as president of the Federation of State Licensing Bodies. Figure 53.1-1 shows the 1998 directors.

FIGURE 53.1-1 1998 Directors for the ABPN. Back row from left: Glenn C. Davis, M.D., Pedro Ruiz, M.D., Nicholas A. Vick, M.D., Michael H. Ebert, M.D., Alan K. Percy, M.D., Darryl C. De Vivo, M.D., Sheldon I. Miller, M.D., Robert Harmon, M.D., John E. Schowalter, M.D. Front row from left: Jos Biller, M.D., Edgar J. Kenton III, M.D., Peter M. Silberfarb, M.D., Elizabeth B. Weller, M.D., Stephen C. Scheiber, M.D., Rosalie A. Burns, M.D., William T. McKinney, M.D., Burton A. Sandok, M.D.

The Advisory Board for Medical Specialties, founded in 1933, was the predecessor of the ABMS. Ophthalmology, Otolaryngology, Obstetrics and Gynecology, and Dermatology and Syphilology were the four existing specialty boards in 1933. Along with these four boards, the American Hospital Association (AHA), the Association of American Medical Colleges (AAMC), the Federation of State Medical Boards, and the National Board of Medical Examiners were the founding sponsoring organizations of the advisory board. ABMS is a nonprofit corporation that is supported by dues from each of the 24 boards. Dues and the number of voting representatives allotted to each board are determined by the number of general certificates issued by a board. Through 1992 biannually the ABMS published the *ABMS Compendium of Certified Medical Specialists,* the only official biographical directory authorized by all 24 medical specialty boards. In 1993 the *ABMS Compendium* merged with the *Marquis Who's Who Directory in Medical Specialties* and became the *Official ABMS Directory of Board Certified Medical Specialists*, now published by Marquis Who's Who. The directory is now available on a CD Rom. Information regarding certification in a specialty, subspecialty certification, or recertification is provided by the certifying boards. Other information, such as medical education and specialty training, is provided by the diplomate. Information about each of the 24 boards is included in the directory. The ABMS also helps individual boards by providing assistance in conducting research projects.

The ABMS assisted with a project of getting the Yellow Pages telephone directories to list the diplomates of the 24 ABMS Boards as board-certified. Diplomates wishing to be listed pay a fee for the listing. The ABMS also initiated a telephone answering service to answer inquiries from callers about whether a physician is certified by one of the ABMS Boards. In addition to the ABMS, in 1972 the Council of Medical Specialties (CMSS), the AAMC, the AMA and the AHA established the Liaison Committee on Graduate Medical Education (LCGME) and the Coordinating Council on Medical Education. The LCGME was given ultimate responsibility for approving all graduate medical education programs. The ABMS was also one of the founders of the Liaison Committee on Continuing Medical Education (LCCME), which accredits programs in continuing medical education. This subsequently became the Accreditation Council on Continuing Medical Education. In 1997 Peter Tanguay chaired the committee. Tanguay served as vice president of ABPN in 1997 in his eighth and final year as a psychiatry director.

American Medical Association The AMA historically provided leadership in accrediting American medical education, beginning with voluntary accreditation of medical schools and internships by 1914. To prepare for accreditation of residency programs, in 1920 the AMA's Council on Medical Education formed committees to establish procedures.

Residency review committees for each of the specialties are responsible for accreditation of residency programs. Until 1975, each committee had final authority for accreditation. Beginning in 1975, each of the review committees reported to the LCGME which, in turn, had final authority. In addition to the five founding organizations noted above, the LCGME has representatives from the public and from the federal government. In 1981, the Accreditation Council for Graduate Medical Education (ACGME) replaced the LCGME as the final authority.

Residency Review Committees for Psychiatry and Neurology Until 1983, the Residency Review Committee (RRC) for Psychiatry and Neurology was a single committee for both disciplines. Since then, each of the disciplines has had its own committee. The Psychiatry Residency Review Committee has 15 voting members: five from the ABPN, five representing the APA, and five representing the AMA, recommended by the Council on Medical Education. The executive vice president of the ABPN and the deputy medical director for education of the APA serve in an ex officio capacity. The APA also recommends one nonvoting resident member of the Psychiatry RRC. Each of the three sponsoring organizations selects three general psychiatrists and two child and adolescent psychiatrists to serve. Daniel Winstead chairs the RRC. Sheldon Miller, psychiatry director of the ABPN, chaired the Psychiatry RRC from January 1, 1997 to December 31, 1998. James Shore, president of the ABPN in 1994, was chairman of the Psychiatry RRC in 1992 and was also elected chairman of the Council of Chairmen of all the RRCs in 1992. He was also appointed chairman of the Council on Graduate Medical Education and Career Development of the APA from 1992 to 1997. James Sculley, Jr., a board director, now chairs this council.

The Neurology Residency Review Committee has six members: two from the ABPN, two from the AMA, and two from the American Academy of Neurology (AAN). The AAN was approved as a third parent of the Neurology RRC in 1992. The usual composition of the Neurology RRC is four adult neurologists and two child neurologists.

The Psychiatry RRC is responsible for reviewing training programs in general psychiatry, child and adolescent psychiatry, geriatric psychiatry, addiction psychiatry, and forensic psychiatry. The Neurology RRC reviews programs for neurology, child neurology, and clinical neurophysiology. Procedures were established for separate review of child neurology programs, and actions were taken on each child neurology application since October 1988. Each program must meet the requirements listed in the annual *Directory of Graduate Medical Education Programs*. The Psychiatry RRC established requirements for programs in geriatric psychiatry, which were approved by the ACGME in 1994 after being rejected in the spring of 1993. These postresidency programs must last at least 1 year and must begin at the fifth postgraduate (PGY-5) year of training or higher. The Psychiatry RRC was advised in the fall of 1991 of the need to establish training requirements for addiction psychiatry. These were approved by the ACGME in 1995. The Neurology RRC prepared requirements for clinical neurophysiology that were initially turned down by the ACGME in 1993 and were revised and approved in 1994. In 1996 the requirements submitted by the Psychiatry RRC for forensic psychiatry were approved.

To be listed in the directory, a program must be reviewed and approved by the RRCs. These committees are responsible for establishing the necessary requirements for programs and submitting them for ultimate approval by the ACGME.

PROCEDURES OF THE ABPN

Executive Vice President The ABPN has had five executive directors since its inception in 1934. The name of the office has been changed from secretary of the board, to executive secretary-treasurer, to executive director, to executive secretary, to its current designation, executive vice president. The first four—Freeman (1934–1946), Francis Braceland (1947–1951), David A. Boyd, Jr. (1951–1971), and Lester H. Rudy (1972–1985)—had served as board directors before serving in their part-time administrative capacity. In 1985, the board selected Stephen C. Scheiber, director of psychiatric residency training and professor of psychiatry at the University of Arizona, to serve as its first full-time executive secretary. He assumed his duties on January 1, 1986. His title was changed in 1989 to executive vice president.

The executive vice president is responsible for the supervision and administration of the affairs of the board. He must establish an effective staff organization to carry out the responsibilities of the board. He coordinates all approved projects, programs, and major activities of the office staff. He ensures that appropriate administrative and adequate staff support exists for all activities of the board and its components, including scheduling business, policy, and committee meetings and preparing and distributing agendas and all background materials before such meetings. He supervises and keeps board records and keeps and distributes minutes of the board meetings and other official meetings under the direction of the secretary. He is responsible for responding to inquiries regarding credentials of individual candidates, for implementing examination procedures by setting up and arranging for sites for the written and oral examinations, for informing candidates of their performance in accordance with the policies of the board, for issuing certificates to successful candidates, and for submitting names of certified neurologists and psychiatrists to the appropriate bodies for publication. He maintains an administrative relationship with the American Board of Medical Specialties, the RRCs, and other relevant organizations. He explicates the policies of the board, articulates the board's position on a variety of issues, and oversees financial and legal matters related to the board.

Credentials Over the years the board has reviewed and revised its training requirements for candidates seeking to sit for its certification examinations. Factors considered about credentials include training program requirements, basic science instruction, knowledge of the specialty, clinical education and training, and cultural differences. In 1976 the board no longer required that candidates complete 2 years of experience in their specialty before admission to the examination. Since 1993 candidates can submit applications during the last 6 months of their final year of training if all training requirements were fulfilled no later than June 30th of the year in which the application was submitted.

To sit for the examination the candidate must submit an application and application fee by February 1st for the fall examinations (an additional late fee is required for those who submit applications after February 1st but before March 1st) along with documentation of satisfactory completion of the board's specialized training requirements and a copy of a current, unlimited license to practice medicine in a state, commonwealth, or territory of the United States or a province of Canada. Candidates who cannot submit a copy of the license before sitting for the written examination must submit one before sitting for the oral examination. Otherwise they are not admitted to the oral examination. Before fall 1994 all part I written examinations were held in the spring; they were changed to the fall in response to a request from the field to move the examination closer to the completion of residency training.

An applicant who seeks admission to examination for certification in psychiatry must have satisfactorily completed an approved PGY-1 and 3 full years of postgraduate, specialized training in a program accredited by the ACGME or The Royal College of Canada. This training must be in the specialty in which the applicant seeks certification. No residency training credit can be given for time spent in a residency program in another specialty. Training programs approved by the RRC and accredited by the ACGME are listed in the *Directory of Graduate Medical Education Programs,* published by the AMA.

Training may be completed on a part-time basis, provided that it is no less than half-time, and credit is not given for less than 1-year blocks of training except when approved by the ABPN Credentials Committee for Psychiatry. To ensure continuity of training, the board requires that 2 of the 3 years of residency following the PGY-1 be spent in a single program.

The board has given much thought to the minimum requirements for PGY-1. Currently it must include a minimum of 4 months of primary care experience and 2 months of neurology. The primary care can be in internal medicine, family practice, pediatrics, or combinations of two or three of these specialties. Emergency medicine rotations must emphasize medical rather than surgical experiences and cannot exceed 1 month of the required primary care training.

Four-Year Training Programs A 4-year program in psychiatry is acceptable if no fewer than 4 months during the first year were spent in an approved program providing supervised, direct responsibility for the general medical care of children, adults, or both. The candidate who spends 12 or more months in such an approved program may do so at any time in the 4 years. Since July 1, 1988, all osteopathic physicians entering a PGY-2 in psychiatry must have successfully completed an ACGME-approved first postgraduate year as described above.

The RRC for Psychiatry, in its special requirements for residency training, has tried to both maintain flexibility and originality in programs and yet set minimum standards. Thus the committee requires that training programs give residents responsibility for the diagnosis and treatment of an appropriate number and variety of psychiatric inpatients for not less than 9 months but no more than 18 months (or its full-time equivalent if done on a part-time basis) in 4 years of training. The 4-year programs must also provide for at least 1 year (or its full-time equivalent if done on a part-time basis) in an organized, well-supervised outpatient program that includes experience with (1) a wide variety of disorders and patient and treatment modalities and (2) brief and long-term care of patients, using both psychodynamic and biological approaches to outpatient treatment. Special requirements include a minimum of 2 months in child and adolescent psychiatry, 2 months in consultation psychiatry, and 2 months in the diagnosis and treatment of neurological patients as well as experience in emergency services, geriatric psychiatry, addiction psychiatry, forensic psychiatry, and others.

Combined Training Programs With Psychiatry Applicants seeking certification in both psychiatry and neurology who began postgraduate training after January 1, 1987, must complete a PGY-1 year that meets the requirements for entry into a neurology program. Additionally, applicants must complete (1) 6 full years of postgraduate training in approved programs in the United States, including 3 full years in psychiatry and 3 full years in neurology, or (2) at the discretion and approval of both training directors and in accordance with RRC requirements, the applicant may complete 5 full years of postgraduate training in approved programs in the United States, including 2 full years in psychiatry, 2 full years in neurology, and a fifth full year of training designed to be eligible for simultaneous credit in psychiatry and neurology. The ABPN has established guidelines for programs for combined training in psychiatry and neurology. Proposals are reviewed by the Credentials Committee for Psychiatry and the Credentials Committee for Neurology. Programs that are approved by both committees are submitted for publication in the AMA's *Directory of Graduate Medical Education*. To date 8 have been approved.

The ABPN and the American Board of Internal Medicine have agreed to a combined training program for Internal Medicine and Psychiatry in 5 years instead of the current 6 years as well as a combined training program for Internal Medicine and Neurology in 5 years instead of the current 6 years. The guidelines for these programs were distributed to interested program directors in the respective disciplines who then must propose a combined program to each of the two boards. Once approved by the two boards, the programs are listed in the *Directory of Graduate Medical Education Programs* of the AMA as combined programs. Twenty-eight such programs have been approved.

The ABPN and the American Board of Family Practice have agreed to a combined training program for family practice and psychiatry in 5 years instead of the current 6 years. Guidelines for these programs were distributed to interested program directors in the respective disciplines who must then propose a combined training program to each of the two boards. Once approved by the two boards, the programs are listed in the *Directory of Graduate Medical Education* of the AMA as combined programs. Twelve such programs have been approved.

Similar combined training programs are available for Neurology and Physical Medicine and Rehabilitation in 6 years instead of the current 7 years, and in Neurology, Radiology, and Neuroradiology in 7 years instead of the current 8.

Internship One of the board's most controversial decisions in the last 30 years was the elimination of the internship requirement in 1970. This move was a product of a 1967 recommendation by the Millis Commission (a citizen's commission on graduate medical education of the AMA) to abolish the internship. The policy of eliminating the internship in psychiatry was adopted in October 1969 for implementation in July 1970. Part of the furor that followed resulted from the board's failure to consult adequately with constituent organizations and educational organizations and to allow sufficient time for the field to debate the decision before its implementation.

In 1974 the board reversed its decision and enacted a new policy to become effective in July 1976, namely that the internship year would be reinstated. Again, the

board faced opposition to its decision. This time the APA requested delaying implementation until 1977 to give programs sufficient time to arrange for the necessary medical experiences and to arrange for appropriate financing of the PGY-1 year. The board consulted sponsoring societies and other relevant professional organizations and delayed reinstatement of the internship until 1977, although programs were advised to implement this reinstatement of the internship as soon as possible.

The ABPN works closely with a number of constituent organizations to prevent a recurrence of the furor that surrounded the internship decision. The ABPN works closely with the APA through its Council on Medical Education and Career Development and through regular meetings of the leadership of the two organizations. The executive vice president served as a consultant through 1993 and in 1994 was appointed a corresponding member of the Graduate Medical Education Committee, and the directors of the board serve on many APA councils and committees. In addition, the board worked closely with the APA Task Force on Recertification, the Working Group on Recertification of the APA, and the Commission on Subspecialization of the APA.

The board meets regularly with the American Association of Directors of Psychiatric Residency Training at its annual meetings, presents updated information to the residency training directors, and participates in workshops at these annual meetings. Similarly, the Residency Review Committee in Psychiatry has representation at this meeting and conducts RRC workshops.

The American College of Psychiatrists, which has primary administrative responsibility for the PRITE (Psychiatric Residency In-Training Examination), sought and obtained board agreement on a project correlating the results of the PRITE with subsequent performance on board examinations. The board cooperated on condition that the confidentiality of information on any individual sitting for the board examinations was not violated. The results of the study revealed a good correlation.

The board also participates in the training directors meeting of the American Academy of Child and Adolescent Psychiatry and has participated in meetings of national organizations of its subspecialties such as the American Association for Geriatric Psychiatry, the American Academy of Addiction Psychiatry, and the American Academy of Psychiatry and the Law.

The ABPN also works closely with the residency training directors. Approximately every 5 years, the ABPN circulates the outline of the part I examination to residency training directors for feedback to help update this important outline. The board sponsored a series of meetings of a task force for written examinations in psychiatry with representation from the APA, in particular relating to the Psychiatric Knowledge and Self-Assessment Examination, the PRITE examination of the American College of Psychiatrists, and the National Board of Medical Examiners for its part I, II, and III examinations for medical students. Representatives from the various committees of the different subspecialties in psychiatry and the neurology written committee also participated. One of the major accomplishments of the task force was the establishment of a common outline regarding topics in psychiatry, which was particularly useful for the PRITE and the part I examination. One of the aims of the task force was to determine whether a common outline regarding topics in psychiatry could be used by all of the related organizations without breaching confidentiality.

Examination Policies and Procedures Surpassing its humble beginnings in June 1935, when only 31 candidates sat for the first examination at the Philadelphia General Hospital, the board in 1998 examined 2330 psychiatrists, 860 neurologists, and 135 child neurologists in November for its part I written examination, and 1830 psychiatrists, 556 neurologists, and 83 child neurologists at three part II oral examinations (Table 53.1-2 and Table 53.1-3). As of January 1, 1999, the board had issued 35,764 certificates in psychiatry, 1,159 in neuropsychiatry, 8,928 in neurology, and 1,151 in child neurology. The board added a fourth examination to the part II examination cycle in 1992, 1993, 1994, and 1995 to accommodate the increasing number of candidates.

Table 53.1-3 Pass Rates—Part I Psychiatry (1987–1998)

Some 67 examination centers in the United States, Puerto Rico, Canada, and Germany were used to administer the 1998 written examinations, including the part I examination and the added qualification examinations. Despite the large numbers, every effort is made to schedule candidates for the part I examination at their chosen location.

In spite of differences between neurology and psychiatry, the board has maintained the strong alliance of the two specialties over the years in the face of periodic and cyclical reviews by the directors regarding splitting the board into two separate boards. The last such serious discussion occurred in 1982. In the first 10 years of the board's history, each candidate was given the same oral examination and performance was evaluated on the basis of the certificate the candidate was seeking. In 1946, the board introduced separate examinations for each of the specialties, and this remains the current policy.

Written Examinations With the increasing numbers of applicants in the 1960s, the board voted to administer a written examination to screen candidates for the oral examination. In 1964 the board contracted with the National Board of Medical Examiners to develop the written examination. Over a 5-year period the written examination was used to test basic knowledge in the two disciplines. The board conducted a study to test whether the written examination predicted how well candidates would perform on the oral examination. Results of the 1965 and 1966 written examinations, convinced the board in 1967 of the validity of the written examination as a screening test. The board also determined that simultaneous administration of the written and oral examinations was too time consuming and costly. Hence, in May 1967, a separate written examination was introduced as part I of a two-step process. The successful completion of part I, which was administered once a year, then led to the scheduling of candidates for the oral part II examination. Unsuccessful candidates for the part I examination can reapply for the written examination annually, with no limit on the number of times a candidate can take the examination. The Part I Written Examination Committee reviews and refines the examination yearly.

In April 1972, a new 4-hour written examination was introduced. All of basic psychiatry and basic neurology was included, which eliminated basic material from the

part II oral examination for the minor specialty. In 1975, the content for psychiatrists and neurologists was separated. For the 1976 examination, the board decided to honor a passing grade on part I for 7 years from the date of passing, provided it was dated after April 1, 1969. Those who passed part I could apply or reapply for the part II examination anytime during the 7-year period. Since March 1987, a passing grade on the part I examination dated March 1987 or thereafter has been valid for 6 years or three attempts to complete the part II examination successfully, whichever comes first. Those who are unsuccessful after three attempts or who fail to pass part II within the 6 years are asked to retake the part I examination.

In 1981, clinical and basic neurology for psychiatry candidates was incorporated into the part I written examination, and neurology was eliminated from the part II oral examination for psychiatry candidates who took the written examination in 1981 or later. A comparable change for neurologists occurred in 1982.

When candidates apply for the part I examination, they receive comprehensive information about the examination, including its length, how the time is divided between the two disciplines, the approximate number of questions devoted to each discipline, and the distribution percentage of specific subject matter on which the candidate will be tested. The Part I Written Examination Psychiatry Committee solicits input from psychiatric educators about the content and uses this input to review the examination content. The board distributes the content in the subspecialty examinations to the subspecialty psychiatric educators to obtain their input as well. Additionally, candidates receive general information about the format of the examination questions and how to maximize their performance during the examination.

Oral Examinations The part II oral examination has sparked more criticism than the written examination. The ABPN is the only one of the 24 boards that continues to use patients as part of the oral examination. All patients used to examine psychiatrists have psychiatric disorders and those for neurologists have neurological disorders. Because of difficulties in recruiting patients and the rising costs of administering the oral examination, the board introduced the audiovisual section of the part II examination in 1976. This format yielded a more standardized examination. Studies evaluating the relation between the patient and audiovisual sections after a 1-year trial period showed a high concordance rate in both specialties: 84 percent for psychiatry and 86 percent for neurology candidates.

Acceptance of the audiovisual section as an alternative to a patient interview led to the current examination procedure for psychiatrists. After successful completion of the part I written examination (which includes basic neurology and psychiatry and clinical neurology for psychiatry candidates), the psychiatry candidates are invited to sit for the two sections of the oral examination: one with a patient and one audiovisual. The audiovisual tape shows a psychiatrist interviewing a patient with a psychiatric disorder; no simulated patients are used. This taped interview is the basis for questions asked by the examiners. The neurologists have since replaced the audiovisual section with a patient vignette section.

Examiners The board devotes considerable time and energy to the selection, orientation, and training of part II examiners. The eight directors select the members of their own examining team from a recommended list of board-certified psychiatrists, including some from the local region where the examination is being administered. Examiners represent a wide spectrum of backgrounds, including academic, institutional, and private practice psychiatrists.

Each examiner receives information regarding the examination and its procedures before the examination. This material includes guidelines on how to evaluate candidates. In 1979, a special 5-hour orientation session was instituted for new examiners. In 1984, the board made this orientation session mandatory for all new examiners. The following year, the board extended this policy and made attendance at the orientation session mandatory for all examiners who had not examined in the previous 4 years. In 1994, this was further modified to include all those who had not examined in the last 2 years. The orientation session focuses on the examination process from the perspective of an examiner. Appropriate and inappropriate examination techniques are demonstrated. New examiners then meet in small groups with senior examiners to role-play examining, and the examiners receive critiques on their examining techniques. The mandatory orientation sessions for new examiners eliminated a plenary session for all examiners with the board of directors. All examiners, old and new, attend a mandated orientation session with a team of examiners under the direction of a psychiatry director who will serve as their team leader during the 2 days of examining.

The board has continued its efforts to standardize the examination. Examination teams now include four to five senior examiners and 20 to 25 primary examiners. Approximately one-half of a director's team is chosen from a national pool, and they examine at all sites during an examination year. The additional examiners are invited from the local region. For each examination, two examiners are scheduled with a single candidate throughout the examination and a senior examiner supervises the experiences for two pairs of primary examiners.

Grading Candidate grading is based on a composite of their performance in both sections of the part II psychiatry examination. If candidates perform marginally in 1 hour, they can redeem themselves in a second hour with an above-average or exceptional performance. Numerical grading was replaced in 1978 by grades of High Pass, Pass, Condition, and Fail. In 1981 the board further refined the grading to Pass, Condition, and Fail. The neurologists have eliminated the Condition grade. All candidate grades for individual sections are then reviewed by the psychiatry directors in a grading session, and they assign a final grade. The passing rates have remained fairly stable over the past decade (Table 53.1-4).

Year	Examined (N)	Passed (N)	Passed (%)
1987	1403	779	56

1998	1830	1058	58

Table 53.1-4 Pass Rates—Part II Psychiatry (1987–1998)

Dissemination of Board Information The board continuously reviews, updates, and changes its policies and procedures, and it communicates changes to its constituency in a number of ways. One method is by an annual report that is circulated to its sponsoring bodies. The report sent to the APA is in turn sent to the *American Journal of Psychiatry*, where it appears under *Official Actions* of the APA with the subtitle “Annual Report of the ABPN, Inc.” The board also participates in the APA Task Force on Communication between the APA and the ABPN, which was established in 1976. The composition of the task force has varied. Originally it consisted of ABPN psychiatry directors, representatives from the APA Council on Medical Education and Career Development, the APA Committee on Graduate Education, and the APA Assembly of District Branches. In 1981, the task force expanded to include representatives from the American Association of Directors of Psychiatric Residency Training (AADPRT) and the American Association of Chairmen of Departments of Psychiatry (AACDP). Subsequently, the size of the Task Force was reduced considerably. The ABPN representative, as recently as 1988, was a former director and president of the board. Beginning in 1987 a full-time psychiatry director was appointed as a member of the task force, and the executive vice president serves in an exofficio capacity. The task force allows the APA to transmit recommendations to the ABPN and the board to inform the APA of current activities and policies. In addition, the leadership of the APA meets regularly with the psychiatry leadership of the ABPN. The executive vice president also meets with the board of trustees and the Assembly of the APA on invitation.

The ABPN has also offered a workshop, “ABPN Update,” at the annual meeting of the APA, which is chaired by the executive vice president with the psychiatry directors as the participants. The most recent workshop was “ABPN Update: Training Requirements to Sit for the ABPN Examination and Certification Process.” The executive vice president and psychiatry board directors have also participated in plenary sessions and other workshops of the APA and the AADPRT. These meetings help minimize misunderstandings and publicize current issues under review and policy revisions by the board.

Child and Adolescent Psychiatry In 1959 the ABPN with the concurrence of the ABMS instituted a certification process for its first subspecialty, Child Psychiatry. The mechanics of the certification process and the establishment of policy is the responsibility of the Committee on Certification in Child Psychiatry, changed in 1987 to the Committee on Certification in Child and Adolescent Psychiatry.

This committee is under the supervision of the board and follows its general policies and guidelines. The committee consists of six board-certified child and adolescent psychiatrists, one board director, and one board-certified pediatrician. Each member serves a 6-year, nonrenewable term. Nominations for the child and

adolescent psychiatrists are solicited from the American Academy of Child and Adolescent Psychiatry (AACAP) and the APA, those for the pediatrician are sought from the American Board of Pediatrics, and the board director is appointed by the board president. The committee elects its members and submits its selections to the board for final approval. The committee is responsible for administering its annual examination. In 1993, 359 candidates sat for the examination. Because of the marked increase in the number of applicants for 1993, a second examination was held in the spring of 1994. Similarly a second examination was conducted in the spring of 1996. As of fall 1998, 4589 candidates have been certified in Child and Adolescent Psychiatry (Table 53.1-5). Since 1987 the examination is conducted on weekends. Approximately 116 ACGME-accredited child and adolescent psychiatry training programs exist in the United States. The passing rate on the child and adolescent psychiatry examination has been fairly constant for the last decade (Table 53.1-6).

Table 53.1-6 Pass Rates—Child and Adolescent Psychiatry (1987–1998)

Applications for the examination in child and adolescent psychiatry must be filed by May 1st preceeding the date of examination for which the candidate is applying. The certifying examination in child and adolescent psychiatry has undergone periodic review and revision that have resulted in major changes. The committee contracted with the Center for Educational Development at the University of Illinois College of Medicine to help conduct studies of the examination process. A study in 1976 reviewed the six sections of the oral examination. As a result, the two basic science sections—History and Literature; and Growth and Development—were eliminated from the oral examination and incorporated into a 2-hour written examination.

In 1973 a 3-year study funded by the Ittleson Foundation, the Grant Foundation, and the Maurice Falk Medical Fund was initiated to “assess systematically and broadly the basic competencies required by a child psychiatrist.” The results of this study were published in 1976 in the monograph “Roles and Functions of Child Psychiatrists.”

This study resulted in several major changes in the examination. Candidates who fail only one section of the examination need only repeat the failed section, not the entire examination. Numerical grades were replaced by grades of High Pass, Pass, Marginal Fail, and Fail. Written clinical vignettes were used to assess consultation skills. Candidates were given a one-paragraph description of a situation in which a child and adolescent psychiatrist is called upon to serve as a consultant in a school, hospital, or courtroom setting. They were then asked to describe orally how they would conduct the consultation. The monograph describes criteria for evaluating this section. In 1981, this section (previously the Interprofessional and Community Relations section) was renamed the Child Psychiatry Consultation section. Beginning in 1999 the consultation section was eliminated and questions regarding consultation will be included in the other three parts of the examination.

Beginning with the February 1978 examination, a passing grade on the written examination was valid for a maximum of 7 years. In 1980 the committee voted that a passing grade on all sections of the oral examination would be valid for a maximum of 4 years. As of 1988, passage of the written examination is valid for 5 years and passage of all portions of the oral examination is valid for 5 ears. In 1978, the committee initiated a project to assess the validity of the child psychiatry examination. With the permission of candidates, training directors were asked to respond to a questionnaire to predict how graduates of their program would perform on the certification examination. They were also asked to grade the performance of candidates during their 2 years of training. The data from this study suggest that training directors can accurately predict the performance of graduates of their programs on the certifying examination.

In 1986 the committee approved combining the format of the Preschool and Grade School sections of the examination. Both clinical vignette and audiovisual tapes are used for the oral examination. The committee continues to evaluate its examination, with recent special attention paid to the sections using videotaped interviews.

Combined Training In 1984 the committee established the Articles of Agreement for the Pilot Project on Training in Pediatrics, Psychiatry and Child Psychiatry. The proposal was approved by the American Board of Pediatrics, the APA, the AACAP, the AADPRT, the AACDP, the Society of Professors of Child and Adolescent Psychiatry (SPCAP), and the Psychiatry RRC. All members of the Pediatrics-Psychiatry Joint Training Committee (PPJTC) were selected by the organizations involved in the project, the ABPN, the Committee on Certification in Child and Adolescent Psychiatry, the American Board of Pediatrics, and the National Institute of Mental Health (NIMH). The executive vice president of the ABPN and the deputy medical director for education of the APA were ex officio members. The NIMH and the University of Illinois funded the first meeting of the PPJTC, in November 1984. Members of the PPJTC made site visits to eight facilities for evaluation of their proposed programs. Six training programs were selected: Albert Einstein College of Medicine, Brown University, Mt. Sinai College of Medicine in New York, Tufts/New England Medical Center, the University of Kentucky, and the University of Utah. The first residents accepted for this triple-board project began their PGY-1 in July 1986. The programs last 5 years, and graduates can sit for the certifying examinations in pediatrics, general psychiatry, and child and adolescent psychiatry upon successful completion of this combined program. The first class graduated in June 1991. Several have chosen academic careers, and there is a trend toward working in consultation-liaison child and adolescent psychiatry.

The ABPN, in conjunction with the American Board of Pediatrics and the NIMH, funded an evaluation of the triple-board project in 1985. The project was studied and evaluated over a 10-year period. Both boards agreed to give permanent status to the triple-board program and have distributed guidelines to programs wishing to submit proposals to both boards. Currently 10 approved programs are listed in the AMA *Directory of Graduate Medical Education*.

Recertification The board has reviewed the issue of recertification. In 1975, the following principles were accepted; (1) the board is responsible for administering a recertification examination, (2) the board is not responsible for educational activities related to the preparation for recertification, and (3) the board is responsible for advising specialty organizations about specific educational deficiencies identified by examination results.

In 1976 the board established a Steering Committee on Recertification with representation from the board and its constituent organizations. Separate subcommittees were established for the two disciplines. Constituent psychiatry organizations included the APA, the Committee on Certification in Child and Adolescent Psychiatry, and the AACAP. Constituent neurology organizations included the American Neurological Association, the American Academy of Neurology, and the Child Neurology

Society. Representatives from the private sector also served on the committee. Recertification plans for psychiatry and for child psychiatry and neurology were submitted to the ABMS in 1979. The proposal included the following principles: (1) candidates must hold a valid certification from the ABPN and a current medical license; (2) recertification would be voluntary; (3) plans for psychiatry, child and adolescent psychiatry, and neurology would be similar but not identical; and (4) the process would not be a repetition of the original certification process.

The ABMS Committee on Certification, Subcertification and Recertification (COCERT) reviewed the proposal and suggested some modifications. The board continued to review recertification issues but did not resubmit a proposal until 1988. The board worked closely with the Task Force of the APA. In 1989, the ABPN established a new policy; beginning in October 1994, all certificates would be 10-year, time-limited certificates, and a recertification mechanism would be put in place no later than 2000. As a minimum, recertification will include a test of cognitive knowledge, and the board will also try to make its examination practice sensitive. In February 1994 the ABPN approved a commission on recertification consisting of three psychiatry directors, two APA appointees, and an AACAP appointee from the board's Child and Adolescent Psychiatry Committee. The commission reports to the Psychiatry Council of the ABPN. The commission endorsed using the APA Practice Guidelines as an educational resource for recertification. It also voted for a written, open-book, take-home examination, with psychiatrists given up to 2 months to submit their answers for scoring. The examination is expected to be given every 6 months.

In the meantime, all 24 boards have been approved for recertification for their specialties. In addition, several boards have begun issuing time-limited certificates that are only valid for a specific time period after passing a board examination. At that point, the diplomate must successfully complete a recertification examination to remain board certified. All new certificates issued by the ABPN are 10-year time limited. New certificates in Geriatric Psychiatry, Clinical Neurophysiology, Addiction Psychiatry, and Forensic Psychiatry are all time limited.

Subspecialty Certification The only subspecialty certificate examination offered by the board in psychiatry for three decades was the one for child and adolescent psychiatry. The board also issues a certificate in Neurology with Special Qualification in Child Neurology. Special requirements must be completed by candidates to qualify for the child neurology examination.

Over the last three decades, the board has at various times reviewed requests for subspecialty certification from other psychiatry groups, such as psychoanalysis, administrative psychiatry, and adolescent psychiatry. Similar requests in neurology have been forthcoming for subspecialty certification in electrophysiology and electrodiagnosis. These requests were either withdrawn or turned down by the board in the past.

In July 1986, the board hosted a conference on subspecialty certification. Six representative groups were invited to attend to initiate or renew a dialogue with the board about subspecialty certification: the American Board of Forensic Psychiatry, which administered its own certifying examination; the American Society for Adolescent Psychiatry; the American Association for Geriatric Psychiatry (AAGP); the American Academy of Psychiatrists in Alcoholism and Addiction (AAPAA); the APA Committee on Administrative Psychiatry, which administers its own certifying examination; and the American Psychoanalytic Association, which has its own certifying process.

Constituent organizations and the board continue to debate the wisdom of offering subspecialty certificates in psychiatry in addition to the child and adolescent psychiatry certificate as well as the recently approved geriatric psychiatry, clinical neurophysiology, addiction psychiatry, and forensic psychiatry certificates. These organizations include the APA, the AADPRT, the AACDP, and the Association for Academic Psychiatry, among others. The APA recommended that the board issue a certificate of added qualifications in geriatric psychiatry in 1987. The board appointed a task force on geriatric psychiatry consisting of representatives from the board, the APA, the American Association of Geriatric Psychiatry, the AADPRT, and an internist, to advise the directors about this proposal. The task force held its first meeting in April 1988, when the American Board of Internal Medicine and the American Board of Family Practice issued their first added qualifications examination in geriatric medicine. In 1988, the ABPN approved geriatric psychiatry as a subspecialty. Since the ABMS must approve any certificates for subspecialization by its member boards, the request for geriatric psychiatry was then submitted to the ABMS. In addition to general certificates, the ABMS had provisions for two types of subspecialty certificates: a certificate in special qualifications and recognition of added qualifications. In 1996 the ABMS voted to simplify the names of certificates and discontinued using the qualifying terms “added qualifications” and “special qualifications.” In the future the ABMS will approve certificates for subspecialization.

A certificate for added qualifications indicated that a candidate had completed at least 1 year of full-time formal training and satisfactorily completed an additional examination in that field administered by the ABMS member board. The training program cannot be freestanding but must be associated with an ACGME or equivalent Canadian-accredited residency. The training program must incorporate a specific and identifiable body of knowledge. The purpose, however, cannot be to train principally for additional technical skills. Also, a specialty board must give the ABMS assurance that it has evaluated the impact and effect of a modified certificate before receiving ABMS approval.

Intent to submit a proposal must be announced to all member boards at least 1 year before the meeting at which the formal proposal will be submitted for a vote. A two-thirds majority of voting members of the ABMS must approve any proposal before it can be effected. The proposal must be distributed 180 days before the vote. The certificate of special qualifications differed from added qualifications in requiring a minimum of 2 years of additional training.

The increased emphasis on subspecialty training and practice has led to the 24 boards issuing 76 special certificates beyond their general certificates as of September 1997. Pediatrics and Internal Medicine had the most (15 and 16, respectively). In March 1999 the ABMS approved a new subspecialty of pediatrics and child neurology: neurodevelopmental disabilities and a new pediatric subspecialty: developmental/behavioral pediatrics.

GERIATRIC PSYCHIATRY The ABMS approved the Geriatric Psychiatry Added Qualifications in September 1989. The first Committee on Certification for Added Qualifications in Geriatric Psychiatry was appointed in the fall of 1989. Recommendations for membership on the committee were submitted by the APA and the American Association for Geriatric Psychiatry (AAGP). The committee consisted of five psychiatrists and one neurologist, and has since increased the number of geriatric psychiatrists and added an internist with added qualifications in geriatric medicine. The committee completed its work on the first examination in July 1990, and the first examination, a 157-item written, multiple-choice examination was administered to 661 candidates in the spring of 1991. Performance results for candidates in 1991 and subsequent years are given in Table 53.1-7. The criteria for taking the geriatric psychiatry examination include being board-certified in psychiatry, having an unlimited license to practice medicine, and completion of a residency in geriatric psychiatry. Through 1996, diplomates devoting 25 percent or more of their professional time to geriatric psychiatry could take the examination without a postresidency training program. The same was true for addiction psychiatry through 1998 and is for forensic psychiatry through 1999.

Year	Examined (N)	Passed (N)	Passed (%)
1991	661	490	74
1992	598	359	62
1994	641	422	66
1995	559	376	67
1996	1023	713	69
1998	72	65	90

Table 53.1-7 Performance—Geriatric Psychiatry Candidates

The ABPN requested that the RRC establish guidelines for postresidency training in geriatric psychiatry at the PGY-5 year level or higher. These guidelines were approved by the ACGME. Programs can now submit proposals for geriatric psychiatry programs for RRC approval. Only graduates of geriatric psychiatry programs have been eligible for the geriatric psychiatry examination since 1997. Only graduates of ACGME-approved geriatric psychiatry programs are now eligible for the geriatric psychiatry examination.

CLINICAL NEUROPHYSIOLOGY The neurologists received ABPN approval (1989) and subsequent ABMS approval (1990) to issue a certificate in added

qualifications in clinical neurophysiology. The test-writing committee includes 12 board-certified neurologists and one board-certified psychiatrist. The first 4-hour, multiple-choice examination was administered in March 1992 at six sites. Of the 306 candidates eligible for the examination (including 7 psychiatrists), 278 were examined, and 227 (82 percent) passed; Examinations were also administered in 1994, 1996 and 1997. A total of 1001 candidates participated and 735 (73%) passed. Candidates who have not completed fellowships must have worked the equivalent of 3 years in clinical neurophysiology following completion of a residency training program. The Neurology Residency Review Committee established requirements for postresidency training in clinical neurophysiology; only those who graduate from programs are currently eligible for this examination, and only those who graduate from ACGME-approved programs will be eligible after 2000.

ADDICTION PSYCHIATRY In 1990 the APA recommended addiction psychiatry for added qualifications. The ABPN accepted the recommendation and its proposal was approved in September 1991 by the ABMS. Nominations were sought for membership on the test-writing committee from the APA and the AAPAA, since renamed the Academy of Addiction Psychiatry (AAAP). The Committee on Certification for Added Qualifications in Addiction Psychiatry held its first meeting in December 1991, and the first written, multiple-choice examination was administered in March 1993. Performance results are given in Table 53.1-8. Only graduates of addiction psychiatry programs are currently eligible for this examination, and only those who graduate from ACGME-approved addiction psychiatry programs will be eligible beginning in 2001.

Year	Examined (N)	Passed (N)	Passed (%)
1993	632	465	74
1994	402	302	75
1996	347	290	84
1997	347	278	80
1998	525	431	82

Table 53.1-8 Performance—Addiction Psychiatry Candidates

FORENSIC PSYCHIATRY The APA recommended that the ABPN issue a certificate in added qualifications in forensic psychiatry. The ABPN accepted the recommendations and submitted a proposal which was approved in September 1992. The first Forensic Psychiatry Committee met in December 1993 and the first examination was administered in October 1994. Performance results are shown in Table 53.1-9.

Year	Examined (N)	Passed (N)	Passed (%)
1994	316	256	82

PUBLICATIONS

The ABPN published the history of its first 50 years, with Marc Hollender, former president and director, as editor. Shore and Scheiber have edited a book on certification, recertification, and continuing medical education for APPI Press.

BOARD RESEARCH

In 1989 the ABPN approved the new full-time position of Research Coordinator for the Board. Dorthea Juul from the University of Illinois accepted this full-time position in 1990. She works closely with the Research and Development Committees of the board in studying the reliability and validity of board examinations. In addition, she contributes regularly to *Academic Psychiatry*, providing abstracts on articles pertaining to medical education and evaluation.

CHAPTER 53. PSYCHIATRIC EDUCATION

53.2 EXAMINING PSYCHIATRISTS AND OTHER TRAINEES

JAMES MORRISON, M.D., AND RODRIGO A. MUÑOZ, M.D.

By the time training is completed, a psychiatrist (or any other mental health professional) has probably been examined many hundreds of times on material that has consumed tens of thousands of study hours. The uses and consequences of all this testing are varied. Some of them are especially important to the individual student as a spur to greater study effort, a signal that the examinee is ready for the next stage in sequential learning, an evaluation of subject matter mastery, a rite of passage or initiation, or status or advertising for those who have passed the examination. In some ways, the examination serves the institution or fellow professionals. It provides feedback regarding teaching effectiveness, measures training program effectiveness, maintains discipline among students, and limits the competition. Finally, testing may serve society as a whole by ensuring quality of the licensee.

During a psychiatrist's march through medical school, postgraduate training, and on to board certification, most of the above-mentioned goals are likely to be a focus of one examination or another. With the maturation of the science of statistics, the story of psychiatric testing has increasingly been that of national examinations. Through the midtwentieth century, individual facilities constructed their own tests; but each year the expense of producing new testing material grew, as did the need to compare the abilities of clinicians who trained at different institutions. Examinations that are standardized throughout the United States are now a central feature of nearly every psychiatry training program.

TEST MAKING, TEST TAKING

Designed to test the extent of clinical knowledge acquired by the end of medical school, the National Board of Medical Examiners (NBME) step II examinations is given twice each year, in August and March of the fourth year of training. Its construction begins with a content outline. Although the NBME will not release the percentage of step II questions devoted to psychiatry, it is one of the five major disciplines represented in this examination. Officials point out that many questions are interdisciplinary.

The psychiatry section development committee comprises eight members who serve 3-year staggered terms. When they come to national board headquarters for 2 days of orientation, each member is assigned to write 50 questions for a total of 350 (the subcommittee chair does not write any). With the help of staff, these questions are then edited to conform to NBME style. Parallel committees and processes apply to each of the other major disciplines: medicine, obstetrics-gynecology, pediatrics, and surgery.

In a group meeting, each question is read aloud by its author. Others in the group may suggest changes in wording, answers, or distractors (the incorrect choices in a multiple-choice examination) before an item is finally accepted. Whenever a question is rejected outright, the author must supply another that tests the same area of knowledge. Questions are also tested by reading them aloud in front of the chairpersons of each of the major subcommittees. No specific degree of difficulty is prescribed. Rather, there must be consensus that each item tests fairly the knowledge that graduating physicians should possess prior to beginning the first postgraduate year (internship). Many questions pose problems that cross the boundaries of two disciplines, for example, the distractors might suggest that the answer could belong to either medicine or psychiatry.

Ultimately, the completed items are pretested in an actual examination. Some 40 different versions of step II will be given during any 1 year. Besides the test questions that contribute to a candidate's score (the NBME calls them *live items*), each version includes a number of items that are being pretested. The live items are the same for all examinations; the pretest items are distributed so that each will be answered by a representative sample of the 50,000 candidates who take the examination each year. The board evaluates the pretest items against the live items and so determines the composition of the next year's examination. The pretest also determines whether any of the distractors are left unchosen; if so, they may be discarded in favor of alternatives that will appeal to more candidates.

For each item a statistic is calculated called *the point biserial discrimination index* (PBDI), which quantifies the correlation between the item and the examinees' overall test performance. If it is positive, a high-scoring candidate tends to do well on the item. A PBDI above 0.20 is desired. New test items may be discarded if they are answered correctly by fewer than 30 percent of examinees or have a negative PBDI.

In recent years two types of question format have emerged as most favored on national tests: the best-single-answer multiple-choice question and the extended matching items (see examples below). This is not to say that multiple choice questions have no drawbacks. Even when composed by professional test writers, they can occasionally be interpreted ambiguously; candidates sometimes complain that subjects are controversial or worse, trivial. But increasingly, several old standbys are now discarded because they are confusing or they assess the examinee's ability to take tests rather than knowledge of the subject material. The true-false question is written in terms of absolutes. Any item that involves a shade of gray requires the examinee to guess what the author had in mind. (Example: “The prevalence of schizophrenia is 1%” might be answered differently by a clinician and an epidemiologist.) The multiple true-false question is a complicated vehicle that requires logic as well as knowledge of subject content. Its instructions are Mark “A” if choices 1, 2, and 3 are correct; “B” if 1 and 3 are correct; “C” if 2 and 4 are correct; “D” if only 4 is correct; “E” if 1, 2, 3, and 4 are correct. (Example: Typical symptoms of somatization disorder include 1. Abdominal pain 2. Seizures 3. Intolerance to foods 4. Impotence.)

Constructing a Test

1. Decide on the pass-fail criterion. A *norm-referenced* test (each candidate's score is reported as it relates to all others' in the group) is designed to produce variance and highlight differences in examinees. A *criterion-referenced* test (each score is given in terms of the absolute percentage correct) yields specific information about what the individual knows. Because both the NBME and American Board of Psychiatry and Neurology (ABPN) Part I examinations are criterion referenced, theoretically all candidates taking either examination could pass.
2. Select the knowledge areas and question content to be tested. Each area will require a certain number of items (about 30) to provide a reliable evaluation. Reliability is increased by greater test length and longer time for the test.
3. Question content should cover important problems that are common or potentially high risk. Questions should assess knowledge likely to be needed by a clinician in the field; avoid minutiae and disorders that are vanishingly rare. Additionally, focus on important areas of clinician knowledge and behavior, such as health and health maintenance, disease mechanisms, diagnosis, and treatment.
4. Determine the question format. Both the national boards and Part I of the ABPN examination rely mainly on multiple choice questions of several types: (1) single best answer, a statement followed by several possible responses from which the candidate must choose; (2) extended matching, as of a series of numbered statements to a series of lettered answers; (3) a vignette followed by several single best-choice questions.
5. Write the questions. Clarity and brevity are desirable qualities (but see no. 6 below). Avoid vague terms such as *usually, frequently, often*, and *may*. Questions should not just measure the ability to memorize; they should require the examinee to retrieve, select, organize, and apply knowledge.
6. Question stems (the information that serves as background to the actual question) that contain detailed information discriminate better between examinees who score well and those who score poorly on the entire test.
7. Devise distractors. These should be neither too hard nor too easy. A distractor that is never selected should be discarded from future editions of the test.
8. Evaluate the new questions for their ability to discriminate top from bottom candidates (i.e., have a positive PBDI). A pretest sample or previous edition of the test will help to determine which candidates will answer an item correctly.

9. After the examination has been given, some items may be found that are often answered incorrectly by top examinees (i.e., they have negative PBDIs). These flawed items must be discarded.

Anatomy of a Single-Best-Answer Test Question

A 31-year-old single woman is admitted to the hospital complaining of voices in her head that tell her to kill herself. She says she has had several prior admissions over the past 6 years, but her clinical chart cannot be found. She has heard voices on and off for many years and believes they may be the result of “interplanetary influence.” An actress by training, she has not worked in her profession since age 24. She has sustained herself by cleaning offices at night and with general relief. Upon close questioning she thinks she might have bumped her head several weeks ago. “But I was drinking,” she says with a giggle, “and I don't remember much about it.” She then denies habitual use of alcohol or other substances.

Fully oriented and coherent, the patient appears distracted during the interview, several times gazing around the room and cocking her head to one side. She interprets the proverb “A stitch in time saves nine” to mean that she should “sew up my ragged sleeve of carelock.” Except for occasional laughter when she says something that does not seem especially funny, her affect is unvarying and she gazes straight at the examiner.

The subject concerns a major area of concern to psychiatrists (psychosis is frequently encountered and fraught with risk).

- The stem is a relatively long, detailed clinical vignette.
  1. What disorder most likely has caused this patient's symptoms?
     A. Alcohol dependence with hallucinosis
     B. Bipolar mood disorder
     C. Schizoaffective disorder
     D. Schizophrenia
     E. Subdural hematoma
  2. Which medication will most likely provide rapid relief of symptoms?
     A. Amitriptyline
     B. Diazepam
     C. Divalproex
     D. Haloperidol
     E. Methylphenidate
  3. The patient's use of the term “carelock” is an example of
     A. Inappropriate affect
     B. Neologism
     C. Paranoia
     D. Perseveration
     E. Tangentiality
- The questions pose several types of problem related to the information provided in the stem, but these are not linked (one answer does not depend on knowing prior answers). Questions require deduction from the facts given, not just recall of isolated facts.
- The distractors are all logical and plausible (they have the same length, format, and type of word or phrase as the correct answer).
- Options are presented alphabetically so as not to favor a given letter or position in the list.
- The third question is actually an older, less satisfactory type of question: it draws on rote memory rather than ability to assess and apply principles.
- The answers (including distractors) are all relatively brief.

If desired, the same vignette could serve as the basis for additional questions about psychopathology, further testing, psychotherapy, family history, and the like.

Sample Extended-Matching Question

For each patient in items 1–5, select from the common set of lettered choices (A–O) the *most likely* diagnosis for the given chief complaint. Each choice may be selected once, more than once, or not at all.

A. Antisocial personality disorder
B. Attention-deficit/hyperactivity disorder
C. Brief psychotic disorder
D. Cocaine withdrawal
E. Dementia of the Alzheimer's type
F. Female sexual arousal disorder
G. Major depressive disorder
H. Mental retardation
I. Posttraumatic stress disorder
J. Pyromania
K. Schizophrenia, disorganized type
L. Schizophreniform disorder
M. Somatization disorder
N. Substance-induced delirium
O. Vascular dementia

1. A 6-year-old whose mother complains of poor progress in the first grade
2. A young married woman with a 6-month history of anorgasmia
3. A college student who cheerfully admits that he has heard voices for 2 months
4. A 24-year-old man arrested for setting fires for building owners who want to collect on insurance
5. An elderly businessman increasingly forgetful of his appointments

Tips for Surviving Written Examinations

1. Answer all questions.
2. Use a watch to help allot sufficient time to each section of the examination.
3. Use the full time allotted.
4. In the absence of definitive knowledge, guess on all questions, unless the test subtracts points for wrong answers (rare today).
5. *Never* and *always* are red flags signaling incorrect distractors.
6. *Possibly, sometimes*, and *maybe* may signal a correct answer.
7. Try to narrow the options by eliminating known incorrect answers.
8. Test writers take pains not to give away correct answers by placing them at any one point on a list.
9. Candidates with time left at the end of the examination should check their work. Research clearly establishes that examinees are far more likely to change an incorrect answer to a correct one than the other way around.

THE PSYCHIATRY BOARDS

The ABPN examination in psychiatry has been administered yearly since 1935. Almost since inception it was given orally; even knowledge in the basic sciences was ascertained by face-to-face query. By the mid-1960s the logistics of an oral examination were complicated by increasing numbers of candidates; an exploding volume of information about psychiatry; and a persisting, increasing demand for an examination procedure that was both impartial and fair. The logical solution seemed to be

a written examination, and during its more than quarter century of use, it has become a relatively inexpensive screening device for the vastly more complicated and expensive oral examinations of Part II.

Part I (Written) Boards The first ABPN examinations depended in part upon essays. Essay questions are easy and inexpensive to write, and they can potentially plumb the depth of a candidate's knowledge. They also have significant disadvantages. Because of the length of time it takes to answer them, relatively few areas of knowledge can be tapped in a single examination. A candidate unfamiliar with just one of, say, five questions may automatically hover perilously close to failure. Essay grading is time consuming and nearly impossible to do without bias. Factors such as poor handwriting or language skills (the latter a problem for some international trainees), which have nothing to do with knowledge of psychiatry, may figure too prominently in the grading process.

The speedy demise of the essay examination and a brief flirtation with a true-false component in the early 1940s cleared the way for various types of multiple-choice question. Several variations on these questions now form the bulk of standardized written psychiatry examinations administered throughout the Western world.

The Part I examination is used partly as a screening tool and partly to assess the candidate's knowledge of basic sciences. It is administered in the autumn of each year at many medical schools and hospitals across the United States. Currently, the Part I examination comprises 7 hours (half each in the morning and afternoon) of computer-scored questions covering both psychiatry and neurology. For psychiatrists, the examination covers the material listed in Table 53.2-1.

For candidates in psychiatry, the psychiatric (major) portion of the examination consists of approximately 260 questions from the following areas:
- Growth and development
- Biological dimensions of psychiatry
- Psychosocial aspects of psychiatry
- Clinical psychiatry, including
  - Phenomenology
  - Diagnosis
  - Treatment

The neurology section (as taken by candidates in psychiatry) consists of approximately 150 questions from the following areas:
- Clinical neurology
  - Neuroanatomy
  - Neuropathology
  - Neuropharmacology
- Clinical diagnostic procedures, including cerebral spinal fluid
- Neuro-ophthalmology
- Electroencephalography
- Neuroimaging
- Therapy and management of patients with neurological disorders

Table 53.2-1 Written Examination for Psychiatry Candidates

Previous editions of this text included somewhat more detailed descriptions of the content of the written examinations. The ABPN no longer permits the publication of copyright material it distributes to candidates who have been accepted to take the Part I examination. This change results from recent litigiousness on the part of a few unsuccessful candidates. The board now finds itself spending inordinate amounts of time and money fighting an increasing (though still small in absolute terms) number of lawsuits brought by unsuccessful candidates who prefer a legal solution to the effort of further preparation as a means for achieving certification.

Board officials have also noted an increase in irregular behavior associated with the certification process. Some candidates have refused to hand in their question booklets at the end of the written examination; some have been found copying answers from the papers of others. The use of forged board certificates also appears to be on the rise. In some cases, psychiatrists have testified in court that they are board certified when they were not.

Standards to Pass To pass Part I, a candidate must pass both the neurology and psychiatry sections. The number of candidates who will pass is not established in advance; rather, the writers of the examination determine what percentage of the questions a successful candidate should be able to answer correctly. However, over the years the pass-fail ratio has remained approximately constant at about three to two. Unsurprisingly, someone taking Part I for the first time is much more likely to pass than is a candidate who has previously failed this examination. A related finding, true for the ABPN examinations as well as for other specialty boards (e.g., Family Practice and Internal Medicine), is that younger candidates consistently perform better than those who are older.

Besides a statement of overall pass or fail for the Part I examination, candidates receive a report giving their subscore test results for the areas mentioned in Table 53.2-1 and for the psychiatry minor (neurology) portion of the examination. Correlations between subscores for the psychiatry major range from about 0.5 to 0.8, indicating that these subtests tap different aspects of learning.

Passing Part I is the only way a candidate can qualify to take Part II. Despite the potential for an oral examination to induce emotional trauma, many candidates see Part I as the real barrier to certification. As far back as 1977 it was noted that 88 percent of psychiatrists who passed Part I on the first try went on to become board certified within the next 4 years; this was true for only 12 percent of those who failed their first try at Part I. Apparently, many candidates who fail on the first attempt either become discouraged and quit or fail again (either part) on a subsequent attempt. Candidates who successfully complete Part I, then fail Part II three times or who allow 6 years to elapse without passing Part II must retake the Part I examination. Table 53.1-2 and Table 53.1-3 list the successful completion rates for Part I and Part II, respectively, over a recent 10-year period.

Part II (Oral Examination) Perhaps in part because it is the most verbal of all the medical sciences, psychiatry has clung tenaciously to the oral examination format. As of this writing it remains the only specialty board to require a witnessed examination of a live patient for certification.

After passing Part I, candidates are scheduled for a Part II examination within the succeeding 12 months. Because scheduling is so complicated, candidates cannot choose the date or place for the Part II examination. However, travel is minimized to some extent by the fact that examinations are offered three times a year in various parts of the country. The location of the Part II examination changes from one year to the next to avoid placing too great a burden on any city's mental health facilities. Most years, one of these examinations is so large (roughly 1000 candidates) that only five cities can accommodate it: Boston, Chicago, New York, Philadelphia, and Washington, D.C. The other two examinations are generally smaller (roughly 500 candidates each) and are distributed geographically around the country.

Part II actually comprises two examinations, each of which involves personal interaction of the candidate with two or more examiners. In one of these encounters, the candidate is questioned about a videotaped interview; in the other, questioning concerns an interview with a live patient that the candidate has just completed under the watchful eyes of the examiners.

Live Patient Examination Nearly everyone regards the interview of an actual patient as the more difficult half of the oral boards. This activity, though in substance no different from what most psychiatrists do every workday, carries enough emotional baggage to make the process far different from any normal patient interview. During this interview, candidates have the opportunity to demonstrate their ability to establish rapport, gather information, elicit and interpret signs and symptoms, and use the information obtained to arrive at a reasoned diagnosis.

This examination is conducted by two psychiatrist examiners unacquainted with the candidate, who has exactly 30 minutes to interview an unfamiliar patient for whom no records or other information have been provided. After the interview has been concluded and the patient has been excused, the examiners offer the candidate a minute or two to review notes and prepare the presentation. During the remaining 28 minutes, the candidate presents a précis of the patient's history; offers a formulation about the diagnosis, dynamics, and recommended therapy; and answers examiner's questions about any of these matters—or any other subject pertaining to clinical psychiatry.

During this entire exercise, the examiners evaluate the candidate's ability to interact with the patient, organize the material, understand and interpret the patient's psychopathology, and think through problems pertaining to diagnosis and treatment. How well the candidate handles these tasks depends in part on having an effective plan for organizing these 60 minutes.

A half-hour witnessed interview without the benefit of collateral information challenges any interviewer. In gathering data that adequately address diagnosis, the candidate must simultaneously demonstrate compassion and tightly control the patient's verbal output. Although the time schedule depends to some extent on the

individual patient, Table 53.2-2 suggests approximate times that should be allotted to the various portions of the interview.

5 minutes	Chief complaint and patient's free discussion of the issues
7 minutes	Specific questions about diagnosis, pertinent negatives, and history of suicidal ideas, violence, alcohol, and drug use
5 minutes	Medical history, review of systems, family history
5 minutes	Personal and social history, evaluate character pathology
5 minutes	Mental status examination
3 minutes	Buffer time: pursue other issues, late-developing leads

Table 53.2-2 Time Allotment for Patient Interview

Careful control over the interview process is vital to obtain the necessary information within the brief time available yet establish and maintain rapport with the patient. After an initial few minutes when the patient speaks freely about the various areas of concern, the candidate should begin using closed-ended questions that rapidly review all pertinent portions of the standard psychiatric history and mental status examination. Loquacious patients and those who tend to wander from the point must be gently, but firmly, herded back onto the path. Although patients who are vague, circumstantial, hard to understand, hostile, or complicated uniformly prove more difficult to interview, candidates should try to regard them as an opportunity to demonstrate a capacity for showing empathy while eliciting information in trying circumstances.

Candidates are especially advised to keep their own verbal output to a minimum; if they are talking, the patient cannot give them information. They should not discuss their own feelings, offer therapy, disagree with any aspect of the patient's own treatment, or show irritation or any other negative affect if the patient is slow to provide the information needed. Confrontation should be avoided at almost any cost, except when a patient's restlessness or other signs of discomfort indicate significant resistance to the entire interview process. Then, the candidate may have to make the patient explain the lack of cooperation. Offering the opportunity to explain a sad or hostile affect might break through the resistance.

Of course, the emphasis in any interview is altered by the presumptive diagnosis. A patient who is cognitively impaired may need a much more concrete style of interviewing that focuses on the mental status evaluation and the activities in a typical day; an older patient needs more time to describe losses (e.g., family, friends, mobility) and difficulties performing activities of daily living. Patients who have a psychosis or an anxiety or mood disorder require special attention to the criteria for the diagnosis according to the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV). But for every patient, one must carefully review personal and social information, including current living situation, work, family, marital status, and leisure activities.

PRESENTING THE PATIENT In presenting the just-gathered information to the examiners, organization is again the key. Examiners expect a brief (5 minutes or so) recapitulation of pertinent facts in the case followed by a formulation, not a verbatim retelling of the entire interview. A suggested outline is given in Table 53.2-3.

Identifying data
Present illness
Past history
Psychiatric history
Medical history
Review of systems
Family history
Personal and social history
Mental status evaluation
Most likely diagnosis
Differential diagnosis
Formulation
Predisposing factors (e.g., genetic)
Psychosocial stressors (e.g., abuse as child)
Stresses that precipitate present illness
Characteristic defenses—adaptive style
Proposed workup
Treatment plan
Prognosis

Table 53.2-3 Outline for Case Presentation

During the presentation, candidates sometimes discover to their chagrin that they have forgotten to obtain an important piece of information. Happily, they get a chance to recover, even from failing to request such vital data as suicidal ideas or substance use. If during the presentation they realize that they omitted something important, they can compensate by stating what they should have asked (with appropriate follow-up questions) and how they would use that information. Sometimes an examiner may even give a candidate a third chance to discuss important information such as suicidal ideas or substance use.

> While presenting a patient whose principal symptoms seemed to be characterological, Dr. A. had sailed right through to the formulation when one of the examiners coughed and asked, “Did you note any thoughts of self-destruction?” After a moment of horror-struck silence, the candidate blurted out, “You mean, like I'm having right now?”
>
> Quickly recovering, Dr. A. continued as follows: “I completely forgot to ask my patient whether she had ever tried to kill herself or ever had any thoughts to that effect. If I were seeing her in my practice, I'd immediately go out, bring her back into the office, and ask, ‘Have you ever had any thoughts about harming yourself, made any suicidal attempts.' I'd want to know all the details of any attempts—methods, degree of suicidal intent, any physical harm. This is really important stuff. Suicidal behavior figures in the diagnostic criteria for the mood disorders as well as borderline personality disorder. And it is quite common in a number of other conditions where it isn't a DSM-IV criterion—schizophrenia, substance abuse, and somatization disorder, for example. I can't imagine forgetting to ask, except that I am pretty nervous.”
>
> At the end of the session, the examiners instantly agreed that Dr. A. deserved to pass.

The presentation is the time for candidates to show how well they can manage clinical problems, set priorities, and recognize and cope with problems resulting from therapy. They must be ready to offer a differential diagnosis, even if the patient's most likely diagnosis seems open and shut. They will also be expected to show that they can defend diagnoses with criteria. Because the diagnosis of any one patient is less important than all the patients the candidate will evaluate throughout a professional lifetime, the examiners are hoping to find a candidate who can reason through a clinical problem.

The formulation organizes into a brief paragraph the biological, psychological, and social factors that influence the evolution of the disease process and produce the current symptoms. It should be followed by suggestions for workup, which might include such procedures as a physical examination, laboratory testing, imaging and such simple devices as obtaining records from previous clinicians and interviewing informants. Of course, all discussions of treatment should be based on the biopsychosocial model.

After an excellent presentation of a patient who had described many symptoms of borderline personality disorder, candidate B. would only consider behavior modification as a treatment option. The examiners repeatedly asked whether medication could be a consideration (the patient did report some depressive symptoms), but Dr. B. wouldn't hear of it: “There is little solid evidence that medication has any long-range effect in BPD.” Even when one examiner postulated an extreme case in which such a patient developed severe depression, the response was the same—refusal to consider another course of action. Despite an outstanding interview, the best the examiners could justify for this otherwise excellent candidate was a grade of Condition.

Interactions with the examiners should be as candid as possible. Candidates should avoid using gamesmanship, trumpeting their own expertise or ignoring examiners' interests and opinions. Respectful acceptance of other points of view suggests the ability to think flexibly. A candidate who does not understand a question should request clarification. Not only is this perfectly in order, it is the safest course to follow. Candidates who cannot answer a question are well advised to say so, then add how they would go about finding the answer. No one is expected to know everything, and many examiners feel that good physicians know their own limits.

Videotape Examination Some candidates consider the videotape examination to be a comparatively easy ride, and in some ways it is. Candidates do not have to manage an interview, only absorb a circumscribed amount of information, and they are not subject to the vagaries of temperament displayed by sometimes highly individualistic patients. Still, the videotape examination, a staple of the Part II examinations since 1982, presents its own challenges that recommend mental preparation, as well as outright practice, prior to the actual event.

Each video comprises about 25 minutes of interview with an actual patient. The quality of the tapes is usually less than professional; if they were not followed by half an hour of intense questioning by two examiners, many would not even be very interesting.

Often the vignette seems sliced from a larger interview. It may appear to have no definite beginning or end, and it will probably omit certain vital facts about the patient, such as age, martial status, or occupation. Some interviews seem almost maddeningly unfocused or even trivial and would surely earn a failing grade if conducted by a candidate for the Part II examination.

With the prospect of a relative information drought, candidates should sit as close as they can to the source and be prepared to absorb every drop. Because it is dangerous to look away from the screen for even an instant, it is probably best to keep note taking to the barest minimum. Otherwise, something important in the way of a behavioral mannerism—a tear, a sidelong glance at the camera—could escape unnoticed. During practice sessions, candidates might try using a mental filing system to storing and later recall pertinent observations. This system depends on filling in an outline similar to the one followed with a live patient interview, except that at the end many more bare spots will exist. Bits and pieces of historical material are likely to be scattered throughout the 20 to 25 minutes the camera spends focused on this patient; these should be mentally recorded under present illness for later use in the presentation. Other sorts of information (e.g., family history, personal and social history, past psychiatric history) should be similarly filed.

EXAMINATION PROCESS The video interviewer will probably not conduct a formal mental status evaluation, effectively restricting firm conclusions about recent memory, capacity for calculations, and the ability to tell similarities and differences. Instead, inferences can be drawn from evidence supplied by cognition and behavior, including focus and attention (Does the patient stick to the topic at hand?), language (Is there any apparent aphasia? What does word use and accent tell about upbringing, education, and place of origin?), memory (Can the patient refer back to early portions of the interview?), insight (Is there an appreciation that something is wrong?), and judgment (What does the patient say that indicates compliance with treatment recommendations?).

After the videotape ends, the candidate and examiners will discuss the case in a private room. The presentation of the videotaped patient should proceed along the same general lines as those used for any other patient (Table 53.2-3). The fragmentary nature of this interview means that many data will be missing. It may be tempting to overinterpret those data that are present. Candidates should avoid this temptation and instead volunteer what questions they would like to ask or further observations they would want to make to answer an important diagnostic question.

Noting that the videotaped patient had several times glanced off screen, Dr. C. hypothesized that the behavior could be caused by hallucinations. “Of course, there could have been activity off-camera that we couldn't see” the candidate volunteered. “I'd need to ask the usual sorts of questions about auditory and visual hallucinations, delusions, and so forth before I could say for sure. Would you like me to go through them?”

Dr. C. was playing it safe by mentioning other reasonable interpretations. This is an excellent practice to follow in discussing the videotape interview, which may well not present sufficient information for a definitive diagnosis. As in a live patient examination, flexible thinking is the key to success.

The examiners usually ask the candidate to select for discussion one diagnosis from the list of differentials. Candidates occasionally come to grief because they are unable to select one; some even refuse. The examiners are not trying to set a trap, but merely want a diagnosis—any one will do—upon which to center a discussion of evaluation and treatment.

Finally, any other question about clinical psychiatry can be raised during the course of the discussion of the videotape examination. Examiners might want to hear the candidate's assessment of the rapport between the patient and interviewer, what steps should be pursued for further evaluation, or how psychotherapy might best succeed with such a patient.

SUCCESS AND FAILURE ON THE ORAL BOARDS

Using the official ABPN grading categories, examiners from one Part II team in the mid-1990s developed a list of areas they regarded as crucial to a candidate's success on the examination as a whole. These criteria examined how the candidate handled two basic types of problems. As a group, candidates who passed the overall examination handled each of these 18 items better than those who failed.

Content. Did the candidate:

1. Use appropriate opening and closing strategies
2. Follow cues to new information
3. Appropriately explore affective cues
4. Demonstrate language and cultural sensitivity in communications
5. Use a questioning technique that was open-ended but appropriately structured
6. Control and direct the course of the interview into a cohesive whole Process. Did the candidate:
7. Obtain enough data about the chief complaint and history of the present illness
8. Begin to sketch in relevant data concerning developmental, family, medical, and social histories
9. Sensitively explore any history of alcohol and drug abuse
10. Sensitively assess risk of suicide and homicide
11. Present an organized, concise summary of important data
12. Recount an organized accurate mental status examination
13. Consider emergency issues such as alcohol or drug use, suicide, and violence
14. Present a rational, organized workup that included additional history, collateral information, and testing
15. Choose an appropriate working diagnosis from a sufficiently broad differential for Axes I, II, and III
16. Use all three dimensions of a biopsychosocial formulation
17. Present a comprehensive treatment plan that included drugs, psychotherapy, and criteria for hospitalization and show a knowledge of family systems and milieu principles
18. Discuss negative and positive prognostic factors and transference and countertransference issues

For the live patient examination, four criteria best predicted outcome in a stepwise logistic regression. In descending order of importance they were treatment plan (item 17), information cues (2), mental status examination (12), and interview control (6). Failing candidates scored lowest on information cues (2) and affective cues (3).

For the videotape examination, the four criteria that best predicted outcome were treatment plan (17), summary (11), differential diagnosis (15), and handling of

emergency issues (13). Failing candidates scored lowest on treatment plan (17) and biopsychosocial formulation (16).

Although as of this writing these preliminary findings had not yet been verified by a larger study, decades of observations and anecdotes related by dozens of board examiners have verified their essential truth.

Problems With Content Issues of content can involve virtually any clinical topic covered in this textbook, but candidates typically encounter difficulties with some of the following.

Organization Organizing and verbally presenting a complicated history is a skill that medical students learn early in training. Unaccountably, it also lies at the core of the difficulties many psychiatrists encounter during the board examinations.

> When asked to present the patient “as best you can” from a somewhat murky videotape examination, Dr. D. encountered disaster. Instead of doing a focused presentation, Dr. D. attempted to recount the undigested interview, pretty much as it had just occurred. Jumping around from present illness to historical data to mental status examination, the candidate became more and more anxious, compulsively—and futilely—shuffling through pages of scrawled notes.

Differential Diagnosis For generations the elementary clinical exercise known as the differential diagnosis has been a mainstay of medical decision making, but the stress of the witnessed interview sometimes causes candidates to narrow their focus, rather than broaden it. Some appear to fear they are being tricked or trapped; others cling to a favorite diagnosis as if it were a life preserver. However, examiners only want to find a pattern of sound diagnostic thinking that will serve future patients well.

Knowledge of Criteria Most candidates are reasonably well versed in the latest diagnostic criteria, but sometimes one will mix up items from two or more criteria sets. Some overinterpret the data and make a diagnosis they cannot defend with the material at hand. Examiners usually try to help the candidate work through such a difficulty. However, they will probably show very little tolerance for the occasional candidate who tries to compensate for knowledge defects by inventing criteria. Here, as everywhere else in the oral examination, it is generally much better to recognize and acknowledge a deficiency than run the risk of appearing intellectually dishonest.

> After doing a fine interview, Dr. E. made the flat statement, “The diagnosis is anxiety disorder not otherwise specified,” and then stopped. The combined efforts of two examiners could not persuade this candidate to admit that another diagnosis was possible. The senior examiner noted, “Once many candidates get the patient to report a very well-defined psychiatric syndrome, they tend to forget that there is a differential diagnosis, with several Axes to consider. Even though the issue has been well addressed [in reading material concerning the boards], many people forget.”

Formulation Even if they have done a reasonably competent job of information gathering, some candidates appear puzzled about what to do with it. They seem incapable of condensing what they have learned into the few sentences required.

> After Dr. F. presented the basic observations about a videotape interview, the examiners asked for a formulation of the patient. What they got was an unaltered repetition of what they had just heard from the patient. With prompting, Dr. F. eventually mentioned diagnosis (two Axes only) but seemed to recognize no opportunities for further investigation.
>
> Later that afternoon, after viewing the same videotape, Dr. G. told the same examiners: “In summary, the patient is a middle-aged man, occasionally tearful, who spoke slowly and mentioned other symptoms that would support a diagnosis of depression. I didn't hear anything about previous episodes or manias, so my best Axis I diagnosis would be major depressive disorder, single episode. However, I'd want to quiz him more carefully about mania. I thought he sort of glossed over the question about drinking, so I'd also have to know more before completely ruling out a substance-related mood disorder. I'd defer an Axis II diagnosis—not enough information. Contributing to his depression could be the fact that his mother died several months ago, which I'd mention on Axis IV, as well as the fact that he has been worried about his job because of missing work. That would also be reflected in his Axis V score. I didn't think he looked hypothyroid so I wouldn't mention it on Axis III, but in addition to routine labs I'd order a thyroid screen in my workup, just to be safe. My treatment plan would be biopsychosocial, and I'd consider...”

Further Evaluation Some candidates appear uncertain about how to proceed in a patient workup. Some suggest laboratory tests that are inappropriate; others cannot explain how they would use the information once they had obtained it. Many ignore that most useful (and inexpensive) of procedures, the collateral interview, which is especially vital when patients are psychotic or have cognitive or personality disorders.

Treatment Recommendations The importance of psychopharmacology to the treatment process and its emphasis in training curriculums have ensured that most candidates are reasonably well prepared in this area. But now and again the specter of treatment complications arises to haunt candidates who should have been better prepared to deal with potential complications of a drug they themselves have recommended. For example, unfamiliarity with the symptoms of neuroleptic malignant syndrome is sure-fire trouble for a candidate who has just recommended the use of haloperidol (Haldol).

> Discussing treatment of a depressed, middle-aged man, Dr. H. advocated trazodone (Desyrel) but failed to mention the possibility of priapism. “Try as we might to suggest that a discussion of sexual complications might be in order, we got nothing for our efforts,” said one of Dr. H.'s examiners. “Now, not knowing the side effect of a particular drug isn't usually a calamity, but it is an infamous side effect, and it was the candidate who suggested it in the first place!”

In recent years, both junior and senior examiners have reported feeling enraged when candidates tell them that they “never do psychotherapy.” “Despite all the good advice about addressing all forms of treatment, many candidates' formulations are completely unidimensional,” one examiner reported. “They just kiss off psychotherapy by saying they refer all patients who need it to a social worker or psychologist. They seem to regard this as relieving them of all responsibility for knowing anything about interpersonal aspects of treatment. For some of us, this attitude is a nail in the coffin.”

Fatal Mistakes Most examiners agreed that a single error is unlikely to cause a Part II board failure. Such an error would have to demonstrate an abysmal ignorance of facts or an overwhelming lack of concern for patient well-being; for example, offering a suicidal patient a month's prescription of potentially lethal medication or, for some examiners, not asking a patient who uses drugs about suicide or failing to ask about a history of violence or substance abuse.

The examiners must be confident that the candidate can competently assess a patient for these behaviors crucial to diagnosis, treatment and, indeed, to life itself. Despite the logic of this principle (not to mention the publicity it has received in books, articles, and board preparation courses), some candidacies still founder on a failure to follow up clues the patient may present. These can include hints about suicide or death, tearfulness, abnormally reduced or excited activity level, and references to substance use.

> “I remember one candidate who didn't pick up on what the patient was saying,” an experienced examiner commented. “This patient had made reference to drug abuse and the candidate just didn't get it. My partner and I hated to do it—this was an obviously bright, young psychiatrist embarking on a promising career, who has since become an internationally known leader in psychiatry. But we were forced to issue a failure. The candidate passed the next year, but I still cringe when we run into one another at meetings.”

Relying on a Cookbook Rather than not knowing drugs, some candidates seem acquainted with little else. The emphasis of the boards is biopsychosocial, which means that, candidates must both be prepared to discuss social interventions (placement, self-help groups, family interventions, and the like) and the myriad iterations of psychotherapy and be conversant with the dosages and adverse effects of the latest psychotropic medications.

An unnecessarily uncomfortable half-hour with examiners was the fate of Dr. I., whose patient had a personality disorder with borderline features.

“For 10 minutes all this candidate would talk about was antidepressant medications,” one of the examiners later complained. “Sure, we all saw the depressive symptoms. But we practically had to beat the candidate up to get a treatment approach that was anything but drugs.”

Dr. I. did pass the boards, but according to the examiner it was “a near thing.”

Despite numerous warnings that there are still no pathognomonic signs in psychiatry and that no disorders have only one treatment, some candidates still pursue a single-minded approach to patients and their problems. They may quote the latest “truth” from a journal article and, when asked to explore alternative possibilities, respond with the journal title, page, and year. In the words of one examiner, this is “tantamount to dying with their rights on.”

Problems With the Process Lack of information (as described just above) is serious but to an extent expected; nobody can be expected to know everything. Difficulty with the interpersonal aspects of the examination is another matter, for it suggests something inherent in the approach to people that could negatively affect the candidate's ability to care for patients.

Inadequate Rapport From the opening moments of the patient interview, some candidates show behaviors that suggest an inability to subject their own needs to those of the patient. They ignore the bits of social behavior that should put the patient at ease: making introductions all around, offering a choice of chairs, explaining the purpose of the examination, giving good eye contact, showing empathy for a patient who is in pain. As one examiner put it, “You rarely see a caring candidate who doesn't do well overall in the examination.”

Rapport is especially an issue when a candidate's behavior indicates insufficient concern for the feelings or emotional state of the patient. Some examinees seem incapable of putting themselves in the patient's shoes; a rare candidate may show an almost unbelievably callous disregard for the feelings of a fellow human.

A recent board patient with an advanced case of acquired immune deficiency syndrome (AIDS) had lost his lover and been abandoned by his family. During the interview he admitted that he felt depressed and often thought about death. When asked about the importance of the family's absence, the candidate responded that it made “little difference, because the patient was dying anyway.”

Inadequate Control Although examiners criticize the excessively controlled interview in which a patient is given insufficient scope to discuss problems freely, they far more often find cause to criticize the inadequately controlled, directionless interview.

While the patient talked, Dr. J. spent most of the interview sessions furiously scribbling notes. Actually, the interview started out well enough, with the patient discussing the anxiety symptoms that had brought him to treatment. But soon he wandered off into a discussion of his wife's recent operation, then the problems the family had had with her surgeon's billing practices. The candidate went right along, transcribing his words with passive diligence. Although one of the examiners did finally try to refocus the interview, little change resulted, and Dr. J. failed.

Examiners hope to witness an interview in which all of the important topics are covered and the candidate identifies and follows up on important questions in a way that makes the patient feel party to a conversation rather than the subject of an interrogation.

Dr. K. had to examine a woman who for 18 months had been an inpatient on a state mental hospital ward. Her problems included bulimia nervosa, obsessive-compulsive disorder, major depressive disorder, and multiple substance-related disorders. “And that was just the Axis I stuff,” the candidate reported later.

Without adequate time to evaluate any of these issues fully, Dr. K. spent a few minutes addressing each of them before easing the patient into a discussion of the next problem. “My examiners seemed to recognize that I could get my arms around each of these issues sufficiently to formulate a plan for further evaluation and management. I didn't feel especially good about my interview, but I passed.”

Anxiety Anxiety can affect all aspects of performance during the board examination. Nearly every candidate feels some anxiety, but a significant minority are virtually incapacitated by it. Anxiety reduces some candidates' ability to respond in a warm and sympathetic manner and may drive others to ignore important questions (e.g., hints of suicide or evidence of cognitive disorder) that must be followed up for a passing performance. Still other candidates report that their minds “go blank” when they try to recall the most elementary didactic material concerning diagnosis or management.

Examiners are human and do take into account the anxiety and stress that nearly all candidates experience. The case of Dr. A., cited above, demonstrates how the candid admission of extreme anxiety helped one candidate recover from a potentially grievous error. However, candidates have used a variety of approaches besides candor to deal with their anxiety. These range from behavior modification therapy to, in extreme circumstances, the use of drugs such as propranolol (Inderal).

Differences With Examiners Most examiners seldom note interpersonal clashes with candidates, but it is not unusual for candidates to report feeling that they have in some way run afoul of one or more examiners. In part this may be fed by anxiety; in part it may be a reaction to the neutral stance examiners must take toward examinees. Whatever the cause, some candidates find themselves arguing with examiners. Others pontificate, attempting to demonstrate special expertise or knowledge that they hope will carry the day. Examiners sometimes consider such behavior arrogant.

Long-time examiners report a recent marked change in the knowledge and stated interests of young psychiatrists. Candidates of a generation ago might know too little about psychopharmacology; now, they may know little else. One report from a senior examiner exemplifies many such reports:

We are seeing a change in candidates' attitudes toward patients and toward medicine in general. Maybe this has been caused by managed care, but some of these young doctors seem disengaged—they'd rather not take responsibility for a patient. They seem to feel that clinical concerns are just a part of the portfolio for making the money that they are hoping for.

Other Problems Examiners report a seemingly never-ending supply of anecdotes that attest to candidates' ability to bring trouble down upon themselves. One fussy candidate began the session by insisting upon moving the furniture and changing the lighting, all the while complaining about the examination room's ambiance. These behaviors created almost instant hostility in the patient, who called the candidate “stupid.” Flustered, the candidate inadvertently kicked the patient. The discussion after the patient left the room focused largely on issues of hostility and countertransference. Only after long debate, with active participation of the team leader, was the candidate given a passing grade.

Some candidates have become so attached to their little plastic bottles of purified drinking water that they bring them into the examination room. Such a distraction invites patients to comment or even ask for a drink.

A Sun Belt candidate journeyed north fully togged out for winter, including a pair of large leather mittens. He seemingly had not decided prior to the examination what to do with the mittens, which rested in his lap throughout the interview. The patient's obvious fascination with the mittens so flustered the candidate that he ended up offering them to the patient as a souvenir. The patient accepted, and the candidate spent valuable time justifying this behavior to the examiners, who had not requested an explanation.

Unusually enthusiastic about taking notes, a candidate spent several minutes of her interview time fighting with her pen. The ink simply would not flow and, flushing, she kept mumbling to herself and scratching holes in the paper. Eventually she asked to borrow an examiner's pen and carried on with the examination.

A candidate spent the first part of the interview weeping copiously in front of the patient. After collecting himself, he explained that he usually wore glasses but had chosen to use contacts for this interview.

An examination location in California was not excessively hot, but it was unseasonably humid. A candidate who was wearing a three-piece suit appeared increasingly

uncomfortable and progressively tense. Before making his case presentation, the examiners encouraged him to make himself as comfortable as possible, but he retained his vest and jacket. Perspiring profusely throughout the question-and-answer period, he appeared to consider it a major victory just to get out of the room into fresh air.

EXAMINERS

ABPN examiners possess one qualification in common: each must be board certified in psychiatry. Each team of examiners is headed by one of the eight psychiatrist members of the ABPN. Each of these team leaders chooses 4 senior and 16 primary examiners, so a team comprises a total of 21 board-certified psychiatrists. Other than expenses, examiners are not reimbursed for their time. Participation is generally regarded as an honor that most examiners anticipate from one year to the next

Two primary examiners stay with the candidate for the entire hour (half-hour for the videotape examination). The senior examiner floats, going in and out of the several rooms as time and fancy dictate.

Other than their names, examiners know nothing about the candidates—not where they trained, what kind of work they do, where they are employed nor, perhaps most significantly, whether a candidate has previously taken Part II. If by chance a candidate and examiner are acquainted, the pairings are rearranged so no question of either favoritism or discrimination can arise. As a further safeguard against any appearance of impropriety, no psychiatrist can work as an examiner who during the previous year has participated in any for-profit board review course.

Candidates sometimes complain that an examiner's attitude seems cold or hostile. Examiners are instructed to maintain a professional distance from the examinees, and they are specifically told not to teach or give feedback. But their attitudes are also expected to be respectful, never hostile, sarcastic, or condescending. The need for absolute confidentiality that pervades the entire examination process prompts the instruction to examiners never to discuss the examination or candidates in public—on the street, in hallways, or on elevators.

GRADING PROCESS

For the live patient examination, each primary examiner grades the candidate on five categories (Table 53.2-4):

Table 53.2-4 Performance Guides for Patient Examination

The physician-patient relationship
The conduct of the interview
Organization and presentation of data
Phenomenology, diagnosis, and prognosis
Etiological, pathogenic, and therapeutic issues (which are subdivided into biological, psychological, and social categories)

Only the last three categories are used for the videotape examination.

Immediately after the 60 minutes are up and the candidate has left the room, each primary examiner independently assigns a preliminary grade for each of these five categories. (Because the first two categories can only be scored *Pass* or *Fail;* and the remaining three can be assigned a grade of *Condition*, the first two categories have greater weight than the others.) Using these preliminary grades, each examiner then independently rates the overall performance as Pass, Condition, or Fail. Only at this point do the primary examiners compare notes to reach a consensus grade (also Pass, Condition, or Fail) for this half of the Part II examination. Usually they agree at once; if not, they may engage in vigorous debate, perhaps involving the senior examiner, until they reach consensus.

The final grade for the entire examination is determined that evening, when the eight team leaders meet. A candidate who earns a passing mark on both the live patient interview and the videotape passes the examination and becomes a diplomate of the ABPN. A failing grade on either examination or a conditional grade on both results in failing the entire examination. When a Condition is combined with a Pass, the team leaders compare the grading card notes written by the primary examiners. The candidate will probably pass if the conditional grade was overall not too low and the comments on the grading cards indicate that weak areas in one examination were handled satisfactorily on the other. The live patient examination offers more opportunity for a compensating good performance, so a videotape conditional grade is more likely to result in an overall pass than a conditional grade on the live patient examination.

PREPARING FOR THE BOARDS

Preparation for Part I should include careful reading of a standard American textbook of psychiatry, preferably one that offers a study guide to provide familiarity with the sort of test question that may be asked. Part II preparation should include several practice interviews with patients of the type likely to be found in public institutions, which provide most of the actual board examination patients. In addition, at least one mock board examination should be undertaken.

How much time should candidates spend in preparation? Data for Part I are entirely lacking. A report two decades ago found that the average Part II candidate put in about 120 hours in preparation. Of course, this time is highly variable; for weak candidates, 120 hours is not nearly enough, whereas a strong candidate just out of training may require little preparation at all. Unhappily, all too often the former learn who they are only as a result of taking the examination itself.

Mock Board Examination For a generation, the mock board examination has been standard preparation for Part II. No psychiatric candidate, even one who has just graduated from residency, should consider taking the oral board examination without one.

To be effective, the mock examination should be as close to the real thing as possible. Although the mock candidate would ideally be evaluated by two examiners, time and fiscal restraints often mandate only one. When this is the case, that lone psychiatrist should:

Have served as an official ABPN examiner. That experience will convey the necessary insight into the rules, process, and spirit of the examination process.

Be someone not well known to the candidate. Friends or colleagues may exaggerate the merits and minimize the deficiencies of a candidate's performance.

Be willing to spend the 90 minutes necessary for this exercise, including the hour-long examination itself followed by 30 minutes or so for critique. The critique should include a point-by-point evaluation of the five areas in which candidates are graded as well as an overall score (Pass, Condition, Fail) and comments on every relevant item of content or process raised during the half-hour patient interview.

Provide a patient. For obvious reasons, this patient must be one with whom the candidate has never had prior contact.

Although the outcome of a mock board interview still depends to some extent on the patient's cooperation, any interview carefully witnessed by a thoughtful, impartial observer should prove a pretty good predictor of the course of the actual board examination. The critique, which the candidate might well (with permission of examiners and patient) want to tape record for later study, may reveal difficulties in one or more of three possible areas, any of which should set in motion an immediate plan of action. The sort of problems noted in this critique will closely parallel problems during the actual board examinations discussed in an earlier section.

Inadequacies of Factual Information Lack of facts concerning any modality of treatment or any psychiatric diagnosis should stimulate further review of relevant sections of a standard psychiatric textbook such as this one. Although no one expects candidates to have memorized DSM-IV criteria, a thorough understanding of their structure and basic content is expected. Because Part II candidates have already passed the rigorous Part I evaluation covering multiple content areas (Table 53.2-1), problems with content should be minimal. Indeed, isolated knowledge deficits may not be devastating if candidates can satisfy the examiners about their ability to provide safe psychiatric care.

> After interviewing a young woman with a first-break psychosis, candidate L. admitted to “complete naiveté” regarding the novel antipsychotic agent she was taking. “If I inherited the care of this patient, I'd look that drug up in *AHFS Drug Information* or PDR. And I'd also discuss it with the drug information pharmacist at our medical center.” During the debriefing, the mock examiner specifically praised this cautious, information-seeking approach to uncharted territory.

Conduct of the Interview Almost any mock board interview is likely to yield some suggestions for improvement—more eye contact, fewer interruptions from the candidate, a different focus or depth when following up on earlier questions. Other findings may require much more extensive remediation.

> “I've got to say, I felt really uncomfortable during much of your interview,” the examiner told Dr. M. during the mock board debriefing. “The patient had a story he was trying to tell, but you kept interrupting to ask questions about which medicines he had taken. And some of the important ideas he did manage to get across—his life didn't ‘seem worth living,' for example—you didn't follow up.”

Interpersonal Differences Although board examiners rarely express negative feelings about the psychiatrists they examine, the reverse is not uncommon. These feelings extend even to mock examinations, where the stress of the moment may provoke feelings of distrust or hostility—the examiner might even feel threatened somehow by the candidate! Under stress, candidates are likely to react by becoming defensive and rigid. They may argue with examiners and cling to a position so tenaciously that they cannot acknowledge, much less accept, the fact that an examiner may be trying to nudge them toward an alternative view of the patient. The fact that a given diagnostic or treatment option may be perfectly justifiable and even correct does not excuse any candidate from the need to demonstrate flexible thinking.

A poor performance on a mock board examination should lead to an immediate reexamination with a different examiner. A conflicting opinion could mean that the problem has been solved or that it is confined to certain types of patients (or examiners)—and justifies yet a third mock examination. A second opinion that confirms the first suggests the need for extensive remediation in one or more of the areas just mentioned. Attendance at one of the numerous board review courses (many of them proprietary) offered throughout the country may be indicated. Table 53.2-4 suggests performance standards that apply to the patient examination.

Review Courses How helpful are the seemingly ubiquitous, definitely expensive review courses offered by universities and private organizations? Other than anecdotal evidence, most of which is only of testimonial quality, essentially no data exist for psychiatry. One study in the field of surgery reported that formal review courses may assist the candidate at high risk of board failure, especially those who have already experienced one or more failures.

To be maximally helpful, a review course should have faculty with previous experience as board examiners and give each student the opportunity to participate in a mock board examination. The course should be taken far enough in advance of the actual examination to allow the opportunity to practice new behaviors.

SUBSPECIALTY BOARD EXAMINATIONS

In addition to the board examinations in general psychiatry, the ABPN offers certificates in five subspecialties. The oldest of these, dating to 1959, is the child and adolescent psychiatry examination. It is a full-fledged board in its own right; the others are qualifications added to the basic general psychiatry boards.

Child and Adolescent Psychiatry To sit for the examination in child and adolescent psychiatry an applicant must have had at least 2 years of training in adult and 2 years in child psychiatry, all in the United States, and must already hold the ABPN certificate in general psychiatry. The structure of the examination parallels that for general psychiatry: a qualifying written examination followed by an oral examination that includes a live patient interview.

The written examination covers core knowledge in the field: child and adolescent development, history, psychopathology, and theory. It contains approximately 100 multiple-choice or matching questions and is administered once a year in a 2-hour session as a part of the overall examination.

The oral examination has three segments, each conducted by two examiners. In the preschool and grade school age segment candidates evaluate two patients, one on videotape and the other in a written vignette, and are in turn evaluated on their ability to observe, to describe the child's important behaviors, to determine what additional information is needed, and to formulate a treatment plan.

In the adolescence segment the candidate interviews an adolescent psychiatric patient in the presence of the two examiners. The evaluation is based on the candidate's ability to conduct the interview, obtain important information, formulate a differential diagnosis, and construct a treatment plan.

In the consultation segment the candidate must discuss two written vignettes, each of which describes a situation in which a judge, physician, school, or social agency requests consultation about a child or adolescent. Candidates are rated on their ability to identify problems and needs, formulate goals, and plan interventions. They must also demonstrate familiarity with the important community resources and discuss relevant ethical, interprofessional, and legal issues.

Success on the Child Boards Compared with the adult boards, the success rate for the child boards is high, about 90 percent overall; 95 percent pass the Part I written examination. Because all candidates have first passed the general psychiatry boards, these figures should not be surprising. In fact, it has been argued that certification rates in child psychiatry should be even higher. Those who disagree cite an inability to synthesize and integrate clinical material as the principal cause for failure.

Certificates of Added Qualifications By examination, diplomates in general psychiatry can earn certificates of added qualifications in various subspecialty fields. Added incrementally since the examination for geriatric psychiatry was introduced in 1991, these now include addiction psychiatry, clinical neurophysiology, and forensic psychiatry. Each requires one additional year of specialty training after the fourth postgraduate year (PGY-4). If obtained at a single center, training may be completed on a half-time basis for all subspecialty areas but clinical neurophysiology, which requires full-time training. By the year 2002, all will require that training be obtained in an institution approved by the Accreditation Council for Graduate Medical Examination (ACGME). Each is a written, multiple-choice examination that requires approximately half a day.

Candidates for these certificates are tested in the following areas:

Addiction psychiatry—biological and behavioral basis of practice, evaluation and consultation, laboratory assessment, pharmacology of drugs, pharmacotherapy, and psychosocial treatment

Clinical neurophysiology—autonomic testing, central electroencephalography (EEG) and electromyography (EMG), evoked potentials, instrumentation, physiology, polysomnography, signal analysis, and surgery intensive care unit (ICU) monitoring

Forensic psychiatry—civil and criminal law and landmark cases, legal regulation of psychiatry, and special issues

Geriatric psychiatry—biological aspects of aging, development and psychosocial aspects of aging, diagnostic methods, the interface between general medicine and psychiatry, neuropsychiatry and neurological aspects of aging, psychopathology and psychiatric diagnosis, and treatment

The numbers and success rates of candidates in recent years are given in separate tables in Section 53.1.

OTHER PSYCHIATRY EXAMINATIONS

The ABPN assesses only graduate psychiatrists, not those in training. It forthrightly claims that it has no educational mandate and that it is not intended to be a way of evaluating training strategies. Because of the time and expense of construction, in-house examinations of cognitive material have been virtually eliminated from most training programs.

PRITE Nationally standardized examinations for residents who are still in training were adopted by many specialties during the last third of the twentieth century. The Psychiatry Residency In-Training Examination (PRITE) has been in use constantly since 1982. Although it is voluntary, the Residency Review Committee for psychiatry requires that each program use a formal, standardized test as a part of its evaluation of trainees. With PRITE the only game in town, by the 1990s nearly every training program nationwide had adopted it, and it was being administered to over 5000 residents each year.

This written examination offers residents the opportunity to track their progress throughout training and to gauge their own performance against that of colleagues. To accommodate the schedules of individual training programs, the PRITE can be administered on any 2 half-days within a 1-week window during the fall of each year; the window reduces the likelihood that questions will be circulated by the first examinees to take it.

The examination is administered with the signed understanding that scores will not be used to decide whether a resident will be dropped from a training program. However, many training directors use the results for individual counseling and for assessing the effectiveness of their programs in teaching the cognitive aspects of psychiatry.

Comparative percentile scores are reported for both the psychiatry and the neurology components of this examination. For the overall test and for each subsection, training directors and each trainee receive the individual's exact numerical scores, ranking compared with peers in that program, and nationwide peer group percentile rank. Training directors learn the grouped percentile ranks on each subtest for the residents in each training year as well as how their residents compare nationally on each question.

Resident input into test item development has been encouraged, causing some feeling that those who so participate reap a competitive advantage for their efforts. But in the words of one participant, “I submitted my questions so long before they were scheduled for use that by the time of the exam, I couldn't remember what I had written!”

Roughly 18 percent of the PRITE emphasis is on neurology and the neurosciences; the remainder is on 10 principal psychiatric knowledge areas: adult psychopathology, alcoholism and substance abuse, behavioral science, child psychiatry, consultation and liaison psychiatry, emergency psychiatry, growth and development, patient evaluation, psychosocial therapies and somatic treatment methods. The sponsors of this examination include the American College of Psychiatrists, American Academy of Child and Adolescent Psychiatry, American Association of Directors of Psychiatric Residency Training, and the Association for Academic Psychiatry.

In contrast to the board examinations, the goal of the PRITE is truly to educate. Not only do trainees receive exact numerical scores referenced to all examinees in that individual's year of training, they also receive copies of the questions and answers, complete with references for further study. Of course, this mandates yearly rewriting of the examination itself, which retains only enough questions from the previous year to allow comparison with examinations given in the years before. Development and administration costs of the examination are borne by the training programs, which pay a flat fee of $80 per resident tested per year. Residents invest only their time.

Some residency training directors report that extreme scores on the PRITE strongly predict outcome of the ABPN Part I examination: “I've hardly ever seen a resident who does extremely well—above the 90th percentile—on the PRITE who has any trouble at all with the boards,” one training director reported. “They hardly even need to study. But I counsel graduating residents who score below 50 percent that they'd better take at least one board review course.”

Since 1996 there has also been a child PRITE, a 50-item test whose purpose and structure are essentially the same as those for the general PRITE examination.

Multiple-Station Examination Format A form of the multiple-station examination, or practical examinations, used for decades in basic science courses, the objective structured clinical examination (OSCE), sparingly reported in the past few years, is a novel attempt to use objective criteria to evaluate trainees' practical clinical skills. Typically, several stations are set up, each involving a clinical problem: a videotaped patient's interview to diagnose, laboratory values to interpret, or an emergency scenario to evaluate. Test results are scored according to criteria the faculty determines in advance. Advantages are that a number of trainees can be evaluated within a short time, evaluations are objective, the material tested is relevant to actual clinical situations, and, in terms of both time and money, the examinations are relatively inexpensive to set up and administer.

MEASURING THE SUCCESS OF EXAMINATIONS

Does interview control really equate to safe practice of psychiatry? How well do the boards (or any other cognitive examination) test what clinical psychiatrists need to know? An analogous question might be, Does success in the 100-yard dash predict a marathon victory?

Over the years, a number of criticisms have been leveled at the board's process. For example, after seven decades there still is no attempt to link residents' performance in training with success on the boards. Eligibility doesn't require training directors to certify that graduates possess skill, knowledge, ethics, or a patient-focused attitude—surviving 4 years of training suffices. And, although it is a principal sponsor of the ABPN, the American Psychiatric Association does not require board certification for full membership. Some writers have alleged that this is because the organization might lose members, money, and political influence; however, no evidence supporting such an accusation has ever been adduced.

Over the years the question of what the board examination predicts has generated far more heat than light. Neither of two important qualities, validity and reliability, has been adequately demonstrated for the psychiatry boards.

Reliability In this context reliability means consistency in a test-retest situation. Although some information about examination reliability is available, much of it was published over a quarter-century ago. ABPN Part I reliability has been rated high on the basis of having a small standard error of the mean (2 to 4 percent); a narrow interval increases the confidence that the examination results are accurate.

Two aspects of reliability as it relates to Part II of the board examination have been addressed: agreement of the two primary examiners and agreement between the videotape and live patient examinations.

Examiner Agreement A 1991 study examined interexaminer consistency for 1422 candidates to evaluate the reliability of the Part II examination. In 67 percent of examinations there was perfect agreement about the candidate's performance. That is, without discussion the two examiners initially each gave the candidate the same Pass, Condition, or Fail grade on either the patient interview or the audiovisual examination. For 26 percent of candidates, there were minor disagreements (i.e., a Condition coupled with either a Pass or a Fail); for only 7 percent of candidates were there major disagreements (a Fail coupled with a Pass). The overall weighted kappa (k) statistic was 0.56, which was judged to show “fair to good agreement beyond chance.” When examiners disagreed, discussion (sometimes involving the senior examiner) usually produced consensus with relative ease.

A study of examination stability drawn from the same data found that in the 7 percent that involved major disagreement (Pass-Fail) between examiners, a thorough review of the candidate's entire performance was usually necessary to reach consensus. Most of these major disagreements turned on the concern of one examiner about something specific the candidate had done or not done. Reporting that the examination process was stable across seasons of the year and different

examination sites, these authors found “no evidence that factors such as examiner fatigue to increasing experience influence interexaminer consistency.”

In a 1990 assessment of the reliability of evaluative judgment, 94 medical school psychiatry department faculty members rated a videotape portraying the first 210 seconds of three separate interviews. The psychiatrists were asked to rate the interviews using a data checklist, a global rating scale, and an estimate of time allotted to various interviewing activities. Only a low level of agreement among raters was found for any of these methods, and this performance did not improve subsequently when videotape segments of twice the length were used.

Finally, in the pilot study that used 18 explicit grading criteria, agreement between raters on both the audiovisual and live patient examinations yielded a broad range of intraclass correlation coefficients (0.37 to 0.77). As of this writing, those authors had not further examined what could indicate a significant opportunity to improve reliability.

Videotape-Patient Agreement Most examineees agree that the videotape examination is a useful learning and testing device. This assessment is clearly endorsed by the ABPN. Several factors are relevant to its utility. It increases the efficiency of the examination by using only half the number of patients that would be needed if every candidate interviewed two patients. Some candidates (and examiners) may find it easier to discuss a videotape, where the data are already provided, than an actual patient, where data collection depends on the vagaries of the clinical interview. In any given half-day, all candidates see the same interview tape, which permits a more uniform, hence more reliable, examination. However, the videotape examination offers no opportunity to evaluate interaction with patients, which probably reduces its overall value as a measurement of clinical competence.

In the early 1980s John Talbott reported data concerning the concordance rate between the live patient and videotape sessions. He defined *nonconcordance* as a Pass coupled with either a Fail or a Condition. *Concordance* was either identical scores on both tests or a Fail coupled with a Condition. (The latter results in an overall failing grade. Because a Pass coupled with a Condition usually results in an overall Pass, this definition yields a conservative estimate of concordance.) Of the 2236 candidates studied, 52 percent had identical grades and 61 percent were concordant, an acceptable rate considering that the two formats test somewhat different skills and carry different weights in the judgment of many examiners. Of the 869 nonconcordant candidates, 303 (35 percent) were highly discordant (they received a Pass coupled with a Fail). A candidate with dissimilar scores was twice as likely to score higher on the videotape session. Possible explanations for these findings: examiners may grade the videotape examination more liberally, residency programs may better prepare their graduates to do well in the cognitive aspects of psychiatry than in the performance skills of patient interviewing, or it may be easier to discuss a patient for whom the data are already provided.

Talbott summarized the distinctions between the two examination formats by noting that the patient interview tests whether “the candidate can set the patient at ease, establish good therapeutic contact, maintain interpersonal relatedness, elicit pertinent information, monitor countertransferential reactions, ask direct and open-ended as well as sympathetic and productive questions, and shift modes as warranted in the interview.” The videotape interview “can obviously ascertain none of these, but instead should concentrate directly on the cognitive aspects of the clinical problems presented (e.g., the mental status, diagnosis, and therapy).”

Limits of Reliability The great strength of the ABPN examination continues to be its weakness: the subjectivity of Part II. Considerable effort has been expended to make it fair and, within the limits of the genre, standardized. Yet from time to time, stories surface that suggest the fragility of its impartiality. These stories do not come solely from erstwhile candidates.

The day before each oral examination, all new examiners and those who have not examined recently are required to attend a half-day course, one purpose of which is to ensure uniform scoring. In one exercise, the novice examiners were divided into groups to view and discuss a videotape of a candidate interviewing a difficult, manic-appearing patient. One group unanimously agreed to pass the candidate. An examiner from that group was later astonished when a friend who had viewed the same video with a different group said, “We all agreed that that candidate should fail.”

Of course, no one can expect all examiners to agree about candidates who appear marginal. But the anecdote suggests how much the power of group thinking can influence even board diplomates who are trying their best to render objective, independent judgments about their fellow psychiatrists. Indeed, for all the efforts to achieve validity, the weight of published evidence has so far demonstrated validity for the board process that, while definite, is modest.

Validity *Validity* is defined here as the ability of an examination to yield an accurate measure of a psychiatrist's clinical adequacy. Several types of validity that have been described are relevant to these examinations, including content, construct, and criterion-based validity.

Content Validity Does the examination evaluate material that experts consider vital for assessing psychiatric capability? The countless hours contributed by many academicians to writing questions would seem to defend a positive answer to this question. In a 1982 survey of 482 psychiatric clinicians and academicians, 92 to 99 percent agreed on which 10 skills were most important for a clinical psychiatrist. In descending order, these were conducting a comprehensive interview, evaluating the need for hospitalization, demonstrating reliability, conscientiousness and integrity, accurate diagnosis, formulating and implementing a treatment plan, assessing potential for suicide and violence, providing supportive psychotherapy, medication use, compassion for patient and family, and recognition of countertransference problems. Although this is exactly the sort of information sought in Part II of the boards, the concept of content validity carries with it the taint of circular reasoning.

Construct Validity A test with construct validity actually measures what it claims to measure. For example, if an examination measures competence in a medical specialty, then test performance should correlate positively with amount of training. This was indeed the finding in a study conducted in 1982 by the American Board of Emergency Medicine. Similar findings are reported yearly for the PRITE. The fact that first-time examinees are far more likely than repeaters to pass either part of the ABPN can be taken to indicate that examination's construct validity.

Criterion Validity In criterion validity a new test is validated against an established measure of supposed great accuracy. When the established measure is made at a future time, as in a follow-up study, it is called *predictive validity*.

A 1975 study of 200 candidates evaluated the predictive validity of Part I. Of candidates who passed Part I on the first try, 88 percent ultimately became board certified, compared with ultimate success by only 12 percent of those who failed their first attempt at Part I. Only about half of all psychiatry candidates passed both parts of the boards on the first try, eliciting this comment from the authors: “This may mean that the exams are deficient, that candidates are insufficiently prepared, or that the exams, despite an admitted need for further improvement, do serve to maintain essential professional standards by not permitting overly easy access to specialty status.”

Comparison of the test scores of 701 physicians who had taken both the 1992 PRITE and 1994 ABPN Part I examination revealed a Pearson correlation of 0.67 between the psychiatry portions of the two examinations. Although the authors considered this correlation “moderate,” one wonders why it wasn't higher. After all, the two examinations used similar methods to test supposedly similar aspects of cognitive learning.

Other Correlations In 1985 Donald Langsley and John Lloyd found a low correlation between performance on Part I and the ratings of training directors, and a 1977 study in Canada failed to show any correlation between a psychiatry in-training evaluation report and other measures of candidate performance such as multiple-choice questions and oral examinations. As with most other cognitive examinations in medicine, extremely limited data validate board diplomates' ability to render care that is better than that given by nondiplomates. The only such mental health study yet reported compared psychotherapy outcome in nine patients with the following evaluations of their therapists: didactic examination, global ratings by trainers, supervisors' ratings based on therapists' recollections of sessions, self-ratings, and independent evaluators' ratings of videotaped sessions. Patient outcome only correlated with the supervisors' ratings, which (as the authors acknowledged) could have been influenced by knowledge of that outcome. This halo effect was subsequently diminished when, after viewing videotapes of their trainees' actual therapy sessions, supervisors revised their overall evaluations downward. It appeared that trainees' personality characteristics and ability to discuss theoretical material could significantly enhance supervisors' opinions of them.

Nonmental health studies also suggest the validity of board certification: (1) lower mortality rates for Medicare populations were found in hospitals that had the highest proportion of board-certified physicians: (2) board-certified surgeons had lower morbidity and mortality rates than surgeons who were not board certified: (3) board-certified emergency specialists performed better in an examination in their specialty: (4) internists who were board certified received higher peer ratings than their colleagues without board status, which may be nothing more than halo effect: and (5) ethics and morals are hard enough to define, let alone measure: However, one study evaluated the possible effect of board certification for physicians disciplined by the Medical Board of the State of California. Board certification was significantly less common ($P < .001$) among physicians against whom any disciplinary measure had been taken (57 percent) than among a comparison group of physicians who had not been disciplined in any way (70 percent). Although the trend for psychiatrists was in the same direction, the difference was not significant (59 vs. 63 percent, P = NS). In this study, physicians who identified their main area of specialization as psychiatry constituted 14 percent of the disciplined physicians,

compared with only 6 percent of the comparison group. Another study found that board certification did not predict medical board discipline for sex-related offenses.

The ability of ABPN certification in general psychiatry to signify quality mental health delivery is often regarded almost as a tenet of faith. With much to recommend it in terms of logic, it remains largely unproved. One review of the evaluation of trainees' problem-solving skills concluded that observation of a single patient-provider encounter was unlikely to predict accurately how that trainee would perform in a different clinical situation. Currently, few data would suggest a more optimistic conclusion about the ability of any examination now employed by psychiatry training programs.

RECERTIFICATION AND THE FUTURE

When the American Board of Family Practice sponsored its first examination in 1969, it issued certificates good for 7 years. The ABFP was only the first; increasingly, time-limited certification is now the norm. Since 1994 the ABPN certificate issued in general psychiatry has been good for 10 years.

The recertification examination in psychiatry is planned as a voluntary, user-friendly, open-book examination to be taken at home. Such a structure, far simpler than the original certifying examination, should boast an extremely high rate of candidate success. Indeed, this must be so; consider the potential alternative, a nightmare of many once-certified psychiatrists who must announce themselves decertified. Who would deny them the right to claim only that they had passed the ABPN some years ago? And what would be the status of such an individual's added qualifications in forensics, geriatrics, or substance abuse psychiatry?

Ideally, certification or recertification for any profession as complicated and high-risk as the care of psychiatric patients requires the evaluation of many qualities. These span a range from highly objective to the most subjective, including knowledge, judgment, skills, and attitudes. Only the first of these can be readily assessed by written examination; the second and third can be evaluated (for a given patient) by observing the candidate conduct an interview with an actual patient, then discuss and defend a formulation and treatment plan for that patient. Although examiners may obtain some indication of attitudes from either a written or oral examination, they will probably learn only as much as the candidate is willing to reveal. What is revealed may apply only to a particular patient or on a given day.

From the experiences and data so far available about the testing of psychiatrists, it appears that whatever methods of testing are used, they present only an imperfect representation of the true qualities any candidate possesses. Because training programs, professional organizations, and examining boards deal with the same relatively small group of individuals, efforts at close collaboration should increasingly be undertaken to meld multiple evaluations of trainees' competence, including residency directors' evaluations, in-residence training examination scores, and written and oral performance on the boards.

SUGGESTED CROSS-REFERENCES

Section 53.1 contains information about the history and current operations of the American Board of Psychiatry and Neurology. The standard psychiatric history and mental status examination are covered in Section 7.1 and Section 7.2. A general discussion of reliability and validity can be found in Section 5.2.

CHAPTER 54. ETHICS AND FORENSIC PSYCHIATRY

54.1 LEGAL ISSUES IN PSYCHIATRY

ROBERT I. SIMON, M.D.

Four overlapping spheres of influence affect psychiatric practice: (1) the psychiatrist's professional, moral, ethical, and legal duties to provide competent care to patients; (2) patients' right of self-determination to receive or reject care; (3) the decisions and directives of courts, legislatures, governmental regulatory agencies, and boards of licensure; and (4) the ethical codes and practices of professional organizations. Psychiatrists must comfortably manage the clinical-legal tensions and conflicts that inevitably arise in everyday practice to practice competently.

In many clinical situations, legal requirements do not necessarily conflict with the provision of good clinical care. Whenever possible, the psychiatrist should attempt to incorporate a legal requirement into the clinical intervention. For example, if a patient is threatening harm to another person, can the psychiatrist enlist the patient in the process of warning and protecting the endangered third party? If not, can the psychiatrist use effective clinical options rather than relying solely upon warning?

Clinical risk management combines the psychiatrist's expertise, a thorough knowledge of the patient, and a clinically useful understanding of the legal requirements governing clinical practice to provide competent clinical care to the patient and (only secondarily) to reduce malpractice risk. For example, keeping adequate patient records is good clinical practice; also, courts generally take the position that what is not recorded is not done. Moreover, without a record, it is much easier for the plaintiff to win a malpractice suit, despite the psychiatrist's provision of good clinical care. For this reason, some liability insurers will not insure psychiatrists who do not keep outpatient records. Ignorance of the law, as it pertains to everyday clinical practice, can unnecessarily limit the psychiatrist's treatment options and lead to destructive defensive practices.

Paradoxically, defensive psychiatry may result in provision of substandard treatment of patients that increases the risk of a malpractice suit. *Defensive psychiatry* refers to any acts or omissions by a psychiatrist that are performed not for the benefit of the patient but rather to avoid malpractice liability or to provide a legal defense against a malpractice claim. Typical examples of defensive psychiatry include unnecessarily hospitalizing a suicidal patient who could be safely treated as an outpatient or refusing to use a neuroleptic such as clozapine (Clozaril) for a chronic, treatment-resistant schizophrenia patient with prominent negative symptoms because of rare reports of agranulocytosis. Such defensive practices invariably harm the therapeutic alliance and may lead to provision of substandard care.

PSYCHIATRIC MALPRACTICE

Psychiatric malpractice is medical malpractice. Medical malpractice is a tort, or civil wrong. It is a noncriminal, noncontract wrong resulting from a physician's negligence that causes injury to a patient under his or her care. Simply put, negligence means doing something that a physician with a duty to care for the patient should not have done, or failing to do something that should have been done as defined by current medical practice. Usually, the standard of care in malpractice cases is established by expert witnesses. The standard of care is also determined by reference to journal articles, professional textbooks and treatises, professional practice guidelines, and ethical practices promulgated by professional organizations.

To prove malpractice, the plaintiff (e.g., patient, family, or estate) must establish by a preponderance of the evidence that (1) a doctor-patient relationship existed that created a *duty* of care, (2) there was a *deviation* from the standard of care, (3) the patient was *damaged*, and (4) the deviation *directly* caused the damage.

These elements of a malpractice claim are sometimes referred to as the 4 Ds (duty, deviation, damage, direct causation). Proof by a preponderance of the evidence as required in a malpractice suit means simply more likely than not. Although the law does not assign a percentage, a preponderance of the evidence is akin to 51 to 49 percent, or just enough evidence to tip the scale one way or the another.

Each of the four elements of a malpractice claim must be present or there can be no finding of liability. For example, a psychiatrist whose negligence is the direct cause of harm to an individual (physical, psychological, or both) is not liable for malpractice if no doctor-patient relationship existed to create a duty of care. Psychiatrists are not likely to be successfully sued if they give negligent advice on a radio program that is harmful to a caller, particularly if a caveat was given to the caller that no doctor-patient relationship was being created. No malpractice claim will be sustained against a psychiatrist if a patient's worsening condition is unrelated to negligent care. Finally, if a psychiatrist treats a patient who is then harmed, no malpractice exists if the psychiatrist did not deviate from the standard of care. In the clozapine example above, proper patient selection, appropriate drug administration, and careful monitoring of the white blood count would likely defeat a malpractice claim if the patient developed agranulocytosis and died.

Not every bad outcome is the result of negligence. Psychiatrists cannot guarantee correct diagnoses and treatments. When the psychiatrist provides due care, mistakes may be made without necessarily incurring liability. Most psychiatric cases are complicated. Psychiatrists make judgment calls when selecting a particular treatment course among the many options that may exist. In hindsight, the decision may prove to be wrong but not a deviation in the standard of care.

This knowledge creates a powerful risk management tool, the risk or benefit note. Recording risk and benefit notes in the patient's chart that carefully describe the rationale for treatments and procedures limits liability exposure. Current clinical judgments that may prove to be wrong later cannot be shown to be negligent when the psychiatrist used reasonable care and documented the reasoning. The law is not interested in punishing errors in judgment per se.

In addition to negligence suits, psychiatrists can be sued for the intentional torts of assault, battery, false imprisonment, defamation, fraud or misrepresentation, invasion of privacy, and intentional infliction of emotional distress. In an intentional tort, wrongdoers are motivated by the intent to harm another person or realize or should have realized that such harm is likely to follow results from their actions. For example, telling a patient that sex with the therapist is therapeutic perpetrates a fraud. Most malpractice policies do not provide coverage for intentional torts. Other legal theories of liability include breach of contract and civil rights violations of the United States Constitution, state constitutions, or federal civil rights statutes.

Malpractice Claims Malpractice claims usually arise when bad outcomes are combined with bad feelings. A good doctor-patient relationship is the most effective natural defense against a lawsuit.

Managed care has transformed the relationship between psychiatrist and patient. Psychiatrists are treating more patients for shorter periods of time. Much less time is available to develop a therapeutic alliance with the patient. Split treatments are common, in which the psychiatrist provides medication and a nonmedical therapist conducts the psychotherapy. The psychiatrist may bear the liability burden in a split-treatment situation.

Psychiatrists are treating more chronic, severely ill patients, frequently as outpatients. Under managed care, the restrictive criteria for psychiatric hospitalization approach the substantive standards for involuntary commitment—severe mental illness and dangerousness. Psychiatrists with large practices and psychiatrists who practice at a number of locations are at higher risk of suit. Supervision of other nonmedical mental health professionals also increases the risk of being sued. Psychiatrists are specializing in geriatric psychopharmacology, dissociative disorders, adolescent addiction medicine, pain management, and adult children of alcoholics, resulting in concentration of risk not usually present in a general psychiatric practice. Some psychiatrists are taking on primary care roles such as managing patients' hypertension and diabetes as well as a variety of acute general medical conditions. The changing health care marketplace also leaves psychiatrists more vulnerable to suits as their relationships with patients are undermined. Many opportunities for bad feelings and bad outcomes exist, including poor

communication, a perceived lack of caring or interest, unavailability during critical events, and perceived unresponsiveness to a patient's particular treatment needs.

The recent malpractice claims experience of the Psychiatrist's Purchasing Group, the liability insurer of members of the American Psychiatric Association, reveals the following approximate frequencies of alleged claims by percentage:

1. Incorrect treatment—33 percent
2. Attempted or completed suicide—20 percent
3. Incorrect diagnosis—11 percent
4. Improper supervision—7 percent
5. Medication error or drug reaction—7 percent
6. Improper commitment—5 percent
7. Breach of confidentiality—4 percent
8. Unnecessary hospitalization—4 percent
9. Undue familiarity—3 percent
10. Libel or slander—2 percent
11. Other (e.g., abandonment, electroconvulsive therapy [ECT], third party injury)—4 percent

The pace of suits alleging the implantation and recovery of false memories of childhood sexual abuse by therapists is accelerating. Borderline patients pose great clinical challenges and associated liability risks. For instance, suicide, violence toward others, the capacity to induce therapist boundary violations, alcohol and drug abuse, impulsive actions, comorbidity, and unstable transferences combined with a tenuous therapeutic alliance all contribute to the increase risk of a bad outcome when treating the borderline patient.

Pursuing a successful claim against a psychiatrist is usually difficult. The plaintiff must prove by a preponderance of the evidence that all four elements necessary to bring a malpractice suit are present. A draw means the plaintiff losses in court. It is comforting that only about 20 to 30 percent of cases brought against psychiatrists are successful.

National Practitioner Data Bank On September 1, 1990, the Health Care Quality Improvement Act of 1986 established the National Practitioner Data Bank. The data bank tracks disciplinary actions, malpractice judgments, and settlements against physicians, dentists, and other health care professionals.

Hospitals, health maintenance organizations, professional societies, state medical boards, and other health care organizations are required to report any disciplinary action taken against providers that lasts more than 30 days. Disciplinary actions include limitation, suspension, or revocation of privileges or professional society membership. Under the Health Care Quality Improvement Act, health care entities and providers are granted immunity from liability when making good-faith peer review reports.

Hospitals must request information from the data bank regarding all physicians applying for staff privileges. Every 2 years, a check of the data bank is required for each physician or other practitioner on the hospital staff. Hospitals that do not comply with these requirements face loss of immunity for professional peer-review activities.

The public does not have access to the data bank. Plaintiffs' attorneys can have access to the data bank only if they can prove that the hospital failed to check the data bank regarding the physician in question. The information obtained can be used only to sue the hospital for negligent credentialing. Physicians can request information from the data bank about their own file at a nominal cost.

Somatic Therapies—Standard of Care The therapeutic use of somatic therapies, including ECT, is evaluated no differently than any other medical or psychiatric procedure in malpractice litigation. The same general standard of ordinary and reasonable care governs whether a psychiatrist's use or failure to use a somatic intervention deviated from the accepted standard of care.

Within the psychiatric profession, no absolute standard protocol exists for the administration of psychotropic medication or ECT. However, clinicians should give careful consideration to the existence of procedures, clinical resources, and practice guidelines, regularly accepted or used by a significant percentage of psychiatrists. For example, the American Psychiatric Association (APA) has published comprehensive findings as task force reports concerning electroconvulsive therapy (1990) and tardive dyskinesia (1992).

Less professional autonomy and flexibility is associated with the use of ECT, which appears to be more rigidly regulated than most other psychiatric treatments. The Joint Commission on Accreditation of Health Care Organizations (JCAHO) considers ECT a *special treatment* procedure, which requires hospitals to have written, informed consent policies concerning its use. In addition, state statutory or regulatory standards, coupled with any specific regulations of a psychiatric facility regarding ECT, could establish a basis for liability, if violated. Nevertheless, no official guidelines should be interpreted as a substitute for sound clinical judgment.

The standard for judging the use and administration of medication, however, is consistent with the more flexible and general “reasonable care” requirement. Use of the *Physicians' Desk Reference* (PDR) to establish or dispute a psychiatrist's pharmacotherapy procedures is a case in point. The PDR is a commercially distributed, privately published reference of medication products used in the United States. The Food and Drug Administration (FDA) requires that drug manufacturers report their official package inserts in the PDR. Although a number of courts have cited the PDR as a credible source of information about medication usage by the medical profession, it does not, by itself, establish the standard of care. Instead, the PDR can be used as one piece of evidence to establish the standard of care in a particular situation.

Most courts now follow the ruling in *Ramon v Farr*, holding that drug inserts alone do not set the standard of care. They are only one factor to be considered, in addition to previous personal experience, the scientific literature, expert testimony, approvals in other countries, and other pertinent factors. The FDA, the PDR, or any other reference source cannot substitute for the psychiatrist's clinical judgment. A substantial body of scientific literature that justifies the clinician's treatment is vastly more persuasive. Similarly, in managed care settings, psychiatrists must vigorously resist efforts to restrict their choice of drugs by predetermined, limited formularies, nor should the choice of generic or proprietary drugs or drug dosages be dictated by others. The treating psychiatrist must determine the specific drug to be prescribed according to the clinical needs of the patient.

Courts recognize the importance of professional judgment and allow psychiatrists and other medical specialists wide latitude in explaining any special diagnostic or treatment considerations that guided their decision making. For example, research in the pharmacological treatment of aggression shows a variety of potentially useful drug therapies—some considered experimental or cutting edge. However, no drug is specifically approved by the FDA for the treatment of aggression.

The courts will consider the fact that rarely does only one treatment choice exist. Moreover, evidence that a treatment procedure is used by at least a respectable minority of professionals in the field could help establish it as a reasonable professional practice. Practice guidelines recommend a variety of treatment approaches but defer to the clinical judgment of the practitioner about the ultimate treatment decision.

The standard of care associated with the use of a somatic therapy to treat a psychiatric patient, at a minimum, should include some variation of the following:

A. **Before treatment**
    1. Complete clinical history (medical, psychiatric)
    2. Current physical examination, when indicated, (performed by the patient's physician or the psychiatrist)
    3. Ordering of necessary laboratory tests and review of all test results
    4. Disclosure of sufficient information to obtain informed consent
    5. Thorough documentation of all decisions, informed consent, procedures, and treatments
B. **During treatment**
    1. Careful monitoring of the patient's response to treatment, including appropriate follow-up and laboratory testing
    2. Prompt adjustments in medications or treatment strategies, as needed
    3. Obtaining a renewed informed consent when treatment is substantially altered or a new treatment is initiated.

Depending on the patient, different treatment interventions require different preparations and precautions. Final treatment decisions rest upon the clinician's medical judgment and a working knowledge of legal issues governing informed consent and patients' rights to refuse treatment.

Somatic Therapies—Legal Liabilities Although no thoroughly reliable data on malpractice claims have been published, lawsuits involving medications appear to constitute a significant share of the litigation filed against psychiatrists. The previously cited malpractice claims experience of the APA reveals that medication error and drug reactions accounted for 7 percent of all claims. Incorrect treatment was the largest malpractice claim category (33 percent). Most malpractice cases fall into one of four categories: suicide, medications, sex, and what some defense attorneys cynically described as “flavor of the month.”

A variety of omissions and poor drug treatment practices commonly result in malpractice actions against psychiatrists or other physicians. The discussion below provides ways to identify problem areas associated with medication treatment.

Failure to Evaluate Properly Sound clinical practice requires that the patient be properly evaluated before any somatic treatment is started. At the very minimum, the psychiatrist should obtain a clinical history and perform a mental status examination. A recent medical examination or continuing medical follow-up by the patient's physician may suffice in lieu of the physical examination or the patient may be referred for a medical evaluation, when indicated.

A number of lawsuits have resulted from the failure to evaluate a patient properly before prescribing psychotropic medication. As a result of this omission, a patient's condition may be misdiagnosed, remain untreated, or worsen. Also, the patient may be exposed to unnecessary drug adverse effects and risks. In managed care settings, psychiatrists must be careful to spend enough time to do a competent evaluation, particularly in split-treatment arrangements.

Failure to Monitor or Supervise Probably the most common act of negligence associated with pharmacotherapy is the failure to supervise the patient's progress while taking the medication, including monitoring the patient for adverse effects. Monitoring may require laboratory testing, physical examination, and medical referral. Serum drug concentrations can be determined for a number of psychotropic medications. The primary indications for obtaining drug concentrations include assessing the therapeutic and toxic levels of medication and patient compliance with treatment. The use of carbamazapine (Tegretol), valproic acid (Depakene), and clozapine requires careful monitoring of the hematopoietic system and the liver. Failing to properly supervise patients taking psychotropic medications may unnecessarily subject them to harmful adverse effects and can delay a change to more effective treatment. A malpractice action may result if a patient is harmed by these omissions.

The question is often asked: How frequently should patients be seen for medication follow-up? The answer is that patients should be seen according to their clinical needs. No stock answer about the frequency of visits can be given. The longer the time interval between visits, however, the greater the likelihood of adverse drug reactions and clinical developments. Patients taking medications should probably not go beyond 6 months for follow-up visits. Managed care policies that do not reimburse for frequent follow-up appointments may result in psychiatrists prescribing large amounts of medications. The psychiatrist is duty bound to provide appropriate treatment to the patient quite apart from managed care or other payment policies.

Negligent Prescription Practices The selection of a medication, initial dosage, form of administration, and other related procedures are all decisions left to the clinical discretion of the treating psychiatrist. The law recognizes that the treating psychiatrist is in the best position to “know the patient” and to determine the best course of treatment under the circumstances. Accordingly, a psychiatrist's prescription practices will be evaluated by a reasonable practice standard. In prescribing psychotropic medication, psychiatrists are required to conform their procedures and decision making with those ordinarily practiced by other psychiatrists under similar circumstances.

Negligent prescription practices usually include exceeding recommended dosages and then failing to adjust the medication level to therapeutic levels, unreasonable mixing of drugs, prescribing medication that is not indicated, prescribing too many drugs at one time, and failing to disclose medication effects. Elderly patients frequently take a variety of drugs prescribed by different physicians. Multiple psychotropic medications must be prescribed with special care because of possible harmful interactions and adverse effects.

Psychiatrists who prescribe medications must explain the diagnosis, risks, and benefits of the drug within reason and as circumstances permit (Table 54.1-1). Obtaining competent informed consent may be problematic if a psychiatric patient has diminished cognitive capacity because of mental illness or chronic brain impairment; a substitute healthcare decision maker may need to provide consent.

Although there exists no consistently accepted standard for information disclosure for any given medical or psychiatric situation, as a rule of thumb, five areas of information are generally provided:

1. Diagnosis—description of the condition or problem
2. Treatment—nature and purpose of proposed treatment
3. Consequences—risks and benefits of the proposed treatment
4. Alternatives—viable alternatives to the proposed treatment including risks and benefits
5. Prognosis—projected outcome with and without treatment

Table 54.1-1 Informed Consent: Reasonable Information to be Disclosed

Informed consent should be obtained each time a medication is changed and a new drug is introduced. If patients are injured because they were not properly informed of the risks and consequences of taking a medication, sufficient grounds may exist for a malpractice action.

Other Other areas of negligence involving medication that have resulted in malpractice actions include failure to treat adverse effects that have or should have been recognized; failure to monitor a patient's compliance with prescription limits; failure to prescribe medication or appropriate levels of medication according to the treatment needs of the patient; prescribing addictive drugs to vulnerable patients; failure to refer a patient for consultation or treatment by a specialist, and negligent withdrawal of medication treatment.

Split Treatment The following clinical vignette illustrates a common problem with split treatment in managed care settings.

> A psychiatrist provided medications for a depressed 43-year-old woman. A master's level counselor saw the patient for outpatient psychotherapy. The psychiatrist saw the patient for 20 minutes during the initial evaluation and prescribed a tricyclic drug. Tricyclic drugs have proved effective in alleviating the patient's depressions. As required by the managed care arrangement, the patient was prescribed enough drugs for follow-up in 3 months. The psychiatrist's initial diagnosis was recurrent major depression. The patient denied suicidal ideation. Appetite and sleep were markedly diminished. The patient had a long history of recurrent depression with suicide attempts. The patient's borderline personality disorder was not diagnosed. No further discussions were held after the initial discussion with the counselor. The counselor, who saw the patient once a week for 30 minutes, was unaware of the borderline personality disorder. The patient also had a chronic alcohol problem. Within 3 weeks, after a failed romantic relationship, the patient stopped taking her antidepressant medication during an alcohol binge. Her depression worsened rapidly. The patient committed suicide with an overdose of antidepressant drugs. The counselor and psychiatrist were sued for negligent diagnosis and treatment.

Psychiatrists must do an adequate evaluation, obtain prior medical records, and understand that there is no such thing as a partial patient. Split treatments are potential malpractice traps because patients can “fall between the cracks” of fragmented care. The psychiatrist retains full responsibility for the patient's care in a split treatment situation. This does not preempt the responsibility of the other mental health professionals involved in the patient's treatment. Section V, annotation 3 of the *Principles of Medical Ethics with Annotations Especially Applicable to Psychiatry* states: “When the psychiatrist assumes a collaborative or supervisory role with

another mental health worker, he/she must expend sufficient time to assure that proper care is given."

In managed care or other settings, a marginalized role of merely prescribing medication apart from a working doctor-patient relationship does not meet generally accepted standards of good clinical care. The psychiatrist must be more than just a medication technician. Fragmented care in which the psychiatrist only dispenses medication while remaining uninformed about the patient's overall clinical status, constitutes substandard treatment that may lead to a malpractice action. At a minimum, such a practice diminishes the efficacy of the drug treatment itself or may even lead to the patient's failure to take the prescribed medication.

Split-treatment situations require that the psychiatrist remain fully informed of the patient's clinical status as well as the nature and quality of treatment the patient is receiving from the nonmedical therapist. In a collaborative relationship, the responsibility for the patient's care is shared according to the qualifications and limitations of each discipline. The responsibilities of each discipline do not diminish those of the other disciplines. Patients should be informed of the separate responsibilities of each discipline. The psychiatrist and the nonmedical therapist must periodically evaluate the patient's clinical condition and requirements to determine whether the collaboration should continue. Upon termination of the collaborative relationship, both treaters should inform the patient either separately or jointly. In split treatments, if the nonmedical therapist is sued, the collaborating psychiatrist will likely be sued, and vice versa.

Psychiatrists who prescribe medications in a split-treatment arrangement should be able to hospitalize a patient, if that should become necessary. If the psychiatrist does not have admitting privileges, prearrangements should be made with other psychiatrists who can hospitalize patients if emergencies arise. Split treatment is increasingly used by managed care companies and is a potential malpractice minefield.

Tardive Dyskinesia It is estimated that at least 10 to 20 percent of patients and perhaps as high as 50 percent of patients treated with neuroleptic drugs for more than 1 year exhibit some probable tardive dyskinesia. These figures are even higher for elderly patients. Despite the possibility for a large number of tardive dyskinesia–related suits, relatively few psychiatrists have been sued. In addition, patients who develop tardive dyskinesia may not have the physical energy and psychological motivation to pursue litigation.

Allegations of negligence involving tardive dyskinesia are based on a failure to evaluate a patient properly, a failure to obtain informed consent, a negligent diagnosis of a patient's condition, and a failure to monitor.

Most of the above-noted allegations of negligence were claimed in the landmark case, *Clites v State*. The plaintiff was a mentally retarded man who was institutionalized from age 11 and treated with major tranquilizers from age 18 to 23. After tardive dyskinesia was diagnosed at age 23, the plaintiff's family sued. The family claimed that the defendants negligently prescribed medication, did not inform the patient of the possibility of developing tardive dyskinesia, and failed to monitor and subsequently treat the patient for the adverse effects of the drugs. The jury found for the plaintiff and awarded damages in the amount of $760,165. This award was affirmed on appeal.

The appellate court ruled that the defendants were negligent and deviated from the standards of the "industry." Among the "deviations" the court noted were the failure to conduct regular physical examinations and laboratory tests, the failure to intervene at the first signs of tardive dyskinesia, the inappropriate use of multiple medications at the same time, the use of drugs for convenience (e.g., "behavior management") rather than for therapy, and the failure to obtain the plaintiff's informed consent.

Electroconvulsive Therapy Although many psychiatrists believe that ECT is a viable treatment for carefully selected patients with certain mental disorders, it has been estimated that only 3 to 5 percent of all psychiatric inpatients in the United States receive ECT. Thus, the potential number of legal actions alleging negligence associated with ECT is low. Nevertheless, lawsuits involving ECT are occasionally brought against psychiatrists. ECT-related injuries have occurred in a variety of circumstances in which negligence has been alleged. These cases fall into three groups: pretreatment, treatment, and posttreatment.

The APA Task Force on ECT recommends the following pretreatment procedures: (1) a psychiatric history and examination to evaluate the indications for ECT, (2) a medical examination to determine risk factors, (3) anesthesia evaluation, (4) written informed consent, and (5) an evaluation by a physician privileged to administer ECT. These recommendations do not define, in any absolute sense, the standard of care for ECT. Nonetheless, the task force report will likely be proffered as evidence of the standard of care in malpractice suits involving ECT. Official treatment guidelines must not be considered a substitute for the psychiatrist's sound clinical judgment, but failure to adequately conduct pretreatment procedures could endanger the welfare of the patient and secondarily result in a lawsuit for negligence.

Cases of ECT-related injuries in which negligence has occurred in the actual treatment process include (1) failure to use a muscle relaxant to reduce the chance of a bone fracture, (2) negligent administration of the procedure, and (3) failure to conduct an evaluation of the patient including the use of X-rays before initiating or continuing treatment.

Patients commonly experience certain adverse effects such as temporary confusion, disorientation, and memory loss following ECT. Sound clinical practice requires that psychiatrists provide reasonable posttreatment care and safeguards. Courts have held that the failure to properly attend to a patient for a period of time following ECT can result in malpractice liability. Posttreatment circumstances in which negligence may be claimed include (1) failure to evaluate complaints of pain or discomfort following treatment, (2) failure to evaluate a patient's condition before resuming ECT treatments, (3) failure to monitor a patient properly to prevent falls, and (4) failure to supervise a patient properly who had been injured as a result of ECT.

ECT-related law suits today are infrequent and do not represent a significant litigation problem for psychiatrists. Administering ECT is no longer associated with increased liability insurance premiums. However, recent developments in right-to-refuse-treatment law and increased statutory regulation of intrusive therapies ensure continued close legal scrutiny of ECT.

Suicidal Patients Psychiatrists are more likely to be sued when their patients commit suicide, particularly when psychiatric inpatients kill themselves. Psychiatrists are assumed to have more control over inpatients, making the suicides preventable.

The evaluation of suicide risk is one of the most complex, dauntingly difficult clinical tasks in psychiatry. Suicide is a rare event. In our current state of knowledge, clinicians cannot accurately predict when or if a patient will commit suicide. No professional standards exist for predicting who will or will not commit suicide. Professional standards do exist for assessing suicide risk, but at best, only the degree of suicide risk can be judged clinically following a comprehensive psychiatric assessment.

A variety of clinically useful assessment approaches are available to the practitioner. Suicide risk assessments are here-and-now evaluations, whose usefulness erodes quickly. Psychiatrists should frequently assess the risk of violence and update risk assessments at significant clinical junctures (e.g., room and ward changes, increased privileges, off-ward passes, discharge). Assessing suicide risk has been compared with weather forecasting. Short-term assessments (24 to 48 hours) are more accurate than longer-term assessments. In the short term, factors that influence future patient behaviors can be identified more precisely.

Assessing suicide risk involves 3 steps: (1) identifying patients at suicide risk, (2) assessing the overall suicide risk after evaluating specific suicide risk factors, and (3) providing treatment interventions that have a logical nexus to the overall suicide risk assessment.

Suicide risk evaluation should be standard practice with all patients, even if they do not exhibit overt suicidal symptoms. A significant number of patients with major affective disorders who commit suicide do not initially display suicidal ideation. Simply asking patients if they are suicidal and obtaining a "no harm contract" is insufficient. A layman could just as easily ask these same questions. Especially with new patients, there is no credible basis for relying upon such reassurances. The clinician's expertise is in taking an adequate psychiatric history and performing and recording a competent suicide risk assessment to direct appropriate clinical interventions.

A review of the case law on suicide reveals that certain affirmative precautions should be taken with a suspected or confirmed suicidal patient. For example, failing to perform a reasonable assessment of a suicidal patient's risk for suicide or implement an appropriate precautionary plan will likely render a practitioner liable. The law tends to assume that suicide is preventable if it is foreseeable. Courts closely scrutinize suicide cases to determine if a patient's suicide was foreseeable. *Foreseeability* is a deliberately vague legal term that has no comparable clinical counterpart, a common-sense rather than a scientific construct. It does not (and should not) imply that clinicians can predict suicide. Foreseeability should not be confused with preventability, however. In hindsight, many suicides seem preventable that were clearly not foreseeable. When considering treatment interventions for the suicidal patient, the clinician must assess both risks and benefits. The clinician

who is guided only by risk assessment is practicing defensive psychiatry to the possible detriment of the patient's care.

When making decisions about off-ward privileges, passes, and discharges, psychiatrists should record the risk-benefit assessment that guides their judgment. The risks and benefits of greater freedom must be weighed against those of continued hospitalization. This is both good clinical practice and sound clinical risk management. If a liability claim arises later, carefully documented risk-benefit assessments that inform the court about the clinician's contemporaneous decision-making process can provide the best malpractice defense.

Suicide Prevention Contracts Suicide prevention, or no-harm, contracts (oral or written) between therapists and patients are designed to encourage patients to call for help rather than commit suicide. These contracts have no legal authority. The danger is that the psychiatrist will place too great a reliance upon the contract and be falsely reassured that the patient is safe. Suicide prevention pacts between psychiatrists and patients should never replace an adequate assessment of suicide risk.

Defenses There are a number of legal defenses against a suicide malpractice claim. An open door policy that allows patients more therapeutic freedom of movement has produced a split in court decisions. Courts consider the specific facts of the case and the hospital staff's reasonableness in applying open door policies. However, juries and judges have difficulty giving credence to an abstract treatment idea when confronted with a dead patient.

The doctrine of sovereign or governmental immunity may bar by statute a finding of legal liability against a state or federal facility.

A suicide may be caused by factors unrelated to the psychiatrist's treatment of the patient. For example, a borderline patient may experience an overwhelming rejection between sessions and commit suicide without first attempting to contact the psychiatrist. The unforeseen rejection, a superseding, intervening variable, may have precipitated the suicide, not any negligent treatment.

The best-judgement defense can often be successfully argued when the suicidal patient was properly assessed and treated. In essence, the defense asserts that the patient committed suicide despite receiving reasonable care. The following clinical vignette illustrates the importance of conducting adequate suicide risk assessments.

A 33-year-old, single male patient committed suicide while on a 4-hour therapeutic pass from the hospital prior to anticipated discharge. The patient was hospitalized with a diagnosis of major depression, single episode and suicidal ideation. The managed care company authorized 2 weeks of inpatient treatment. The patient steadfastly denied suicidal thoughts or impulses after admission. He experienced moderate-to-severe depression, anhedonia, global insomnia, hopelessness, agitation, and loss of appetite. The patient signed a suicide prevention contract, promising to inform the psychiatrist or staff immediately of any suicidal ideation or impulses. After antidepressant treatment was started, the patient's energy level improved.

The psychiatrist and the hospital were sued by the patient's parents for wrongful death. In court, the plaintiff's expert testified that a suicide risk assessment would have determined that the patient was a significant suicide risk and that no pass should have been issued. The expert found no evidence in the psychiatric record that a formal suicide risk assessment was conducted before the pass was issued. She opined that not recording a suicide risk assessment was a violation of the standard of care. She further testified that the patient was at greater risk of suicide after administration of an antidepressant drug because the patient now had more energy to carry out his suicidal intent. Finally, the expert opined that the psychiatrist should not have relied on a no harm contract to prevent suicide in lieu of performing a suicide risk assessment.

The defendant psychiatrist testified that the patient's willingness to sign a no harm contract indicated the presence of a therapeutic alliance and the motivation to get well. The psychiatrist further testified that he had performed a formal suicide risk assessment that indicated a low-to-moderate suicide risk. It was an oversight on his part not to record the suicide risk assessment. In the psychiatrist's judgment, the therapeutic benefit of a pass outweighed the low-to-moderate suicidal risk.

The defense psychiatric expert testified that the psychiatrist met the standard of care by assessing the risk of suicide and weighing the suicide risk against the therapeutic benefits of a pass. The expert noted that the psychiatrist had not placed total reliance on the no-harm contract, but had used it appropriately to assess the working alliance with the patient. On cross examination, the defense expert admitted that the suicide risk assessments should have been recorded, but he felt that this was not the cause of the patient's suicide. The expert concluded by stating that a patient who is intent upon committing suicide cannot be stopped from doing so by the psychiatrist or the hospital, even if the patient is “totally locked up.”

The jury found for the plaintiffs, awarding $350,000 in monetary damages. When the jurors were polled by the defense attorney immediately after rendering the verdict, they indicated that a lack of documentation of the psychiatrist's decision-making process prevented their giving credibility to his testimony.

Violent Patients Psychiatrists who treat violent or potentially violent patients may be sued for failure to control aggressive outpatients and for the discharge of violent inpatients. Psychiatrists may be sued for failing to protect society from the violent acts of their patients if it was reasonable for the psychiatrist to have known about the patient's violent tendencies and if the psychiatrist could have done something that could have safeguarded the public. In the landmark case, *Tarasoff v Regents of the University of California*, the California Supreme Court ruled that mental health professionals have a duty to protect identifiable, endangered third parties from imminent threats of serious harm made by their outpatients. Since then, courts and state legislatures have increasingly held psychiatrists to a fictional standard of having to predict the future behavior (dangerousness) of their potentially violent patients. Research has consistently demonstrated that psychiatrists cannot predict future violence with any dependable accuracy.

The duty to protect patients and endangered third parties should be considered primarily a professional and moral obligation and, only secondarily, a legal duty. Most psychiatrists acted to protect both their patients and threatened others from violence long before *Tarasoff*.

If a patient threatens harm to another person, most states require that the psychiatrist perform some intervention that might prevent the harm from occurring. In states with duty-to-warn statutes, the options available to psychiatrists and psychotherapists are defined by law. In states offering no such guidance, health care providers are required to use the clinical judgment that will protect endangered third persons. Typically, a variety of options to warn and protect are clinically and legally available, including voluntary hospitalization, involuntary hospitalization (if civil commitment requirements are met), warning the intended victim of the threat, notifying the police, adjusting medication, and seeing the patient more frequently. The duty to protect allows the psychiatrist to consider a number of clinical options. Warning others of danger, by itself, is usually insufficient. Psychiatrists should consider the *Tarasoff* duty to be a national standard of care, even if they practice in states that do not have a duty to warn and protect.

A number of states have enacted immunity statutes limiting the responsibility of therapists for their patients' violent acts. Most of these statutes provide immunity for disclosures made to fulfill the duty to protect. The number of states passing such statutes increases every year. Definitions vary considerably concerning when the duty arises and how to discharge it. Most statutes require an actual threat made against a clearly identifiable victim before a duty to warn or protect arises. Most often, discharging the duty involves warning the intended victim and law enforcement authorities. Unfortunately, the duty to warn rather than protect is more often relied upon by immunity statutes. Thus, the duty to warn may be defensively invoked as a risk-management tool. Sometimes, warning by itself may induce violence. Thus immunity statutes may encourage reflexive rather than reflective patient management.

If a patient gives the psychiatrist good reason to believe that a warning should be issued to an endangered third party, the confidentiality of the communication that gave rise to the warning may be lost. The warning of endangered third parties has resulted in psychiatrists being compelled to testify in criminal cases.

The *Tarasoff* duty was originally applied to the outpatient setting. However, the same legal duty to protect individuals and society from harm by mental patients arises concerning the release of violent patients. The scope of the duty to warn is usually narrower than the duty not to release a violent patient. In cases involving failure to warn and protect an endangered third party, the violence was serious and imminent, and the victim was usually identifiable and foreseeable. The duty not to release a violent patient has a broader scope because these patients often do not express specific threats toward persons or groups and thus pose a threat to the general public. In release cases, courts have extended the therapist's duty beyond that owed to readily identifiable victims. The number of malpractice suits alleging negligent release is at least five to six times the number of outpatient cases alleging a *Tarasoff* duty.

The physician has a general duty to protect other members of society. This duty is not new to the law. The doctor-patient relationship often gives the physician insider

information about the potential for violence that no one else possesses. The duty to warn and protect arises from the concept of latent dangers to which the physician is privy but not the endangered persons. To practitioners, this reasoning makes more clinical sense than the legal argument of a special relationship between doctor and patient creating the duty to protect endangered persons.

Psychiatrists should not discharge patients without arranging for adequate aftercare. Doomed-to-fail discharges must be avoided by considering what is different in the patient's clinical condition and situational circumstances. The patient's willingness to cooperate with the psychiatrist is critical to follow-up treatment. The psychiatrist should structure the follow-up visits to encourage compliance. Scheduling the patient as soon as possible for appropriate treatment programs that are readily accessible facilitates patient adherence. A study of Veterans Affairs (VA) outpatient referrals showed that when inpatients were referred to the VA mental health clinic, approximately 50 percent failed to keep their first appointments. However, the psychiatrist's ability to ensure follow-up care is limited. Most patients retain the right to refuse treatment after discharge. This must be acknowledged by both the psychiatric and legal communities.

The treatment of psychiatric inpatients has changed dramatically in the managed care era. Most psychiatric units, particularly those in general hospitals, have become short-stay, acute-care, psychiatric facilities. Under managed care, only the sickest, most acute patients are admitted, and then only for short-term hospitalization. Strict scrutiny by utilization reviewers ensures that these patients are hospitalized for brief periods. The purpose of hospitalization is crisis-intervention management, safety, and stabilization of the patient. Treatment is being provided by a variety of mental health professionals, yet the psychiatrist often bears the burden of liability for treatments gone awry. Little opportunity is usually available during the hospital stay to develop a therapeutic alliance with patients. The psychiatrist's stock-in-trade, the ability to communicate with patients, is severely curtailed. All these factors greatly increase the risk for a malpractice suit alleging premature or negligent discharge of potentially violent patients. Managed care restrictions on length of hospital stay must not be allowed to interfere with clinically based decisions indicating a need for continued hospitalization. The American Medical Association has issued guidelines for discharging inpatients, entitled “Evidence-Based Principles of Discharge and Discharge Criteria.”

In either outpatient or inpatient settings, psychiatrists will likely meet the standard of care if they reasonably assess the patient's potential risk for violence, which then directs the choice of clinical interventions. For example, a history of past violence should alert the clinician to future violence. Professional standards are described in the psychiatric literature for the assessment of the risk of violence. However, no standard of care exists for the prediction of individual violent behavior. Psychiatrists should assess the risk of violence frequently, updating risk assessments at significant clinical junctures (e.g., room and ward changes, increased privileges, off-ward passes, discharge). Assessing the risk of violence is a here-and-now determination. Probability risk assessments of violence become progressively less accurate beyond the immediate short term (e.g., 24 to 48 hours). A risk-benefit assessment should be conducted and recorded that lays out the clinician's reasoning both for and against issuing a pass or discharge.

A psychiatrist evaluated a 43-year-old man and made the diagnosis of delusional disorder, jealousy type, after obtaining the following history:

Approximately 6 months before the evaluation, the patient began to believe that his wife was having an affair with her boss. This idea grew into a conviction. The wife vehemently denied his accusations and demanded that the patient see a psychiatrist after he began making threats against her boss. He acquiesced, though he felt there was nothing wrong with him.

After making the diagnosis, the psychiatrist recommended continued outpatient visits and medication and discussed the possibility of hospitalization. Involuntary hospitalization was not considered because of a requirement of a recent overt violent act in the commitment statute. The psychiatrist assessed the risk of violence as high. The patient refused to come back for any more visits, saying he would make no further threats. There is no history of prior violence. When the psychiatrist informed the patient that she had a duty to warn the boss of the danger, the patient stated, “Go ahead, he knows anyway.” As required by state law, the psychiatrist called the threatened individual and informed him of the patient's threats and high risk for violence. The boss dismissed the threats “as so much nonsense.” In addition, the psychiatrist informed the law enforcement authorities.

Six weeks later, the psychiatrist reads in the paper that the patient shot and killed the boss, his wife, and himself. A year later, the psychiatrist was sued by the boss's family for a failure to warn and protect the murdered individual. In the suit, the estate claimed that the psychiatrist neither stressed the seriousness of the threat sufficiently nor properly assessed the patient for involuntary hospitalization. The complaint stated that a medical certification for involuntary hospitalization should have been obtained by the psychiatrist so that the court could decide on the appropriateness of the petition. Her records clearly documented the diagnosis, treatment recommendations, the serious warning to the boss, and the informing of law enforcement authorities.

The state statute governing *Tarasoff*-type cases contained an immunity provision that precluded the imposition of legal liability against mental health professionals when endangered third parties are warned of potential violence threatened by a patient and the police are also informed. The lawsuit was dismissed by the court on a motion for summary judgment made by the psychiatrist's attorney. The lawsuit was precluded by the state immunity statute. The claim that the psychiatrist did not consider involuntary hospitalization was also dismissed because the state's commitment statute required an overt act of violence within 30 days of an evaluation. Thus, the patient did not meet substantive criteria for civil commitment.

A state superior court jury awarded Wendell Williamson, a former University of North Carolina law student, $500,000, holding Myron B. Liptzin liable for negligent treatment that resulted in his former patient's violent acts on January 26, 1996, after treatment ended on May 25, 1994. In the criminal trial, Williamson was found not guilty by reason of insanity in the random shooting murders of 2 men and the serious injury of a police officer near the campus. Williamson was institutionalized with a diagnosis of paranoid schizophrenia.

In the civil suit, the patient alleged that Liptzin, then director of student health psychiatric services, failed to correctly diagnose and explain the seriousness of his illness. Despite improvement with antipsychotic medication while under Liptzin's care, the plaintiff claimed that his treatment was mismanaged by Liptzin not properly arranging for a referral to another psychiatrist following Liptzin's retiement. Liptzin countered that he encouraged Williamson to attend a mental health clinic during the summer; however, he did not make a specific referral. He had given the 26-year-old Williamson a 30-day supply of antipsychotic medication and urged the patient to have his family physician refill the medication if he did not contact a psychiatrist. After discharge, Williamson stopped taking his medication. A judge upheld the $500,000 jury award but the decision is being appealed.

The patient did not appear violent nor make any violent threats at the time of termination. Psychiatrists and other mental health professionals cannot provide society with guarantees of saftey either during or after treatment. Most patients retain the right to refuse treatment and to stop their medications. Violent behaviors are the result of complex, dynamic interactions among a variety of clinical, personality, social, and environmental factors that vary across time and situations. The Liptzin result is unprecedented. It is doubtful that this case will establish a new standard of care for the termination of patients.

RIGHTS OF PATIENTS

Involuntary Hospitalization An individual may be involuntarily hospitalized only if certain statutorily mandated criteria are met. Three fundamental substantive criteria serve as the foundation for all statutory commitment requirements: the individual must be (1) mentally ill, (2) dangerous to self or others, or (3) unable to provide for one's basic needs (gravely disabled). Each state determines which criteria are required and defines what each means. Terms such as “mentally ill” are often loosely described, which shifts the responsibility for proper definition to the clinical judgment of the petitioner.

In addition to persons with mental illness, a number of states have enacted legislation that provides for involuntary hospitalization of three other distinct groups: developmentally disabled (mentally retarded), substance addicts (alcohol, drugs), and mentally disabled minors. Special commitment provisions usually govern the requirements for admission and discharge of mentally disabled minors in addition to numerous due process rights afforded these individuals.

Currently, most mentally ill patients are being treated as outpatients. Most involuntary hospitalizations are for short periods. Involuntary hospitalization of psychiatric patients usually occurs when violent behavior threatens to erupt toward self or others and when patients become unable to care for themselves. These patients often have mental disorders that readily meet the substantive criteria for involuntary hospitalization. Violent individuals who do not suffer from a mental disorder are not candidates for involuntary hospitalization; they are the responsibility of law enforcement authorities.

Clinicians do not actually commit patients. Civil commitment comes under the sole jurisdiction of courts or other, quasi-judicial bodies. The psychiatrist initiates medical certification that brings the patient before the court, usually after a brief period of evaluation. In seeking medical certification the psychiatrist must be guided

by the treatment needs of the patient and the protection of the patient or others who may be endangered by the patient.

The most common type of lawsuit for involuntary hospitalization alleges that a psychiatrist failed to act in good faith and to adhere to statutory requirements, resulting in a wrongful commitment. Generally, these lawsuits are brought under the theory of false imprisonment. Other areas of liability for alleged wrongful commitment include assault and battery, malicious prosecution, abuse of authority, and intentional infliction of emotional distress.

In most states, psychiatrists are granted qualified immunity from liability if they use reasonable professional judgment and act in good faith when petitioning for commitment. The psychiatrist may be sued if evidence exists of willful, blatant, or gross failure to adhere to statutorily defined commitment procedures.

Most states recognize the right of inpatients to refuse treatment. Even though the patient is involuntarily hospitalized, the hospitalization does not negate a presumption of competence. In most states, involuntarily hospitalized patients who refuse medication require a separate court hearing for adjudication of incompetence and the provision of substituted consent by the court. Recently, persons hospitalized under criminal commitment have been accorded a qualified right to refuse treatment. The courts have found that patients' constitutional right to due process is “adequately protected by the exercise of professional judgment” within the medical peer review process of the institution.

Hospitalized patients possess other rights. Patients possess rights of visitation, although these rights can be temporarily suspended for proper cause relating to the patient's care and treatment. Free communication by hospitalized patients through mail, telephone, or visitors is considered a right, unless protection of the patient or others requires supervision of communications. The right to privacy includes allowing patients to have secure locker space, private toilet and shower facilities, and minimum square footage of floor space. Confidentiality is also protected. Economic rights include the right to have and spend money and to handle one's own financial affairs responsibly. In most jurisdictions, involuntarily hospitalized patients do not lose their civil rights, such as the right to manage their own money. Hospitalized patients must be paid for their work in certain jurisdictions unless it is truly therapeutic labor (i.e., work not connected with maintenance of the hospital). “Patient rights” are not absolute and often must be tempered by the clinical judgment of the mental health professional. Inevitably, disputes over perceived or real violations of patients' rights arise. In some jurisdictions, a civil rights officer or ombudsman is mandated by statute to mediate these disputes.

Managed Care Psychiatrists have certain responsibilities toward patients treated in managed care settings, including the responsibilities to disclose all treatment options, to exercise appeal rights, to continue emergency treatment, and to cooperate reasonably with utilization reviewers.

Responsibility to Disclose Psychiatrists have a continuing responsibility to the patient to obtain informed consent for treatments or procedures. All treatment options should be fully disclosed, even those not covered under the terms of a managed care plan. A number of states are enacting legislation making gag rules that limit information about treatment provided to patients under managed care illegal. Managed care organizations cannot require affiliated physicians to limit or withhold advice about treatment options to Medicare beneficiaries, even if those treatments are not covered. Congress has banned gag rules that prohibit health care providers from advising Medicare beneficiaries who choose the health maintenance organization (HMO) option about medical treatments that the HMO does not cover.

Responsibility to Appeal The American Medical Association Council on Ethical and Judicial Affairs states that physicians have an ethical obligation to advocate for any care that they believe will materially benefit their patients, regardless of any allocation guidelines or gatekeeper directives.

Responsibility to Treat Physicians are liable for failure to treat their patients within the defined standard of care. The treating physician has sole responsibility to determine what is medically necessary. Managed care programs generally limit or deny payment for services not the actual services. Psychiatrists must be careful not to discharge suicidal or violent patients prematurely merely because continued coverage will not be approved by a managed care company.

Responsibility to Cooperate With Utilization Review As an ally of the patient and in the provision of good clinical care, the psychiatrist should cooperate with utilization reviewers' requests for information upon proper authorization from the patient. When benefits are denied, one must understand and follow grievance procedures carefully, return telephone calls from review agencies, and provide documented, solid justification for continued treatment.

Boundary Violations Increasingly, psychiatrists and other mental health professionals are being sued for treatment boundary violations that lead to patient exploitation and harm. Monetary and sexual exploitation are the most common.

The therapist establishes treatment boundaries to define and secure the professional relationship that promotes a therapeutic alliance with the patient. The boundary guidelines listed in Table 54.1-2 are accepted by most clinicians, regardless of their treatment orientation. Absolute boundary standards do not exist. Much of the variability in establishing boundaries arises from the nature of the patient, the type of treatment, the nature of the therapist, and the status of the therapeutic alliance. Sound treatment boundaries facilitate a fluctuating, reasonably flexible, psychological interaction between therapist and patient.

Maintain relative therapist neutrality
Foster psychological separateness of patient
Protect confidentiality
Obtain informed consent for treatments and procedures
Interact verbally with patients
Ensure no previous, current or future personal relationship with the patient
Minimize physical contact
Preserve relative anonymity of therapist
Establish a stable fee policy
Provide consistent, private and professional setting
Define time and length of sessions

Table 54.1-2 Boundary Guidelines for Psychotherapy

Once treatment boundaries are established, problems about boundaries (boundary issues) that inevitably arise from the patient are grist for the therapeutic mill. Boundary violations are strictly created by the therapist. Boundary crossings occur commonly in every therapy and are quickly identified and rectified, causing no harm to the patient.

Sexual exploitation of patients is preceded by progressively serious boundary violations. The earliest boundary violations often begin at the end of the session “between the chair and the door.” Patient and therapist doff their treatment roles to begin a social relationship. Therapy should be considered to be in progress until the patient leaves the office. The time and space “between the chair and the door” can be scrutinized for early warning indicators of inchoate boundary violations.

The principle of abstinence is central to keeping sound treatment boundaries. Therapists must abstain from using a patient for their personal advantage. The therapist's personal gratification should come from the work with the patient. Payment received for the therapist's professional services is the only material gratification permitted.

When making interventions with patients, therapists can spot-check the soundness of their boundaries by asking two basic questions: (1) Is the intervention being made to advance the patient's treatment or for the personal gratification of the therapist? (2) Is the intervention part of progressive boundary violations? Boundary violations need not prove fatal to the patient's treatment if they are caught in time, turned to account for the sake of the patient's treatment, and self-scrutinized by the therapist.

Confidentiality Confidentiality refers to the right of a patient to have communications spoken or written in confidence to a psychiatrist kept undisclosed to outside parties without authorization. Four general sources provide the bases for recognizing and safeguarding patient confidences. First, all 50 states and the District of Columbia have acknowledged this right of protection by creating some form of confidentiality provisions in either professional licensure laws or confidentiality and privilege statutes. In 1996 the United States Supreme Court (in *Redmond v Jaffe*) ruled that communications between psychotherapist and patient are confidential and need not be disclosed in federal trials. The second source, with the longest tradition, comprises the ethical codes of the various mental health professions. Third,

common law has long recognized an attorney-client privilege; developing case law has established similar protection for physicians and psychotherapists. Fourth, the right of confidentiality may be subsumed under the right of privacy.

Breach of Confidentiality Once the doctor-patient relationship is created, the professional has an automatic duty to safeguard a patient's disclosures. This duty is not absolute because circumstances exist in which breaching confidentiality is both ethical and legal.

Patients may waive confidentiality in a variety of situations including managed care settings. Medical records routinely go to potential employers or to insurance companies to obtain benefits. A limited waiver of confidentiality usually exists when a patient participates in group therapy. Whether a group member can be compelled in court to disclose information shared by another group member during group therapy remains unsettled. Many state confidentiality statutes provide statutory exceptions to confidentiality between the psychiatrist and the patient in one or more situations. Apart from statutory disclosure requirements and judicial compulsion, no legal obligation exists to provide information, even to law enforcement officials. In section 4, annotation 8, The *Principles of Medical Ethics with Annotations Especially Applicable to Psychiatry* states “Psychiatrists at times may find it necessary, in order to protect the patient or the community from imminent danger, to reveal confidential information disclosed by the patient.”

Patients' access to their own records is usually controlled by state statutes. These statutory provisions can be found under the heading of “medical records” or the much broader term “privilege.” The rules governing patient's access to their own records are complex and vary considerably in each jurisdiction.

The material contained in the psychiatric record can cause an iatrogenic exacerbation of a patient's mental disorder. Every effort should be made to be present when the patients review their records to clarify statements and answer questions. The physical record is the property of the psychiatrist. The information contained in the record, however, belongs to the patient. The original record should not be relinquished to the patient; only a copy should be provided.

TESTIMONIAL PRIVILEGE

Testimonial privilege, a statutorily created rule of evidence, permits the holder of the privilege (e.g., the patient) to exercise the right to prevent the person to whom confidential information was given (e.g., the psychiatrist) from disclosing it in a judicial proceeding. The patient—not the psychiatrist—holds the privilege that controls the release of confidential information. It is called “testimonial privilege” because it applies only to the judicial setting. Privilege statutes represent the most common recognition by the state of the importance of protecting information provided by a patient to a psychotherapist. This recognition departs from the essential truth-finding purpose of the American system of justice by insulating certain information from disclosure in court. This protection is justified by the special need for privacy in the doctor-patient relationship, that outweighs the quest for an accurate outcome in court.

Privilege statutes cover most of the mental health professions. Cases have been successfully litigated in which the broader physician-patient category was applied to the psychotherapist in the absence of an applicable statute.

Exceptions to Testimonial Privilege Privilege statutes also specify numerous exceptions to testimonial privilege. The most common exceptions include child abuse reporting, civil commitment proceedings, court-ordered examinations, competency proceedings, and cases in which a patient's mental state is in question as part of litigation. This last exception, known as the patient-litigant exception, commonly occurs in will contests, workers' compensation cases, child custody disputes, personal injury litigation, and malpractice actions.

Liability An unauthorized or unwarranted breach of confidentiality may cause a patient serious emotional harm. Consequently, a psychiatrist may be held liable for such a breach based on at least four legal theories: malpractice (breach of confidentiality), breach of statutory duty, invasion of privacy, and breach of (implied) contract.

SEXUAL MISCONDUCT

Therapist-patient sex is almost always preceded by progressive boundary violations in treatment. Patients are often psychologically damaged by both the precursor boundary violations and the end-stage sexual misconduct of the therapist. Sexual misconduct does not occur in isolation; it usually involves a variety of negligent acts of omission and commission.

Civil Liability Psychiatrists who sexually exploit their patients are subject to civil and criminal actions in addition to ethical and professional licensure revocation proceedings. Malpractice is the most common legal action (Table 54.1-3)

Civil lawsuit
Negligence
Loss of consortium
Breach-of-contract action
Criminal sanctions (e.g., statutory, adultery, sexual assault, rape)
Civil action for intentional tort (e.g., battery, fraud)
License revocation
Ethical sanctions
Dismissal from professional organizations

Table 54.1-3 Sexual Exploitation: Legal and Ethical Consequences

In a sexual exploitation case, the plaintiff has the difficult burden of proving that the exploitation actually took place. This burden is met if the plaintiff can provide corroborating evidence to support the claim such as testimony from other abused (former) patients, letters, pictures, hotel or motel receipts, and identification of distinctive therapist body markings.

If the defendant practitioner admits to the sexual misconduct, then the plaintiff is left with the responsibility of showing that he or she sustained injuries as a result. Usually, patient injury occurs in the form of emotional damage such as trust problems and a worsened psychiatric condition. Expert psychiatric testimony establishes the type and extent of psychological damage and affirms a breach in the standard of care. The number of states with civil statutes proscribing sexual misconduct is steadily increasing.

Three basic types of remedies are codified in the statutes of a number of states: reporting, civil liability, and criminal penalties. Reporting statutes require the disclosure to state authorities by a therapist who learns of any past or current therapist-patient sex. States that have civil statutes proscribing sexual misconduct incorporate a standard of care that makes malpractice suits easier to pursue. Some of these statutes restrict unfettered discovery of the plaintiff's past sexual history. Criminal sanctions are often the only remedy for exploitative therapists without malpractice insurance, for therapists who are unlicensed, or for therapists who do not belong to professional organizations.

Criminal Sanctions A number of states have passed statutes that make sexual activity by a therapist with a patient a criminal act. Moreover, sexual exploitation of a patient, under certain circumstances, may be considered rape or some analogous sexual offense and may therefore be criminally actionable. Typically, the criminality is determined by one of three factors: the practitioner's means of inducement, the age of the victim, or the availability of a relevant state criminal code.

Sex with a current patient may be prosecuted under sexual assault statutes if the state can prove beyond a reasonable doubt (i.e., with 90 to 95 percent certainty) that the patient was coerced into engaging in the sexual act. Usually, this type of evidence is limited to the use of some form of substance to either induce compliance or reduce resistance. However, a variety of methods have been used by therapists to coerce patients into sexual submission such as anesthesia, ECT, hypnosis, drugs,

force, and threats of harm. To date, claims of “psychological coercion” through manipulation of transference phenomena have not successfully met the level of proof necessary to prosecute a criminal case. In cases involving a minor patient, the issues of consent or coercion are irrelevant, since minors and incompetent persons (including adult incompetent persons) are considered unable to provide valid consent. Therefore, sex with a child or an incompetent person is automatically considered a criminal act.

Licensure and Ethical Codes State licensing organizations, unlike professional associations, may discipline offending professionals more effectively and punitively by suspending or revoking their license. Licensing boards are not as constrained as the courts, which require rigorous rules of evidence in trial procedures. It is generally less difficult for the patient to seek redress through this means. In the vast majority of cases in which the evidence was reasonably sufficient to substantiate a claim of sexual exploitation, the professional's license was revoked or the professional was suspended from practice for a period of time.

Patients can bring ethical charges against psychiatrists before the district branches of the APA. There is no time limit for bringing ethical charges. Ethical violators may be reprimanded, suspended, or expelled from the APA. All national organizations of mental health professionals proscribe sexual relations between therapist and patient. Ethical charges can be filed only against members of a professional group; this option is not available to patients of therapists who do not belong to a professional organization.

RECOVERED MEMORIES

The current clamorous controversy concerning recovered memories of sexual abuse threatens to undermine the credibility of the mental health professions. The debate has generated intense passions that have driven an increasing number of recovered memory cases into the courts. Patients alleging recovered memories of abuse have sued parents and other alleged perpetrators. In a number of instances, the alleged victimizers have sued therapists who, they claim, negligently induced false memories of sexual abuse. In an aboutface, some patients have recanted and joined forces with others (usually their parents) to sue therapists.

The memory debate has polarized a number of therapists into believers and disbelievers. Most therapists hold personal beliefs about the validity of recovered memories of sexual abuse that are somewhere between the extremes. Strongly held personal biases about recovered memories represent a new occupational hazard for clinicians. Such feelings can undermine the therapists' duty of neutrality to their patients, creating deviant treatment boundaries and the provision of substandard care.

Litigation in recovered memory cases is expected to soar in the coming years. Some predict multimillion dollar verdicts against mental health practitioners. A jury awarded over $10 million to the plaintiffs in a case alleging that therapists implanted memories of satanic sexual abuse. A fundamental allegation in these cases is that the therapist abandoned a position of neutrality to suggest, persuade, coerce, and implant false memories of childhood sexual abuse. The guiding principle of clinical risk management in recovered memory cases is maintenance of therapist neutrality and establishment of sound treatment boundaries.

Further complicating the matter is the empirical evidence about memory mechanisms, which (as is typical for any emerging science) reveals contradictory findings about how and what persons retain in memory and forget in various settings. Empirical studies often fail to distinguish whether allegedly repressed memories are not retrieved or simply not reported to researchers.

Valid risk management has a solid clinical footing and is secondarily informed by awareness of the legal issues. The following risk management principles should be considered when evaluating or treating a patient who recovers memories of abuse in psychotherapy:

1. Maintain therapist neutrality—do not suggest abuse
2. Stay clinically focused—provide adequate evaluation and treatment for patients presenting problems and symptoms
3. Carefully document the memory recovery process
4. Manage personal bias and countertransference
5. Avoid mixing treater and expert witness roles
6. Closely monitor supervisory and collaborative therapy relationships
7. Clarify nontreatment roles with family members
8. Avoid special techniques (e.g., hypnosis or sodium amytal) unless clearly indicated; obtain consultation first
9. Stay within professional competence—do not take cases you cannot handle
10. Distinguish between narrative truth and historical truth
11. Obtain consultation in problematic cases
12. Foster patient autonomy and self-determination—do not suggest lawsuits
13. In managed care settings, inform patients with recovered memories that more than brief therapy may be required
14. When making public statements, distinguish personal opinions from scientifically established facts
15. Stop and refer, if uncomfortable with a patient who is recovering memories of childhood abuse
16. Do not be afraid to ask about abuse as part of a competent psychiatric evaluation

SECLUSION AND RESTRAINT

Seclusion and restraint raise complex psychiatric legal issues. Seclusion and restraint have both indications and contraindications (Table 54.1-4 and Table 54.1-5). Seclusion and restraint have become increasingly regulated over the past decade.

1. Prevent clear, imminent harm to the patient or others
2. Prevent significant disruption to treatment program or physical surroundings
3. Assist in treatment as part of ongoing behavior therapy
4. Decrease sensory overstimulation*
5. At patient's voluntary reasonable request

* Seclusion only.
Reprinted with permission from Simon RI: *Concise Guide to Psychiatry and the Law for Clinicians*, ed 2. American Psychiatric Press, Washington, DC, 1998.

Table 54.1-4 Indications for Seclusion and Restraint

1. Extremely unstable medical and psychiatric conditions*
2. Delirious or demented patients unable to tolerate decreased stimulation*
3. Overtly suicidal patients*
4. Patients with severe drug reactions, overdoses or requiring close monitoring of drug dosages*
5. For punishment or convenience of staff

* Unless close supervision and direct observation are provided.

Table 54.1-5 Contraindications to Seclusion and Restraint

Legal challenges to the use of restraints and seclusion have been brought on behalf of institutionalized mentally ill and mentally retarded persons. Typically, these lawsuits do not stand alone but are part of a challenge to a wide range of alleged abuses.

Generally, courts hold, or consent decrees provide, that restraints and seclusion be implemented only when a patient creates a risk of harm to self or others and no less-restrictive alternative is available. Additional restrictions include the following:

1. Restraint and seclusion can only be implemented by a written order from an appropriate medical official
2. Orders are to be confined to specific, time-limited periods
3. A patient's condition must be regularly reviewed and documented
4. Any extension of an original order must be reviewed and reauthorized

The acceptability of restraint or seclusion for the purposes of training was recognized by the Supreme Court in *Youngberg v Romeo*, which challenged the "treatment" practices at the Pennhurst State School and Hospital in Pennsylvania. The Court held that patients could not be restrained except to ensure their safety or, in certain undefined circumstances, "to provide needed training." Although recognizing that the defendant had a liberty interest in safety and freedom from bodily restraint, the Court noted that these interests were not absolute nor in conflict with the need to provide training. The Court also held that decisions made by appropriate professionals regarding restraining the patient would be presumed correct. Psychiatrists and other mental health professionals have lauded the decision because the Court recognized that professionals are better able than the courts to determine the needs of patients, including deciding when restraint is appropriate.

Most states have enacted statutes that regulate the use of restraints, often specifying the circumstances in which restraints can be used—usually when a risk of harm to self or danger to others is imminent. Statutory regulation of the use of seclusion is much less common. About one-half of states have laws governing seclusion. Most states with laws regarding seclusion and restraint require some type of documentation of their usage. A number of courts and state statutes outline certain due process procedures that must be followed before restraint or seclusion can be used for nonclinically indicated, disciplinary purposes. These include some form of notice, a hearing, and involvement of an impartial decision-maker.

The APA Task Force on the Psychiatric Uses of Seclusion and Restraint has developed guidelines for the appropriate use of seclusion and restraints, and the JCAHO has promulgated guidelines for hospitals regarding seclusion and restraint requirements. Professional opinion concerning the clinical uses of physical restraints and seclusion varies considerably among psychiatrists. Seclusion can be justified on both clinical and legal grounds for a variety of uses, unless precluded by state freedom from restraint and seclusion statutes.

COMPETENCY: A CORNERSTONE CONCEPT

Competency is a broad concept, encompassing many different legal issues and contexts. Its definition, requirements, and application can vary widely depending upon the context such as health care decision making, executing a will, standing trial, or confessing to a crime.

In general, competency refers to some minimal mental capacity required to perform a specific, legally recognized act or to assume some legal role. When patients' mental competency is in doubt, a court scrutinizes their perception of reality and memory functions, since these abilities bear on the reliability of their responses or testimony.

Incompetent is a legal term applied to individuals who are considered by law not to be mentally capable of performing a particular act or assuming a particular role. The adjudication of incompetence is issue specific. A psychiatric patient who is adjudicated incompetent to execute a will may not be automatically incompetent to do other things, such as consenting to treatment, testifying as a witness, marrying, driving, or making a legally binding contract.

Competency, in both the civil and the criminal context, is commonly raised in two situations—when the person is either a minor (under age 18) or mentally disabled. Minors are not considered legally competent in some situations and require the consent of a parent or designated guardian. Minors who are considered emancipated or mature or who are competent to consent in some cases of medical need or emergency are generally an exception to this rule.

Mentally disabled persons present more complex issues in evaluating competency. A lack of competency cannot be presumed from a person's treatment for mental illness or from institutionalization. Mental disability does not necessarily render a person incompetent or incompetent in all areas of functioning. Foolish decisions by themselves do not denote mental incompetence but are merely an inevitable consequence of the human condition. More often, the psychiatrist must determine if any specific functional incapacities exist that render a person unable to make a particular kind of decision or to perform a particular type of task.

Health Care Decision Making Competency to consent and the right to refuse treatment go hand in hand. Under most circumstances, competent patients have a right to refuse treatment. Forcing treatment against the wishes of a competent patient may result in a suit for assault and battery as well as malpractice. Merely because patients are psychotic does not necessarily mean that they lack sufficient health care decision-making capacity. Nor does involuntary hospitalization deprive a patient of the right to refuse treatment in most states.

Some psychiatric patients who suffer from impaired mental capacity may have difficulty giving valid informed consent to proposed diagnostic procedures and treatments. One study of informed consent found that the schizophrenia and depression groups demonstrated poorer understanding of treatment disclosures, poorer reasoning in decision making regarding treatment, and a greater likelihood of failing to appreciate their illnesses or the potential treatment benefits. The legal requirement that the psychiatrist obtain competent informed consent for proposed treatments and procedures is not negated simply because the patient appears to need medical intervention or would likely benefit from it. Psychiatrists must ensure that the patient or an appropriate substitute decision-maker has given a competent consent before proceeding with treatment.

For a patient's consent to be informed, three essential elements must be satisfied: competency, information, and voluntariness. The patient must be given enough information to make a knowledgeable decision. The decision (consent) must be given voluntarily by a person who is legally competent. Gag rules imposed on psychiatrists in managed care settings to keep patients from being fully informed about treatment options are antithetical to obtaining a valid informed consent.

Several exceptions exist to the requirement of informed consent. The most common is the emergency exception, in which consent is implied when the patient is unable to give consent (e.g., unconsciousness) and is suffering from an acute, life-threatening crisis that requires immediate medical attention. Other exceptions include incompetency (substitute decision-maker necessary), therapeutic privilege (withholding full disclosure if informing would seriously worsen patient's condition or foreclose rational decision making), and waiver (patient competently declines being informed). Clinicians must be especially careful not to use these exceptions to circumvent the requirement of obtaining informed consent. When asserting an exception to obtaining informed consent, the clinician's reasons should be carefully documented.

Levels of Competency Competency is usually narrowly defined legally as cognitive capacity. No firmly established criteria exist for determining a patient's competence. A minimal level of decision making must exist in which the patient can at least (1) understand the particular treatment being offered; (2) make a discernible decision, one way or another, regarding the treatment that has been offered; and (3) communicate that decision verbally or nonverbally.

This minimal standard of decision-making capacity obtains only a simple consent. The patient does not give an informed consent, because alternative treatment choices are not provided. There are generally four standards for determining incompetency in decision making. Based upon levels of mental capacity required, these standards are (1) communication of choice, (2) understanding the information provided, (3) appreciation of one's situation and the risks and benefits of options available, and (4) rational decision-making

Psychiatrists usually prefer the rational decision-making standard in determining whether an individual is incompetent, but most courts accept the first two standards. Rational decision-making occurs when a patient's consent reflects that patient's freedom of choice, personal needs, and values applied to the risks and benefits of appropriate treatment options. The clinician should consider obtaining legal advice if the competency issue cannot be resolved by additional medical and psychiatric

consultation.

Except in an emergency, patients lacking health care decision-making capacity need an authorized representative or guardian appointed to make health care decisions on their behalf. Table 54.1-6 lists a number of consent options that may be available, depending on the jurisdiction.

1. Proxy consent of next of kin
2. Right-to-die statutory surrogate laws (spouse or court appointed guardian when treatment wishes of patient unstated)
3. Advance directives (living will or durable power of attorney)
4. Adjudication of incompetence; appointment of guardian
5. Institutional administrators or committees
6. Treatment review panels
7. Substituted consent of the court

Table 54.1-6 Common Consent Options for Patients Lacking the Mental Capacity for Health Care Decision-Making

Guardianship Guardianship is a method of substitute decision-making for individuals who have been judicially determined to be unable to act on their own behalf. Historically, the state or sovereign possessed the power and authority to protect the estate of incompetent persons.

This traditional role is carried forward in the purpose of guardianship today. In a number of states, separate provisions exist for the appointment of a “guardian of one's person” (e.g., substitute health care decision-maker) and a “guardian of one's estate” (e.g., someone authorized to make contracts to sell one's property). The latter guardian is frequently called a *conservator*, although this designation is not uniformly used throughout the United States. In some jurisdictions a further distinction is made between *general* (plenary) and *specific* guardianship. The latter guardian is restricted to exercising decisions about a particular area such as major or emergency medical procedures. The disabled person retains the freedom to make decisions about all other medical matters. By contrast, general guardians have total control over the disabled individual's person, estate, or both.

Under our system of law, an individual is presumed competent unless adjudicated incompetent. In many states, the Uniform Guardianship and Protective Proceeding Act or the Uniform Probate Code is used as a model for laws governing competency. The threshold requirement of incompetency is defined by the Uniform Guardianship and Protective Proceeding Act as:

impaired by reason of mental illness, mental deficiency, physical illness or disability, advanced age, chronic use of drugs, chronic intoxication, or other cause (except minority) to the extent of lacking sufficient understanding or capacity to make or communicate reasonable decisions.

Patients suffering from severe psychiatric disorders may meet the above definition. The standard of proof required for a judicial determination of incompetence is clear and convincing evidence. Although the law does not assign percentages to proof, clear and convincing evidence is in the range of 75 percent certainty.

States vary in the extent of their reliance on psychiatric assessments in determining incompetence. Nonmedical personnel including social workers, psychologists, family members, friends, colleagues, and even the individual who is the subject of the proceeding may testify.

Substituted Judgment Psychiatrists may find the time and effort required to obtain an adjudication of incompetence unduly burdensome. It can be inimical to providing competent treatment in a timely manner. Often, families are reluctant to face the formal court proceedings necessary to declare their family member incompetent, particularly when sensitive family matters may be disclosed. A common solution is to seek the legally authorized proxy consent of a spouse or relative acting as a de facto guardian when the refusing patient is thought to be incompetent. Proxy consent by next of kin, however, is not available in every state.

The President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research (1982) recommends that the relatives of incompetent patients be chosen as proxy decision-makers for three reasons: (1) the family is generally most concerned about the good of the patient; (2) the family is usually the most knowledgeable about the patient's goals, preferences, and values; and (3) the family deserves recognition as an important social unit to be treated, within limits, as a single decision-maker in matters that intimately affect its members. Some states allow proxy decision-making by statute. Some statutes merely state that another person may authorize consent on behalf of an incompetent patient; other statutes mention specific relatives.

Unless proxy consent is provided by state statute or by case law, good faith consents by next of kin should not be relied upon by psychiatrists treating patients believed to be incompetent. The appropriate procedure is to seek judicial recognition of a family member or other substitute decision-maker. Increasingly, state statutes are eliminating proxy consent as an option for mentally disordered individuals lacking health care decision-making capacity.

For psychiatric patients who continue to lack sufficient mental capacity to make health care decisions, an increasing number of states provide administrative procedures authorized by statute that permit involuntary treatment of incompetent and treatment-refusing mentally ill patients. All 50 states and the District of Columbia permit individuals to create a durable power of attorney, that is, one that endures even if the competence of the creator does not. A durable power of attorney agreement permits next of kin to consent to treatment on behalf of the patient who can no longer make such a decision.

Physician-Assisted Suicide With increasing legal recognition of physician-assisted suicide for terminally ill persons, psychiatrists are likely to be called upon to become gatekeepers. This role would be a radical departure from the physician's code of ethics that prohibits participation by an ethical doctor in any intervention that hastens death. Every proposal for physician-assisted suicide requires a psychiatric screening or consultation to determine the person's competency to commit suicide. The presence of psychiatric disorders associated with suicide, particularly depression, must be ruled out as the driving factor behind the request for physician-assisted suicide. The ethics of this controversial gatekeeping function are hotly disputed.

Lower court decisions in New York and Washington State have struck down prohibitions against physician-assisted suicide. Currently, most states have such prohibitions. In *Washington v Glucksberg*, the Supreme Court unanimously ruled that the Constitution does not guarantee Americans a right to commit suicide with the help of a physician, leaving the issue for state legislatures to decide. While acknowledging that terminally ill persons can endure great agony, the Court relied upon moral and legal arguments in its ruling, placing greater emphasis on traditional American condemnation of suicide and valuing life.

CRIMINAL PROCEEDINGS

Under the common law, the basic elements of a crime are (1) the mental state or level of intent to commit the act (known as the *mens rea* or guilty mind), (2) the act itself or conduct associated with committing the crime (known as *actus reus* or guilty act), and (3) a concurrence in time between the guilty act and the guilty mental state. The state must prove beyond a reasonable doubt that the defendant committed the criminal act with the requisite intent in order to convict a person of a particular crime.

A person's mental status and reality testing can play a critical role in determining whether a defendant is required to stand trial to face criminal charges, is acquitted of the alleged crime, is sent to prison, is hospitalized or be sentenced, or (in some extreme cases) is executed. Before any defendant can be criminally prosecuted, the court must establish that the accused is competent to stand trial, that is, defendants must understand the charges brought against them and have sufficient rational mental capacity to assist counsel with the defense. The United States Supreme Court in *Dusky v United States* established the legal standard for determining pretrial competency.

Competency to Stand Trial An impairment that puts into question a defendant's competence is usually associated with a mental disorder or defect. However,

persons may be found incompetent to stand trial even if they do not suffer from a mental disease or defect. The presence or absence of a mental illness is irrelevant if the defendant can meet competency requirements. Legal criteria, not medical or psychiatric diagnoses, govern competency. Diagnosis is relevant only to the question of restoring, with treatment, the defendant's competency to stand trial.

Checklists and structured interviews are available that assess specific psychological factors applicable to competency standards. The *Interdisciplinary Fitness Interview* can be used by both lawyers and mental health professionals. It permits a detailed examination of psychopathology and legal knowledge, using explicit scales to rate each response in the competency evaluation. *Evaluating Competencies: Forensic Assessments and Instruments* is also a standard reference in the field.

The presence of mental impairment does not automatically render the defendant incompetent. The impairment must be considered in the context of the particular case or proceeding. For example, mental impairment that renders an individual incompetent to stand trial in a complicated tax fraud case may not render that individual incompetent for a misdemeanor trial. Psychiatrists must be able to apply their clinical findings to the legal standards enunciated in *Dusky* when assessing competency to stand trial.

Insanity Defense The insanity defense is one of the most controversial issues in American jurisprudence. Defendants with mental impairments who are found competent to stand trial may seek acquittal on the claim of insanity, alleging that they were not criminally responsible for their actions at the time the offense was committed. The term “insanity” is a legal construct, not a psychiatric diagnosis.

The M'Naghten test of insanity was used in the vast majority of states until the 1960s. This test originated in 1843 from the first English case where the burgeoning science of psychiatry played a significant role. In a celebrated murder trial, Daniel M'Naghten (Fig. 54.1-1) was found to be insane and thus not guilty. M'Naghten shot and killed Edward Drummond, secretary to British Prime Minister Robert Peel. M'Naghten suffered from the delusion that Peel and the pope were conspiring against him. He intended to kill Peel, but shot Drummond by mistake. The judicial response to a parliamentary inquiry into the case produced the official M'Naghten test:

FIGURE 54.1-1 Daniel M'Naghten. His 1843 murder trial led to the establishment of rules still generally observed in legal insanity pleas. (Courtesy of Culver Pictures.)

The jurors ought to be told in all cases that every man is to be presumed to be sane, and to possess a sufficient degree of reason to be responsible for his crimes, until the contrary be proved to their satisfaction; and that to establish a defense on the ground of insanity, it must be clearly proved that, at the time of the committing of the act, the party accused was labouring under such a defect of reason, from disease of the mind, as not to know the nature and quality of the act he was doing; or, if he did know it, that he did not know he was doing what was wrong.

Criminals commit crimes for a variety of reasons. The law presumes that they do so rationally and of their own free will and thus merit some form of punishment. However, some offenders are so mentally disturbed that they are found to be incapable of acting rationally. Civilized societies have deemed it a violation of fundamental principles of fairness and morality to punish such persons. To do so would thwart two major tenets of punishment—retribution and deterrence.

No precise, generally accepted definition of legal insanity exists. Tests of insanity have always been controversial and have undergone much modification and refinement over the years. The insanity defense standard has four basic elements:

1. Presence of a mental disorder
2. Presence of a defect of reason
3. A lack of knowledge of the nature or wrongfulness of the act
4. An incapacity to refrain from the act

The presence of a mental disorder has remained the consistent core of the insanity defense; the other elements have varied in importance over time. Thus, the insanity defense standard varies throughout the United States, depending upon which state or jurisdiction has control over the defendant raising the defense.

The most stringent insanity standard is applied to defendants tried in a federal court who are governed by the Comprehensive Crime Control Act of 1984. This act was passed following public outrage over the acquittal of John Hinckley, Jr. (Fig. 54.1-2), by reason of insanity, after his attempt to assassinate President Ronald Reagan. The Act provides an affirmative defense to all federal crimes if, at the time of the offense, “the defendant, as a result of a severe mental disease or defect, was unable to appreciate the nature and quality or the wrongfulness of his acts. Mental disease or defect does not otherwise constitute a defense.” This standard eliminates the volitional or irresistible impulse prong of the four-part insanity defense stated above. It does not permit a defense based on a defendant's inability to conform his or her conduct to the requirements of the law. The defense is limited to defendants who cannot appreciate the wrongfulness of their acts (i.e., the cognitive prong of the defense). In a number of jurisdictions as well as in federal law (Comprehensive Crime Control Act), the burden of proof has shifted from the prosecution to the defense.

FIGURE 54.1-2 John Hinckley, Jr. In 1980, he shot President Ronald Reagan and Press Secretary James Brady. Hinckley was found not guilty by reason of insanity in 1982. The Brady Bill, a gun control bill, became law in 1993. (Courtesy of Wide World Photos.)

Despite the restrictions placed upon insanity defense standards following the Hinckley verdict, a number of states follow some version or accept totally the American Law Institute (ALI) test of insanity. The ALI test has two parts: a person is not responsible for criminal conduct if at the time of such conduct as a result of mental disease or defect he lacks substantial capacity either to appreciate the criminality (wrongfulness) of his conduct or to conform his conduct to the requirements of law.

As used in this article, the terms “mental disease or defect” do not include an abnormality manifested only by repeated criminal or otherwise antisocial conduct.

Thus, the ALI test contains both a cognitive and a volitional prong. Both John Hinckley, Jr., and Jeffrey Dahmer (Fig. 54.1-3) were tried under the ALI test. For example, Dahmer had struggled hard against his aberrant sexual impulses in the 7 years that elapsed between his first and second killings. However, the fact that Dahmer could plan his murders and systematically dispose of the bodies convinced the jury that he was able to control his behavior. All the testimony bolstered the notion that like most serial killers, Dahmer knew what he was doing and knew right from wrong. Finally, the jury did not accept the defense that Dahmer suffered from a mental illness to the degree that it had disabled his thinking or behavioral controls.

FIGURE 54.1-3 Jeffrey Dahmer. His murder trial for the deaths of 17 young men and boys gained widespread notoriety after accusations of cannibalistic practices were made. Dahmer was killed in prison by a psychotic inmate in 1994. (Courtesy of Wide World Photos.)

Nevada recently joined Montana, South Dakota, and Utah in abolishing the special plea of insanity altogether. At the same time, it established the plea of guilty but mentally ill. In Montana, evidence of insanity is admissible to negate *mens rea*.

In making an insanity determination, the threshold issue is not the existence of a mental disease or defect per se, but the lack of substantial capacity caused by it. The lack of mental capacity due to causes other than mental illness may suffice. For example, under certain circumstances, mental retardation may provide an adequate basis for an insanity defense.

Diminished Capacity The law recognizes shades of mental impairment that can affect *mens rea*, but not necessarily to the extent of completely nullifying it. The concept of “diminished capacity” was developed for these situations.

Diminished capacity allows the defendant to introduce medical and psychological evidence that relates directly to the *mens rea* for the crime charged, without having to assert a defense of insanity. For example, in the crime of assault with the intent to kill, psychiatric testimony may be permitted to address whether the offender acted with the purpose of committing homicide at the time of the assault. When a defendant's *mens rea* for the crime charged is not supported by clinical evidence, the defendant is acquitted only of that charge. The diminished capacity defense does not lead to total exculpation of criminal responsibility nor to automatic commitment to a mental institution.

Exculpatory and Mitigating Conditions Automatisms, intoxication, seizure disorders, and metabolic conditions have met with very limited success as exculpating or mitigating defenses to criminal charges.

Automatisms The automatism (or unconscious) defense recognizes that some criminal acts may be committed involuntarily. *Automatism*, defined as “having performed in a state of mental unconsciousness or dissociation without full awareness,” is applied to actions or conduct occurring “without will, purpose, or reasoned intention.”

For conviction for a crime, a criminal state of mind (*mens rea*) must be accompanied by the commission of a prohibited act (*actus reus*). The physical act must be conscious and volitional. Statutory and common law in most jurisdictions specifically excludes from the *actus reus* a reflex or convulsion, a bodily movement occurring during unconsciousness or sleep, acts during hypnosis or resulting from hypnotic suggestion, and a bodily movement that is not conscious and voluntary.

The classic, though rare, example of an automatism is the person who commits an offense while sleepwalking. Courts have held that such individuals do not have conscious control of their physical actions and therefore act involuntarily. This defense exists for persons committing a crime during a state of unconsciousness caused by a concussion following a head injury, involuntary ingestion of drugs or alcohol, hypoxia or hypoglycemia, or epileptic seizures.

There are clear limitations to the automatism defense. The automatism defense is not available if the person was aware of the condition prior to the offense and failed to take reasonable steps to prevent the crime. If, for example, a defendant with a known history of poorly controlled epileptic seizures loses control of a car during a seizure and kills another person, that defendant cannot assert the defense of automatism.

Generally, intoxication is not a defense to a criminal charge because it usually results from a person's own actions. However, most states consider voluntary alcoholism relevant in determining whether the defendant possessed the *mens rea* necessary to commit a specific-intent crime or whether there was premeditation in a crime of murder. The mere fact that the defendant was voluntarily intoxicated does not justify a finding of automatism or insanity.

A distinct difference exists when, because of chronic, heavy alcohol use, the defendant is suffering from an alcohol-induced organic mental disorder. If credible clinical evidence is presented that an alcohol-related psychiatric disorder such as alcohol hallucinosis, withdrawal delirium, amnestic disorder, or dementia associated with alcoholism caused significant cognitive or volitional impairment, a defense of insanity or diminished capacity might be upheld.

Another mental state defense occasionally raised by criminal defendants is that the assaultive behavior was involuntarily precipitated by a seizure disorder. This condition is often diagnosed as temporal lobe epilepsy. Aggressive behavior is asserted to primarily result from an uncontrollable, randomly occurring, abnormal brain dysrhythmia. The legal argument that such individuals should not be held accountable for their actions may prevail. Despite its simplicity and rare success in the courts, little significant empirical data support these claims.

Defenses based on metabolic disorders rarely succeed. However, the notorious “Twinkie defense” was part of a successful strategy to defend Dan White (Fig. 54.1-4), charged with two counts of murder in the shooting of San Francisco Mayor George Moscone and Supervisor Harvey Milk. The jury returned a verdict of voluntary manslaughter. White's defense was based on the theory that the ingestion of large amounts of sugar contributed to a state of temporary insanity. Public outrage over the verdict in the Dan White case led to the repeal of the diminished capacity defense by the California legislature in 1981.

FIGURE 54.1-4 Dan White. The former San Francisco supervisor killed San Francisco Mayor George Moscone and Supervisor Harvey Milk at City Hall in 1978. White's “Twinkie defense” helped reduce his crime for murder to manslaughter, for which he served 5 years. White committed suicide after he was released from prison. (Courtesy of Wide World Photos.)

Guilty But Mentally Ill A number of states have established an alternative verdict of guilty but mentally ill. Under guilty but mentally ill statutes, if the defendant pleads not guilty by reason of insanity, this alternative verdict is available to the jury. Under an insanity plea, four outcomes are possible: not guilty, not guilty by reason of insanity, guilty but mentally ill, and guilty.

The problem with guilty but mentally ill is that it is an alternative verdict without a difference. It is basically the same as finding the defendant just plain guilty. The court must still impose a sentence upon the convicted person. Although the convicted person supposedly will receive psychiatric treatment if necessary, this treatment provision is available to all prisoners. Moreover, the frequent unavailability of appropriate psychiatric treatment for prisoners adds an additional element of spuriousness to the guilty but mentally ill verdict. Guilty but mentally ill is essentially no different than finding a defendant “guilty but suffering from lumbago.” Moreover, research shows that persons found guilty but mentally ill have fewer furloughs and longer sentences.

CIVIL LITIGATION

Psychiatrists provide consultation and testimony in a number of areas of civil litigation including malpractice, personal injury, discrimination, child custody, will contests, workers' compensation, disability claims, toxic torts, and a wide variety of other cases where psychiatry and law intersect. Psychiatrists are frequently asked by lawyers to evaluate individuals with alleged posttraumatic stress disorder. Specific guidelines are available for the forensic assessment of posttraumatic stress disorder in litigation.

Forensic psychiatry is now an officially recognized subspecialty. The American Board of Psychiatry and Neurology now offers added qualifications in forensic psychiatry. Forensic psychiatry is defined by the American Academy of Psychiatry and the Law as follows: “Forensic psychiatry is a subspecialty in which scientific and clinical expertise is applied to legal issues in legal contexts embracing civil, criminal, correctional or legislative matters.”

Psychiatrists who enter the legal arena must be aware of the fundamentally different roles of a treating psychiatrist and the forensic psychiatric expert. Treatment and expert roles do not mix. Unlike the orthopaedist, for example, who usually possesses objective, concrete information such as the X-ray of a broken limb to demonstrate physical injuries in court, the treating psychiatrist relies primarily upon the subjective reporting of the patient. In the clinical context, psychiatrists work with the patient's perception of the problems (narrative truth), not necessarily objective reality (historical truth). To maintain confidentiality, most psychiatrists do not speak to third parties to corroborate their statements. The law, however, is concerned with proofs that can be reasonably established by facts. Uncorroborated, subjective patient reporting will likely be attacked in court as speculative, self-serving, and unreliable.

The treating psychiatrist is, and should be, a total ally of the patient. Psychiatrists cannot effectively treat patients that they dislike. This positive bias in favor of the patient is a proper treatment stance that fosters a working therapeutic alliance. In the clinical situation, the psychiatrist's attention is directed toward the diagnosis and treatment of mental disorders. This again is an appropriate focus for the treating psychiatrist.

In court, credibility is a critical asset. Opposing counsel will pursue every opportunity to portray the treating psychiatrist as a subjective mouthpiece for the plaintiff—which may or may not be true. Also, court testimony by the treating psychiatrist may disclose information that may not be legally privileged but is perceived as private and confidential by the patient. Such a disclosure by the therapist is likely to seriously harm the therapeutic relationship. In addition, psychiatrists should inform patients about the consequences of releasing treatment information, particularly in legal matters. Section 4, annotation 2 of the *Principles of Medical Ethics with Annotations Especially Applicable to Psychiatry* (1995) states:

The continuing duty of the psychiatrist to protect the patient includes fully apprising him/her of the connotations of waiving the privilege of privacy. This may become an issue when the patient is being investigated by a government agency, is applying for a position, or is involved in legal action.

When the treating psychiatrist testifies concerning the patient's need for future treatment, an inherent conflict of interest emerges. Therapists stand to benefit economically from treatment recommendations for their patients. Although this may not be the intention of the psychiatrist at all, opposing counsel will be sure to point out that the psychiatrist has a financial interest in the case.

Although opposing counsel may depict forensic experts as hired guns, they are free of conflicting treatment roles. No doctor-patient relationship is created during forensic evaluation with its accompanying treatment biases toward the patient. The expert usually can review a wide variety of records and interview numerous people who know the litigant. Furthermore, the forensic expert considers the possibility of exaggeration or malingering because of the litigation context and the absence of treatment bias. The forensic psychiatrist does not have a conflict of economic interest when recommending treatment for the litigant.

Treating psychiatrists should remain solely in treatment roles with their patients. If testimony on behalf of a patient is required, the psychiatrist should testify as a fact witness rather than as an expert witness. As a fact witness, the psychiatrist will be questioned about the number and length of visits, diagnosis, and treatment. No opinion evidence concerning causation of the injury or extent of damages is usually given. In some jurisdictions, however, the court may attempt to convert a fact witness into an expert witness when the treating psychiatrist takes the stand. Psychiatrists must remain ever mindful of the many double-agent roles that can develop when mixing psychiatry and litigation.

SUGGESTED CROSS-REFERENCES

Competence is linked to delirium and dementia, discussed in Chapter 10; to schizophrenia, discussed in Chapter 12; to delusional disorders, discussed in Section 13.2; to impulse-control disorders, discussed in Chapter 22; and to Alzheimer's disease, discussed in Section 51.3c. Factitious disorders are discussed in Chapter 17 and malingering in Section 27.2. Criminality is discussed in Section 27.3. Emergency psychiatry, including suicide, is discussed in Chapter 29. Biological therapies are discussed in Chapter 31. Mental retardation is discussed in Chapter 34. Child abuse is discussed in Section 49.4. Medical-legal issues and ethical issues in geriatric care are discussed in Section 51.6b and Section 51.6c, respectively. Hospital and community psychiatry are discussed in Chapter 52. Ethics in psychiatry is discussed in Section 54.2.

54.2 ETHICS IN PSYCHIATRY

PETER B. GRUENBERG, M.D.

As used in this section, ethics in psychiatry is not the same as psychiatric ethics. While there is a body of wisdom referred to as ethics, and a subset of ethics called medical ethics, and a further subset of ethics called psychiatric ethics, ethics in psychiatry deals mainly with the ideal behavior of the ethical psychiatrist and the ethical principles that determine the expected behavior of the ethical psychiatrist.

During the past decade, psychiatric ethics has, unfortunately, had to define itself. Psychiatric ethics has had to resist politicization from many diverse quarters. Recently, some opponents of managed care have suggested that anyone—psychiatrist or businessman—who advocates or participates in a managed care plan is, per se, unethical. At the other extreme, some proponents of managed care presume that a psychiatrist practicing fee-for-service medicine is unethical.

The public became painfully aware of psychiatric ethics because of several celebrated cases that were the object of national attention. Pundits told their viewers and readers what is, and what is not, ethical behavior for a psychiatrist, and sadly, they were often correct. Thus one must review the basic principles of ethics and trace the development of current thinking as it relates to psychiatric ethics.

BASIC ETHICAL PRINCIPLES

A survey of basic ethical principles in psychiatry was summarized by James Rosenberg and Spencer Eth as follows:

Psychiatric ethics is a body of rules and principles in a state of flux, adapting to changes in psychiatry and psychiatry's place in the world at large.

Ethics and Morals The semantic distinction between morals and ethics generally refers to those values a society accepts as universal principles contrasted with the principles that are relative to a particular context or era. General moral principles govern the behavior of all citizens and are deemed both universal and immutable. In Judeo-Christian society the prevailing standard is that each person should treat every other person as that person would wish to be treated by others. Not surprisingly, overlap with the law is considerable.

The term “ethics” is usually reserved for the moral principles restricted to certain groups, such as those in a profession. That role-bound morality can consist of internal or external standards of ethical conduct. For the psychiatric profession, *The Principles of Medical Ethics with Annotations Especially for Psychiatry* (thereafter, *The Principles*), developed by the American Psychiatric Association (APA), is an example of an internal standard used by the profession's major organization to regulate the behavior of its members. Judicial, legislative, or executive bodies may impose external standards as well.

Distinguishing between an ethical dilemma and an ethical violation is important. One is faced with an ethical dilemma when asked to choose between two ethically legitimate alternatives, such as preserving patient confidentiality or protecting endangered third parties. An *ethical conflict* involves the compromise of an ethical principle, usually because of self-interest, such as patient-therapist sexual relations.

APA Sanctions For ethical violations the APA may expel members from the organization or, for less severe violations, suspend membership for a time. During that time a member may be required to undergo supervision or extra training. For still less severe violations a member may be reprimanded or admonished, with no effect on membership status. Expulsion or suspension from the APA is publicly reported. Further, such actions must be reported to the National Practitioners Data Bank.

Core Principles Which of the four core ethical principles—autonomy, nonmaleficence, beneficence, and justice—dominates depends on the particular situation. On one hand, respect for patient autonomy is salient when psychosurgery is proposed, but the principle of social justice may be in force in deciding who receives an expensive new medication that is scarce. The most pervasive ethical conflict in psychiatry and in medicine as a whole is that between *autonomy*, the right of patients to self-determination, and *beneficence*, the duty of physicians to act in the best interest of their patients.

Autonomy The principle of *patient autonomy* is of central importance and, conceptually, is in many ways coextensive with the legal concept of competence. A patient makes an autonomous choice by giving informed consent when that choice is (1) intentional, (2) free of undue outside influence, and (3) made with rational understanding. Usually, when patients respond to a choice by saying “yes,” the desire to comply is assumed. However, that assumption may not be valid with a highly confused patient.

Nonmaleficence *Nonmaleficence* is the duty of the psychiatrist to avoid either inflicting physical and emotional harm on the patient or increasing the risk of such harm. That principle is captured by *primum non nocere*, “first, do no harm.”

Beneficence The principle of *beneficence*—to prevent or remove harm and promote well-being—was the primary driving principle of medical and psychiatric practice throughout history until the rise of consumerism and other factors in the late 1960s. The expression of the principle is paternalism, the use of the psychiatrist's judgment as to what course of action is best for the patient or research subject.

Psychiatrists have historically justified beneficent paternalism on the basis of their superior knowledge, greater objectivity, and powerful desire to help their patients. A common example of the primacy of beneficence is the decision to hospitalize a suicidal patient involuntarily. That unilateral act implies either that the patient's autonomy is intact but must be overridden by the potential for dangerous behavior or that the patient's capacity for autonomous choice is impaired by the mental illness and must be ignored. Here is an example of the distinction between *weak paternalism*, acting beneficently when the patient's impaired faculties prevent an autonomous choice, and *strong paternalism*, acting beneficently despite the patient's intact autonomy.

Guidelines have been proposed for permitting beneficence to overrule patient autonomy: when the patient faces substantial harm or risk of harm, the paternalistic act is chosen that ensures the optimal combination of maximal harm reduction, low added risk, and minimum necessary infringement on patient autonomy. For example, convincing an acutely suicidal patient to enter the hospital voluntarily confers the environment necessary to contain the suicidal behavior, poses little added risk for most patients, and preserves more patient autonomy than involuntary hospitalization or a breach of confidentiality to an intervening third party on an outpatient basis.

Justice Like the principles of autonomy, nonmaleficence, and beneficence, the principle of justice in psychiatry does not operate in a vacuum but is responsive to the ever-changing social, political, religious, and legal mores of the moment.

HISTORY

The changing ethical landscape of psychiatric research and practice can perhaps best be understood as the continuous revision of the basic skeleton of Hippocratic teachings. The elements of the original Hippocratic oath include the following: medicine is a closed profession; use those treatments in which you are skilled and defer to specialists those in which you are not; maximize patient health and minimize harm; avoid sexual relations and other exploitative self-interests; confidentiality; and penalties for violations. Several factors were responsible for the explosion of interest in the psychiatric profession's ethical conduct in the 1970s. In the long

history of mental health care, that era marked the first time that patient autonomy—in the form of consumerism and civil rights activism, including the women's movement—encroached on the tradition of medical paternalism.

Modern psychiatry is dotted with well-publicized cases of patient abuse under the guise of paternalism. Examples include lobotomy, the shock therapies, lysergic acid diethylamide (LSD) experimentation, and the commitment of Soviet dissidents to mental institutions for the purpose of political oppression. The profession has seen major judicial and governmental intrusions into its practice in such areas as confidentiality and involuntary hospitalization and treatment.

During the Second World War, charges were made that involved the behavior of physicians acting under the direction of the Third Reich of Germany. Some medical leaders felt that the Hippocratic Oath did not adequately address some grossly inhumane behavior of the German doctors. In the 1950s and 1960s the Oath of Geneva at medical school graduations sometimes replaced the Oath of Hippocrates. This was, perhaps, the first time in 2000 years that the medical profession began to question and modify its own ethical models.

In the 1970s two social movements came together to sound a wake-up call to the medical profession. The rise of both consumerism and feminism took the entire medical profession to task. Paternalism gave way to autonomy. Patients had rights and they knew it! A hospital patient who asked a nurse “What's that pill?” would no longer tolerate the answer: “It's what Doctor is giving you to make you better.” Women would no longer tolerate sexual behavior from or with their doctors. They protested, they formed self-help groups, and they played a large role in establishing ethics committees at the district branch levels of the APA.

PROFESSIONAL CODES

Most professional organizations and many business groups have codes of ethics. Such codes reflect a consensus about the general standards of appropriate professional conduct. The American Medical Association's (AMA) Principles of Medical Ethics, the APA's *Principles*, and the American College of Physicians Ethics Manual articulate ideal standards of practice and professional virtues of practitioners. These codes include exhortations to use skillful and scientific techniques, to self-regulate misconduct within the profession, and to respect the rights and needs of patients, families, colleagues, and society. Such exhortations are reinforced by ethical principles such as beneficence, utility, autonomy, respect, and justice.

In recent years, there has been increased interest in the use of professional codes of ethics as a standard of criticism and as a means of regulating professional misconduct. Some hospitals withdraw privileges from a psychiatrist who has been expelled for ethical reasons, and malpractice coverage may be denied.

The 1995 edition of *The Principles* provides a useful and comprehensive example of a professional code geared to the psychiatric profession. The manual covers a broad array of psychiatric ethical issues, from fee splitting and sex with former patients to psychiatrists' participation in executions, all of which are unethical (Table 54.2-1). Another useful manual is the 1995 edition of the *Opinions of the Ethics Committee on the Principles of Medical Ethics With Annotations Especially Applicable to Psychiatry*. This manual, developed by APA Ethics Committee members and consultants, provides answers to commonly asked ethical questions. A summary of ethical questions and answers is provided in Table 54.2-2.

Table 54.2-1 The Principles of Medical Ethics With Annotations Especially Applicable to Psychiatry

Table 54.2-2 Ethical Questions and Answers

The Principles, if carefully read, will suggest to the student and practitioner certain behaviors that are expected of an ethical psychiatrist and certain behaviors deemed by the profession to be unethical and unacceptable. The APA and its district branches have a carefully worked-out set of procedures to be followed if a member of that organization is accused of violating the ethical principles. While these procedures are not perfect, they seem to have served the profession well for more than 20 years. Further, they are changed in response to changes in federal and state laws and the oversights that have become apparent.

From a practical point of view, the transgressions that psychiatrists most frequently commit fall into a few categories, and certain activities may fit in more than one category:

1. Sexual boundary violations;
2. Nonsexual boundary violations;
3. Violations of confidentiality;
4. Mistreatment of the patient (incompetence, double agentry); and
5. Illegal activities (insurance, billing, insider stock trading).

SEXUAL BOUNDARY VIOLATIONS

Sexual activity with a current or former patient is unethical. The rest is commentary.

By far the most publicized ethical transgression of psychiatrists involves sexual activity with a patient or a former patient. A variety of defenses have been advanced by psychiatrists accused of such activity; yet it should be obvious what a sexual activity is, what a patient is, and what a former patient is.

The Principles is quite clear on the subject. Sexual activity with a current or former patient is unethical. Glen Gabbard has studied a great many psychotherapists who have gotten into trouble because of sexual involvement with patients. He categorized them into some interesting groups including psychotic disorders, predatory

psychopathy and paraphilias, lovesickness, and masochistic surrender.

Clearly, with such different types of psychotherapists involved in sexual activity with patients, no one pattern of behavior can provide a danger signal. Yet, if one studies complaints brought to professional societies, a rather distinctive pattern does emerge, the slippery slope of smaller violations leading to greater violations.

> A male therapist is treating a female patient who may have some borderline personality traits. During a particularly emotional session, the doctor holds the patient's hand or puts his arm around her shoulder to comfort her. Perhaps there is even a hug; later, another emotional session and another hug, this time a bit longer. Soon each session ends with a hug, maybe a hug and a kiss on the cheek. Later the patient calls the doctor in the evening, sobbing. The doctor makes a house call; more hugs, more kisses. A suicide gesture is often catalytic. This scenario can get quite complicated and involved but it is not uncommon. At this point the situation is, without question, a psychiatric emergency. The doctor must obtain an immediate consultation from an experienced colleague. Unfortunately, this option is rarely taken. Whether due to embarrassment, fear of criticism from the community, denial, or unwarranted omnipotence, the scenario usually progresses down the slippery slope, and sexual activity replaces treatment.

An argument occasionally put forward is that the sexual activity is consensual. That is, it takes place between two autonomous adults, and consequently they should be able to do as they please. Yet even a rudimentary knowledge of dynamic psychiatry reveals that the two adults are rarely autonomous. Powerful, unconscious forces are at work in all doctor-patient relationships. The patient does not have to lie on a couch five times a week to develop transference. Transference occurs in every encounter with a patient. Even the brief medication-management visit produces transference (and countertransference). *The Principles* is quite clear in Section 2.1.

Although not spelled out in *The Principles*, sexual activity with a patient's family member is also unethical. This is most important when the psychiatrist is treating a child or adolescent. Most training programs in child and adolescent psychiatry emphasize that the parents are patients too and that the ethical and legal proscriptions apply to parents (or parent surrogates) as well as to the child. Nevertheless, some psychiatrists misunderstand this concept. Sexual activity between a doctor and a patient's family member is also unethical.

NONSEXUAL BOUNDARY VIOLATIONS

The preceding section points out that any sexual activity with a current or former patient is unethical. That is simple, straightforward, and unambiguous. Nonsexual boundary violations are far less clear and far less obvious. The overriding principle is that exploitation of the doctor-patient relationship or therapist-client relationship for purposes other than treatment is probably unethical. In their definitive book *Boundaries and Boundary Violations in Psychoanalysis* Gabbard and Eva Lester describe many types of boundaries in doctor-patient relationships. The relationship between a doctor and a patient for the purposes of providing and obtaining treatment is what is usually called the *doctor-patient relationship*. That relationship, for that purpose, has a boundary around it and boundaries within it. Either person may cross the boundary.

Not all boundary crossings are boundary violations. For example, a patient may say to a doctor at the end of an hour “I have left my money at home and I need a dollar to get my car out of the garage. Will you lend me a dollar until next time?” The patient has invited the doctor to cross the doctor-patient boundary and set up a lender-borrower relationship as well. Depending upon the doctor's theoretical orientation, the clinical situation with the patient, and other factors, the doctor may elect to cross the boundary. One can then debate whether the boundary crossing is also a boundary violation. A *boundary violation* is a boundary crossing that is also exploitative. It gratifies the doctor's needs at the expense of the patient. The doctor is responsible for preserving the boundary and for seeing to it that boundary crossings are held to a minimum and that exploitation does not occur. Harm to the patient is not a component of a boundary violation. For example, using information supplied by the patient, (e.g., a stock tip) is an unethical boundary violation although no obvious harm may come to the patient. For purposes of discussion, nonsexual boundary violations may be grouped into several arbitrary (overlapping and not mutually exclusive) categories.

Business Almost any business relationship with a former patient is problematic, and almost any business relationship with a current patient is unethical. Naturally, the circumstance and location may play a significant role in this admonition. In a rural area or a small community, one might be treating the only pharmacist (or plumber or couch upholsterer) in town; then one does business with the pharmacist/patient and tries to keep boundaries in check. Ethical psychiatrists try to avoid doing business with a patient or a patient's family member or asking a patient to hire one of their family members. Ethical psychiatrists avoid investing in a patient's business or collaborating with a patient in a business deal. A recent nonfiction book, *Hollywood on the Couch*, describes in embarrassing detail a series of alleged boundary violations committed by famous psychiatrists whose patients were prominent in motion pictures, television, and the stage. Psychiatrists in this well-documented book became involved in the businesses of their patients, much to the detriment of the treatment. Psychiatrists served as “advisors” to their patients' movies, and celebrities were appointed to “Scientific Advisory Boards” of their therapists.

> A successful businessman, Mr. Z. was treated by Dr. A. Sometime after termination, Dr. A. contacted Mr. Z. to initiate a social relationship. Dr. A. called Mr. Z. “Charlie” and Mr. Z. called Dr. A. “Dr. A.” Mr. Z. told Dr. A. that several potential investors were interested in a business that Mr. Z. was starting. Dr. A. said that he would be interested in becoming a principal investor. A deal was struck. Slowly Dr. A. bought more of the business, and despite his promise not to do so, Dr. A. took over control of the business. The business grew because of the acumen of Mr. Z., but Dr. A. became even greedier and attempted a total coup. In the process of taking over the business, Dr. A. used knowledge gained while treating Mr. Z. (some of his strengths and some of his weaknesses). He used the still-present transference in convincing Mr. Z. to turn over still more control to Dr. A., (Mr. Z. still called him “doctor,” and Dr. A. still called him “Charlie”). A lawsuit resolved matters in Mr. Z.'s favor. Mr. Z. now has an abiding mistrust of psychiatrists.

Solicitation of Funds Solicitation of funds from current or former patients presents many ethical problems and financial dilemmas. Psychiatrists' knowledge of interpersonal relationships and especially their knowledge of unconscious factors that affect behavior, make this the only medical specialty troubled by the solicitation of funds from current and former patients. During the past decade, as public funding for research and the support of mental health facilities diminished, directors had to look to other sources for money. One source that has been tapped is the affluent patient. Medical and surgical colleagues have sought financial support from their patients for decades and evidently thought little of the ethical implications of doing so. Now, private psychiatric hospitals and psychiatric departments of medical schools and general medical hospitals have gotten on the fund-raising train. Foundations have been set up by local and national mental health organizations. The problem arises when psychiatrists associated with such organizations seek donations from their patients or former patients. *The Principles* states that psychiatrists should not exploit information furnished by their patients (e.g., financial status and philanthropic proclivities) and should not use their position of power to influence patients (e.g., what to do with their spare cash). Notice that in these examples, the doctor might not even directly benefit from such solicitations. However, there have been instances in which a psychiatrist has attempted to influence a patient to contribute funds to the doctor's own foundation or research projects. In one highly publicized case, a psychiatrist persuaded a patient to give him a generous annual stipend so that he could be free to do his uncompensated research. The APA sanctioned him. The chair of a university psychiatry department wrote to his faculty urging them to contact some of their affluent and grateful patients and solicit money for his department. An ethical psychiatrist-professor wrote to the APA Ethics Committee asking for guidance. The committee suggested that this request was inappropriate because it encouraged faculty members to violate *The Principles* through undue influence and breaking confidentiality. The scheme was dropped.

Ideological Issues Ideological issues can cloud one's judgment and may lead to ethical lapses. Any clinical decision should be based on what is best for the patient; the psychiatrist's ideology should play as little a part as possible in such a decision. The ethical psychiatrist, then, must attend to current research, new approaches, and the results of such approaches. An obvious example of this problem is the psychiatrist who is convinced that an analytic approach is the only way to treat such conditions as major depression, bipolar disorder, and schizophrenia. Current research suggests that other approaches are as useful or more useful in many cases. The patient's welfare and the patient's wishes must be considered in such a situation. A psychiatrist who is consulted by a patient with an illness such as this should tell the patient what forms of treatment are available to treat the illness and allow the patient to decide upon a course of treatment. Naturally, psychiatrists should recommend the treatment that they feel is in the best interest of the patient, but ultimately, the patient should be free to choose.

Social The particular locale and circumstances must be considered in any discussion of the behavior of an ethical psychiatrist in social situations. The overarching principle is that the boundaries of the psychiatrist-patient relationship should be respected. Further, if options exist, they should be exercised in favor of the patient. Problems often arise in treatment situations when friendships develop between the psychiatrist and the patient. Objectivity is compromised, therapeutic neutrality is impaired, and factors outside the consciousness of either party may play a destructive role. Such friendship should be avoided during treatment. Similarly, psychiatrists should not treat their social friends for the same set of reasons. Obviously, in an emergency, one does what one must.

Hollywood on the Couch is an entertaining look at how not to conduct a practice. The authors describe many doctor-patient relationships in which the boundaries between social relationships, business relationships, sexual relationships, and the putative doctor-patient relationship became so blurred that meaningful treatment

was impossible.

Special attention must be paid to the temptation to socialize with the patient's family or to allow a patient to establish a relationship with the doctor's family. This is especially worrisome when the patient is a child and social or sexual relationships are established with the patient's parent.

It is tempting to ask favors of a patient, especially if the favor involves no great effort from the patient. Yet the unintended results may be upsetting. The slippery slope phenomenon operates in this area as well. Asking a patient to mail a letter may seem innocuous. To whom is the letter addressed? To another patient? To the Medical Board? Just to the phone company? If it is mailing a letter this week, is it getting the doctor a coffee next week? If the patient is a car dealer might the doctor ask for a special deal?

A psychoanalyst treated an attorney for several years and both felt that the treatment went well. About a year after termination, the doctor's son graduated from law school. Lawyer positions were hard to obtain. By then the former patient was in charge of a large legal organization of just the type that the doctor's son wanted to join. Would it have been proper for the doctor to contact his former patient to see if a door could be opened? Could the doctor have suggested that his son contact the former patient and mention the fact that he was that doctor's son? Certainly no direct harm would have come to the former patient (assuming the doctor's son was competent). Yet, *The Principles* prohibits such a boundary crossing because it would be exploitative and would be influencing the former patient in a way not directly relative to treatment. (See Principles 1.1 and 2.2 in Table 54.2-1.)

Financial For psychiatrists who practice in the private sector, dealing with the patient about money is a part of treatment. Issues surrounding setting the fee, collecting the fee, and other financial matters are grist for the mill. Even so, ethical concerns must be observed. *The Principles* advises the doctor on such matters as charging for missed appointments and other contractual problems. Ethics complaints against doctors are frequently precipitated by financial issues; thus the doctor must recognize the power that these issues have in the therapeutic relationship. Since the psychotherapeutic relationship is so much like a social relationship—the office looks like a living room, the doctor wears regular clothes, some patients might, without recognizing it, assume that a friendship exists that forgives payment of a fee. When the bill is presented, feelings, even though they are unconscious, are ruffled. The idea that psychiatric services are dispensed in a contractual context cannot be emphasized enough. Early in their careers psychiatrists are often reluctant to discuss fees openly out of a sense of embarrassment over discussing money or a sense of protecting the patient. A prominent psychiatrist once commented that most of his patients could discuss naked aggression, murderous fantasies, and unusual sexual reveries more easily than they could discuss their personal finances.

How an ethical psychiatrist handles the situation when a patient temporarily or permanently runs out of money is important. There are many options—some more problematic than others. The psychiatrist can certainly lower the fee, but caution is needed because a fee lowered to the point where the treatment is not somehow being compensated may evoke countertransference resentment. The number of patients being seen at a reduced fee is a similar consideration. Running up a bill can also be a problem. Is there an expectation of eventually being paid? Is the hypertrophic bill a sham? The frequency of sessions may have to be altered. Any psychiatrist who sees private patients will definitely face these problems.

Some psychiatrists have entered into barter arrangements. Such arrangements are fraught with technical, legal, and ethical potholes. How, for example, can the value of a barter be established? Does an hour of a contractor's time value have the same as an hour of the psychiatrist's time? If not, how will the doctor feel and how will the contractor feel? How will this affect the objectivity of the doctor in decisions about the patient? What if the contractor installs the light switches a bit out of place? What feelings are stimulated in the doctor? Does he ask that they be fixed and risk angering the patient? Does he swallow it and risk having his own anger come out in some unintended way? Does he make an interpretation? The “cleaner” course is obviously to charge the patient a fair fee and expect the patient to pay it. The Internal Revenue Service takes a dim view of barter arrangements and feels that two sets of taxes are being avoided. Technically, tax must be paid by each party on the fair market value of the bartered services received. Overlooking this may be collusion with the patient in an illegal activity.

Insurance *The Principles* states that one must deal honestly with patients and colleagues. That would certainly extend to insurance companies and managed care entities. Since psychiatric services are compensated according to contracts between patients and their insurance companies, psychiatrists must respect both parties to the contract. It is tempting to exaggerate a patient's symptoms to obtain payment for certain services for them. Nevertheless, in doing this, one is substituting compassion for honesty. Similarly, listing a procedure code that does not accurately reflect the services performed violates not only ethical principles but the law as well. Listing a diagnosis that is covered rather than a more accurate one is similarly problematic. The rationalization is that since the insurance and managed care companies are a priori unprincipled in their policies, psychiatrists may hedge a bit in their reports. It is equivalent to saying “taxes are too high” and so not reporting income.

CONFIDENTIALITY

> All that may come to my knowledge in the exercise of my profession or outside of my profession or in the daily commerce with men, which ought not to be spread abroad, I will keep secret and will never reveal.

Hippocrates

> No provider of health care shall disclose medical information regarding a patient of the provider without first obtaining an authorization

California Civil Code 56.10(a)

> The identification of a person as a patient must be protected with extreme care... A psychiatrist may release confidential information only with the authorization of the patient or under proper legal compulsion.

The Principles

Although the medical profession overall is bound by rules of confidentiality—from Hippocrates to current state law—such rules seem to apply especially to the field of psychiatry. Psychiatrists are generally not troubled by hearing an internist ask a patient at a cocktail party how the new antihypertensive medicine is working out. However, psychiatrists are quite concerned if a psychiatrist in a similar situation asks a patient how he or she is doing with his new antipsychotic medicine. Psychiatrists take in stride the orthopaedist who comments on an athlete's rotator cuff injury (his or her patient or not) but are outraged if a psychiatrist comments on a celebrity's substance abuse problem (his or her patient or not). Both psychiatrists and the public have every right to be outraged and one can only wonder why the outrage does not apply to the internist and the orthopaedist. Patients expect confidentiality from psychiatrists, and patients own the confidentiality. That confidentiality survives even the death of the patient and is subsequently owned by the executor, not by the psychiatrist. A confidence cannot be broken just because the patient died. Psychiatrists must diligently guard against breaking confidences even with a release if that release was not signed by someone in an informed state of mind. A blanket release of information, often signed upon applying for insurance, submitting a claim, entering a hospital, and similar circumstances, is not an informed consent. The psychiatrist must ensure that a release of information applies to the situation at hand. It is often suggested that whenever a request for information about a patient appears, the doctor should call the patient to verify consent to the disclosure.

Frequently psychiatrists get official-looking documents with the words “Subpoena Duces Tecum” on top and a signature at the bottom directing them to allow certain records to be copied or commanding them to produce the records somewhere. Most such documents do not come from a court, but from a lawyer's office. If there is any question that the patient has not consented to such disclosures and has not signed an informed consent to release such records, the ethical psychiatrist should contact the patient and come to some understanding. Patients who do not wish such records released may wish to have their lawyer attempt to quash the subpoena. Failing that, the psychiatrist may wish to ask the court to uphold the patient's right to privacy or at least determine what must (and what must not) be released. In certain jurisdictions patients may waive their right to privacy and confidentiality under certain circumstances (e.g., bringing their own mental state into a lawsuit). It is not within the psychiatrist's field of expertise to determine if the patient has waived that right. It is the job of the patient's lawyer or a judge or both.

Overall, psychiatrists should never discuss their patients outside the office. Some psychiatrists feel that it is all right to discuss cases at the dinner table with their spouse and family. After all, they say, “I trust my spouse and kids.” However, trust is beside the point. Patients assume that what they tell the psychiatrist stays inside the consulting room. Merely informing a spouse of the identity of one's patient violates the ethical principles. Attempting to disguise an identity to keep a patient's case history anonymous is tempting fate.

A recent ethics case involved a psychiatrist who mentioned one of his patients to a social group. Details of the case were revealed although not the patient's name. Some members of the social group knew that one of their friends was in treatment with the psychiatrist, and they easily deduced the patient's identity. This led to considerable embarrassment to the patient. The doctor in attempting to defend himself said that if the patient wanted privacy he should not have revealed that he was in treatment with the doctor. This argument was refuted. It is always the doctor's job to protect the privacy of the patient.

Mandatory Reporting The Tarasoff case is an example of the legal system's attempt to solve a social problem—the need to safeguard life—by creating an ethical dilemma for the psychiatrist. This case, which began as a civil lawsuit, ended up with the California Supreme Court ruling that a pyschotherapist has a duty to warn and protect a potential victim of a potentially dangerous patient. The court proclaimed that the principles of justice and nonmaleficence outweighed the principle of beneficence (confidentiality). Most states have agreed with the Tarasoff court and have enacted laws requiring psychotherapists to warn potential victims or to warn the police when an identified person is threatened.

Tarasoff I Does establishment of a therapist-patient relationship oblige the therapist to care for the safety of not only the patient but also others? This issue was raised in 1976 in the case of *Tarasoff v Regents of University of California* (now known as *Tarasoff I*). In this case, Prosenjit Poddar, a student and voluntary outpatient at the mental health clinic of the University of California, told his therapist that he intended to kill a student readily identified as Tatiana Tarasoff. Realizing the seriousness of the intention, the therapist, with concurrence of a colleague, concluded that Poddar should be committed for observation under a 72-hour emergency psychiatric detention provision of the California commitment law. The therapist notified the campus police both orally and in writing that Poddar was dangerous and should be committed.

Concerned about the breach of confidentiality, the therapist's supervisor vetoed the recommendation and ordered all records relating to Poddar's treatment destroyed. At the same time, the campus police temporarily detained Poddar but released him on his assurance that he would “stay away from that girl.” Poddar stopped going to the clinic when he learned from the police about his therapist's recommendation to commit him. Two months later, he carried out his threat to kill Tatiana. The young woman's parents then sued the university for negligence.

The California Supreme Court deliberated the case for the unprecedented time of about 14 months and ruled that a physician or a psychotherapist who has reason to believe that a patient may injure or kill someone must notify the potential victim, the victim's relatives or friends, or the authorities.

The discharge of the duty imposed on the therapist to warn intended victims about danger may take one or more various steps, depending on the case. The court stated that it may call for the therapist to notify the intended victim or others likely to notify the victim of the danger, to notify the police, or to take whatever other steps are reasonably necessary under the circumstances.

The *Tarasoff I* decision has not drastically affected psychiatrists; it has long been their practice to warn the appropriate people or law enforcement authorities when a patient presents a distinct and immediate threat to someone. According to the APA, confidentiality may, with careful judgment, be broken when (1) a patient probably will commit murder, and the act can be stopped only by the psychiatrist's notification of the police; (2) a patient probably will commit suicide, and the act can be stopped only by the psychiatrist's notification of the police; and (3) a patient, such as a bus driver or an airline pilot, who has potentially life-threatening responsibilities shows markedly impaired judgment.

The *Tarasoff I* ruling does not require that therapists report a patient's fantasies; instead, it requires them to report an intended homicide; it is the therapist's duty to exercise good judgment.

Tarasoff II In 1982 the California Supreme Court issued a second ruling in the case of *Tarasoff v Regents of University of California* (now known as *Tarasoff II*), which broadened its earlier ruling, the duty to warn, to include the duty to protect.

The *Tarasoff II* ruling stimulated intense debates in the medicolegal field. Lawyers, judges, and expert witnesses argue the definition of protection, the nature of the relationship between the therapist and the patient, and the balance between public safety and individual privacy. Clinicians argue that the duty to protect hinders treatment because a patient may not trust a doctor if confidentiality is not maintained. Furthermore, because it is not easy to determine whether a patient is dangerous enough to justify long-term incarceration, unnecessary involuntary hospitalization may occur because of a therapist's defensive practices.

As a result of such debates in the medicolegal field since 1976, the state courts have not made a uniform interpretation of the *Tarasoff II* ruling (the duty to protect). Generally, clinicians should note whether a specific identifiable victim seems to be in imminent and probable danger from the threat of an action contemplated by a mentally ill patient; the harm, in addition to being imminent, should be potentially serious or severe. Usually, the patient must be a danger to another person, not to property, and the therapist should take clinically reasonable actions.

In a few cases (none successful so far) claims have already been advanced that a *Tarasoff*-like duty applies to potential infection of partners with human immunodeficiency virus (HIV) by patients under mental health treatment. The breach of confidentiality in *Tarasoff* cases is justified only by the threat of violence. Laws vary confusingly by jurisdiction. The ideal solution is to persuade the patient to make the disclosure and report the matter to the public health authorities.

Dealing With the Press It is quite flattering (at first) for a psychiatrist to be called by the news media and be asked about a person who may be in the news. The person may or may not be the patient of that doctor. Section 7.3 of *The Principles* is quite specific. Psychiatrists may comment on mental illness generally, but not offer opinions about either their patients or a person who is not their patient.

In 1964 Barry Goldwater, an outspoken, conservative man, ran for President of the United States. A magazine sent a questionnaire to nearly all the psychiatrists in the United States asking: “Do you believe Goldwater is psychologically fit to serve as President of the United States?” The magazine sent out 12,356 questionnaires and received 2417 responses. Of these, 1189 psychiatrists said the candidate was not psychologically fit to serve as president. The cover of the magazine ran its main story with the title “1,189 Psychiatrists Say Goldwater is Psychologically Unfit to be President!” How many of these psychiatrists actually examined the candidate? How many of them obtained permission to reveal the results of their examination? On what basis, then, did so many outstanding psychiatrists lose their moral bearings and offer a psychiatric or medical opinion on this man's mental state. By reading about him in the newspaper? By watching him on TV? The authors of *The Principles*, which was written nine years later in 1973, considered this event when they wrote Section 7.3.

In the mid-1990s the wife of a famous athlete and a friend of hers were murdered. Her former therapist immediately contacted the media to describe the psychological events that were going on with the victim and with her husband. The press alternated between being shocked that a therapist would reveal such material and being fascinated at having such a loquacious source. Many psychiatrists and other mental health professionals commented about the victim and the victim's husband, the suspect. The psychiatrist who was attending to the husband-suspect was appropriately silent.

ETHICS IN MANAGED CARE

Recent changes in how psychiatrists are compensated for their services have stimulated much criticism of both the managed care industry and the doctors who work in and for it. Some claim that the inner conflicts caused by working in a managed care environment are insurmountable. Some have declared that participating in a managed care scheme is per se unethical. Others, while lamenting the existence of managed care, have said that one can function ethically in such an environment. A significant number of psychiatrists believe that managed care provides the answer to overuse of limited services, contains costs, and offers the opportunity for outcome studies. There may be some truth to each point of view.

Conflict of Interest There is nothing new about a physician having a conflict of interest regarding how services are provided and how payments are received. In a fee-for-service environment, the more services a physician provides, the greater is the fee. That leads to the conflict of interest in which physicians may provide an abundance of service to increase their fee. Psychiatrists take that conflict as a given and advise trainees to put the interest of their patients before their own and provide only the service that is needed. Yet all psychiatrists are aware of egregious examples of interminable treatments, prolonged hospitalizations, and treatments of unconscionable intensity that are clearly in the interest of the physician or the hospital or both. There have been a few outcries in the press, and some governmental agencies took some miscreants to task, but few complaints of ethics violations were made. Recently, a proposal was made to the APA that any psychiatrist who limited services to a patient covered by a managed care program should be declared guilty of unethical behavior and expelled. This proposal was not accepted, but it received a great deal of support during the debate. (No analogous proposal was made during the era of multiyear hospitalization for adolescent conduct disorder.) These anecdotes underline the difference in the perception of conflict of interest when restrictions are imposed on psychiatrists from the outside

(managed care) and when restrictions must be self-imposed (fee for service). Yet, the ethical principles are the same. *The Principles* section 1, annotation 1, states: "A psychiatrist shall not gratify his or her own needs by exploiting a patient." This clearly applies in both the fee-for-service environment and the managed care environment. Thus, it would be unethical for psychiatrists working as a managed care reviewer to deny needed care to patients on the basis of their employer's cost-containment policy rather than on the honest belief that they did not require the service. On the same principle, it would be unethical for a treating psychiatrist to dishonestly claim that a patient was suicidal (if that were not the case) to obtain payment for services that the treating psychiatrist believes is necessary.

Contracts In the not too distant past, patients came to see doctors and paid out of their pockets for their treatment. This practice continued for psychiatrists somewhat longer than for our other medical colleagues. Under managed care, both doctor and patient operate under a set of rules written by insurance companies and managed care companies. Anyone who is a party to such a contract is bound by its provisions. Doctors have, at least, a slight advantage. They can and should study each contract and understand all the provisions in it. If a managed care contract has provisions they cannot live with, doctors can and should reject the contract. For example, if a contract has a gag provision that prohibits the doctor from telling patients of the existence of procedures or medicines that might help them but are not paid for by the company, the doctor might well reject the contract. Sadly, most patients cannot pick their contract. Employers buy health coverage on the basis of the least costly package, not the one with the fairest benefit plan. Employees get what is offered. Still, doctors must operate under the contract that they have agreed to and which the patient has agreed to albeit reluctantly. Section 2, annotation 5 of *The Principles* states: "Psychiatric services, like all medical services, are dispensed in the context of a contractual arrangement between the patient and the treating physician. The provisions of the contractual arrangement, which are binding on the physician as well as on the patient, should be explicitly established."

APA GUIDELINES FOR ETHICAL PRACTICE IN ORGANIZED SETTINGS

The APA has issued the following addendum to *The Principles* to help physicians clarify existing ethical standards contained in that document and excerpted above.

Psychiatrists have a long and valued tradition of being essential participants in organizations that deliver health care. Such organizations can enhance medical effectiveness and protect the standards and values of the psychiatric profession by fostering competent, compassionate medical care in a setting in which informed consent and confidentiality are rigorously preserved, conditions essential for the treatment of mental illness. However, some organizations may place the psychiatrist in a position where the clinical needs of the patient, the demands of the community and larger society, and even the professional role of the psychiatrist are in conflict with the interests of the organization.

The psychiatrist must consider the consequence of such role conflicts with respect to patients in his/her care and strive to resolve these conflicts in a manner that is likely to be of greatest benefit to the patient. Whether during treatment or a review process, a psychiatrist shall respect the autonomy, privacy and dignity of the patient and his/her family.

These guidelines are intended to clarify existing standards. They are intended to promote the interests of the patient, and should not be construed to interfere with the ability of a psychiatrist in an organized setting. The principles and annotations noted in this communication conform to the statement in the preamble to *The Principles of Medical Ethics*. These are not laws but standards of conduct which define the essentials of honorable behavior for the physician.

1. *Appropriateness of Treatment and Treatment Options*
   a. A psychiatrist shall not withhold information that the patient needs or reasonably could use to make informed treatment decisions, including options for treatment not provided by the psychiatrist. [sect 2, annotation 5; section 5, annotations 2 and 3].
   b. A psychiatrist's treatment plan shall be based on clinical, scientific or generally accepted standards of treatment. This applies to the treating and the reviewing psychiatrist.
   c. A psychiatrist shall strive to provide beneficial treatment which shall not be limited to minimum criteria of medical necessity.
2. *Financial Arrangements*
   When a psychiatrist is aware of financial incentives or penalties which limit the provision of appropriate treatment for that patient, the psychiatrist shall inform that patient and/or the designated guardian.
3. *Review Process*
   A psychiatrist shall not conduct reviews or participate in reviews in a manner likely to demean the dignity of the patient by asking for highly personal material not necessary for the conduct of the review. A reviewing psychiatrist shall strive as hard for a patient he/she reviews as for one he/she treats to prevent the disclosure of sensitive patient material to anyone other than for clear clinical necessity.

SUGGESTED CROSS-REFERENCES

Ethics pertains to all domains of psychiatric research and practice. Of special interest are Section 4.2 on sociology and psychiatry; Chapter 9 on the classification of mental disorders; Chapter 19 on sexuality; Section 28.5 on death, dying, and bereavement; Section 29.1 on suicide; Section 30.11 on evaluation of psychotherapy; Section 28.4 on genetic counseling; Section 31.31 on electroconvulsive therapy, Section 31.22 on psychosurgery; Section 51.6b and Section 51.6c on legal and ethical issues in geriatric psychiatry; Section 52.1 on public psychiatry; Section 51.5a on financial issues; on the economics of psychiatry, Section 54.1 on legal issues in psychiatry; and Section 55.1 on the history of psychiatry.

CHAPTER 55. PSYCHIATRY: PAST AND FUTURE

55.1 HISTORY OF PSYCHIATRY

RALPH COLP, JR., M.D.

BEGINNINGS OF PSYCHIATRY

In the first civilizations in Egypt and the Near East, mental illness was attributed to the magical forces of malevolent deities, and the main therapists were priests who used religious and magical rites to counter those forces. Belief in those evil deities—called demons after the advent of Christianity—prevailed in many primitive societies; in the history of civilized societies, credence in demons fluctuated in complex ways.

GREEK AND ROMAN PSYCHIATRY

In the civilizations of ancient Greece and Rome, psychiatry was a province of religious cults for healing illnesses and of schools of philosophy and medicine (often part of philosophy), which viewed mental illness as mainly psychological, mainly somatic, or a mixture of both psyche and soma; thus, the three enduring psychiatric viewpoints were established.

Greek Psychiatry

Hippocrates The writings of the physician Hippocrates (460–370 BC)—now thought to be the work of unknown authors—propounded the view that the human body contains four essential humors—phlegm, yellow bile, black bile, and blood—which are secreted by different organs, possess different qualities, and vary with the seasons. The brain was considered the seat of life, and its normal functioning required a balance between the humors. Large excesses of phlegm caused a form of dementia, yellow bile caused manic rage, and black bile caused melancholia. Small excesses of these three humors and blood also produced phlegmatic, choleric, and sanguine personalities. It was the first attempt to explain differences in temperaments and personalities.

DISEASES AND TREATMENTS The Hippocratic authors were the first to rationally describe and classify such diseases as epilepsy, mania, paranoia, organic toxic delirium, postpartum psychosis, phobias, and hysteria, which they named and believed to be confined to women and to be caused by a wandering uterus. They associated melancholia with an aversion to food, despondency, sleeplessness, irritability, and restlessness, and they believed that personal hygiene, bathing, and dieting were essential to keep the humors in balance; in cases of insanity, they tried to eliminate excess humors by purgatives, cathartics, and (if necessary) bleeding.

Plato and Aristotle The philosopher Plato (427–347 BC) divided the soul into three parts: rational, appetitive (lusts and greed), and spirited-affective. Madness occurred when the appetitive soul lost the influence of the rational soul or when a divine disturbance of the soul produced either inspired or destructive behavior. For treating disease, Plato advocated a verbal dialectic between a patient and a philosopher or a physician, a question-and-answer dialogue that enabled the patient to alleviate an illness by developing a state of philosophical knowledge.

Plato's pupil Aristotle (384–322 BC) believed that mental illness occurred when the soul was subjected to changes in temperature, black bile, and the emotions. He was the first to describe accurately the affections of desire, anger, fear, courage, envy, joy, hatred, and pity.

Phrenitis The term “phrenitis” was used in ancient Greece to refer to an inflammation that produced disturbances in both the mind and the body, and whose location was never anatomically or conceptually well defined. In the nineteenth century it was replaced by “delirium,” “confusion,” and “clouding.” The clinical behavior it describes continues to be important to modern psychiatry.

Psychological Treatments In addition to Hippocratic somatic and medical treatments, the Greeks developed three psychological treatments: methods of inducing sleep, interpreting dreams (often performed by priests in temples, most notably those of Aesculapius, the god of healing), and using words to encourage, console, and gain knowledge of an illness (e.g., when using Plato's dialectics).

Roman Psychiatry

Stoicism and Epicurianism The Romans generally followed the psychiatric teachings of the Greeks and were influenced by Greek Stoic and Epicurean beliefs that passions and unsatisfied desires act on the soul to produce mental illnesses and that those illnesses can be controlled by achieving, through thoughts and conduct, a mental state of *ataraxia*, or lack of perturbation. (Some modern tranquilizers have been classified as ataractics.)

Galen The greatest Roman physician was Galen (AD 130–200), who consolidated and augmented Greek medical and psychological thinking. He conceptualized that the humors exist in normal and abnormal forms and that four qualities—hot, cold, dry, and moist—are essential in forming human temperaments. To the previous concept of *pneuma* (a vital spirit) he added the concepts of natural spirits and animal spirits. He divided the soul into three parts: reason and intellect, courage and anger, and carnal appetites and desires. He believed that diseases are caused by adverse external influences (e.g., bad diet and bad air) acting on an existing predisposition (an abnormality of a humor or pneuma) and that psychological disorders cause physical disorders and vice versa. Treatment should oppose what is unnatural in a disease (cooling the feverish, warming the chilled) and should be in accord with the patient's age, temperament, and way of life.

Galen's writings, especially his treatise *On Melancholia,* influenced medical thinking for nearly 15 centuries. After his death the creativity of ancient medical writing went into a profound and protracted decline.

Treatment of the Insane Neither Greece nor Rome took social responsibility for treating the insane. The exceptions were a few persons who were admitted to Aesculapian sanctuaries and Roman soldiers who were admitted to military hospitals. Most of the seriously insane were kept under restraint at home by their families. The Romans had laws for appointing guardians to protect the holdings of the insane and for declaring them legally incompetent. Insanity was evaluated by judges, not by physicians. The insane were feared and hated (except those thought to be divinely inspired), beaten, imprisoned, and driven away.

MIDDLE AGES

The 1000 years after the fall of the western Roman empire, AD 400–1400, saw an Arab Islamic empire extending from the Near East to Spain, an eastern Christian Byzantine empire, and Christian western European feudal kingdoms.

Christian Western Europe

Causes of Illness The main supernatural causes of illness were thought to be evil astrological influences (astrology was the main scientific guide for physicians) and demons entering the body and possessing the soul. The writings of Hippocrates and Galen that had survived in Arabic translations and were then translated into Latin

influenced some physicians. Some observed that mental illness could be caused by somatic or psychological conditions.

Illness and Treatment Some often-observed psychiatric reactions were (1) symptoms of possession by the devil, who was supposed to choke and throw its victims about; (2) dance mania, characterized by an irresistible urge to dance and make noises; and (3) *acedia,* a form of depression occurring in anchorites when they experienced distressful doubts about being able to live a religiously meaningful life. Treatment was by physicians or lay persons claiming to possess special powers. Treatment varied and included exorcism of demons by magical techniques, medicinal treatments recommended by Hippocrates and Galen, and time-honored folk remedies (including the use of plants, animal parts, and such esoteric medicines as bark from a tree from Paradise).

Hospitals and Asylums Since Islam held that society is responsible for the kindly care of the insane, the Arabs built hospitals with psychiatric divisions in Baghdad (750) and Cairo (873); they also built special insane asylums in Damascus (800), Aleppo (1270), and the Muslim-ruled Spanish city of Grenada (1365).

Christian attitudes toward the insane fluctuated between rejection and toleration. Because the insane harbored demons, they were incarcerated in madmen's towers and were periodically expelled from towns. An insane person might also be condoned as a fool who lacked a mind because of God's favor and who needed to be cared for. Thus, in the fourteenth century, several hospitals in western Europe cared for the mentally ill, in addition to those with physical illness. Historians have usually recorded that the first Christian western European asylum caring exclusively for the insane was in Valencia Spain in 1409, and that this was followed by other Spanish asylums that were built under the influence of Islam. Michael Stone has recently stated that the first asylum in Europe was built in Hamburg in 1375. While some of Hamburg's insane were confined in a tower little is known about their treatments, or how these differed from those in other medieval cities.

“Bedlam” It was probably around 1400 that Bethlem hospital in London began for unknown reasons to admit the insane, who perhaps because they were verbally and physically violent appear to have displaced the other sick; so that by the sixteenth century Bethlem had assumed its role as a madhouse. Over the following centuries, while becoming known in popular culture as “Bedlam” (defined as “a place of uproar”), it became a special and unique institution, pioneering in the asylum management and care of the insane. *The History of Bethlem* (1997), by Jonathan Andrews, Asa Briggs, Roy Porter, and Penny Tucker, is a 750-page epic narrative, that often has vivid passages, and that will become an essential reference for all who are interested in the history of psychiatry and the asylum.

RENAISSANCE

Witches In 1486 fear of witchcraft—injury inflicted by someone using supernatural devices—was stimulated by the publication of *Malleus maleficarum (Witches' Hammer)* by Henry Kramer and James Sprenger, two theologians who had been designated by the Pope to act as papal inquisitors into witchcraft. *Malleus* described witches as mainly women who showed psychotic or hysterical symptoms and sexual delusions, but it also suggested that any affliction in a male or female could be a sign of witchcraft. It prescribed inquisitorial tortures that would force confessions of guilt from those who were accused. The ideas of *Malleus* then fused with the ideas of other theologians (Catholic and Protestant) of a conspiracy against Christendom and with popular beliefs in demonology. The result was a witch-hunting craze that led to the execution of many thousands of people (mostly women) on charges of being witches and only abated after about 150 years.

Physicians and Books

Paracelsus Born in Switzerland of German parents, Paracelsus (ca. 1493–1541) was the most famous physician of his time. His medical ideas were influenced by medieval philosophy, astrology, magic, and myths and were often confused, contradictory, and controversial. Rejecting the prevailing humoral theory of diseases, he postulated that man had a divine spirit and base animal instincts (lust, covetousness, and the passions of the soul) and that psychiatric illness was the triumph of instincts over spirit, caused by the stars stimulating the instincts. Consequently the physician must study both the instinct dominant in a patient and the star that corresponds to it. Treatments included psychotherapy, venesection, trephination (perforation of the skull), and the administration of sulfur—used because its sedative effects were thought to promote the healing actions of “Sympathy” (one of the main forces in the cosmos). Because he believed that emotions caused physical illness, Paracelsus has been called one of the first “psychosomaticists.”

Books Five sixteenth- and early seventeenth-century authors published new views in different areas of psychiatry. Juan Luis Vives (1493–1540) was born in Spain and lived mainly in Holland and Belgium where his work as a scholar was influenced by the humanism of the North European Renaissance. (His Spanish Jewish parents had converted to Christianity and then been condemned by the Inquisition.) In his *Of Soul and Life* (1538) he anticipated modern dynamic psychology and described for the first time the importance of psychological associations in forming emotions and in recollecting and forgetting past events. The Spanish physician Juan Huarte de San Juan (ca. 1530–1592) in *The Examination of Men's Wits* (1575) made an early attempt to evaluate characteristics and differences in human intelligences. The Italian writer Giambattista Porta (1535–1615) made a pioneer attempt in *The Human Physiognomy* (1586) to compare human morphological and psychological traits.

Weyer In 1563 the German-Dutch physician Johann Weyer (1515–1588) published *De Praestigiis Daemonum (The Deception of Demons),* which was based on 12 years of observing witches. In it Weyer emphasized the difference between magicians who willingly took instruction from the devil, and witches who were not responsible for their deeds and were often mentally unstable and ill from medical causes, who needed the help of physicians. Weyer criticized the *Malleus* and stated that some women only confessed to being witches because of torture. George Mora observed in his introduction to the English translation of *De Praestigius* that Weyer's role as a pioneer of modern psychiatry is “difficult to assess”; that for centuries his work was ignored by those interested in psychiatric illness; and that only recently, with the advent of psychodynamic theories and psychotherapies, was Weyer seen as a precursor of these approaches.

Plater The Swiss physician Felix Plater (1536–1614) published two large books, *Practice of Medicine* (1602) and *Observations of Diseases Injurious to Body and Mind* (1614), that classified and described all known diseases and advanced the process of separating psychological knowledge from philosophy and theology. He also was a pioneer in recognizing degrees of mental handicap (i.e., that some mentally handicapped persons may have exceptional ability in one area, that some are mentally disturbed and some are not) and in making autopsies on and studying the neuropathology of handicapped individuals.

Advent of Syphilis During the years 1530–1546 Girolamo Fracastoro (1484–1553), an Italian physician and humanist, published accounts of a new epidemic illness with loathsome and disfiguring symptoms and significant mortality. He named it syphilis and correctly stated that it was caused by sexual contact between two persons. The concept of sexual contagion was new, and syphilis caused a unique and unprecedented mass fear about the danger of sexual activity—a fear that was later sustained when chronic syphilis was recognized as a major cause of dementia. That fear was equaled only by recent fears of acquired immune deficiency syndrome (AIDS).

SEVENTEENTH CENTURY

Seventeenth-century thought on mental illness was influenced by the work of two eminent English physicians—Thomas Willis (1621–1675) and Thomas Sydenham (1624–1689)—an Italian papal physician, Paolo Zacchia (1584–1659), and an Oxford dean of divinity, Robert Burton (1577–1640).

Willis (who performed autopsies on some of his patients) recognized the difference between mental symptoms of gross brain disease and diseases in which the brain seemed normal, which he attributed to disturbed animal spirits. Sydenham gave a comprehensive account of the many symptoms of hysteria, observed that it occurred in both males and females, and ascribed it to abnormal animal spirits. His classification of the causes of disease symptoms into “remote” or “external” (inordinate actions of the body and mind), immediate (a disorder of animal spirits), and antecedent (a “faulty disposition of the animal spirits”) resembled the modern psychiatric endeavor of constructing atheoretical classifications of mental disease. Sydenham's classification may also have been the first attempt to incorporate contemporary physiological and psychological knowledge into a systematic analysis of insanity.

Zacchia in *Questiones medico-legales* (1621–1635) insisted that the physician, rather than the lawyer, should evaluate the mental state of a person. That view was the beginning of forensic psychiatry. Burton in *The Anatomy of Melancholy* (1621) provided authoritative summaries of writings on melancholy from ancient times through the Renaissance. *The Anatomy* was widely read and caused some forms of melancholy to become fashionable in England.

Incarceration of the Insane In 1656 an edict of the French monarchy created a new hospital administrative organization for Paris that consisted of asylums for the insane and other institutions, each with directors who were empowered to detain persons for indefinite periods and who over the next century locked up groups of insane persons along with indigents, orphans, prostitutes, homosexuals, aged persons, and those chronically ill. Similar incarcerations occurred in Germany.

However, few insane persons were confined in other European countries. In England after 1660 most insane persons were kept at home or were left to roam; only a

few were sent to private madhouses or new public asylums in great towns.

EIGHTEENTH CENTURY

With the influence of the eighteenth-century Enlightenment, belief in the power of rational thinking replaced belief in Hippocratic, Galenic, and demonic ideas and led to new theories of mental illness.

Sauvages and Nosology The French physician Boissier de Sauvages (1706–1767) in his *Nosologia methodica* (1763) divided all known diseases into natural classes, orders, genera, species, and varieties (similar to the way naturalists had divided plants and animals). There were 10 classes of diseases, with class 8 containing species of psychiatric illnesses. The nosology was artificial, but it stimulated physicians to rethink their concepts of disease.

Cullen and Neurosis Two years after Sauvages's nosology the English physician William Cullen (1710–1790) published his own nosology. He used for the first time the term “neurosis” and its adjective “neurotic” to describe a variform group of mental diseases (including apoplexy, paralysis, dyspepsia, hypochondriasis, epilepsy, and hysteria), which he thought were caused when parts of the brain were simultaneously in unequal states of excitement and collapse. Later the meaning of the term “neurosis” would undergo several changes.

Gall and Phrenology Franz Joseph Gall (1758–1828) was a German physician who taught that the brain contained separate organs that occupied specific areas and shaped the personality and that those organs were revealed in the configurations of the head and could be mapped on its surface. This doctrine, with modifications by Gall's pupil Johann Gaspar Spurzheim (1776–1832) and the English lawyer George Combe (1788–1858), became the science of phrenology. Because it offered views on human nature, phrenology became popular during the early nineteenth century in England, France, and the United States.

Treatment of the Insane For most of the eighteenth century, the insane inmates in public mental asylums were often regarded as having incurable diseases and were subjected to physical restraints, beatings, and constant fear (in some private asylums treatment was more lenient). Toward the end of the century that harsh treatment was changed by reforms that abolished most restraints and created an asylum regimen in which the mental patient was respected as a person. These reforms were carried out by the Italian physician Vincenzo Chiarugi (1759–1820) in 1789 in the hospitals of Santa Maria Nuova and of Bonifazio in Florence, Italy; by the English layman and Quaker, William Tuke (1732–1822), who in 1796 founded the York Retreat outside the English city of York; and by Jean Baptiste Pussin (1746–1809?), assistant to the French physician Phillippe Pinel (1745–1826), who in 1797 removed the fetters from the inmates in the Paris hospital of Bicêtre.

Pinel's Empiricism and Moral Treatment In his influential 1801 book *A Treatise on Insanity,* based on empirical observations of patients in the Bicêtre, Pinel made a new classification of mental illnesses—mania, melancholia, idiocy, and dementia—and stated that they were caused mainly by heredity and influences from the environment. He also described how (through an asylum regimen of education, reasoning, and persuasion) many symptoms of insanity could be alleviated. He called this regimen the “moral treatment of insanity.”

EARLY NINETEENTH CENTURY

During the first half of the nineteenth century, the view that mental retardation was a defect of intellectual function different from insanity or dementia became well established; psychiatry became a specialty apart from medicine; and leading psychiatrists in France, England, the United States, and Germany were usually guided by principles of moral therapy in their work with patients.

France

Esquirol Jean Etienne Dominique Esquirol (1782–1840) was the most influential psychiatrist of his time. He further developed the theory and practice of moral therapy, seeing the asylum as the most powerful weapon against mental illness, and was one of the authors of an 1838 law providing an asylum in every department of France, with detailed provisions for patient care, a truly comprehensive law that is still in force in the late twentieth century. His influential book *Mental Maladies: A Treatise on Insanity* (1838), guided by Pinel's empirical approach, differentiated between *hallucination* (a term he coined) and illusion; he divided insanities into monomania, a partial insanity that included paranoia and obsessive-compulsive disease (an early clinical recognition of this disease), and a general delirium-like mania. He inaugurated what was probably the first course in psychiatry and trained physicians to be asylum directors. Among his pupils, Jean-Pierre Falret (1794–1870) and Jules Baillarger (1809–1890) independently described and named circular insanity, and Jacques-Joseph Moreau de Tours (1804–1884) described the psychotic effects of taking the drug hashish. He was the first psychiatrist to delineate the symptoms of a drug-induced psychosis.

England In 1813 Samuel Tuke (1784–1857), grandson of William Tuke, made the York Retreat into one of the most renowned moral treatment asylums in the world by publishing a widely read book, *Description of the Retreat*. In 1839 the physician John Conolly (1794–1866) started a movement to abolish mechanical restraints and later chemical restraints such as bromide and chloral hydrate for overactive asylum patients; practitioners of moral treatment had sometimes used restraints. Nonrestraint was accepted at the first (1841) meeting of the Association of Medical Officers of Hospitals for the Insane, today the Royal College of Psychiatrists, which in 1853 founded the *Asylum Journal,* today the *British Journal of Psychiatry*.

United States

Rush Benjamin Rush (1745–1813) was the most famous American physician of his time and became known as the father of American psychiatry, and his book *Medical Inquiries and Observations upon the Diseases of the Mind* (1812) was the first comprehensive book on mental illness by an American. However, Rush's belief in somatic causation (what he believed to be the morbid actions of cerebral blood vessels) and his nonacceptance of moral treatment caused his influence to wane after his death, when prominent superintendents of American asylums were practicing moral treatment.

American Psychiatric Association In 1844 13 asylum superintendents founded the Association of Medical Superintendents of American Institutions for the Insane (today called the American Psychiatric Association) and its official periodical, the *American Journal of Insanity* (today called the *American Journal of Psychiatry*). Imbued with a belief in moral treatment, those 13 founders (in the view of Constance McGovern) “took on the responsibility for the mentally ill, convinced themselves they could manage and cure the insane, and set out to persuade everyone else.” Their work was, at first, enhanced by lay reformers—most notably Dorothea Dix (1802–1887)—who influenced legislators to create or expand more than 30 institutions for the insane.

Germany After Johann Reil (1759–1813) in *Rhapsodies about the Application of Psychotherapy to Mental Disturbances* (1803) and Johann Christian Heinroth (1773–1843) in *Disturbances of the Mind* (1818) had emphasized the role of psychological factors in mental illness, Wilhelm Griesinger (1817–1868) in *Mental Pathology and Therapeutics* (1845) took an opposing somatic view and argued that mental diseases are brain diseases, even though it was not yet possible to correlate specific brain damage with a specific psychiatric disease. Griesinger later became professor of psychiatry and neurology in Berlin, directing university clinics and laboratories in studies of the anatomy and the pathology of the brain. This work and the discovery in 1861 of a speech center in the brain by the French physician Paul Broca (1824–1880), led to the school of brain psychiatry, represented by Theodore Meynert (1833–1892) in Vienna and Carl Wernicke (1848–1905) in Breslau, which attempted to localize psychiatric phenomena in real or imagined brain structures.

LATE NINETEENTH CENTURY AND EARLY TWENTIETH CENTURY

Theory of Degeneration A theory of mental illness, propounded by two French psychiatrists, Benedict-Augustin Morel (1809–1873) and Valentin Magnan (1835–1916), held that a variety of mental illnesses ranging from insanity to obsessions and compulsions could be congenitally inherited from parents who were afflicted by similar diseases and that the predisposition could slowly become activated into a disease by repeated transmission from parent to child or it could suddenly be activated by the effects of such external events as social traumas, alcoholism, syphilis, and other infections.

The concept of degeneration was, for a time, accepted by prominent psychiatrists. The German psychiatrist Richard von Krafft-Ebing (1840–1902) in *Psychopathia sexualis* presented various cases of sexual perversions (he first coined the terms “sadism,” “masochism,” and “sexual bondage”) and homosexuality, stating that they were often caused by degeneration. His book won respect from lawyers and scientists, and it founded the science of sexology. The Italian psychiatrist Cesare Lombroso (1836–1909) in *The Delinquent Man* (1876) and *The Female Offender* (1893) postulated that criminals represent a degenerate biological phenomenon that can be identified on the basis of physiognomy. Although those postulations were incorrect, Lombroso's books inspired a school of criminal anthropology in Italy, out of

which developed the science of criminality.

Classification of Functional Psychoses

Kraepelin When Emil Kraepelin (1856–1926) was a professor of psychiatry at the universities of Dorpat (then a part of Russia) and at Heidelberg and Munich in Germany, he studied the objective symptoms and clinical life histories of thousands of psychotic patients. In 1899, in the sixth edition of his textbook of psychiatry, Kraepelin classified the major psychoses into two groups. Manic-depressive psychosis (formerly called circular insanity) patients usually recovered; dementia precox, which deteriorated to dementia and which consisted of three subgroups—hebephrenia and catatonia, described by Ewald Hecker (1843–1909) and Karl Kahlbaum (1828–1899) in 1871 and 1874, and dementia paranoia, described by Kraepelin and separated from paranoia and paraphrenia. The classification excluded causes and psychological influences and was based on morbid outcome, although Kraepelin later conceded that some patients with dementia precox recovered. It gave clinical meaning to many disconnected facts and created new disease entities.

Bleuler The Swiss psychiatrist Eugen Bleuler (1857–1939) in *Dementia Praecox or the Group of Schizophrenias* (1911) showed that because dementia precox does not always become dementia, it can more accurately be called “schizophrenia.” He also introduced the terms “autism” and “ambivalence” and described the schizoid personality.

Shock Treatments In the 1920s and 1930s convulsions produced by metrazol given by the Hungarian psychiatrist Ladislas Meduna (1896–1964) and by insulin used by the Viennese physician Manfred Sakel (1900–1957) resulted in remissions in the symptoms of schizophrenic patients. In April 1938 two Italian psychiatrists, Ugo Cerletti (1877–1963) and Lucio Bini (1908–1964), produced convulsions by means of electroshock. Electroconvulsive treatment (ECT) largely replaced metrazol and insulin in the treatment of schizophrenia in the 1940s and early 1950s and was found to be most effective in treating mood disorders. Today (while its use has declined because of the use of antipsychotic and antidepressant medications) modified forms of ECT are still used to treat mood disorders.

Descriptions of Psychoses

Korsakoff's Psychosis In 1889–1890 the Russian psychiatrist Sergei Korsakoff (1853–1900) described a syndrome caused by chronic alcoholism, characterized by multiple neuritis, failure of memory, pseudoreminiscences, and disorientation. Korsakoff is usually considered the first notable psychiatrist in Russia.

Alzheimer's Disease In 1906 the German neuropathologist Alois Alzheimer (1864–1915) reported a case of progressive psychosis and dementia in a 51-year-old woman with neurofibrillary degeneration and plaques in the brain. The disorder was named after him as a form of presenile dementia.

General Paresis In 1826 the French physician Antoine Bayle (1799–1858) stated that general paresis, then probably the most common organic psychotic disease, was a separate clinical entity. That assertion was then ignored or disputed. Only in 1912, after advances in bacteriology, immunology, and pathology, was the syphilitic origin and pathogenesis of general paresis demonstrated.

Medical Treatment of Psychoses

Fever In 1917 the Austrian psychiatrist Julius von Wagner-Jauregg (1857–1940) caused remissions in general paresis with malaria-induced fever. For that he became (in 1927) the first psychiatrist to receive the Nobel Prize. In the 1940s malaria therapy for general paresis was superseded by penicillin.

Pellagra and Vitamin Deficiency Pellagra, a major cause of dementia in the southern United States, was cured between 1912 and 1937 by the addition of foods containing pellagra-preventive factor, now known as niacin or nicotinic acid.

Classification of Neuroses In the late nineteenth century *neurosis* had come to mean a psychiatric illness caused by changes in brain function in which no organic lesion could be found and that (unlike a psychosis) was not inherited. The two major neuroses were neurasthenia and hysteria.

Neurasthenia The term *neurasthenia* was first used by the American neurologist George Miller Beard (1840–1883) in 1869 to describe a syndrome of physical and mental exhaustion that had previously been called *hypochondriasis*. The syndrome was prevalent and fashionable among American and European middle-class persons until about 1920 and was treated by rest cures (often consisting of isolation from the patient's parents), exercise, massage, and electrical stimulation of various parts of the body.

Hysteria Concepts of hysteria were influenced by the development of hypnosis. An unrecognized form of hypnosis was practiced in the eighteenth century by the Austrian physician Franz Anton Mesmer (1734–1815), who successfully treated hysteria and many other illnesses by putting patients in a trance and invoking the healing powers of an invisible and impalpable fluid that he called “animal magnetism.” In 1843 the English surgeon James Braid (1795–1860) showed that Mesmer's influence could be self-induced by fixating on an inanimate object and that it was caused not by animal magnetism but by a subjective impression made on the nervous center. Braid called it “neurohypnotism,” which was subsequently shortened to hypnosis. During the 1880s Jean-Martin Charcot (1825–1893), first professor of diseases of the nervous system at the University of Paris (who made Paris an international center for neurological studies), began using hypnosis to study the symptoms of the female patients in the Salpetrière. Through hypnosis he was able to produce many of these symptoms and he erroneously claimed that hypnosis was a pathological state that occurred only in hysterics. That claim was disputed by two leading French hypnotists, Ambroise August Liébeault (1823–1904) and Hippolyte Bernheim (1840–1919), who correctly claimed that most persons could be hypnotized and that hypnosis could be used as a psychotherapeutic procedure in neurotic illnesses.

Freud and the Creation of Psychoanalysis The disputes about neurotic patients and hypnosis stimulated the young Viennese physician Sigmund Freud (1856–1939), who had studied with Charcot and observed the work of Liébeault and Bernheim, to study these patients. In the 1890s he began diagnosing them as suffering from separate clinical illnesses which he called “anxieties,” “phobias,” and “obsessions”; terms that would subsequently influence the diagnosis and classification of neuroses.

At first Freud, along with his physician friend Joseph Breuer (1841–1925), treated these patients with hypnosis. Then by himself he originated a new method that consisted of free thought association and interpretation of dreams, which in 1896 he first called “psychoanalysis.” Using this method, he was able to show that neurotic patients suffer from memories of past traumatic events that they repressed into the unconscious parts of their mind and that when those memories were brought into consciousness by psychoanalysis and reexprienced with the support of the psychoanalyst, the neurotic symptoms were alleviated. The method revealed that the illnesses of these patients (their hysterical symptoms, anxieties, phobias, and obsessions) were caused by unconscious memories of past illicit sexual encounters. The concept of the unconscious had been known to philosophers since the seventeenth century; however, no one had thought that it could be used to investigate and treat psychiatric illnesses.

In 1900 *The Interpretation of Dreams* was published. It was Freud's most insightful work, and it revolutionized psychiatric thought and practice as well as other areas of thought. In it Freud showed how processes of condensation, distortion, disguise, and secondary elaboration transform unconscious latent dream content into conscious manifest content. His analysis of his own dreams, which was part of his self-analysis, was one of the most revealing psychological introspections ever recorded. Freud's *Three Essays on the Theory of Sexuality* (1905), with its explanations of the stages of sexual development and the psychological origins of what were then called the sexual perversions, altered scientific and moral views of sexuality.

Freud was about 50 years old when he formed his main psychoanalytic ideas. For the remaining 30 years of his life, he further developed those ideas and trained a growing number of adherents to become psychoanalysts. Psychoanalytic societies were formed in Europe and the United States; members were required to complete a didactic personal analysis and to adhere to Freud's main tenets. Freud's work became well known in the U.S. after the Clark University conference in 1909 (Fig. 55.1-1).

Fuller (*subsequently continued their interest in psychoanalysis). (Courtesy of American Psychiatric Association.)

Other Concepts of Psychoanalysis and of the Unconscious Several of Freud's followers—Alfred Adler (1870–1937), Carl Gustav Jung (1875–1961), Otto Rank (1884–1939), Karen Horney (1885–1952), and Sandor Rado (1890–1972)—had theoretical differences with him that often centered on the importance that he had assigned to the effects of early sexual experiences on the adult personality. These differences led them to create their own versions of psychoanalysis and psychotherapy. Two psychiatrists made observations of the unconscious that were independent of psychoanalysis: the American, Morton Prince (1854–1929), gave an account of a multiple personality; the Frenchman, Pierre Janet (1859–1947), originated the concept of *psychasthenia,* a weakness in the nervous system that resulted in the dissociation of parts of consciousness, obsessions, phobias, and anxieties. He also postulated that traumatic experiences caused hysteria with dissociation of feelings and memories related to experiences.

Projective Psychological Tests Concepts of the unconscious were used in projective psychological tests, in which persons projected unconscious feelings and conflicts into their perceptions of various visual stimuli. Two tests used frequently in diagnostic evaluations of psychiatric patients were the 1921 inkblot test of the Swiss psychiatrist Hermann Rorschach (1884–1922) and the 1935 Thematic Apperception Test (TAT) of the American physician and psychologist Henry Murray (1893–1988).

American Psychiatry

Treatment of the Insane

ASYLUMS In the late nineteenth and early twentieth centuries mental asylums changed from practicing the therapeutic ideas of moral therapy into institutions for custodial care where patients lived crowded together in unsanitary conditions; suffered from diseases, hopelessness, and abuse; and had little therapeutic contact with those who cared for them. One reason for these changes was an increase in patients who were chronically ill, consisting in part of poor immigrants who were unable to work, elderly persons who were transferred from almshouses to mental hospitals, and an influx of patients with neurosyphilis. Further, psychiatrists and those who worked in asylums had developed negative views about their work and the incurability of those with chronic psychoses.

PSYCHIATRIC HOSPITALS AND MENTAL HYGIENE In response to the need for hospital treatment of persons with acute psychoses, psychiatric hospitals were founded. In New York City, Bellevue Hospital (1879) and the Pathological Institute of the New York state hospital system (1895), later called New York State Psychiatric Institute, were founded. Boston Psychopathic Hospital (later called the Massachusetts Mental Health Center), was founded (1912) as a department of Boston State Asylum, the first psychiatric hospital connected with an asylum and the first to open an outpatient department to study the psychiatric illnesses of children. Similar hospitals were founded in Albany, New York, and in Illinois, Wisconsin, and Michigan. The staffs of those hospitals later included such new psychiatric professionals as psychiatric social workers, clinical psychologists, and occupational therapists.

In 1908 Clifford Beers's book *A Mind That Found Itself* was published. It was a widely read memoir of the bad treatment he had received as a mental patient in three asylums. In 1909 Beers founded the National Committee for Mental Hygiene, which aimed at controlling and preventing mental disorders and which began what was called “the mental hygiene movement” by the rising Swiss-born American psychiatrist Adolf Meyer.

Meyer When Adolf Meyer (1866–1950) was about 30, he stated in an article in the *American Journal of Insanity* his fundamental psychiatric belief that neither a purely somatic nor a psychological approach would suffice by itself but “that all mental activity must have its physiological side and its anatomical substratum... combinations of [nerve] cells....A disease of these cells... means at the same time a *physiological* and a *psychological* disorder; destruction of these cells, a destruction of *physiological* and *psychological* ‘function.' ”

From 1912 to 1940 Meyer was the director of the Henry Phipps Psychiatric Clinic and professor of psychiatry at the Johns Hopkins School of Medicine in Baltimore. As the dominant figure in American psychiatry, he developed his previous belief into the concept of psychobiology, which regarded a psychiatric patient as a biological entity who experienced unique reactions to biological and social influences. When those reactions were comprehensively delineated by taking the patient's life history, they revealed (in the words of Leston Havens) a “broadening perception of the significant reality for understanding pathological human nature” and “the gradual admission of factors hitherto unrelated to mental illness into an understanding of it.”

In treating patients, Meyer stressed common-sense counseling, social service, psychotherapy administered in community clinics by psychiatrists and social workers, child-guidance clinics, and aftercare for discharged asylum and hospital patients. His work has become so much a part of contemporary American psychiatry that his influence is often overlooked.

National Mental Health Act and the National Institute for Mental Health During World War II the need for psychiatry was shown when Selective Service boards rejected more than a million men because of mental disorders. Brief psychotherapy was able to return many servicemen who had experienced psychological problems back to active duty. At the end of the war, many psychiatrists were imbued with therapeutic optimism, and there was a popular belief that environmental stress contributed to mental maladjustment and that purposeful human interventions could alter psychological outcomes.

That attitude led Congress in 1946 to pass the National Mental Health Act, which for the first time in American history provided generous financial support for both psychiatric education and research. It also founded the National Institute of Mental Health (NIMH) with the goals of conducting research into mental illness (especially schizophrenia) and training large numbers of mental health personnel to provide psychiatric care. The above events positioned the United States in the forefront of advances in psychiatry.

MIDDLE AND LATE TWENTIETH CENTURY

During the past five decades the history of psychiatry, especially in America, has been characterized by numerous and unprecedented advances and some failures.

Lobotomies During the late 1940s and early 1950s, under the influence of two neurologists—Egas Moniz (1874–1955) and Walter Freeman (1895–1972)—many intractable psychotic and obsessive-compulsive patients were treated by lobotomies, the destruction of the white matter of the frontal lobes of the brain. Some patients improved, but others suffered severe and irreversible personality deterioration. With the advent of the psychotropic drugs, the use of lobotomies declined markedly. In 1949 Moniz along with the Swiss neurophysiologist Walter Hess was awarded the Nobel Prize in Physiology and Medicine.

Child Psychiatry In 1945, following the growth of child guidance clinics, the American Association of Psychiatric Clinics for Children was founded. Its aims were

maintaining certain standards in the clinics and in the training of the child psychiatrists, who along with psychologists and social workers staffed the clinics. This led to the development of child psychiatry as a specialty that then separated from adult psychiatry with the formation of the American Academy of Child Psychiatry (1953) and the establishment, by the American Board of Psychiatry and Neurology, of child psychiatry as a board-certifiable medical specialty (1959).

Double-Blind Tests In double-blind tests a drug or a procedure and a placebo are compared in such a way that neither the patient nor the therapist involved in the treatment know which preparation is being administered. The tests were used in medicine in 1937 by the American physician Harry Gold and in psychiatry in 1954 by Mogens Schou (1918–) to evaluate lithium, and by John Hampson, David Rosenthal, and Jerome Frank to evaluate the effectiveness of mephensin in relieving psychiatric symptoms. Since then the tests have been used in psychiatry to evaluate the effectiveness of various drugs and procedures.

Psychotropic Drugs

Chlorpromazine In 1952 two French psychiatrists, Jean Delay (1907–1987) and Pierre Deniker (1917–1999), reported that a new drug, chlorpromazine (Thorazine), significantly tranquilized hospitalized patients with chronic schizophrenia without causing undue depression. Chlorpromazine was called a “neuroleptic” because it reduced, rather than paralyzed nervous activity; it was also called an “antipsychotic.”

In the United States double-blind tests conducted by the NIMH showed that the use of chlorpromazine and other newly developed antipsychotics shortened the hospitalizations of some acutely psychotic patients and helped some chronically psychotic patients to either live outside an asylum for the first time or better tolerate living in an asylum.

Benzodiazepines In 1960–1963 the American pharmaceutical company of Hoffman-La Roche marketed two benzodiazepine compounds, chlordiazepoxide (Librium) and then diazepam (Valium), which largely replaced meprobamate (Equanil, Miltown) as methylphenidate anxiolytic drugs in cases of nonpsychotic anxiety. Hoffman-La Roche and other companies then developed other anxiolytic benzodiazepines, including clonazepam (Klonopin) in 1975, lorazepam (Ativan), in 1977 and alprazolam (Xanax) in 1981. They became among the most widely prescribed drugs in America.

Tricyclic Drugs and Monoamine Oxidase Inhibitors After the 1957 reports of the Swiss psychiatrist Roland Kuhn (1912–) and the American psychiatrist Nathanial Kline (1916–1983) and his associates, two classes of drugs were found effective in the treatment of depressions: imipramine (Tofranil)-type drugs (the tricyclic antidepressants) and the monamine oxidase inhibitors (MAOIs). The MAOIs caused episodes of severe hypertensive crisis. British psychiatrist Barry Blackwell (1934–) showed that the episodes were related to eating certain foods, especially cheese containing tyramine, but the MAOIs could be used if those foods were omitted.

In the late 1950s and early 1960s American and English psychiatrists found that tricyclic drugs and MAOIs alleviate certain severe states of anxiety.

Selective Serotonin Reuptake Inhibitors These have been developed for the treatment of depression by different American pharmaceutical companies since 1988, and include fluoxetine (Prozac), paroxetine (Paxil), and sertraline (Zoloft). They have shown fewer adverse effects than the tricyclics and MAOIs, and they largely superseded the use of the older antidepressants and have been therapeutically successful in various recurrent mood disorders, including chronic depressive and dysthymic disorders. They have also been used for obsessive-compulsive disorders. The diagnostic advances of the last two editions of *Diagnostic and Statistical Manual of Mental Disorders* (DSM) have made the clinical indications for their use more precise, so that many cases of depression—once the province of psychiatrists—can now be adequately managed by primary care physicians.

Lithium In 1949 the Australian psychiatrist John Cade (1912–1980) wrote an article for the *Medical Journal of Australia* showing that lithium quieted a group of hospitalized patients with mania and that their mania recurred when lithium was withdrawn. In 1954 the Danish psychiatrist Mogens Schou (1918–) validated Cade's work in a double-blind study. However, many psychiatrists questioned lithium's therapeutic effectiveness and emphasized its toxicity, and not until 1970 did the Food and Drug Administration (FDA) approve the use of lithium in America. Over the past two decades the following drugs carbamazepine (Tegretol), valproate (Depakene), neurontin (Gabapentin), lamictal (Lamotrigne), and topamax (Topiramate) have been used to treat patients with mania who did not respond well to or were intolerant of lithium.

Psychostimulants In 1937 the American pediatrician Charles Bradley (1902–1979) reported in the *American Journal of Psychiatry* that treatment with benzedrine had improved the behavior of a group of children who had been hospitalized because of (what was then diagnosed as) “behavior disorders.” For decades afterward there were occasional reports of stimulants being used to treat disturbed behavior in children and adults. In the 1980s and 1990s with the development of the diagnosis of attention-deficit disorders in children and in adults, stimulants such as amphetamine and methylphenidate (Ritalin) began being regularly used to successfully treat some patients with these disorders.

Serotonin-Dopamine Antagonists Clozapine (Clozaril) was developed in the 1970s, but because of the risk of agranulocytosis, the FDA did not permit its use in the United States for years. In 1988 the American psychiatrist John Kane (1945—) showed that it was an efficacious antipsychotic medication, and in 1989 the FDA permitted its American marketing, along with safeguards of weekly white blood cell counts and weekly drug dispensations. Risperidone (Risperdal) was developed in 1984, and in the 10 years before the FDA permitted its marketing, it was tested in large populations and shown to be effective and safe in the treatment of psychoses. Since 1994 clozapine and risperidone have been successful in treating persons with schizophrenia who were refractory to other medications and in ameliorating positive and negative symptoms of schizophrenia (including delusions, hallucinations, blunting of affect, and avolition).

Olanzapine (Zyprexa) was approved for use by the FDA in 1996. Like clozapine and risperidone, it was effective against both positive and negative symptoms of schizophrenia. It has been found to be more effective than haloperidol in the treatment of schizoaffective disorder and in the treatment of general psychotic symptoms. It has a lower potential than haloperidol to evoke tardive dyskinesia. There are no published data on switching from clozapine or risperidone to olanzapine, and until data to the contrary are available it should not be assumed that olanzapine has better therapeutic effects than clozapine or rispiridone.

Chemical Theories of Mental Illness The clinical advances in psychopharmacology stimulated research in neurochemistry and the development of new concepts about the chemical causes of psychiatric diseases. Since successful psychopharmacological drugs decreased the brain chemical dopamine in patients with schizophrenia and increased the brain chemicals norepinephrine and serotonin in patients with depression, neuroscientists theorized that some cases of schizophrenia were caused by increased dopamine concentration and that two subtypes of depressive illness exist: one caused by norepinephrine deficiency and the other by serotonin deficiency. Although these theories are unproved and perplexing, they have continued to guide neuroscientists in their search for new drugs.

The concept that mental health is influenced by the fluctuations of body chemicals resembled in some ways the 2500-year-old Hippocratic concept that mental and physical health depends on the equilibrium of the four body humors.

Deinstitutionalization In the United States some of the influences for the deinstitutionalization of mental patients were burgeoning public criticisms of the snake-pit environments of state asylums; the 1949–1956 open-door policy of several English hospitals (meaning both unlocked doors and a higher discharge rate of hospital inmates); a reduction of asylum patients, which began in 1956 (for decades previously the asylum population had been increasing) and which was only partly caused by the use of the new antipsychotic drugs; and a 1958 presidential address to the American Psychiatric Association by Harry Solomon, asserting that the state asylums were bankrupt and should be liquidated.

In 1961 the Joint Commission on Mental Illness and Mental Health (an interdisciplinary organization representing 36 medical and paramedical organizations, including the American psychiatric, psychological, and medical associations) issued a report, Action for Mental Health, recommending that the large state asylums be converted to small regional centers for intensive patient evaluation and treatment and that community mental health clinics, general hospitals, and mental hospitals be established. In October 1963 President John F. Kennedy signed the Community Mental Health Centers Act, which directed that these recommendations be carried out.

Community Care Over the past three decades, as the number of patients treated in asylums declined (there was an 82 percent reduction in long-term asylum inmates in the period 1950–1989), other institutions for treatment appeared. Acutely ill patients are now mainly treated in the psychiatric units of general hospitals and sometimes in nonhospital settings of private homes or specially formed households. Most chronically ill patients, especially aged adults, are cared for in nursing homes and also in board-and-care homes, halfway houses (so called because, in the course of a patient's therapy, they were located between the hospital and full community living), supervised or semisupervised apartments, and other facilities (including partial hospital programs, psychosocial clubhouses, supported

employment, vocational rehabilitation, and supported education).

While many aspects of community care are problematic, fragmented, and in need of integration and while (for unknown reasons) the homeless population (which contains many mentally ill individuals) has been growing, these shortcomings (in the words of Gerald Grob) “should not be permitted to conceal the more important fact that a large proportion of severely and persistently mentally ill persons have [because of the programs and institutions of community care] made a more or less successful transition to community life.”

National Alliance for the Mentally Ill Although community care often increased contacts between mentally ill persons and their families, relatively little attention had been given to the needs of such families. In September 1979 the National Alliance for the Mentally Ill (NAMI) was founded, and it has since become (in the opinion of David A. Rochefort) “perhaps the most potent consumer lobbying force ever to manifest itself in the mental health arena.” It is a passionate advocate for research into the biological causes of insanity and for better care and support for both the insane and their families. NAMI also functions as a mutual-help organization.

Nosology In 1974 a task force (later called a “work group”) of the American Psychiatric Association (APA), chaired by Robert Spitzer, prepared the third edition of DSM (DSM-III); a revision, DSM-III-R, with Janet Williams as text editor, was published in 1987. Those two editions differed radically from the two previous editions by approaching psychiatric disorders in two ways. First, the objective clinical manifestations of a disorder were carefully delineated; with emphasis on symptoms and deemphasis on causes. Since this approach resembled that of Kraepelin it was called the “neo-Kraepelin revival.” Second, disorders were given new classifications and new names, which often conveyed both the precise attributes of the disorder and advances in knowledge. For example, “inadequate personality” was replaced by three personality disorders; narcissistic, borderline, and dependent; bulimia was first classified; advances in sexology necessitated new delineations of paraphilias and types of sexual dysfunctions; advances in child psychiatry necessitated describing and naming many new disorders of childhood; alcoholic disorders were classified into a number of new diagnostic categories, each with its list of specific diagnostic symptoms; from a mixture of cognitive and behavioral abnormalities a group of symptoms in adults and children were designated attention-deficit disorder while other behavioral symptoms were grouped as conduct disorder; and, as a result of the psychiatric symptoms suffered by American soldiers in the Vietnam War, the diagnosis of posttraumatic stress disorder was described (in DSM-II traumatic stress response had been subsumed under the rubric “adjustment disorder of adult life.”)

Although these two DSMs had some limitations (many nonpsychotic illnesses presented not as distinct symptoms but as fluctuating mixtures of anxiety and mood disturbances that did not run distinct courses), they were the first diagnostic manuals to be widely accepted both academically and clinically, and they became the diagnostic “Bible” to those who treated psychiatric patients.

From 1988 to 1994 a new APA task force, chaired by Allen Frances, with Harold Pincus as vice-chairperson and Michael First as text editor, worked on preparing the fourth edition of DSM (DSM-IV). Preparation of DSM-IV drew on the research on diagnosis that was generated in part by DSM-III and DSM-III-R and involved a comprehensive, systematic review of the relevant literature, analysis and reanalysis of the collected data, and field trials that compared alternative options and studied the possible impact of suggested changes. The resulting volume, published in May 1994, is the most up-to-date classification of mental disorders for health professionals. It continued the descriptive, atheoretical approach of the two previous DSMs. Some of its changes were discussions of differential diagnosis, course, prevalence, and other aspects of certain illnesses; elimination of the term “organic mental disorders,” because it incorrectly implied that other mental disorders do not have a biological component; deletion of passive-aggressive personality disorder and addition of borderline personality disorder; renaming multiple personality disorder “dissociative identity disorder”; and the addition of an appendix that noted the influence of culture and ethnicity on psychiatric illnesses and diagnosis.

Psychotherapies The aims and scope of psychotherapy have grown from the treatment and alleviation of symptoms in psychiatric patients to the management of a wide variety of personality distresses (such as unhappiness and unfulfillment, social malaise, and social isolation), with the aim of providing greater self-assertion and greater emotional fulfillment.

Types of Psychotherapy Because psychotherapists are often guided by theories that they then modify to meet the particular needs of the patients, the history of their work has been characterized by great diversity and the evolution of perhaps 100 types of psychotherapy.

PSYCHOANALYTIC THERAPIES Melanie Klein (1882–1960) and Anna Freud (1895–1982) formed two different ways of applying psychoanalysis to play therapy with children and different concepts of child development. Harry Stack Sullivan (1892–1949) formed the interpersonal theory, stressing the interpersonal reactions of persons, and coined the terms “participant observer” and “consensual validation” to describe the reactions between patient and therapist. Erik H. Erikson (1902–1994) developed concepts of adult identity, identity diffusion, and crisis. Donald Winnicott (1896–1971) observed transitional objects and transitional phenomena to which persons become deeply attached and was part of the Independent Group of Psychoanalysts in England. Jacques Lacan (1901–1981) emphasized language and the need to make contact with the prelanguage period in the unconscious and was influential in French psychiatry. Heinz Kohut (1913–1981) originated self-psychology and three new views of transference. James Masterson (1926–) and Otto Kernberg (1928–) developed two different concepts for diagnosing and treating borderline and narcissistic disorders.

BEHAVIOR THERAPY Behavior therapy originated in the experiments of the American psychologist John Watson (1878–1958) on behaviorism and the Russian physiologist Ivan Pavlov (1849–1936) on conditioned reflexes. It was then shaped by several trends, including Andrew Salter's (1914–) conditioned reflex therapy, B. F. Skinner's (1904–1990) operant conditioning, Joseph Wolpe's (1915–) psychotherapy by reciprocal inhibition, and trends that emphasized cognitive processes and their adaptive nature. Today behavior therapy consists of a blend of cognitive and behavioral approaches that are aimed at overcoming maladaptive behaviors.

OTHER THERAPIES Brief psychotherapy aims at producing insight and personality changes in a short time. Aaron Beck's (1921–) cognitive therapy aims at rearranging a person's maladaptive thoughts and actions. Carl Roger's (1902–1987) client-centered psychotherapy has patients take responsibility for their feelings and direct the course of their therapy. Fritz Perls's (1893–1970) Gestalt therapy holds that a neurotic patient is repressing one part of the whole (German *Gestalt*) and that, by therapeutically reliving a painful experience, the patient can restore wholeness. Eric Berne (1910–1970), in transactional analysis, postulates that a lifescript created in early childhood by parents shapes and inhibits a person's life and that inhibition can be overcome by deciphering that script. Existential psychotherapy, propounded by the German psychiatrist and philosopher Karl Jaspers (1883–1969), emphasized here-and-now interactions and feelings rather than past events and rational thinking. Milton Erickson (1901–1980) developed hypnotic psychotherapy, in which hypnosis was used to overcome patients' resistance to therapeutic changes.

The above therapies involve one patient; other therapies involve couples (marital and sex), families, and groups. In 1935 two American alcoholics founded a 12-step movement of group psychotherapy for the treatment of alcoholism (Alcoholics Anonymous), which has since evolved to cover a wide range of addictive or assumed-addictive behaviors (including food-related disorders, codependency, gambling, drug, and tobacco addiction) as well as the impact of addictive behavior on family members (Al-Anon), and on the teen-aged children of alcoholics (Alateen).

Evaluations of Psychotherapy Over the past two decades psychological treatments have been shown effective in patients with neurotic symptoms and moderate personality disorders. However, patients benefit to variable degrees; much remains to be learned about the type of psychotherapy and the characteristics of patient and therapist in each particular treatment.

Biofeedback Through the use of instruments, biofeedback provides persons with representations of involuntary or subthreshold physiological processes that they may then be able to control voluntarily by changing their behavior. Biofeedback has been used to treat various psychosomatic diseases. Because it can detect the physiological markers of a patient's denial, resistance, and other defense mechanisms, biofeedback may also be considered as an adjunct for most of the psychotherapies mentioned above.

Social Influences The practice of psychotherapy was influenced by changes in mental health laws and managed care.

MENTAL HEALTH LAWS The late 1960s saw radical reforms in mental health laws; they peaked in the 1970s and subsided by the mid-1980s, but they left changes. They emphasized the rights of the mentally ill to contest involuntary hospitalization and refuse treatments, so that it became, in the words of Paul Applebaum, “axiomatic that [psychiatric] services must be provided in a manner that minimizes intrusions on individual rights and maximizes recourse to independent review when infringements occur.” A shift of the insanity defense from “not guilty by reason of insanity” to “guilty but mentally ill,” allowed the courts to monitor an individual's posttrial psychiatric treatment. Two notable cases in which psychotherapists were sued by third parties who were involved with patients that they were treating—*Tarasoff,* 1976, and *Ramona*, 1994—alerted therapists to the risks posed to them by third parties and the need to protect themselves against these risks, sometimes by warning potential victims about the danger posed by patients they are treating.

MANAGED CARE The increasing costs of psychotherapy led to development of managed care, which curtails costs in various ways, including requiring that a treating therapist submit frequent, written progress reports to a managed care panel and sometimes limiting the number of psychotherapy sessions to 5 to 20 a year. Thus the confidential psychiatrist-patient relationship that excluded all third parties, and the therapeutic options of psychiatrists to treat patients in ways they deemed most appropriate (doing insight-oriented therapy that often required frequent sessions over a prolonged period of time), were constrained in the interests of cost-effectiveness. While one psychiatrist has suggested that some of his colleagues may be able to adapt to managed care by developing business expertise and creating "physician-run managed care programs that can bring medical ethics and patient care values to the market," many other psychiatrists, whose expertise (and professional success) has been in patient-centered therapy, face an uncertain and troubled future.

Histories of Psychiatry General histories of psychiatry were published by Nolan D. C. Lewis (1941), Gregory Zilboorg and George Henry (1941), Jerome Schneck (1960), Franz Alexander and Sheldon Selesnick (1966), Erwin Ackernecht (1959, 1968), and Michael Stone (1996). A history of psychiatry from the eighteenth century to the present was published by Edward Shorter in 1996. John Howells edited *World History of Psychiatry* (1975), consisting of accounts by 42 psychiatrists of the histories of psychiatry in most of the countries and regions of the world; Benjamin Wolman's *International Encyclopedia of Psychiatry, Psychology, Psychoanalysis, and Neurology* (1977) contained short, concise, biographies and histories; and Sharon Romm and Ron Friedman edited *History of Psychiatry* (1994), which offers scholarly histories of psychiatric theories, treatments, and institutions. There have been English translations of the works (in whole or in part) of Hippocrates, Galen, Paracelsus, Weyer, Pinel, Esquirol, Mesmer, Heinroth, Charcot, Griesinger, Kahlbaum, Meynert, and Kraepelin, along with their biographies and new biographies of Wagner-Jauregg by Magda Whitrow (1993), Charcot by Christopher Goetz, Michael Bonduelle, and Toby Gelfand (1995), and Dorothea Dix by Thomas Brown (1998). Ida Macalpine and Richard Hunter edited *Three Hundred Years of Psychiatry: 1535–1860* (1964), a sourcebook of selected English texts and translations of influential European texts that chronicles the growth of English psychiatry up to the time when it became an established branch of medicine. Chris Thompson edited *The Origins of Modern Psychiatry* (1987), containing important psychiatric texts from 1856 to 1938.

Special Areas of Psychiatry The past decades saw a proliferation of histories confined to particular areas, by authors from various disciplines: social, intellectual, and legal historians; sociologists; criminologists; anthropologists; historians of science and medicine; and psychiatrists and other mental health professionals. The histories that focus on countries in a historical period emphasize the intellectual, social, and cultural matrices from which ideas about mental illness and mental deviance have developed, for example, Bennett Simon's *Mind and Madness in Ancient Greece: The Classical Roots of Modern Psychiatry;* Michael W. Dols's *Majnun; The Madman in Medieval Islamic Society;* Michael MacDonald's *Mystical Bedlam: Madness, Anxiety, and Healing in 17th Century England;* Roy Porter's *Mind-Forg'd Manacles: A History of Madness in England from the Restoration to the Regency;* McGovern's *Masters of Madness: Social Origins of the American Psychiatric Profession;* Jan Goldstein's *Console and Classify: The French Psychiatric Profession in the 19th Century;* George Drinka's *The Birth of Neurosis: Myth, Malady, and the Victorians;* Janet Oppenheim's *Shattered Nerves: Doctors, Patients and Depression in Victorian England;* Tom Lutz's *American Nervousness, 1903: An Anecdotal History;* and Francis George Gosling's *Before Freud: Neurasthenia and the American Medical Community, 1870–1910*.

The above intellectual-cultural emphasis was also applied to the following histories of theories, treatments, and illnesses: Wesley Smith's *The Hippocratic Tradition;* Oswei Temkin's *Galenism: Rise and Decline of a Medical Philosophy, The Falling Sickness: A History of Epilepsy from the Greeks to the Beginnings of Modern Neurology*, and *Hippocrates in a World of Pagans and Christians;* Jose Pinero's *Historical Origins of the Concept of Neurosis;* Stanley Jackson's *Melancholia and Depression: From Hippocratic Times to Modern Times;* Adam Crabtree's *From Mesmer to Freud: Magnetic Sleep and the Roots of Psychological Healing;* Alan Gauld, *A History of Hypnotism;* and Léon Chertok and Isabelle Stengers, *A Critique of Psychoanalytic Reason: Hypnosis as a Scientific Problem from Lavoisêr to Lacan*. Three recent books, Sander Gilman, Helen King, Roy Porter, G. S. Rousseau, and Elaine Showalter, *Hysteria Beyond Freud* (1993), Mark Micale, *Approaching Hysteria: Disease and Its Interpretations* (1995), and Helen King, *Hippocrates' Woman: Reading the Female Body in Ancient Greece* (1998), have revolutionized the historiography of hysteria and ancient Greek ideas about the nature of womens' bodies.

German Berrios and Roy Porter edited *A History of Clinical Psychiatry: The Origin and History of Psychiatric Disorders* (1995), which delineates the history of major psychiatric disorders (dementia, stroke, Parkinson's disease, schizophrenia, depression, neuroses, and personality disorders) from both the clinical and the social-historical perspectives. Stanley Finger wrote *Origins of Neuroscience: A History of Explorations into Brain Function* (1993).

ANOREXIA NERVOSA Sonja van't Hof's *Anorexia Nervosa: The Historical and Cultural Specificity: Fallacious Theories and Tenacious Facts* (1994) gives a history of how—from 1860 to the 1940s—the illness came to be recognized as a clinical entity. She also discusses its epidemiology and contends that (contrary to some opinions) it has not increased.

FORENSIC PSYCHIATRY Daniel Robinson's *Wild Beasts & Idle Humours* (1996) gives a history of the insanity defense from antiquity to the present, and Applebaum's *Almost a Revolution* (1994) discusses the changes in American mental health laws in the past 25 years.

CHILD PSYCHIATRY Stone's "Child Psychiatry before the Twentieth Century" (1973) gives some of the opinions on the psychology of normal (and sometimes aberrant) children from the sixteenth through the nineteenth centuries, before child psychiatry became a clinical specialty.

In 1997 two histories of military psychiatry were published: Hans Binneveld, *From Shell Shock to Combat Stress. A Comparative History of Military Psychiatry* (translated from the Dutch by John O'Kane); and Anthony Babington, *Shell-Shock. A History of the Changing Attitudes to War Neurosis*.

HISTORIES OF ASYLUMS Studies of the changes in the characteristics of the asylums and mental institutions for the insane in nineteenth-century England and America have been published by Andrew Scull, *Museums of Madness: The Social Organization of Psychiatry in Nineteenth Century England, The Most Solitary of Afflictions: Madness and Society in Britain 1700–1900, Masters of Bedlam: The Transformation of the Mad-Doctoring Trade;* Gerald Grob, *Mental Institutions in America; Social Policy to 1875* and *Mental Institutions and Mental Illness and American Society, 1875–1940;* and David Rothman, *The Discovery of the Asylum*. These three authors disagreed about the meanings of the changes that they described. Book-length studies have been published on the following nineteenth and early twentieth century mental hospitals: Ticehurst private asylum and the York Retreat, both in England (Charlotte MacKenzie and Anne Digby); the Pennsylvania Hospital for the Insane in Philadelphia (Nancy Tomes); the New York State Lunatic Asylum at Utica and the Willard Asylum for the Chronic Insane (Ellen Dwyer); and the Eastern State Hospital in Williamsburg, Virginia (Norman Dain); the New York State Psychiatric Institute (Lawrence Kolb and Leon Roizen); and the Boston Psychopathic Hospital (Elizabeth Lunbeck).

VIEWS OF DEINSTITUTIONALIZATION Two different views on the causes and meaning of deinstitutionalization have been propounded, first by Scull, *Decarceration: Community Treatment and the Deviant—A Radical View;* and then by Grob, *From Asylum to Community: Mental Health Policy in Modern America* and *The Mad Among Us: A History of the Care of America's Mentally Ill,* and (in England) by Kathleen Jones, *Asylums and After; A Revised History of the Mental Health Services: From the Early 18th Century to the 1990s*.

ACCOUNTS OF FREUD, PSYCHOANALYSIS, AND PSYCHOANALYSTS Freud has become the most written about figure in the history of psychiatry. Following Peter Gay's comprehensive biography. *Freud: A Life for Our Time* (1988), there has been an unceasing outpouring of books on special aspects of Freud's life and work. Some of the more recent of these are Lisa Appignanesi and John Forrester, *Freud's Women* (1992) on Freud's relationships with women including family members, patients, disciples, and friends and how he developed his theories of sexual differences and female sexuality. Gilman's two 1993 books, *Freud, Race, and Gender* and *The Case of Sigmund Freud: Medicine and Identity at the Fin de Siècle,* offer new views on Freud's attitudes toward his Jewish origins and on the influences that shaped his identity as a physician. John Kerr, *A Most Dangerous Method: The Story of Jung, Freud, and Sabina Spielrein* (1993), presents new information on the conflict between Freud and Jung and on early psychoanalytic ideas and treatments; and Peter Newton's *Freud: From Youthful Dream to Mid-Life Crisis* (1995) describes how psychoanalysis originated during a series of developmental periods and transitions in Freud's early to middle years.

Reuben Fine wrote *History of Psychoanalysis* up to 1979, and Nathan Hale's two volumes—*Freud and the Americans* and *The Rise and Crisis of Psychoanalysis in the United States*—give a history of psychoanalysis in America from 1876 to 1985. Edith Kurzwell, in *The Freudians: A Comparative Perspective* (1989), compares the varying impacts of psychoanalysis on areas of culture, medicine, and psychiatry, in five countries—Germany, Austria, France, England, and the United States.

Book length biographies have been written about the following psychoanalysts: Alfred Adler (Paul Stepansky), Marie Bonoparte (Celia Bertin), Anna Freud (Elisabeth Young-Bruehl), Helene Deutsch (Paul Roazen), Erik Erikson (Lawrence Friedman), Ernest Jones (Vincent Brome), Otto Rank (James Lieberman), Carl Jung (Frank McLynn), Karen Horney (Bernard Paris), Harry Stack Sullivan (Helen Perry), Wilhelm Reich (Myron Sharaf), Sandor Ferenczi (Martin Stanton), Melanie Klein (Phyllis Groskurth), Henry A. Murray (Forest Robinson), Sandor Rado (Roazen and Bluma Swerdloff), and Donald Winnicott (Adam Phillips). Paul Stepansky compiled and edited *The Memoirs of Margaret S. Mahler* (1988), and Geoffrey Cocks edited *The Curve of Life: Correspondence of Heinz Kohut, 1923–1981* (1994). Elisabeth Roudinesco, in *Jacques Lacan and Co. A History of Psychoanalysis in France, 1925–1985* (1990), (an English translation of the second volume of Roudinesco's

1982–86, two-volume history of psychoanalysis in France from 1885–1985, entitled *La Bataille de Cent Ans*, “The Hundred Years Battle”), gives an account of Lacan and his work that touches on much of the culture and intellectual life of the century.

Today, while the influence of psychoanalysis on American psychiatry has declined—as shown by the creation of the last three DSMs—and while there continues to be an intense controversy about its value and validity, Micale and Porter have commented that: “Freud's place as one of the supreme makers of the 20th-century mind, alongside Darwin, Marx, and Einstein, remains secure.”

Accounts of Behavior Therapy Alan E. Kazdin wrote *History of Behavior Modification* (1978), and book-length biographies of Ivan Pavlov (B. P. Babkin), John Watson (Kerry Buckley), and B. F. Skinner (Daniel Bjork) have appeared.

Histories of Psychiatric Drugs Frank Ayd and Barry Blackwell edited *Discoveries in Biological Psychiatry* (1984), which contains reminiscences by the discoverers or those close to them of the main psychiatric drugs, and Ayd added the essay “The Early History of Modern Psychopharmacology” (1990). Robert Maxwell and Shohreh Eckhardt in the section on psychiatric drugs in *Drug Discovery: A Casebook and Analysis* (1990) provided detailed accounts of the scientific processes that revealed the therapeutic uses of chlorpromazine, haloperidol, imipramine, the MAOIs, lithium, and the benzodiazepines. Solomon Snyder's *Drugs and the Brain* (an updated 1996 edition of a book first published in 1986) provides a comprehensive survey of the major psychoactive drugs, how they act on the brain and affect behavior, and the history of how they came to be used. David Healy has published two important books: in *The Psychopharmacologists. Interviews by Dr. David Healy* (1996), several pioneer psychopharmacologists discuss, along with their particular discovery, aspects of the professionalization of their work, with the founding of new journals, institutes, and societies; in *The Antidepressant Era* (1997) Healy delineates the history of psychopharmacology from the discovery of chlorpromazine to the current uses of fluoxetine and sertraline, emphasizing what the antidepressants reveal both about the workings of the brain and the sociology of drug marketing.

The quarterly, multidisciplinary *Journal of the History of the Behavioral Sciences* has appeared since 1965. In March 1990 the quarterly journal *History of Psychiatry* appeared, the first English-language journal devoted entirely to the history of psychiatry, published in England, and edited by two English scholars, Berrios (1940–) and Porter (1946–). Since its inception it has been (as stated in its first issue) “completely international, both in terms of contributions and contributors,” and has published articles by varied contributors (including historians, historians of medicine and psychiatry, practitioners of medicine and psychiatry) that have provided important primary information on all aspects of illness.

In 1993 Micale (1957–) and Porter edited and published *Discovering the History of Psychiatry,* the first booklength collection of essays by leading authorities on the lives and work of the major historians of psychiatry and psychoanalysis. It also contained essays on other themes and topics in the history of psychiatry, including the origin of myths and the position of women. Dora Weiner in “‘Le geste de Pinel': The History of a Psychiatric Myth,” shows that the famous episode of Pinel freeing the French insane from their chains in 1793 was a myth created largely by Pinel's son and students; that the insane were first freed in 1797 by Pussin, an assistant to Pinel, and that the latter then approved and followed up on Pussin's action. Tomes, in “Feminist Histories of Psychiatry,” emphasizes the absence of women in the histories of psychiatry before the 1960s and then shows how the recent work of feminist historians has depicted Victorian women as psychiatric patients in and outside of asylums, madwomen in literature, scientific objects in male-authored textbooks of psychology and medicine; and as early practitioners of psychiatry and psychoanalysis. Those feminist historians have formed a new, and still growing, subspecialty in the history of psychiatry.

In the introduction Micale and Porter indicate the many diverse factors that have influenced writings on the history of psychiatry.

Psychiatric history may inform, instruct, and entertain. It may reflect the intellectual personality, the cultural background, or the emotional temperament of the historian. It may be informed by internal disciplinary dimensions of a clinical, theoretical, or professional nature. And it may be shaped externally by contemporary social movements or political exigencies. It may also embody cultural structures and processes of a deeper and longer-term nature. Psychiatric historiography has served purposes that are antiquarian, pedagogical, justificatory, and ideological.

Micale and Porter further state that a study of the methodology and epistomology of the history of psychiatry is much needed.

Future Histories of Psychiatry Bennett Simon (1933–), in a 1996 review of several recent histories of psychiatry, contends that there is no good one-volume history of psychiatry because the field is in a state of “great creative flux,” with so many varied and different histories that no one history can please all. Simon further believes that “we are also living ‘in a time of fallen heroes'—the idealizations that once allowed certain unified histories to be written have been analyzed, deconstructed, demythologized, and at times found to be based on more fiction than fact. These same idealizations also allowed a more unified field of psychiatry... My hope is that the kinds of history of psychiatry now being written and the attendant debates about that history may contribute to a renewal and revitalization of the currently ‘decentered' and at times demoralized field of psychiatry. Figures like Pinel and Charcot, and perhaps even Freud, may once again become centers of historical discourse, but this time for an audience aware of the pitfalls of idealization and the obfuscation to which idealization can be put. I believe we will begin to see a return to an appreciation of heroes and heroines in the past, but an appreciation more solidly grounded in an appreciation of the complexities and ambiguities within which they worked. History might help us thus see the new kinds of heroism required in the confusing and difficult state of psychiatry today, the ability to have vision and purpose and steadfastness but not be blind to the legitimate tensions and disagreements that are part and parcel of our enterprise.”

Some of the major individuals and events in psychiatry, past and present, are described in Table 55.1-1.

Table 55.1-1 Persons and Events in Psychiatry

SUGGESTED CROSS-REFERENCES

Many sections of this textbook contain historical information related to their specific subjects. Of particular interest are Section 4.1 on anthropology and psychiatry, Section 4.2 on sociology and psychiatry, Section 5.1 on epidemiology, Section 6.1 on psychoanalysis, Chapter 7 on other psychodynamic schools, Section 11.1 on the classification of mental disorders, and Section 29.2 on the psychiatric aspects of AIDS. Chapter 31 covers drugs used in psychiatry and other biological therapies. Section 33.1 gives an overview of child psychiatry, Section 52.1 discusses legal issues in psychiatry, Section 26.1 gives a history of psychosomatic medicine, Section 31.10 gives an evaluation of psychotherapy, and Section 53.2 discusses the future of psychiatry.

55.3 THE FUTURE OF PSYCHIATRY

PETER D. KRAMER, M.D.

The course of American clinical psychiatry for the last century would have humbled any prognosticator. Every one of its major developments was surprising. First, the rise to dominance of Sigmund Freud's talking cure, followed by the splintering of psychoanalysis into competing schools. Then, the development at the height of psychoanalytic influence, of a biopsychosocial paradigm, the transformation of military psychiatry into the community mental health movement. Antihistamine-based antipsychotic and antidepressant medications; the lithium revolution; the resurgence, beginning when psychoanalytic influence was at its peak, of a Germanic diagnostic system, the acceptance of the therapeutic milieu as a standard for hospital care was followed by the large-scale deinstitutionalization of the chronically mentally ill, the influence of outcome studies, bringing popularity for simple cognitive and behavioral therapies, and the erosion of many forms of mental health care delivery under pressure from insurers, just as these same outcome studies had bolstered the case for psychotherapy.

The course of change in psychiatry is especially hard to predict because the field is so responsive to external influence. Freud turned to physics to give shape to his metapsychology, and subsequent theorists have borrowed from systems theory and cybernetics. Progress in the science of psychiatry has relied on advances in a variety of disciplines, from engineering to genetics. Meanwhile, the practice of psychiatry is reshaped constantly by the ambient social, political, and economic organization. The very substrate of psychiatry, the object it acts upon and intends to influence, has an erratic history. The *self* or *person* is a concept constantly reshaped by changes in technology, social organization, and spiritual belief. To foretell the course of psychiatry would entail knowing the future of humankind and its achievements.

Even contemporary trends are hard to gauge. For most of the twentieth century, the core discipline in psychiatry was psychoanalysis. Today, cutting-edge discoveries arise most often from biological psychiatry. Perhaps the profession is in the midst of a paradigm shift. In that case, psychotherapy may disappear while psychiatry merges with neurology to form a uniform medical specialty based on brain sciences. Alternatively, if current changes are incremental, psychiatry may continue for some time to embrace both physiological and psychological interventions.

PSYCHOPHARMACOLOGY

Perhaps the safest prediction as the century closes is that the coming decades will see a continued proliferation of biological therapies for disorders of brain and mind. Clinically, psychiatry has been transformed in recent years by the availability of more potent and more specific medications. Conditions long considered refractory are approached routinely with medication: clomipramine (Anafranil) and the selective serotonin reuptake inhibitors (SSRIs) often ameliorate obsessive-compulsive disorder and the negative symptoms of schizophrenia sometimes respond to clozapine (Clozaril) or other serotonin-dopamine antagonists. Medications such as the SSRIs are now mainstays in the treatment of conditions such as dysthymic disorder and the minor mood disorders, that were once the exclusive province of psychotherapy.

The scope of psychopharmacology has been further expanded by three concomitant developments: the incorporation into psychiatric practice of medications traditionally associated with other specialties (e.g., antiepileptic agents including valproate [Depakene] and carbamazepine [Tegretol]), the legitimation of medications previously out of favor (notably the psychostimulants); and a renewed interest in polypharmacy, especially the augmentation of antidepressant drugs.

Barring a series of therapeutic disasters, certain trends will continue. New medications will be introduced, especially medications specific to receptor subtypes or particular brain pathways or regions. Existing medications will find broadened application and the indications for psychopharmacology will be expanded. The pace may accelerate as advances in computing and molecular biology (especially techniques for characterizing receptors) facilitate drug development. These changes will be accompanied by the development of novel biological interventions, perhaps including transplantation of brain elements, introduction of psychoactive genetic fragments into adult cells, and innovations in the ways medications are delivered to parts of the brain. The flowering of psychobiological therapeutics may combine with advances in the basic sciences to affect every aspect of psychiatry, from therapeutics to metapsychology.

Diagnosis A new range of choices for clinicians will create a demand for biologic markers of illness and for ways to predict and monitor treatment success. In psychiatry as in the rest of medicine, genetic profiles may be used to predict liability to illness and responsiveness to specific interventions. Brain imaging may move into the clinical arena as an aid to guiding treatment—perhaps supplemented by chemical or electrophysiological tests or other biological or psychological indicators yet unknown. The field may yet see the secular analogue of the ontological lapsometer imagined by the novelist Walker Percy, a hand-held brain imager that could diagnose the state of the soul.

The increased scope of biological treatment will create pressures on the diagnostic system. In the latter half of this century, acceptance of lithium (Eskalith) for the prophylaxis of manic-depressive illness (bipolar I disorder) gave an important spur to the predominance of what Walter Menninger called the Linnean tradition of diagnosis, that is, division of illness into ever finer subcategories. Recent trends indicate a continued proliferation of diagnostic categories—perhaps to the point where computers become necessary diagnostic aids.

Many of the newer medications already available have broad-spectrum utility. The SSRIs are variously reported to have roles in the treatment of obsessive-compulsive disorder, depressive disorders, bulimia nervosa, impulsive aggression, premenstrual syndrome, and the personality disorders, to mention only a few of many indications. A tension has thus developed between the diagnostic system and the commonest tools of psychiatry. The medications seem to cry out for a different sort of taxonomic system, one based on the state of neuroreceptors or neural pathways.

Perhaps the discovery of biologic markers of the relevant brain states will give rise to a new axis of psychiatric diagnosis or a new grouping of syndromes. In the interim, theorists have speculated that medications typically affect functions or dimensions of mind (e.g., aggression) rather than illness, and one can imagine a taxonomy that would address the relevant functions or dimensions. The future may even include a return to a diagnostic tradition that is (in Menninger's terms) Hippocratic, expressing the clinician's assessment of the complex state of the individual patient—but from a psychopharmacologic perspective rather than, or in addition to, a psychotherapeutic one. Such a system might require that clinicians exercise the subtlety and attention to detail that once characterized the anamnesis preparatory to psychoanalytic treatment.

Prophyaxis New psychiatric tools may revitalize another dream, mental illness prevention. Clinicians are already debating whether to use medication prophylactically in defined situations (e.g., just after delivery by a mother with a history of postpartum psychosis). As the pathology of psychic trauma is further elucidated, much broader forms of medication-based prevention may become possible, such as interrupting the cascade of stress hormones produced in response to important stressors. The death of a parent predisposes a child to future depression, but perhaps the profession will find pharmacological interventions to avert that association. Such capabilities would evoke profound ethical challenges; is prevention of illness always humane or can it be dehumanizing?

Treatment Similar issues are bound to arise in response to the broadened scope of pharmacological treatment of existing conditions. Researchers have already turned their attention to *formes frustes* of psychiatric disorders—levels of mood disorder, autistic disorder, and attention-deficit disorders that would previously have been deemed subsyndromal. Emerging evidence indicates that available medications can mitigate subsyndromal states. At the same time, the field is witnessing a resurgence of Darwinism, in the guise of evolutionary psychology. In the Darwinian perspective, much of what otherwise would be labeled illness is reconceptualized as an adaptive response, perhaps to bygone challenges. More popularly, learning disabilities have been reframed as “learning differences”—what was once called “minimal brain dysfunction” is now deemed a normal variant. These trends will demand reconsideration of the definition of health and illness. For the moment, the tendency in psychiatry is to expand the realm of pathology, for example, by conceptualizing subsyndromal symptomatic depression as an illness. The field may have to choose between, on the one hand, recognizing an ever-expanding domain of illness and, on the other, acknowledging that psychiatric interventions can be applied

appropriately in the treatment of variant normal states.

Indeed, the field will most likely find itself facing the ethical questions raised by the ability to enhance normal functioning. Preliminary research indicates that SSRIs can affect the social behavior of people who suffer no psychiatric disorder whatsoever, perhaps in an adaptive fashion. And the greatly increased prescribing of methylphenidate (Ritalin) for underperforming schoolchildren has underlined the need to distinguish treating defect from heightening performance.

Since drug development largely targets neural receptors and pathways and since the receptors and pathways implicated in illness are presumed to underlie normal temperament, issues of what has been called cosmetic psychopharmacology (the use of medication to change normal but undesirable or unrewarded traits for normal and desired or rewarded ones) will likely become real and even common in the profession. The use of psychotherapy to improve the mood or social functioning of healthy people is widely accepted. As the scope of psychopharmacology becomes indistinguishable from that of psychotherapy, the profession will need to grapple with the use of medication for enhancement and with the distinction between such use and drug abuse. Issues of prevention, definition of illness, and enhancement may elicit a comprehensive conceptual resolution that will be part of the process of self-definition of the psychiatric profession.

TRENDS

Of course, progress in psychopharmacology will come in tandem with developments in basic and clinical research. These are even harder to foresee, but to the extent that psychiatry mimics the rest of medicine, researchers will search for causes of mental illness in such disciplines as genetics, infectious disease, endocrinology, and immunology.

Surprises may include a new overarching theory of mind and mental illness, such as Sigmund Freud elaborated at the turn of the twentieth century, but for the moment, the future seems to hold a varied collection of explanations. This eclecticism may result in further subspecialization within psychiatry or in the transfer to other disciplines of illnesses previously considered psychiatric, as occurred in the past with tertiary syphilis, the vitamin deficiencies, and endocrine disorders. Regarding subspecialization, recent years have seen increased interest in sex-related aspects of pharmacology, a development with vague parallels to the feminist psychotherapy movements of the 1960s. The future likely holds an increased interest in the role of gender, race, and ethnicity in optimal psychiatric care. At the same time, computer-assisted consultation, either by algorithm or with colleagues at distant sites, may sustain the viability of general psychiatric practice.

PSYCHOTHERAPY

Perhaps the greatest mystery is the future of psychotherapy. Particularly in the last half of the twentieth century, psychotherapies proliferated to include treatments based on behavioral and cognitive principles, strategic and systems theory approaches, and many others. Although outcome research is limited in its findings, it has gained in influence, so that although research rarely shows distinctions in efficacy between psychotherapies, treatments that are most easily “manualized” and tested have become increasingly popular. These include cognitive psychotherapy, the interpersonal approach of Gerald Klerman, and (most recently) dialectical-behavioral therapies.

Within the line of therapies that begins with classical psychoanalysis, the recent movement has been away from approaches that attempt to remedy unconscious conflict and toward those (e.g., self psychology and the intersubjective school) that attempt to remedy posited deficits in personality structure, in part by applying empathy as a diagnostic and therapeutic instrument. A series of therapies take into account the research on attachment pioneered by John Bowlby and others. These treatments are more in tune with current theories of mind and of child development than were their predecessors, and they hold forth the possibility of a conceptual and clinical integration of psychotherapeutic and psychopharmacologic approaches. Meanwhile, research of the most preliminary sort points to the possibility of documenting—and in the future perhaps quantifying or monitoring—the central physiological effects of psychotherapy.

Considering scientific and intellectual opportunity only, the future of psychotherapy in psychiatry might look bright. But this view ignores other trends. Psychotherapy has suffered a decline in reputation and status for various reasons including a harsh reassessment of the character and achievements of many of the founders of psychotherapy, a series of scandals involving undue intimacy and other abusive behaviors on the part of practitioners, and controversy regarding the efficacy and scientific integrity of the discipline. At the same time, psychotherapy within psychiatry has been vulnerable to changes in health care delivery systems, notably cost-cutting measures on the part of third-party payers and fourth-party reviewers of health care. The result is a reliance in all disciplines on brief and unambitious treatments, marginalization of psychotherapy within training programs, and widespread discouragement about the ability of psychiatry to maintain psychotherapy as a central element in its identity. One notable dissenter from this pessimism is Leston Havens, who argues that members of a growing and vigorous middle- and upper-middle class throughout the world will ask themselves, “What's for me?” a question best answered by psychotherapy.

This debate reveals the extent to which the future of psychiatry rests on social and economic forces external to the discipline. Even progress in psychopharmacology depends on continued financial opportunities for drug manufacturers, a circumstance that was briefly called into doubt during the health care policy debates of the early 1990s. Other areas of the field, such as public-sector psychiatry, including community mental health care, are particularly at the mercy of shifts in public policy.

Despite multiple sources of uncertainty, a picture of a possible future psychiatry emerges. It is more closely allied with the rest of medicine through the basic sciences and biologically based treatments. Yet, it maintains a distinctive character, both because of its particular requirements for Hippocratic diagnosis and its ongoing use of a distinctive technology, psychotherapy (whether or not primarily administered by psychiatrists). It continues to comprehend tensions between mind and brain, while continuing its theoretical work to minimize that division. It remains intimately tied to a host of human interests, from its sister sciences to philosophy to the social forces it lives amidst. There is even the possibility that psychiatry, with its insistent dialectical attention to mind and brain, will become a model for the rest of medicine, so that psychiatry will not so much respond to its environment as reshape it.

SUGGESTED CROSS-REFERENCES

Biological therapies are covered in Chapter 31. Psychoanalysis and other psychological therapies are covered in Chapter 30. Evolutionary biology is discussed in Section 4.3.
