Depression is also associated with an increase in postsynaptic 5-HT $_{2}$ receptor density. A variety of antidepressants, including the tricyclics, have been shown to downregulate the 5-HT$_2$ receptors. The 5-HT$_2$ receptors principally mediate excitatory effects, while the 5HT $_{1A}$ receptors have an inhibitory effect in the brain; thus these two systems act in opposition. In preclinical experiments, administration of a 5-HT $_{2}$ antagonist enhances the effects of serotonin. Thus, the downregulation of 5-HT$_2$ receptors with tricyclic treatment appears to facilitate the effects of serotonin at postsynaptic 5-HT $_{1A}$ receptors.

In the noradrenergic system, as a consequence of blockade of the norepinephrine transporter, turnover of norepinephrine falls and the concentration of 3-methoxy-4-hydroxyphenylglycol (MHPG), a metabolite of norepinephrine, drops rapidly, within 24 hours. Presumably, this effect results from the presynaptic a$_2$-adrenergic autoreceptor; however, the role of the presynaptic autoreceptor and its possible subsequent desensitization is not as well described for the noradrenergic system as it is for the serotonin system. During this period, the postsynaptic, b-adrenergic receptor, is downregulated, or decreased in density. This downregulation is associated with a corresponding reduction in activity of cyclic adenosine monophosphate (cAMP), the second messenger for the b-receptor.

Early theories of depression posited depletion of serotonin, norepinephrine, or both of these neurotransmitters. Administration of the tricyclic agents was thought to enhance the availability of both neurotransmitters. Subsequent theories suggested that the changes in pre- and postsynaptic receptors were a likely explanation for the delayed effects of these drugs in depression. In the serotonin system, desensitization of presynaptic 5-HT $_{1A}$ autoreceptors and sensitization of postsynaptic serotonin receptors are both changes consistent with enhanced serotonin transmission. Theories of norepinephrine action, however, have become more complicated with the knowledge that postsynaptic b-adrenergic receptors are, in fact, downregulated. It has been suggested that even with downregulation of postsynaptic receptors, the net effect of reuptake blockade is still enhanced formation of the second messenger cAMP. These changes are part of the postreceptor signal transduction cascade, which is a current focus of research on the mechanism of antidepressant action.

An understanding of how the antidepressant drugs act does not necessarily implicate a particular neurotransmitter in the pathophysiology of depression. Recent studies with tryptophan depletion illustrate this point. Administration of a tryptophan-free diet rapidly depletes serotonin. Depressed patients who have been successfully treated, relapse following tryptophan depletion. Further, the subjects who relapse are those treated with serotonergic agents; those treated with norepinephrine agents are relatively unaffected. Alternatively, administration of a-methyl-para-tyrosine, which interrupts the synthesis of catecholamines, causes relapse in patients successfully treated with noradrenergic agents, while those receiving serotonergic drugs are relatively unaffected. Tryptophan depletion in untreated depressed patients, however, has no effect on the patient's depression. These studies support the view that the action of these two types of drugs is, in fact, mediated by serotonin and norepinephrine, but they do not necessarily imply that alterations in these neurotransmitter systems are central to the pathophysiology of depression.

Early theories of antidepressant action suggested that it might be possible to identify serotonergic and noradrenergic depressions on the basis of the relative deficiencies of metabolites associated with each of these neurotransmitters and thus predict which type of antidepressant would be most effective. A number of studies investigated the predictive value of MHPG pretreatment, but their findings were relatively disappointing. These studies were, in part, hampered by the use of agents such as amitriptyline and imipramine, which are not selective.

Secondary Effects The tricyclic and tetracyclic compounds have effects on a variety of other receptors (Table 31.30-1). In particular, these compounds block muscarinic receptors, producing anticholinergic effects. They block histamine type 1 (H $_{1}$) receptors and they block a$_1$- and a$_2$-adrenergic receptors. They affect fast sodium channels, which explains their adverse cardiac effects. These compounds vary considerably in the potency of these effects. Amitriptyline is the most anticholinergic. Doxepin is one of the most potent H $_{1}$ antagonists marketed.

Pharmacokinetics

Absorption The tricyclic and tetracyclic drugs are absorbed in the small intestine, and absorption is reasonably complete and rapid. Peak concentrations following ingestion occur within 2 to 8 hours. One exception is protriptyline, which is absorbed more slowly, with peak concentrations obtained between 6 and 12 hours. Maprotiline also has more-delayed absorption, with peak concentrations occurring in 8 hours or more. Because the primary action of these drugs occurs over several weeks, the timing of peak concentrations is relatively unimportant for treatment of depression. It may have implications for side effects, especially during initial dosing.

Volume of Distribution The tricyclic and tetracyclic compounds are basic lipophilic amines. As a result, they are concentrated in a variety of tissues throughout the body and have a high volume of distribution. In cardiac tissue, for example, drug concentrations exceed those in plasma.

Plasma-Protein Binding Because of their lipid solubility, these compounds are extensively bound to plasma proteins. Binding of the tricyclic and tetracyclic drugs is generally 90 percent or greater. One exception are the hydroxy metabolites of the tricyclics which have somewhat lower plasma protein binding.

First-Pass Metabolism Following absorption, the drug is taken up in the circulation and passes first through the liver, where metabolism of the drug begins (the first-pass effect). As a result, a reduced amount of the compound actually enters the systemic circulation.

Hepatic Metabolism Clearance of the tricyclic and tetracyclic compounds is principally the result of hepatic metabolism. Renal clearance accounts for only a small portion of drug elimination. Rates of hepatic metabolism vary widely from person to person. Elimination half-lives for most of the tricyclic and tetracyclic compounds are about 24 hours or longer, thus the drugs can be given once a day (Table 31.30-2). Amoxapine, which has a shorter half-life, is an exception.

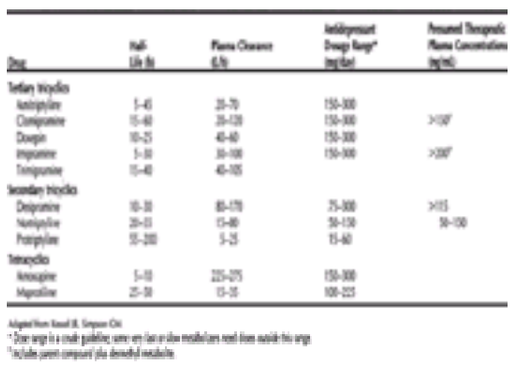

Table 31.30-2 Pharmacokinetic Parameters and Clinical Information for Tricyclic and Tetracyclic Drugs

There are two principal metabolic pathways: demethylation of the side chain and hydroxylation of the ring structure. Demethylation converts the tertiary amine to a secondary amine; examples are the conversion of amitriptyline to nortriptyline and imipramine to desipramine. This process alters the activity of the compound. The tertiary amines are relatively more serotonergic; the demethylated amines are relatively more noradrenergic.

Hydroxylation of the compounds results in hydroxy metabolites. The concentration of the metabolite of nortriptyline, 10-hydroxynortriptyline usually exceeds that of the parent. For desipramine, 2-hydroxydesipramine is present at concentrations approximately 45 percent of those of the parent, but these ratios are quite variable. The ratio of hydroxy metabolite to parent increases in rapid metabolizers. Hydroxyimipramine and hydroxyamitriptyline are present at quite low levels that appear to be clinically unimportant. The hydroxy metabolites are then conjugated and excreted. The conjugated metabolites are not active.

Hydroxynortriptyline and hydroxydesipramine are active compounds. Both have antidepressant activity. Hydroxydesipramine is comparable to the parent in terms of

norepinephrine reuptake blockade. There are two isomers of hydroxynortriptyline, E- and Z-10-hydroxynortriptyline. E-10-hydroxynortriptyline concentrations are four times those of the Z isomer. E-10-hydroxynortriptyline also blocks uptake of norepinephrine but is about 50 percent as potent as nortriptyline. The clinical significance of high concentrations of less potent hydroxynortriptyline is not entirely clear, but if high concentrations of hydroxynortriptyline interfere with the action of nortriptyline, this might explain the therapeutic window described for this drug. In both cases, the hydroxy compounds are less anticholinergic than their parent compounds. The hydroxy metabolites have other effects as well. They appear to contribute disproportionately to the cardiac conduction abnormalities associated with the tricyclic drugs.

The principle metabolic pathway for amoxapine is hydroxylation. 7-hydroxyamoxapine and 8-hydroxyamoxapine are produced, which differ in their clinical activity. 7-hydroxyamoxapine has high-potency neuroleptic properties but a short half-life. 8-hydroxyamoxapine is metabolized more slowly and appears to contribute to the drug's antidepressant action.

An area of great interest in recent years has been the identification of the specific isoenzyme pathways involved in the metabolism of a variety of drugs, including the antidepressants. The cytochrome P450 (CYP) isozyme 2D6 (CYP 2D6) pathway appears to be responsible for hydroxylation of desipramine and nortriptyline. Demethylation of the tertiary amine compounds appears to involve a number of cytochrome P450 isoenzymes, including CYP 1A2, 3A4, and 2C19. These hepatic isoenzymes are under the control of specific genes, and the gene loci have been identified for several of these isoenzymes, including CYP 2D6. Approximately 5 to 10 percent of whites are homozygous for the recessive autosomal CYP 2D6 trait, resulting in deficient hydroxylation of desipramine and nortriptyline. These individuals are known as poor metabolizers, while those with adequate 2D6 isoenzyme are extensive metabolizers. The resulting variability in plasma concentrations is substantial, often described as a 40-fold variation among individuals (Fig. 31.30-2). Even among the extensive metabolizers, there can be moderate variability from individual to individual in the rates of metabolism. Various methods have been used to phenotype the individuals who are slow or fast metabolizers. One technique is debrisoquine phenotyping. Rates of formation of the debrisoquine metabolite in the urine are used to characterize the metabolic rate of CYP 2D6. In clinical practice, blood monitoring for desipramine and nortriptyline concentrations is more readily available than debrisoquine assays, and the concentrations in blood of the compounds themselves are more often used as an index of the rate of metabolism.

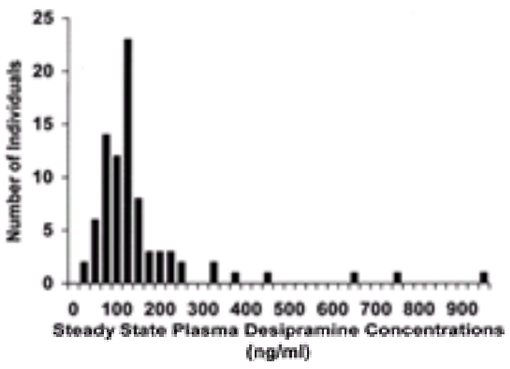

FIGURE 31.30-2 Distribution of steady-state desipramine concentrations in 83 inpatients receiving desipramine (2.5 mg/kg a day). (Adapted from Nelson JC: J Clin Psychiatry *45:*10, 1984.)

Steady-State Concentrations Clinicians must understand the concept of steady state if plasma concentration monitoring is used. Steady state is the point at which plasma concentrations plateau for a given fixed dose. The usual convention in pharmacology is that steady state is achieved after five times the half-life. After five half-lives, the concentration of the drug should be 97 percent of the maximal concentration achieved for that dose. In fact, for the clinician, it is also worth remembering that after three half-lives, the drug will have achieved about 87 percent of the steady-state concentration. The latter is important when dose adjustments are urgently required. If blood concentration monitoring is used, a trough sample (before the next dose) is drawn when the patient has reached steady state. At steady state, drug concentrations are relatively stable as long as the dose is constant, the patient is compliant, and no drugs with interactive effects are added.

When the drug concentration is measured, the total of both the free and bound tricyclic fractions are reported. Few laboratories are prepared to measure free levels, yet free levels are directly related to the concentration of drug in the cerebrospinal fluid. The free concentration depends on dose and hepatic clearance and is not affected by absorption, the volume of distribution, or plasma-protein binding. The latter is one of the most misunderstood aspects of pharmacokinetics. If the concentration of binding protein is low, the total (free and bound) concentration may be low, but the absolute free concentration is unaffected. If another drug affects binding, the absolute free concentration remains unaffected. In these instances, the free fraction may increase because the bound portion decreases, but the absolute free concentration is unchanged.

The biological variability of drug concentrations is not frequently described. In outpatients, the day-to-day variability of nortriptyline concentrations (the coefficient of variation equals the standard deviation divided by the mean plasma concentration) has been reported to be 25 percent. In inpatients at steady state, day-to-day variability of desipramine is approximately 10 to 15 percent. This means that if the average plasma concentration is 150 ng/mL, two thirds of samples obtained will be ±10 percent or within the range of 135 and 165 ng/mL. As a result of this variability, research studies of drug concentrations frequently use the average of two or three plasma samples drawn at steady state to estimate the concentration. For clinical purposes, usually only one sample is drawn, and the clinician needs to remember that even if the laboratory error is low (less than 5 percent), the extent of biological variability means that blood concentrations are better viewed as estimates rather than as precise measures.

Linear Kinetics Drugs for which concentration increases in proportion to dosage within the therapeutic range are said to have linear pharmacokinetics. For most of the tricyclic drugs, kinetics appear to be relatively linear, although there are some exceptions. Desipramine, for example, appears to have nonlinear kinetics in the usual dosage range. The patients most vulnerable to nonlinear changes during increasing dosages are the rapid metabolizers—in other words, patients who at usual doses have very low blood concentrations. Increasing dosages in these patients result in a disproportionate rise in the drug concentration. Nortriptyline appears to have relatively linear kinetics within the usual dosage range. In overdose, nonlinear changes are more likely to occur, and the clinician cannot assume that usual rates of drug elimination will be maintained.

Effects of Aging The pharmacodynamics and pharmacokinetics of drug treatment in the elderly are complicated. A number of changes occur. For example, the ratio of fat to lean body mass increases and cardiac output and hepatic blood flow decrease. There may be further changes associated with medical illness. Yet, the magnitude of these changes are relatively minor in relation to the dramatic variability of hepatic metabolism. Metabolic changes with age appear to vary with the isoenzymes involved. The CYP 3A4 pathway, for example, does appear to decrease or slow with age. Most studies of the tertiary amines (e.g., imipramine) suggest that concentrations of these drugs are increased somewhat in the elderly. The CYP 2D6 isoenzyme pathway, however, is not similarly affected by aging. Concentrations of nortriptyline and desipramine appear to be relatively unaffected by aging. Similarly, the relation of drug concentrations to therapeutic effects appears to be relatively similar in younger and older adults for these agents. Renal clearance of the hydroxy metabolites does decrease with age. Concentrations of hydroxynortriptyline may be substantially elevated in older patients.

Alternatively, the clearance of tricyclic compounds in children is increased. Half-lives of imipramine are shorter and ratios of desmethylimipramine to imipramine are higher, consistent with more-rapid metabolism.

DESIGN AND INTERPRETATION OF CLINICAL DRUG STUDIES

Efficacy in Depressive Disorders The clinical efficacy of the tricyclic and tetracyclic compounds in major depression is well established and was extensively reviewed by John Davis and Alexander Glassman in the fifth edition of this text. Imipramine is the best-studied compound. In 44 placebo-controlled studies, imipramine was more effective than placebo in 30. Overall, in studies reporting response rates (*N* = 1334), 65 percent of the patients completing treatment with imipramine were substantially improved, while 30 percent of those on placebo were similarly improved. In a meta-analysis of intent-to-treat response rates for placebo-controlled studies of tricyclic drugs in outpatients, reported in the Agency for Health Care Policy and Research (AHCPR) guidelines, response rates were 51 percent for imipramine and 30 percent for placebo. In most comparison studies, the other tricyclic and tetracyclic antidepressants have been found to be comparable

to imipramine in efficacy.

In addition to efficacy in acute depression, the tricyclic compounds are also effective for maintenance treatment. Several early studies demonstrated that maintenance treatment with a tricyclic reduced the relapse rate associated with placebo by about 50 percent. These studies, however, often used low doses. Subsequently, an important study by the Pittsburgh group found that if the full dose of imipramine used for acute treatment was continued, nearly 80 percent of the depressed patients maintained their improvement, while only 10 percent of those on placebo remained well at the end of a 3-year period. In this study, maintenance psychotherapy had an intermediate effect, with about 30 percent of the patients remaining well. This study again confirmed the value of maintenance treatment and underscored the importance of continuing the full dose of imipramine. Yet, the magnitude of the findings may in part relate to the sample selected, namely, patients with recurrent depression who had been symptom free between prior episodes. In clinical practice, if patients with chronic depression, prior residual symptoms, or comorbid psychiatric disorders are included, the number of patients who remain in remission may be lower.

Subtypes of Depression The efficacy of the tricyclic compounds varies in different subtypes of depression. Kuhn thought it was essential to establish the efficacy of imipramine in endogenous inpatients. The tricyclic compounds have been frequently studied in severely depressed inpatients and found to be effective. It has been suggested that the tricyclics may be more effective than the selective serotonin-reuptake inhibitors (SSRIs) in severe major depressive disorders with melancholic features. The issue remains unsettled, in part, because of the paucity of studies of the SSRIs in severe melancholic depression.

The tricyclic and tetracyclic compounds have often been studied in anxious depression. Three of the compounds—doxepin, amoxapine, and maprotiline—have Food and Drug Administration (FDA) approval for use in patients with depression and symptoms of anxiety. For many years, clinical lore suggested that amitriptyline was most effective for anxious depression; however, there is little evidence from direct comparison studies that these compounds differ in their efficacy for treatment of anxiety associated with depression. Three studies found that among depressed patients, those with high levels of anxiety respond less well to amitriptyline, imipramine, or desipramine than those with lower levels of anxiety. Yet, these drugs are still more effective than placebo in anxious depressed patients, and it is not established that other classes of antidepressants are more effective in these patients.

In patients with atypical features (defined by the Columbia University or the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* [DSM-IV] criteria), imipramine is more effective than placebo but significantly less effective than the monoamine oxidase inhibitors (MAOI). Little information is available regarding comparisons of tricyclic drugs and SSRIs in atypical depression.

Major depressive disorder with psychotic features is less responsive than is nonpsychotic depression to tricyclics used alone. However, several open trials and one prospective study have found that tricyclic drugs combined with an antipsychotic agent are effective in psychotic depression. One double-blind study compared the efficacy of amoxapine with that of the combination of perphenazine (Trilafon) and amitriptyline and found amoxapine to have comparable efficacy in psychotic depression.

In controlled studies of patients with bipolar disorder depression, imipramine was found less effective than tranylcypromine (Parnate) or fluoxetine (Prozac). These studies and others suggest that tricyclic drugs are more likely to induce mania than the newer serotonergic agents or bupropion (Wellbutrin).

Tricyclic antidepressants appear to be effective in elderly patients, but overall drug and placebo response rates appear to be lower than they are in nonelderly patients, although the same appears to be true for other drug classes such as the SSRIs. In children and adolescents, the tricyclics have not demonstrated superiority over placebo.

The tricyclic drugs are effective in dysthymia. Imipramine and desipramine have both been studied in controlled trials and are more effective than placebo for acute treatment of dysthymia and for maintenance treatment.

Relations of Dosage, Plasma Concentrations, and Response Early studies of the tricyclic antidepressants (particularly imipramine) demonstrated that in patients with endogenous major depressive disorder, aggressive dosing, in the 200 to 300 mg a day range, was more effective than lower doses. Because of the adverse effects associated with tricyclic drugs, therapy was usually begun at lower dosages and then titrated upward. The rationale was that patients would accomodate to these side effects and, over time, be able to tolerate higher doses. The need for dose titration and the time required appeared to be obstacles to the use of these drugs by nonpsychiatrists. Studies of these agents in nonpsychiatric settings consistently showed evidence of underdosing.

Knowledge of the wide interindividual variability of tricyclic drug plasma concentrations led to the hope that drug concentration monitoring might ensure that therapeutic concentrations were achieved, and might help to avoid toxic levels. In carefully selected endogenous or melancholic inpatients with major depression, treatment with adequate concentrations of imipramine or desipramine resulted in response rates of about 85 percent. These studies suggested that adequate concentrations in blood would help to maximize response. Alternatively, the careful selection of patients in these studies may have resulted in samples that are not representative of typical clinical practice.

An American Psychiatric Association (APA) task force reviewing the information on blood concentrations and response concluded that a relation had been demonstrated for nortriptyline, for which plasma concentrations between 50 and 150 ng/mL were more effective than lower or higher levels (Table 31.30-2). For imipramine, concentrations above 200 ng/mL were more effective than lower levels. For desipramine, the findings of several individual studies have been variable; however, there was general agreement that concentrations below 110 to 115 ng/mL were not effective. Most studies with an appreciable number of patients at higher plasma concentrations found that response did not decline with higher concentrations, although in one study, patients with concentrations above 155 ng/mL did less well. For both desipramine and imipramine, it appeared that blood concentrations above 300 ng/mL were more likely to be associated with serious adverse effects.

For amitriptyline, it has been more difficult to establish a therapeutic relation of concentration and response. In part, this may be related to the fact that during amitriptyline administration, three active compounds are present (amitriptyline, nortriptyline, and hydroxynortriptyline), and it is unclear whether concentrations of the three compounds should be simply summed or whether a more complicated relationship exists, given that nortriptyline and hydroxynortriptyline have a therapeutic window. During amitriptyline administration, responders usually have total amitriptyline and nortriptyline concentrations in the neighborhood of 150 to 250 ng/mL, but as stated, there is not good agreement between studies. For clomipramine, blood concentrations of 150 to 300 ng/mL (total of clomipramine and desmethylclomipramine) have been suggested for antidepressant effectiveness. Higher doses are usually employed in the treatment of obsessive-compulsive disorder. The data relating blood levels and response are limited for the other tricyclic and tetracyclic compounds.

The clinical value of blood concentration monitoring has been the subject of considerable controversy. It has been suggested that blood concentration is not related to response in depressed outpatients. Indeed, the relation of blood concentration and response has been best demonstrated in inpatients, probably because placebo response rates are low in melancholic inpatients; and drug-placebo differences are reasonably substantial, so the drug effect is relatively easy to detect. In outpatients, placebo rates are higher, the difference between drug and placebo is substantially reduced, and the effect of drug treatment is harder to detect. Moderately depressed outpatients may be a heterogeneous group and include patients who are less responsive to drug treatment. Finally, many studies have not been designed to investigate blood concentration relationships. Fixed dosing is required, and a significant portion of patients in the sample must achieve plasma concentrations below the suspected threshold. If all patients achieve plasma drug concentrations above a lower threshold, no relation with response will be found. It is logical to conclude that blood concentration relationships determined in severely depressed inpatients might be used to guide treatment of outpatients, particularly treatment-resistant patients for whom the clinician wants to ensure that adequate blood concentrations were obtained.

Plasma Concentrations and Toxicity The alternative question is whether blood concentration monitoring might help to avoid toxicity. A variety of data supports this view. The risk of delirium is substantially increased at tricyclic plasma concentrations above 450 ng/mL and moderately increased at levels above 300 ng/mL. However, most of the patients included in these studies were receiving amitriptyline, the tricyclic drug most likely to be associated with delirium. The risk of cardiac arrhythmia is also substantially increased at higher blood concentrations. First-degree atrioventricular block increases with plasma concentrations of imipramine above 350 ng/mL and increases substantially when concentrations exceed 450 ng/mL. The risk of seizures also increases in patients at higher doses and (presumably), higher blood concentrations, although a plasma concentration threshold has not been demonstrated for seizures. The risk of seizures for clomipramine is 1.66 percent with doses above 250 mg a day but is about 0.50 percent for doses up to 250 mg a day. On average, a dosage of 250 mg a day corresponds to a plasma concentration of about 500 ng/mL. In one large sample of patients with obsessive-compulsive disorder at steady state on clomipramine 250 mg a day, the average blood concentration was 155 ng/mL for clomipramine and 335 ng/mL for desmethylclomipramine, or a total of 490 ng/mL. For the older drugs amitriptyline and imipramine, the risk of seizures also appears to be increased at dosages exceeding 250 mg a day. Following overdose, tricyclic drug concentrations in blood can exceed 1000 ng/mL, and the risk of delirium, stupor, cardiac abnormalities, and seizures increase substantially.

One problem in appreciating the relation of toxicity to increased blood concentrations is that although the risk may increase, actual rates are still low, and large samples are required to demonstrate the difference in risk. Certain types of toxicity (e.g. delirium) may have early warning signs, and dosage can be reduced unless the symptoms of delirium are mistaken for symptoms of the underlying psychiatric disorder. Alternatively, there may be no early signs of seizures and cardiac arrhythmia to alert the clinician to reduce dosage. Blood concentration monitoring might be most useful to reduce the risk of these particular adverse effects.

EFFECTS ON SPECIFIC ORGANS AND SYSTEMS

The clinical manifestation of so-called side effects results from the interaction of direct effects of the medication on specific organs and indirect effects of the medication on depression and its associated somatic symptoms. Depression is accompanied by a variety of somatic symptoms; for example, headache, constipation, poor memory, drowsiness, and difficulty sitting still are observed in more than 50 percent of untreated inpatients with major depression. Other symptoms, such as palpitations, dry mouth, tremors, lightheadedness, and poor coordination are reported by more than 40 percent of depressed patients prior to treatment. The determination of whether a physical symptom is an adverse effect of a drug or a symptom of depression involves a judgment about whether the symptom is new or has worsened during drug treatment. Unfortunately, severely depressed patients may not remember accurately that the somatic symptom of concern was more severe prior to the introduction of medication. During treatment, one of the strongest predictors of overall adverse effects reported is the level of depression at the time of assessment.

Antidepressant drugs do, of course, produce new somatic symptoms. The in vitro potency or affinity of antidepressant compounds for various receptor sites (Table 31.30-2) is one method for comparing the likelihood that various agents will produce side effects. The other pharmacological factor that needs to be considered is the bio-availability of the drug.

Central Nervous System In the central nervous system, the principle action of the tricyclic and tetracyclic agents is to alleviate depression. These agents do not have a direct mood-elevating effect. They do not produce euphoria. Rather, they reduce the symptoms of depression. Apparently related to their effects on brain amines, these compounds can cause or aggravate psychotic symptoms and induce mania.

The central anticholinergic and antihistaminic effects of the tricyclic and tetracyclic drugs can produce confusion or delirium. The incidence of delirium is dose dependent; it increases at blood concentrations above 300 ng/mL and may rise to 67 percent when blood concentrations exceed 450 ng/mL in patients receiving the tertiary amines particularly amitriptyline.

Seizures can occur with all of the tricyclic and tetracyclic agents. Seizures are dose and blood concentration related. For clomipramine, the risk for seizures is reported to be 0.5 percent in doses up to 250 mg a day; at higher doses, the seizure risk increases to 1.67 percent. For maprotiline, the overall risk of seizures is reported to be 0.4 percent, but, again, the risk of seizures increases at dosages above the maximum recommended dosage of 225 mg a day. Determination of seizure risk for some of the older compounds was hampered by less rigorous data collection at the time of marketing. In one meta-analysis of data for imipramine, patients receiving less than 200 mg a day had a seizure rate of 1 in 1000. In patients receiving more than 200 mg a day, the rate was 0.6 percent. In patients receiving 250 to 450 mg a day, reported rates vary from 1 to 4 percent, but since several of these samples were small, these rates had wide confidence intervals. Seizure rates for the secondary amines have not been well described. The mechanism by which tricyclic drugs produce seizures is not well understood, although it is proposed that antidepressant drugs may act at the g-aminobuteric (GABA)-receptor chloride-ionophore complex, inhibiting chloride conductance and consequently inducing convulsions. The risk of convulsions is clearly increased in patients with predisposing factors including a prior history of seizures, brain injury, and presence of neuroleptic agents. The risk of seizures increases substantially following overdose.

A fine, rapid tremor can occur with the tricyclic agents and may be a clinical indication of an elevated blood concentration. Because the 7-hydroxy metabolite of amoxapine has neuroleptic properties, administration of amoxapine carries the potential risk of neuroleptic malignant syndrome (which has been reported) and tardive dyskinesia.

Several of the tricyclic compounds and maprotiline have clinically significant antihistaminic effects. Doxepin is one of the most potent H_1 receptor blockers known. Central H_1 receptor blockade can contribute to sedation and delirium. Antihistaminic effects also appear to be related to the increased appetite and associated weight gain that patients develop with long-term treatment.

Autonomic Nervous System The tricyclic drugs block muscarinic receptors and can cause a variety of anticholinergic adverse effects including dry mouth, constipation, blurred vision, urinary hesitancy, and an ocular crisis in patients with narrow-angle glaucoma. The tricyclic and tetracyclic compounds vary substantially in their muscarinic potency (Table 31.30-2). Amitriptyline is the most potent, followed by clomipramine. Of the tricyclic drugs, desipramine has the least severe anticholinergic effects. Amoxapine and maprotiline also have minimal anticholinergic effects. Anticholinergic effects can contribute to tachycardia, but tachycardia commonly occurs in patients receiving desipramine, which has minimal anticholinergic effects. It seems likely that noradrenergic effects also contribute to the increased pulse. Increased sweating is another secondary effect that can occur with use of the tricyclic compounds. The mechanism for this symptom is unclear, but it may be associated with noradrenergic effects.

Cardiovascular Effects Orthostatic hypotension is one of the most common reasons for discontinuation of tricyclic antidepressant treatment. Orthostatic hypotension can occur with all of the tricyclic drugs, but it is less pronounced with nortriptyline. It has been suggested that orthostatic hypotension is caused by a $_1$-adrenergic blockade; however, the postural reflex is primarily affected. Resting supine blood pressure may be unaffected or may be raised. Orthostatic hypotension is most likely to occur or is most severe in patients who have preexisting orthostatic hypotension.

Desipramine has been reported to raise supine blood pressure in younger patients, although it is not clear this effect is limited to that age group. This effect may be similar to that reported for venlafaxine (Effexor).

Tachycardia occurs with all tricyclic drugs, not just the more anticholinergic agents. Both supine and postural pulse changes can occur. Patients do not accommodate to the pulse rise, which can persist for months. Tachycardia is more prominent in younger pa tients who appear more sensitive to the sympathomimetic effects of these agents and is one of the most common reasons for drug discontinuation in this age group.

The effect of tricyclic antidepressants on cardiac conduction has been a subject of great interest. Cardiac arrhythmia is the principle cause of death following overdose. As a result, for many years there was great concern about the use of tricyclic antidepressants in patients with heart disease. The effect of these agents has now been well described. These agents have type I antiarrhythmic qualities, or quinidine-like effects. Apparently, through inhibition of Na^+, K^+-adenosine triphosphatase (ATPase), the tricyclic compounds stabilize electrically excitable membranes and delay conduction, particularly His-ventricular conduction.

At therapeutic blood concentrations, tricyclic drugs can have beneficial effects on ventricular excitability. Alternatively, in patients with preexisting conduction delay, the tricyclic antidepressants can further delay conduction and cause heart block. The QTc interval is regarded as the best index of who might be vulnerable to this effect. Patients with a QTc interval of 450 milliseconds or more are at increased risk and are not candidates for tricyclic antidepressant treatment. The risk of cardiac toxicity is further increased by high blood concentrations. For example, first-degree atrioventricular heart block is increased with imipramine plasma concentrations above 350 ng/mL and is increased more than 30-fold in patients with plasma concentrations above 450 ng/mL.

Tricyclic drugs do not appear to adversely affect cardiac contractility or cardiac output. Studies using radionuclide angiography indicate no adverse effect of imipramine or doxepin on cardiac output, even in patients with diminished left ventricular ejection fractions. Severe orthostatic hypotension was common in these patients.

Recently, another possible hazard of tricyclic drugs was suggested. Based on the report of the Cardiac Arrhythmia Suppression Trial (CAST) studies, which found that type I antiarrhythmic drugs given following myocardial infarction actually increased the risk of sudden death, Alexander Glassman, Steven Roose, and Thomas Bigger suggested that the tricyclic drugs may pose similar risks. Thus the clinician considering long-term use of tricyclic drugs in patients with ischemic heart disease needs to weigh this possible risk against possible benefits.

Hepatic Effects Drug-induced hepatitis can occur with these agents. Mild increases of liver enzymes are not uncommon and usually can be monitored safely over a period of days or weeks without apparent harmful consequences. However, acute hepatitis can occur quickly and is associated with very high enzyme levels (e.g.,

aspartate aminotransferase [AST] levels >800) within days. The rise in enzymes can be either hepatocellular or cholestatic and may precede clinical symptoms, especially in the hepatocellular form. This is a dangerous and potentially fatal condition. The antidepressant must be discontinued. The etiology is not well established but, in some cases, appears to be a hypersensitivity reaction. The risk of severe drug-induced hepatitis is not well established but appears to be between 1 in 1000 and 1 in 100.

THERAPEUTIC INDICATIONS

Indications The tricyclic and tetracyclic compounds have a variety of clinical uses. In fact, it is interesting to consider what these agents might have been called originally had their effectiveness in panic disorder, obsessive-compulsive disorder, pain, or other syndromes been described before their antidepressant action.

All of the tricyclic and tetracyclic compounds discussed in this chapter are approved by the Food and Drug Administration (FDA) for use in the United States for the treatment of depression, with the exception of clomipramine. Clomipramine is also used for depression and in Europe is regarded by many as the most potent antidepressant. This view is based on the dual action of the compound on both serotonin and norepinephrine and empirical data suggesting that this agent is more effective than SSRIs in severely depressed inpatients.

While a variety of antidepressants appear to be effective in depressive disorders, this is not the case for obsessive-compulsive disorder. In this instance the serotonergic antidepressants (e.g., clomipramine) appear to be substantially more effective than noradrenergic tricyclic drugs (e.g., desipramine). Among the tricyclic drugs, clomipramine is the only agent approved by the FDA for use in obsessive-compulsive disorder.

Other Indications The tricyclic agents have been used for a variety of other clinical indications without FDA approval. They are effective in panic disorder; in fact, imipramine was the first drug found effective in these patients.

Amitriptyline has been popular among nonpsychiatrists for use in chronic pain syndromes and migraine headache prophylaxis. During treatment of pain, the usual dosage is lower (up to 75 mg a day) and effects occur more quickly (usually within 3 to 4 days) than in depression. These differences suggest a different mode of action of amitriptyline in pain syndromes. Tricyclic drugs appear to be of some benefit in chronic fatigue syndrome.

For many years, desipramine was commonly prescribed for attention-deficit/hyperactivity disorder in children. Reports of sudden death, apparently of cardiac origin, in children under 12 years, substantially reduced the use of this drug in younger patients. Imipramine has been used for treatment of enuresis in children, with FDA approval. It is doubtful, however, that the risk of cardiac problems would be substantially lower with imipramine than with desipramine in young children.

These drugs have been extensively studied in schizophrenic patients. However, in the absence of a major depressive syndrome, they appear to have limited value, and their use for treatment of negative symptoms has been eclipsed by the introduction of the atypical neuroleptic agents.

PRECAUTIONS AND ADVERSE REACTIONS

Central Nervous System Effects The central anticholinergic effects of tricyclic drugs can produce delirium and seizures. Both of these adverse effects are dose dependent and become more frequent at elevated blood concentrations. The incidence of delirium increases at blood concentrations above 300 ng/mL and becomes common in levels above 450 ng/mL, especially with amitriptyline. The clinician should be aware of this possibility because the signs of delirium may be mistaken for a worsening of the depression. This diagnostic dilemma can be especially problematic in patients with psychotic depression. Patients with concurrent dementia are particularly vulnerable to the development of delirium. Intramuscular or intravenous physostigmine (Antilirium, Eserine) can be used to reverse or reduce the symptoms of delirium. However, the short duration of action of this agent makes its continued use difficult.

Because delirium and seizures depend on dosage and blood concentration, the first goal is to reduce the risk by avoiding unnecessarily high serum concentrations. Some experts advocate routine blood concentration monitoring. This question continues to be debated. A strong case can be made for monitoring in patients at increased risk (e.g., elderly patients and patients with dementia or a history of seizures). Blood monitoring can also be helpful in patients who fail conventional doses, to determine what dosages are required to reach therapeutic levels.

Autonomic Effects As mentioned, tricyclic drugs can cause a variety of anticholinergic adverse effects, including dry mouth, constipation, visual changes, urinary hesitancy, delirium, and an ocular crisis in patients with narrow-angle glaucoma. Use of nortriptyline or desipramine, which are less anticholinergic, can help reduce the likelihood of these problems.

Anticholinergic effects can be annoying but usually are not serious. In some circumstances, however, these effects can be severe. An ocular crisis in patients with narrow-angle glaucoma is an acute condition associated with severe pain. Urinary retention can be associated with stretch injuries to the bladder. Constipation can progress to severe obstipation. (Although paralytic ileus has been described, seldom are bowel sounds absent.) Patients with obstipation have considerable distress. Medication must be discontinued, and appropriate supportive measures instituted. The frequency of severe anticholinergic adverse reactions is increased in elderly persons and in patients receiving concomitant neuroleptic drugs.

Some anticholinergic effects may benefit from other interventions. Patients with urinary hesitancy may benefit from the use of bethanechol (Urecholine) at a dose of 25 mg three or four times a day. Patients with constipation often benefit from regular use of stool softeners. Patients with narrow-angle glaucoma who are receiving pilocarpine eye drops regularly can be treated with a tricyclic drug, as can those who have had an iridectomy. Patients with chronic open-angle glaucoma are not affected by tricyclic agents.

Cardiovascular Effects Orthostatic hypotension is one of the most common reasons for discontinuation of tricyclic antidepressant treatment. Orthostatic hypotension is less common with nortriptyline and is most likely to occur in patients who have preexisting orthostatic hypotension. Elderly patients are not only more likely to have preexisting hypotension but are also more vulnerable to the consequences of orthostatic hypotension—falls and hip fracture. Often, orthostatic hypotension occurs at relatively low blood concentrations. Further, while the subjective experience of lightheadedness may improve with time, the actual orthostatic blood pressure changes do not accommodate within a reasonable period of time (e.g. 4 weeks). Thus, unless the plasma concentration is elevated and the dosage can be reduced, patients who are experiencing serious symptomatic orthostatic hypotension may not be treatable with a tricyclic antidepressant. Fludrocortisone (Florinef) has been used to raise blood pressure, but it is not very effective. If patients are receiving antihypertensives, it may be possible and helpful to reduce these agents.

Tachycardia occurs with all the tricyclic drugs, not just the more anticholinergic agents. Both supine and postural pulse changes can occur. Patients do not accommodate to the pulse rise, which can persist for months. While an eight- to ten-beat increase in heart rate may be subjectively tolerated by the patient, a sustained increase in heart rate may have adverse consequences for the elderly patient because of increased cardiac work. Tachycardia is more prominent in younger patients who appear to be more sensitive to the sympathomimetic effects of these agents and is one of the most common reasons for drug discontinuation in this age group. Propranolol (Inderal) at low dosages may help to reduce the tachycardia unless it is associated with significant hypotension that propranolol might aggravate.

Cardiac Conduction Effects The tricyclic antidepressants have type I antiarrhythmic effects. Patients without conduction delay tolerate the tricyclics well. They may be helpful in patients with premature ventricular beats. However, the tricyclic antidepressants can further delay conduction in patients with preexisting conduction delay and cause heart block. As mentioned above, patients with a QTc interval of 450 milliseconds or more are at increased risk and are not candidates for tricyclic antidepressant treatment.

Hepatic Effects Mild increases of liver enzymes usually can be monitored safely over a period of days or weeks without apparent harmful consequences. However, as discussed above, acute hepatitis develops quickly and is associated with very high enzyme levels. In this situation, the antidepressant must be discontinued. If it is clear which drug caused the hepatitis, that drug should not be introduced again because the next reaction may be more severe. Unfortunately it is not uncommon for the patients to be receiving several medications, making the offending agent hard to identify. If a random blood test indicates mildly elevated liver enzymes, enzyme levels can be followed for a few days to distinguish the more severe form of hepatitis from mild enzyme elevations.

Other Adverse Effects Sexual dysfunction is a potential problem with a variety of antidepressant drugs but appears to be more frequent with clomipramine. Unlike many of the adverse effects, which are more likely to be reported early in treatment, this effect may be more bothersome to the patient in the second or third month of

treatment, after the depression has improved. Numerous pharmacological antidotes have been described but without controlled trials.

Tricyclic drugs can cause allergic rashes. They are sometimes associated with photosensitivity reactions. Various blood dyscrasias also have been reported, but fortunately, these are very rare.

Overdose Because the risk of overdose is increased in depressed patients, the target population for antidepressants use, the lethality of antidepressant drugs in overdose is of great concern. It is suggested that a tricyclic overdose of 10 times the daily dose can be fatal. Death most commonly occurs as a result of cardiac toxicity. However, seizures and central nervous system depression can occur. In 1996 amitriptyline was the second leading cause of death by overdose in the United States (after acetaminophen). The total number of fatalities for amitriptyline was comparable to those for all other tricyclic and tetracyclic drugs combined; yet, the other tricyclic and tetracyclic compounds are also dangerous in overdose. Desipramine has the highest fatality rate (deaths per ingestions). Amoxapine has been reported to produce high rates of seizure in overdose. Because the newer selective serotonergic antidepressants are generally safe in overdose, subtle differences in lethality between the tricyclic and heterocyclic compounds have become relatively unimportant.

Teratogenicity A definitive link between the tricyclic and tetracyclic compounds and teratogenic effects has not been established, although isolated reports of morphogenesis have been reported. Neonatal drug withdrawal can occur. This syndrome includes tachypnea, cyanosis, irritability, and poor sucking reflex. If possible, tricyclic and tetracyclic medications should be discontinued 1 week prior to delivery. The tricyclics are excreted in breast milk at concentrations similar to those in plasma. The actual quantity delivered, however, is small (e.g., if the drug concentration is 300 ng/mL and the amount of milk ingested is 120 mL, the drug dose is only 36 µg, or less than 0.1 mg). These low amounts result in undetectable drug levels in the infant. Because the risk of relapse is a serious concern in patients with recurrent depression and these risks may be increased in some patients during pregnancy or the postpartum period, the risks and benefits of continuing or withdrawing treatment need to be discussed with the patient and weighed carefully.

DRUG INTERACTIONS

Pharmacodynamic Interactions There are two principle types of drug interactions—pharmacodynamic and pharmacokinetic. Pharmacodynamic interactions are those in which the actions of two drugs interact, usually in a deleterious manner. Because tricyclic drugs have acute effects on amine uptake, they are potentially dangerous when given with the MAOIs. The most dangerous sequence is to give a large dose of a tricyclic drug to a patient already on an MAOI. This can result in a sudden increase in catecholamine concentration and a potentially fatal hypertensive reaction. If used cautiously, these two compounds can be used together to treat patients with refractory depression. Treatment is begun with lower doses and the two compounds are started together, or the tricyclic is administered first. Once begun, coadministration may actually reduce the risk of tyramine reactions; however, because this effect is variable, the usual MAOI diet is maintained.

Other pharmacodynamic interactions can occur. By blocking the transporters, tricyclic drugs block the uptake and thus interfere with the action of quanethidine. Quinidine poses two problems. First, the tricyclics have quinidine-like effects, so their effects on cardiac conduction are potentially additive with those of quinidine. In addition, quinidine is a potent enzyme inhibitor that can raise tricyclic drug levels, further adding to the problem.

Pharmacokinetic Interactions Most of the recent emphasis on drug interactions has focused on pharmacokinetic interactions, especially enzyme inhibition. A number of drugs can block the metabolic pathways of tricyclic drugs, resulting in higher and potentially toxic levels. Desipramine has been of particular interest because its metabolism is fairly simple, via the CYP 2D6 isoenzyme (Fig. 31.30-2). Because there are no major alternative pathways, inhibition of CYP 2D6 can result in high desipramine plasma concentrations. A number of drugs inhibit CYP 2D6. Quinidine, mentioned above, is a potent CYP 2D6 inhibitor. Drugs of special concern in psychiatry are fluoxetine and paroxetine (Paxil). At usual doses (e.g., 20 mg a day) fluoxetine, on average, raises desipramine levels three- to fourfold in extensive metabolizers. In slow metabolizers, enzyme inhibitors have less effect because the patient is already deficient in this enzyme. Some individuals on desipramine may experience a greater effect, but they are likely to be rapid metabolizers who would have low levels on a usual dose. Paroxetine would be expected to have effects similar to those of fluoxetine. Sertraline (Zoloft) has less effect on CYP 2D6. At 50 mg a day, sertraline, on average, increases desipramine levels about 30 to 40 percent. Higher doses evoke proportionally greater inhibition, but it is still substantially less than the 300 to 400 percent increase seen with fluoxetine or paroxetine. Venlafaxine, nefazodone (Serzone), mirtazapine (Remeron), and citalopram (Celexa), appear to have minimal effects on CYP 2D6. Nortriptyline metabolism would also be expected to be blocked by CYP 2D6 inhibitors, but the magnitude of this interaction has not been well studied.

The other group of drugs commonly used in psychiatry that interact with tricyclic drugs are the antipsychotic drugs. Chlorpromazine and perphenazine, at antipsychotic doses, inhibit CYP 2D6. The magnitude of the effect appears to be somewhat less than that with the SSRIs (e.g., perphenazine on average doubles desipramine levels), but this effect varies with dosage and the neuroleptic drug used.

Because tertiary tricyclic drugs are metabolized by several pathways (CYP 1A2, 3A4, and 2C19), an inhibitor of one pathway would be expected to have less effect on these compounds. Drug interactions with the tertiary amines do occur but appear to be less robust and are not as well described as those for desipramine.

The other type of pharmacokinetic drug interaction is enzyme induction. Unlike enzyme inhibition, which occurs quickly, enzyme induction involves synthesis of new enzyme. As a result, the full effect of an enzyme inducer may take 2 to 3 weeks to develop and similarly, if the inducer is discontinued, takes 2 to 3 weeks to dissipate. Barbiturates and carbamazepine (Tegretol) are the two potent inducers most commonly encountered. Although CYP 2D6 is thought to be noninducible, phenobarbital reduces the availability of desipramine by about 40 percent. Apparently, other enzymes such as CYP 3A4 are induced, which speed up the metabolism of the tricyclic drugs. Attaining an effective blood concentration of a tricyclic drug in the presence of barbiturates or carbamazepine can be difficult. Phenytoin (Dilantin) is also an enzyme inducer, but its effects on the tricyclic drugs appear to be less dramatic. Nicotine induces the CYP 1A2 pathway and may affect tertiary tricyclic drugs; secondary tricyclic drugs such as desipramine appear to be less affected by nicotine.

Alcohol has a complicated interaction. Acute ingestion of alcohol can reduce first-pass metabolism resulting in higher tricyclic drug concentrations. Because of the association of alcohol use and tricyclic overdose, this may be an important factor resulting in higher tricyclic levels following overdose. Alternatively, chronic use of alcohol induces hepatic isoenzymes and may lower tricyclic drug levels.

LABORATORY INTERFERENCES

The tricyclic compounds are present at low concentrations (nanograms per milliliter) and are not likely or known to interfere with other laboratory assays. It is possible that they may interfere with the determination of neuroleptic blood concentrations because of their structural similarity and the low concentrations of some neuroleptic drugs.

Two types of assays are performed for the tricyclic and tetracyclic antidepressants. Following overdose, an immunoassay is commonly performed to determine whether a tricyclic is present and estimate the concentration. This assay is sensitive, simple to perform, and rapid. However, the immune assays are not specific and can cross-react with metabolites and other drugs; thus they are not precise quantitative measures. A quantitative measure is needed for therapeutic drug monitoring, and a slower turnaround time for the laboratory is usually acceptable. A high-performance liquid chromatography (HPLC) assay is sufficiently precise for this purpose and is usually employed. In a competent laboratory the coefficient of variation is usually less than 10 percent. This assay is relatively specific; but other drugs can interfere. Because the HPLC technique has many modifications (the extraction method, the column used), and because these modifications determine which drugs will interfere, the interfering drugs vary by site. A clinician who frequently obtains tricyclic plasma concentrations is best advised to use one laboratory and find out from that laboratory what agents interfere with their assay.

DOSAGE AND ADMINISTRATION

At one time, amitriptyline and imipramine were the two most commonly prescribed antidepressants, but because of their anticholinergic and antihistaminic adverse effects, they are no longer the tricyclics of choice. Nortriptyline and desipramine are now preferred because of better tolerability. Nortriptyline has the least effect on orthostatic hypotension and the well-established therapeutic window for nortriptyline can be viewed as an advantage because blood concentration monitoring can be used to ensure a therapeutic level. Desipramine is the least anticholinergic and can also be monitored to achieve adequate concentrations. In theory, desipramine should be slightly safer in a patient at risk for cardiac conduction problems, because the hydroxymetabolite concentrations are lower than those for nortriptyline; however, this theoretical advantage has not been empirically demonstrated and in overdose, desipramine appears to be the most lethal tricyclic drug.

Most studies of nortriptyline, find that an average dose needed to reach a blood concentration of 100 ng/mL is about 75 mg a day; however, as indicated, there is considerable variability. For desipramine, the average dose required to reach a target level of 160 ng/mL is 3.0 mg/kg, or 180 mg a day for a 60-kg patient. Both

nortriptyline and desipramine can be adjusted to full dosage quickly, but the clinician needs to assess such factors as medical health, age, concurrent medications, and the severity of the depression before deciding how quickly to adjust dosage. In older patients, medically ill patients, or patients with less-severe depression, treatment can be started by giving a low dose once a day at bedtime. If tolerated well, the dosage can be increased every 3 days. Once the patient is receiving a lowmoderate dose (e.g., 50 mg of nortriptyline) a blood sample can be drawn after 5 to 7 days to determine the plasma concentration. Because the kinetics of nortriptyline are linear, a proportional adjustment in dosage can be made to reach a level of 100 ng/mL. With desipramine, dosage can also be adjusted relatively proportionately, but patients with very low initial plasma levels (very rapid metabolizers) are likely to have nonlinear changes, thus the dosage increase is reduced. Gradual dosage increases are safer but can take weeks. The clinician needs to weigh the need for safety against the need for rapid treatment. This need is usually obvious in severe depression, but rapid treatment can also help reduce the likelihood that a patient who is already discouraged will drop out of treatment. Once the patient is at an adequate dosage, treatment should be continued for 4 to 6 weeks. If there is no change after 3 to 4 weeks, other strategies might be considered. If there is partial response after 3 to 4 weeks, the drug should be given more time. There is some controversy about the value of increasing the dosage if the patient fails this trial. If the plasma concentration is just within the effective range (e.g., 55 ng/mL for nortriptyline or 125 ng/mL for desipramine), then increasing the dosage may be helpful. However, if the drug plasma concentration is already well within the therapeutic range (e.g., 100 ng/mL for nortriptyline or 160 ng/mL for desipramine), the likelihood of response with further dosage increase is minimal, and substantially below what would be achieved with augmentation strategies or switching to a new compound. Further, for nortriptyline, if the plasma level is near the upper limit (e.g., 140 ng/mL) a dosage reduction could be considered. One of the values of a tricyclic trial using drug concentration monitoring is that the efficacy of the drug can be determined after a single trial at an adequate concentration.

If patients experience adverse effects this approach may be altered. Patients on desipramine who report insomnia can be dosed early in the day. For both nortriptyline and desipramine, sedation and anticholinergic effects may diminish with time, and gradual dosage adjustment may help to manage these effects. Blood pressure and pulse changes do not usually accommodate during the first 4 weeks, and gradual dosing does not help to avoid these effects. In patients at high risk for adverse effects, the dosage can be increased in gradual steps every 2 to 3 days to assess tolerance. If anticholinergic adverse effects occur, allowing more time between dose increases will allow the patient to accommodate to these side effects.

Prospective Dosing Techniques Conventional dosing techniques involve administration of a given dose for a long enough time (usually 4 to 6 weeks) to determine whether that dose is effective. Sometimes two or even three drug trials are needed before the best or necessary dosage is determined. Once therapeutic blood concentrations were established, it was tempting to think that dosage could be rapidly adjusted to achieve an effective drug concentration during the first drug trial. Various methods were devised for rapidly adjusting dosage. In one method, a single test dose was administered, two or more samples were drawn to determine clearance of the drug, and the appropriate dosage was calculated. A simpler method used a similar test dose but only one sample was drawn, usually 24 hours later; then dosage was adjusted on the basis of previously established data or a nomogram. This method appeared to be most applicable for nortriptyline, which has linear kinetics, and was also effective for desipramine, because while some patients on desipramine had nonlinear changes, the targeted level was within a broad range. Prospective dosing methods were also reported for amitriptyline and imipramine; however, because of sedation and anticholinergic adverse effects, rapid dosing of these drugs was not feasible.

Several factors have limited the popularity of prospective dosing methods. First, the drug concentration after a single dose is very low, often between 10 and 20 ng/mL. The laboratory performing the assay must be prepared to determine drug concentrations accurately in this range. However, most laboratories do not use low internal standards that permit precise determination of low values and the error is magnified during dosage adjustment. Second, the utility of a blood concentration value for rapid dosage adjustment requires rapid turnaround time from the laboratory. Tricyclic concentration determinations are complicated and tedious and most laboratories are not prepared to provide these values quickly. Finally, even if a precise initial blood concentration value were available quickly, both the clinician and patient may be reluctant to increase the dose quickly to its full level, particularly in an outpatient setting. A more practical and clinically feasible method is to start treatment with a low-moderate fixed dosage, obtain a blood sample after 5 to 7 days on that dosage, and make further adjustments on the basis of that result.

Exceptions Elderly depressed patients may require more gradual dosing to assess tolerance, but most studies of desipramine and nortriptyline indicate that the final dosages and blood concentrations required for response will be similar to those needed in younger patients.

Lower starting dosages are used in panic patients, and dosage is increased slowly to avoid exacerbating panic attacks. In obsessive-compulsive disorder, higher doses of clomipramine are used than are used in depression. In part, this is because obsessive-compulsive disorder responds more slowly and less completely than depression; thus, dosage is raised to ensure the most effective treatment.

If amitriptyline is used for pain, dosages up to 75 mg a day are used. When effective, the action of the drug is observed within the first week.

At this time, it is not clear when the tricyclic antidepressants would be used in children. It is recommended that desipramine not be used in children under 12 because of possible adverse cardiac effects, but the same logic might apply to other tricyclic drugs. The tricyclic drugs have not been shown to be more effective than placebo in adolescents with depression, although this probably relates in part to diagnostic problems. Conceivably, a tricyclic drug might be given to a depressed adolescent whose parent has had a good response to a tricyclic drug. The lethality of tricyclic drugs in overdose should be kept in mind. Younger patients are likely to require higher doses than adults (on a milligram per kilogram basis) to reach the same plasma concentration, but effective plasma ranges have not been established for children.

P>Tricyclic and heterocyclic preparations are shown in Table 31.30-3.

Drug	Tablets	Capsules	Parenteral	Solution
Imipramine	10, 25, 50 mg	75, 100, 125, 150 mg	12.5 mg/mL	—
Desipramine	10, 25, 50, 75, 100, 150 mg	—	—	—
Trimipramine	—	25, 50, 100 mg	—	—
Amitriptyline	10, 25, 50, 75, 100, 150 mg	—	10 mg/mL	—

31.31 ELECTROCONVULSIVE THERAPY

KEITH E. ISENBERG, M.D. AND CHARLES F. ZORUMSKI, M.D.

Electroconvulsive therapy (ECT) is an important nonpharmacological intervention that is effective treatment for patients suffering from certain severe neuropsychiatric disorders. Psychotropic medications produce significant improvement in most patients with major affective disorders and schizophrenia. However, a substantial minority of patients either do not respond to pharmacological treatment, suffer severe adverse effects that make medications intolerable, or have severe symptoms that benefit from urgent intervention and rapid response. For such patients, ECT offers a useful, safe, and, in some cases, lifesaving intervention. ECT involves the passage of a brief electrical current through the brain to induce a generalized central nervous system (CNS) seizure under general anesthesia and muscle relaxation. Although favorable response to ECT can occur quickly, the clinical benefits typically require multiple treatments administered over a period of several weeks. The procedure is generally well tolerated by patients and can be used prophylactically to sustain a partial or complete remission of symptoms. Adverse effects such as memory impairment are minimized by recent advances in the administration of ECT. Presently, ECT is the most effective treatment available for hospitalized patients with major depression, and it is useful in the management of patients with mania, catatonia, schizophrenia, and certain neurological disorders.

HISTORICAL OVERVIEW

The first use of convulsive therapy for the treatment of a psychiatric disorder in modern times dates to Ladislaus von Meduna in 1934. The decision to use this form of treatment was based on the belief that patients with psychosis and epilepsy exhibited improvement in psychotic symptoms following spontaneous seizures. Hypothesizing a biological antagonism between seizures and psychosis, von Meduna used camphor injections to induce seizures in psychotic patients. Of the first 26 patients treated by von Meduna, 13 exhibited partial or complete remission of symptoms. The long action of the camphor injections was associated with numerous clinical problems, which prompted a search for a less traumatic way to induce seizures. von Meduna found that pentylenetetrazol, an agent now known to inhibit g-aminobutyric acid (GABA) type A ($GABA_A$) receptors, was an improvement over camphor injections but was still associated with a number of problems.

In 1938, Luigi Bini and Ugo Cerletti documented the first therapeutic use of electrically induced seizures in humans. Bini and Cerletti were intrigued by the idea of using controlled doses of electrical current for therapeutic purposes but had initially found the treatment dangerous in animals. Although a number of animals stimulated electrically died, Bini and Cerletti observed that the deaths resulted from direct current flow through the heart and that current applied across the head did not carry severe cardiac risks. Following a series of successful experiments in animals, these investigators administered the first ECT to a 39-year-old man who suffered from an acute psychosis. The patient was treated with a series of 11 electrically induced seizures and experienced a dramatic improvement in his psychotic disorder. Electrical induction of seizures was more reliable than the pharmacological approaches used by von Meduna. Following the success of Cerletti and Bini, Lothar Kalinowsky introduced ECT to the United States in 1939.

These initial efforts opened the door to more general use of ECT in an era when most of the currently available psychotropic agents were unknown. Early treatments were fraught with numerous difficulties, including a high incidence of fractured and dislocated long bones as well as compression fractures of the spine. The fractures resulted from severe muscle contractions produced by the direct electrical current flow through the body and the tonic phase of the generalized seizures. In 1940 A. E. Bennett introduced the use of curare as a muscle relaxant to avoid these muscle contractions and minimize the risk of fractures. Equally notable improvements in ECT anesthetic technique included routine use of general anesthesia and vigorous oxygenation throughout the procedure coupled with cardiac and oxygen saturation monitoring to prevent cardiopulmonary complications and minimize hypoxia.

Other innovations in ECT technique (Table 31.31-1) have been developed in an effort to maintain the therapeutic efficacy of the treatment, prevent major adverse effects, and improve the acceptance of the procedure. The therapeutic benefits of chemically induced seizures and the failure of subconvulsive electrical impulses to induce an effective clinical response suggested the necessity of a seizure for ECT to be efficacious. Brief-pulse electrical stimulators and nondominant hemisphere electrode placements diminish the cognitive adverse effects of the treatment. As currently practiced, ECT is a relatively safe and effective means of treating patients with major psychiatric disorders.

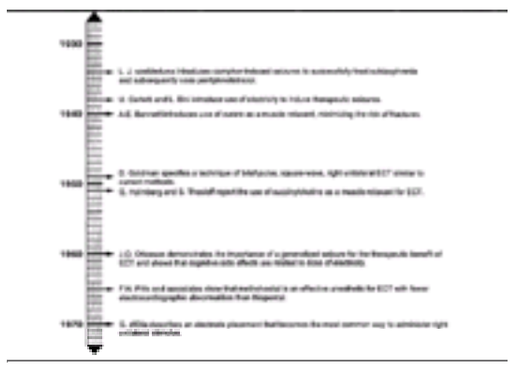

Table 31.31-1 Historical Developments in the Administration of Electroconvulsive Therapy

The use of ECT in psychiatry has waxed and waned over the years. Initial enthusiasm for ECT in the treatment of schizophrenia was gradually replaced by awareness that the procedure was particularly helpful for depression. Innovations described above may result in greater acceptance but usually add to the expense of the procedure as well as enhancing the benefits of ECT. The treatments, largely given at public institutions in the years after inception, are currently more frequently administered at private institutions. It is presently estimated that as many as 100,000 patients per year are treated with ECT.

ELECTRICAL FACTORS IN ECT

ECT Stimulators Considerable evidence indicates that the repeated production of generalized CNS seizures is required to produce the clinical benefits of ECT. Thus, the goal of an ECT treatment session is to induce a generalized seizure of “adequate” duration in the CNS. Subconvulsive electrical stimuli or those inducing only partial (focal) seizures have no therapeutic benefit. Similarly, treatments in which seizures are terminated immediately following stimulation are ineffective. Understanding how seizures are produced by electrical stimulation and how the electrical stimuli used for ECT are quantified requires knowing several basic electrical principles.

Excitable tissues are stimulated by the flow of current (or more properly by the movement of ions across the cell membrane). Current (I) is measured in units of amperes and is defined as the amount of charge (Q) measured in coulombs flowing per unit time (t). Thus, $I = Q/t$. The force that drives current flow is the applied

electrical field (measured in volts [V]). The relationship between current and voltage is given by Ohm's law: $V = IR$, where R is the resistance to current flow measured in ohms. Ohm's law holds for direct current (DC) circuits. An ECT treatment involves the application of electricity as an alternating current (AC); the resistance term of the circuit is more properly described as impedance (Z). *Impedance* includes the DC resistance as well as terms for *capacitance* (the ability to store charge on conductors that are separated by an insulator) and *inductance* (the ability to induce a voltage across the tissue). Since the brain usually contains no metal, the inductance term is not relevant. However, the ability to store charge on either side of the lipid bilayer is a fundamental biophysical property of cell membranes; thus capacitance is important to the ECT circuit. Furthermore, impedance has both static and dynamic components; unfortunately, little is presently known about the dynamic impedance changes associated with ECT. In the ECT circuit, most of the static impedance to current flow is across the skull (approximately 18,000 ohms/cm), while the impedance to current flow across the skin and through brain tissue is only about 200 ohms/cm. When an electrical stimulus is applied via electrodes placed on the patient's head, the low-impedance pathway is along the skin between the electrodes. Thus, most of the stimulus is shunted between the stimulating electrodes and little (<20 percent) enters the cranial cavity to stimulate the nervous system.

Based on these electrical principles, it is possible to understand how ECT stimulators work. These devices typically have only one of two outputs: they are either current generators or voltage generators. In a constant-current stimulator, the applied current is independent of the impedance between the electrodes. According to Ohm's law, the applied voltage varies directly with the impedance. Thus when the impedance between the electrodes is high, the applied voltage from a constant-current stimulator can become very high (sometimes exceeding 500 V, depending on the maximal output of the stimulator). Because the power (measured in watts) dissipated between the electrodes is a product of current and voltage ($P = IV$, or $P = I2R$), significant risk of local tissue damage exists if the impedance between the electrodes is too great. With most constant-current stimulators, the operator is required to perform a self-test prior to stimulating the patient. This test administers a low-amplitude current to test the interelectrode impedance. If the impedance exceeds a limit deemed safe by the manufacturer, the test fails. In the case of a failed self-test, improved contact between the electrodes and the skin usually lowers impedance. Somewhat counterintuitively, when impedance between the ECT electrodes is too low, induction of convulsions with a constant-current stimulator can be more difficult. The difficulty with low-impedance seizure induction develops because the applied voltage becomes too low to drive significant current flow through the high resistance of the skull.

Most ECT devices presently used in the United States are constant-current stimulators. A second type of ECT stimulator uses a constant voltage source. In these devices, the current varies with the resistance between the electrodes; high impedance can cause difficulty inducing seizures because the current flow is too low. Constant-current stimulators offer the advantage of easier quantification of the electrical stimulus. Because current is fixed, the amount of charge (coulombs) administered is simply a product of the current and the time during which current flows (Charge [Q] = It). With a constant-voltage stimulator, calculations of administered charge require information about impedance.

The waveform of the output is another important characteristic of ECT stimulators. Older ECT devices were sine-wave generators. At a frequency of 60 cycles per second (60 Hz), each half sine wave lasts 8.3 ms with a significant stimulus flowing about 75 percent of this time. A basic property of neuronal action potentials, the cellular activity driving generalized seizures, is a duration of a few milliseconds. Furthermore, following an action potential there is a period of several milliseconds during which it is either impossible or relatively difficult to fire a second action potential (termed the *absolute and relative refractory periods*). During a sine-wave stimulus, much of the current flow occurs during inexcitable periods. Thus, sine waves tend to drive neuronal firing rather inefficiently. A constant-step stimulus applied for a long period of time is even more inefficient. A device that administers repeated brief pulses (0.5 to 2.0 milliseconds) of current to trigger action potential firing at rates similar to the intrinsic firing patterns of neurons in critical regions of the CNS is preferred. The benefits of brief-pulse stimuli compared with step pulses or sine waves have been documented in experimental preparations. Evidence suggests that pulses less than 0.5 millisecond in duration (referred to as “ultrabrief” pulses) are likely to be ineffective ECT stimuli. However, this issue may need reexamination in light of recent studies demonstrating the importance of seizure threshold in determining clinical outcome from ECT.

Most ECT stimulators use brief-pulse outputs, typically at frequencies of 30 to 100 Hz. When brief-pulse outputs are given with a constant-current generator, it is relatively easy to quantify the electrical stimulus. The administered charge is calculated by adding the total time that brief pulses are applied and multiplying this duration by the pulse amplitude. In most constant-current stimulators each cycle consists of one positive and one negative pulse. Thus, the calculation of stimulus duration (D) is given by: D = pulse width × pulse frequency × 2 × train duration. Most constant-current stimulators used in the United States have maximal charge outputs of 500 to 600 mC. Assuming an interelectrode impedance of 200 ohms, this output translates into a stimulus energy of less than 100 joules (watt-seconds). Because stimulus energy requires information about the interelectrode impedance and impedance measures must take into account both static and dynamic factors, it has been preferable to quantitate ECT stimuli in units of charge rather than units of energy.

Seizure Threshold The work of Harold Sackeim and colleagues demonstrated that features of the electrical stimulus interact with the mode of stimulus to play a role in the therapeutic benefits of ECT. When treatments are administered with electrodes placed bitemporally (Fig. 31.31-1), minimally suprathreshold electrical doses produce significant clinical benefits. However, treatment with nondominant hemisphere unilateral electrode placement at stimuli minimally above the seizure threshold produces only marginal clinical improvement, despite inducing what appear to be generalized seizures of adequate duration. Sackeim and colleagues extended this work to demonstrate that benefits of unilateral ECT increase significantly when electrical doses at least 2.5 times the seizure threshold are used. These studies suggest that the degree to which the electrical stimulus exceeds the seizure threshold is critical in determining therapeutic effects of unilateral treatments. Sackeim and colleagues confirmed earlier work suggesting that electrical dose plays a role in the cognitive adverse effects of ECT. Higher stimulus intensities are associated with greater memory impairment. Thus, attention to seizure threshold is becoming a major concern in centers that use ECT.

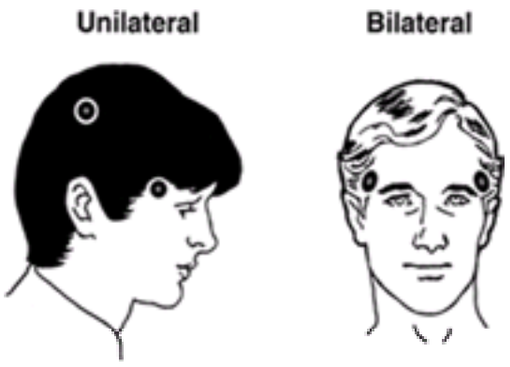

FIGURE 31.31-1. Types of electrode placement used with ECT—bilateral (right) and right unilateral nondominant (left). In the latter case, a wide centroparietal-frontotemporal derivation (d'Elia placement) is depicted.

Seizure threshold is defined empirically as the minimum amount of electrical charge that induces a generalized CNS seizure. There is some debate concerning the proper length of a threshold seizure and whether duration should be measured by electroencephalogram (EEG) or by motor seizure in an isolated limb. Some centers use a cutoff of 25 seconds, but this limit is arbitrary. Sackeim and colleagues found a great deal of patient-to-patient variability in seizure threshold, with estimated values exhibiting about a 40-fold difference. A number of factors appear to influence seizure threshold, including age, sex, and electrode placement. Seizure thresholds tend to be higher in men than in women and higher in older patients than in younger patients. Age-related differences may reflect differences in skull density as well as plasticity of an aging nervous system. Electrode placement also plays a major role, with bilateral (bitemporal) placements having a higher threshold than non–dominant hemisphere placements. Other variables include the patient's electrolyte and hydration status (e.g., hyponatremia and hypocalcemia are associated with lower seizure thresholds) as well as concomitant use of CNS-active medications. Anticonvulsants, benzodiazepines, barbiturates, sedative-hypnotics, and certain antiarrhythmic drugs are associated with higher seizure thresholds, whereas theophylline derivatives, lithium, and sedative-hypnotic and alcohol withdrawal are associated with lower thresholds. ECT has anticonvulsant effects, so recent treatment with ECT can influence threshold measurements. Recent work suggests that perhaps the most important determinant of seizure threshold with current stimulators is pulse duration and frequency.

The nature of the electrical stimulus and the anesthetic drugs used for the ECT procedure may also influence seizure threshold. For example, sine wave stimuli are inefficient and tend to yield higher thresholds. With brief-pulse treatments, pulses of shorter duration (0.5 ms) and lower frequency (30 to 40 Hz) produce lower thresholds than longer-duration pulses (2.0 ms) administered at high frequencies (70 to 100 Hz) for a given amplitude of current pulses. Among anesthetic agents, barbiturates and propofol (Diprivan) clearly raise seizure threshold. Anesthetics that may have less effect on seizure threshold include etomidate (Amidate), ketamine (Ketolar), and alfentanil (Alfenta), but this issue has not received adequate systematic study. Prior to delivering the electrical stimulus, vigorous hyperventilation and

decreased carbon dioxide concentration may also help to lower threshold.

Several electrical dosing schedules have been described for estimating seizure threshold. Typically these dosing regimens begin with a low electrical charge (e.g., 25 mC); increases in the charge are delivered according to a predetermined plan until a generalized seizure is induced. In clinical settings, threshold titrations involving a minimal number of stimulations (four or five) are preferred to diminish the risks associated with titration. The last stimulation in the titration series is given at maximal charge. About 30 seconds are allowed between stimulations to ensure that the prior stimulus has not produced a seizure. When the stimulus is near threshold, onset of a generalized seizure may be delayed for several seconds.

ECT MECHANISMS

Possibly no treatment in psychiatry is more misunderstood or more maligned than ECT. In part, this stems from the fact that ECT is one of the most invasive procedures used by psychiatrists. Furthermore, critics of ECT are often bothered because the mechanisms responsible for the therapeutic and adverse effects are not well understood. The lack of mechanistic understanding should come as no surprise, since unequivocal information about the pathophysiology of most major psychiatric disorders is lacking. The lack of understanding of ECT mechanisms does not result from a lack of hypotheses. Systematic reviews reveal more than a hundred theories in the literature dealing with this topic, ranging from psychological and psychodynamic explanations to molecular, biochemical, neuroendocrine, and structural theories. Various theories are not mutually exclusive but rather indicate the complexity of the CNS and the multitude of academic disciplines interested in providing mechanistic explanations.

Certain hypotheses can be dismissed fairly easily. For example, there is no evidence that fear, psychological regression, increased medical attention, anesthetic medications, or brain hypoxia result in therapeutic effects. Similarly, memory loss does not contribute to the benefits of ECT. Most of the major innovations in ECT technique, including the use of brief-pulse generators, titrated electrical doses, and nondominant hemisphere stimulation, have been directed toward minimizing this adverse effect while maintaining treatment efficacy. The latter point is particularly important since memory loss is a popular lay theory about ECT. Opponents of ECT have argued that the treatment works by damaging the CNS. This topic has been dealt with in detail in two excellent reviews by Richard Weiner and D. P. Devanand and colleagues. Based on careful and thorough reviews of the literature, including both human and animal studies, these authors conclude strongly that there is no evidence that ECT produces structural damage to the brain.

Currently, it is believed that the therapeutic and adverse effects of ECT result from changes in CNS biochemistry and physiology. Furthermore, the beneficial effects of ECT require several treatments over a period of several days, which has spurred considerable interest in understanding the effects of repeated brief seizures on CNS function. One major difficulty in understanding critical effects of ECT is that the treatment is administered to human beings with severe psychiatric disorders, while most detailed biochemical studies are conducted in presumably normal animals, particularly rodents. While studies in animals must be viewed with some skepticism, insights generated in animal studies have often been useful in understanding human pathophysiology. Improvements in CNS functional imaging methods lend hope that sophisticated biochemical studies in humans will be possible in the future. An additional problem with understanding the effects of ECT is that the treatment affects multiple CNS systems. Studies of the effects of repeated seizures are unlikely to produce insights into disease mechanisms because it will be difficult to determine causal relations.

The best hope for understanding ECT mechanisms may exist when considering disorders whose underlying biology is better understood; Parkinson's disease is one such example. In this disorder there are clear disruptions of dopaminergic transmission in the striatonigral pathway. Drugs that increase dopamine function or diminish muscarinic cholinergic function are useful in treating motor symptoms of the disorder. Thus, it might be expected that ECT would alter dopamine or muscarinic cholinergic responses in the CNS. Indeed, electroshock (ECS) in animals rapidly increases dopamine concentrations in the frontal cortex and striatum while having variable effects on resting dopamine concentrations. Dopamine autoreceptor sensitivity is diminished following ECS and D_1 dopamine receptor agonists enhance stimulation of adenylate cyclase. These effects suggest enhanced dopamine transmission following ECS. Effects on D_1 receptor binding have been variable, with no change in the striatum and increases in the substantia nigra. Although less consistently found, evidence suggests that ECS diminishes muscarinic function in some CNS regions. Together, these effects of ECS suggest plausible mechanisms for the antiparkisonian effects of ECT in humans.

P>Over a course of treatment, ECT has anticonvulsant effects that raise seizure threshold and decrease seizure duration. There has been considerable work on the cellular correlates of seizure generation in the CNS; this is also an area in which the effects of ECT can be potentially understood. At a fundamental level, anticonvulsant drugs do one of two things: enhance inhibition or diminish excitation. Since GABA is the principal fast inhibitory transmitter in the mammalian CNS and drugs that enhance GABAergic transmission via GABA, receptors (e.g., barbiturates, benzodiazepines, loreclezole) have anticonvulsant effects, it might be expected that ECS would alter this system. Some evidence suggests that GABA levels increase in certain CNS regions following ECS, suggesting a possible increase in tonic inhibition. There is also evidence that ECS causes increases in $GABA_B$ (baclofen [Lioresal]-sensitive) receptors. These sites mediate both presynaptic and postsynaptic inhibition at certain synapses. It is less clear whether ECS produces consistent changes in $GABA_A$ receptors. Interestingly, ECS produces changes in endogenous opiate systems that could have anticonvulsant effects, and some evidence suggests that the anticonvulsant effects of ECS in animals are blocked by naloxone (Narcan), a broad-spectrum opiate receptor antagonist. ECS also upregulates certain opiate receptors (e.g., those for D-alanine-D-leucine-enkephalin [DADLE]. A third potential anticonvulsant mechanism is via release of endogenous adenosine. Periods of increased electrical activity in the CNS, including seizures, promote extracellular release of adenosine, which in turn acts on several receptor types to produce inhibition. Adenosine A_1 receptors are upregulated in neocortex but not hippocampus or striatum following ECS, suggesting regional increases in inhibition. Caffeine, a drug used to increase ECT seizure durations clinically, antagonizes adenosine A_1 receptors, suggesting a possible link to seizure termination mechanisms. However, caffeine has other effects (e.g., phosphodiesterase inhibition and release of calcium from intracellular stores) that could also contribute to increased duration of seizure. Effects of ECS on the glutamate system that is the prime mediator of fast excitatory synaptic transmission could also be important but have received less systematic attention.

Understanding how ECT produces memory impairment would be helpful, since it could potentially lead to strategies to diminish this adverse effect. Although cellular mechanisms involved in memory are not well understood, changes in several transmitter systems could contribute. For example, the antimuscarinic effects of ECS could be involved, because drugs that disrupt this system produce cognitive impairment and delirium in humans. Similarly, the increased inhibition that possibly contributes to the anticonvulsant effects of ECS could be involved, and drugs that alter inhibitory systems (e.g., barbiturates, benzodiazepines, alcohol) are associated with amnesia (blackouts). Some evidence suggests that the phenomenon of long-term potentiation (LTP) could be a cellular correlate of memory formation in the CNS. This process occurs when glutamatergic synapses are used repeatedly under conditions in which receptors of the *N*-methyl-d-aspartate (NMDA) class are activated. Although the mechanisms are not well understood, it appears that ECS and generalized seizures disrupt LTP generation in animals. An interesting possibility is that ECT-induced seizures produce a form of NMDA receptor–mediated LTP inhibition that has been described in rodent hippocampal slices. Since there is presently intense interest in mechanisms involved in LTP, these insights may shed some light on ECT-induced cognitive impairment, particularly anterograde amnesia.

Because the mechanisms involved in psychiatric disorders are so poorly understood, several indirect strategies have been used to assess ECT mechanisms. One of the favored strategies has been to compare the effects of ECS in animals with the effects of psychotropic medications. This approach assumes that ECT and psychoactive drugs exert their effects by similar means. Certainly some of the effects described above could contribute to beneficial effects of ECT. For example, the usefulness of anticonvulsants (valproic acid [Depakene], carbamazepine [Tegretol]) in management of affective disorders makes it possible that the anticonvulsant effects of ECT contribute to therapeutic benefits. One interesting finding is that ECS and a variety of antidepressant medications produce b-adrenergic receptor subsensitivity, suggesting some commonality in mechanism. Additionally, ECS increases norepinephrine turnover and a_1-adrenergic receptor sensitivity and decreases presynaptic a_2-adrenergic receptors. ECS also appears to enhance the effects of the serotonergic system but differs from chronic antidepressant medication treatment in producing increases in serotonin (5-hydroxytryptamine [5-HT]) type 2 (5-HT_2) receptor binding in the cerebral cortex. These findings suggest that ECT may have important actions on monoaminergic transmission that contribute to therapeutic effects.

Advances in understanding receptor biology and gene function in the CNS over the past decade offer hope of eventually achieving a better understanding of the CNS effects of ECT. Beyond transmitter receptors, considerable interest now exists in defining effects of ECT on second messenger systems and gene transcription. Effects on gene transcription and protein synthesis could be particularly important, since effects of the treatment tend to develop slowly and persist for some period of time. Similar approaches in the study of CNS plasticity during chronic exposure to psychotropic medications and drugs of abuse are already paying dividends in understanding long-term changes associated with drug exposure.

INDICATIONS FOR ECT

Major Depression For patients with severe major depression, ECT is the most effective treatment available and the standard against which other treatments can be

judged. A substantial body of experimental evidence supports the use of ECT in the treatment of depression (Table 31.31-2). ECT was developed prior to general acceptance of the prospective, randomized, double-blind clinical trial as the most rigorous method of evaluating benefits of treatment, a circumstance that applies to numerous other procedures and many psychotherapies. Evaluation of the efficacy of ECT was further facilitated by development of standardized assessment instruments and acceptance of well-defined diagnostic criteria. Results of studies shown in Table 31.31-2 deserve further comment. Substantial numbers of patients participated in each trial; the number in parentheses indicates the number of individuals enrolled in a given trial, when this information is available. Five of the six studies clearly show ECT to be superior to sham procedures; benefits of ECT occur despite the weak but consistent pattern of improvement observed in the placebo-treated population, similar to that seen in other trials of antidepressant treatment. Most of the studies used sine-wave stimulators to induce a seizure. Studies reported at later dates may have benefited from flaws noted in the design and execution of the first two studies reported. In aggregate these studies demonstrate the overwhelming superiority of ECT to sham, a result that is sustained in clinical practice.

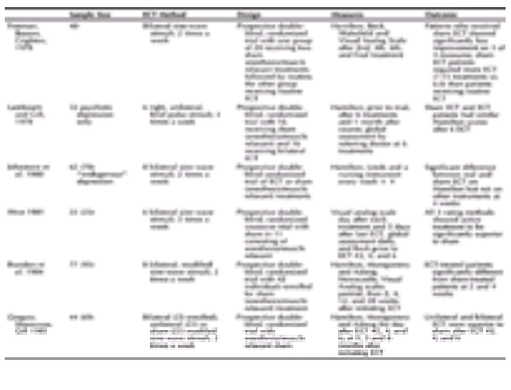

Table 31.31-2 Effectiveness of ECT in the Treatment of Depression

ECT is effective in producing significant-to-complete symptom remission in more than 70 percent of patients with previously untreated major depression. Despite this benefit, ECT rarely is the treatment of first choice for depression. In part, this stems from the usefulness of pharmacological and psychotherapeutic interventions for depression and from the significant adverse effects of ECT, particularly memory loss and confusion. Furthermore, misunderstanding and misinformation among psychiatrists and the lay populace about the role of ECT compound the problem. ECT is most often used for depressed patients who have failed to respond to one or more trials of antidepressant medications, including individuals who cannot toler ate the adverse effects of medications as well as those who do not respond to therapeutic doses of medications. Thus the effectiveness of ECT in treating patients who are known medication nonresponders is of interest, since these patients could be unresponsive to any biological treatment. Depending on how ECT response is defined, it appears that more than 50 percent and perhaps as many as 70 percent of medication nonresponders exhibit significant improvement with ECT. A major difficulty in this population is not the initial response to ECT but rather the ability to maintain remission following clinical improvement. Evidence now indicates that patients who have failed particular medications should not be treated again with those medications after they respond to ECT. Rather, other antidepressant medications, particularly those to which the patient has previously shown a good response or to which the patient has not been previously exposed, should be used for maintenance therapy. Alternatively, following a successful course of ECT, continuation or maintenance ECT can be implemented with good clinical results. The difficulty with maintenance ECT lies in the need to administer treatments on an ongoing, outpatient basis and problems with treatment adverse effects, particularly memory impairment.

ECT should be strongly considered as the initial choice for some depressed patients, including individuals with particularly severe symptoms, including psychosis, marked suicidal intent, and refusal to eat. Because response to medication is often delayed for days to weeks, ECT offers the prospect of more rapid, perhaps lifesaving response. Other patients for whom ECT is considered first-line therapy include those with a prior history of nonresponsiveness to medications who have had a prior good response to ECT. Finally, consideration should be given to patient preference; psychiatrists should always present ECT as a treatment option to patients suffering from depression, an important alternative to psychotherapy and pharmacotherapy.

No clinical symptoms of depression or demographic variables uniquely predict a favorable response to ECT; it has been used to treat depression in a variety of clinical populations, including elderly adults, medically ill patients, pregnant women, and adolescents. No evidence suggests undue risk in any of these populations or lack of ECT responsivity. When considering ECT use in these populations, the risks and benefits of treatment must be weighed carefully, particularly in patients with severe medical illnesses for whom anesthesia alone carries increased risk. In most regions, ECT use in adolescents is restricted legally but may be administered following consultation with parents or guardians and appropriate medicolegal review.

Some depressed patients may not respond to ECT. For example, some evidence suggests that depression in patients with preexisting somatization disorder may be less responsive to the treatment. Additionally, ECT appears to be relatively ineffective for some psychiatric disorders, including somatization disorder, personality disorders, obsessive-compulsive disorder, and primary anxiety disorders. In some of these patients, however, ECT can be effective in treating concomitant depressions that do not respond to antidepressant therapy.

Mania In general, acute mania responds well to treatment with mood stabilizers and antipsychotic medications, the first-line treatments for the disorder. Some patients with mania, however, either cannot tolerate medications or fail to respond to medications. Additionally, some patients with mania have severe symptoms, including exhaustion, extreme agitation, and delirium. ECT should be considered as an effective therapeutic alternative for these patients. The prospectively collected evidence that ECT is effective treatment for mania is presented in Table 31.31-3. The number in parentheses indicates the total number of patients enrolled in the larger trial; over 75 percent completed the initial phase of this trial. Although neither of the studies is as well designed as the studies considering the benefits of ECT in the treatment of depression, both used constant-current square-wave generators to induce seizure and are thus similar to current ECT practice. A number of retrospective studies further support the observation that perhaps more than 80 percent of individuals suffering from mania exhibit a partial or complete remission of symptoms. Electrode placement in treating mania is controversial, with some studies indicating a better response to bilateral treatments. As in depression, manic patients should be treated with ECT until symptomatic improvement plateaus or adverse effects preclude further treatments. When ECT is stopped, pharmacological management with medications such as mood stabilizers should be instituted. Maintenance ECT can also be an option for some patients with bipolar disorder. Because of its effectiveness against both mania and depression, ECT should be considered early in the treatment of depressed patients with bipolar disorder.

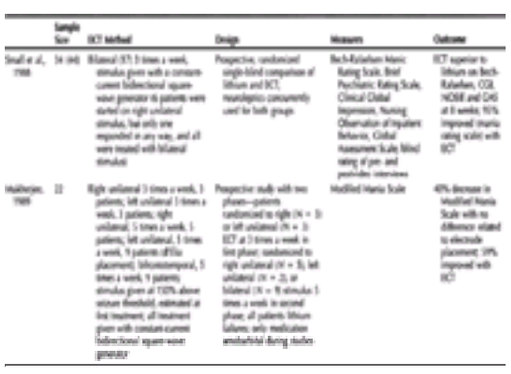

Table 31.31-3 Effectiveness of ECT in the Treatment of Mania

Schizophrenia There is little evidence that ECT alters the chronic symptoms of schizophrenia, including either chronic positive (delusions, hallucinations) or negative (flat affect, poverty of thought content) features of the disorder. Nevertheless, ECT can be effective in management of acute psychotic exacerbations, with as many as 80 percent of patients responding favorably. In schizophrenic patients with acute exacerbations, antipsychotic medications are the mainstays of treatment. ECT should be reserved for patients who either have very severe symptoms or who cannot tolerate or fail treatment with psychotropic medications. Acute psychotic symptoms typically respond to 8 to 12 treatments, although some patients may require additional treatments depending on their clinical response and, ability to

tolerate adverse effects. Treating schizophrenic patients with prolonged courses of ECT appears to produce no substantial clinical benefit and is associated with severe memory loss and confusion. Some schizophrenic patients who respond well to a short-term course of ECT may benefit from maintenance treatments, although most of these patients will also be treated with antipsychotic medications.

Catatonia Catatonia is a syndrome characterized by stupor, mutism, and motor symptoms and is associated with a variety of psychiatric, neurological, and medical disorders. Most often the syndrome is observed in patients with schizophrenia or bipolar disorder. Regardless of the underlying disorder, catatonia responds relatively well to ECT, with improvement in motor symptoms (posturing, rigidity, catalepsy) usually occurring after only a few (three to five) treatments. Some patients, however, require longer courses of treatment for full remission of symptoms. ECT can be particularly effective in patients who develop extremely severe symptoms including exhaustion (lethal catatonia) and delirium. The beneficial effect of ECT upon motor symptoms may explain its usefulness in management of patients with severe forms of neuroleptic malignant syndrome, a syndrome that shares a number of features with severe catatonia, including marked muscular rigidity and autonomic instability.

Neurological Disorders In addition to its beneficial effects in catatonia and neuroleptic malignant syndrome, ECT also improves motor symptoms of Parkinson's disease, particularly rigidity and bradykinesia, independent of effects on the depressive symptoms that often accompany this disorder. Interestingly, ECT may prolong the “on” periods in patients who experience the “on-off” phenomenon associated with antiparkinsonian drug use. In general, the beneficial effects of ECT in parkinsonism are time-limited, with relapse occurring over 4 to 6 weeks. Some evidence suggests that maintenance ECT can benefit these patients, but systematic studies examining this issue are needed.

Over a course of treatment, ECT has anticonvulsant effects, with increased seizure threshold and decreased seizure duration. In the past, this prompted the use of ECT to treat patients with intractable epilepsy. Presently, no evidence indicates that ECT is more effective for these patients than anticonvulsant medications, and the treatment is rarely, if ever, used for this purpose. The anticonvulsant effects of ECT are time limited, dissipating over several weeks. Epileptic patients referred for ECT do not appear to be at substantially increased risk for worsening of their seizures either during or following a course of ECT. Patients with epilepsy who are referred for ECT should remain on anticonvulsant medications through the course of treatment because significant risks are associated with discontinuing these medications. There is no need to increase the dosage of anticonvulsants during a course of ECT unless increases in medication are warranted on the basis of clinical history.

Since memory loss and confusion are major adverse effects of ECT, it is surprising that it has been used in the management of severe delirium. As with the catatonic syndrome, ECT improves delirium associated with a variety of psychiatric, medical, and neurological disorders. In particular, ECT appears to be effective in managing the severe agitation and exhaustion that some of these patients experience. Most of the evidence for beneficial effects of ECT in delirium is from anecdotal reports, and ECT is usually considered only in patients who have failed more conventional management.

GENERAL PATIENT MANAGEMENT

Informed Consent ECT is typically an elective medical procedure involving general anesthesia, muscle relaxation, and electrical stimulation. The procedure should be performed after obtaining in formed patient consent, documented in writing. Consent requires a thorough discussion with the patient and when possible, with the patient's family, of the details of the procedure, indications for treatment, risks from treatment, adverse effects, alternative forms of treatment, and risks of no treatment. A number of excellent pamphlets and videotapes are available to aid psychiatrists in presenting this information. While these can be very helpful, they do not replace direct dialogue between the treating physician and the patient.

Some patients with severe psychiatric disorders are unable or unwilling to give informed consent for ECT. Yet, ECT may be indicated and deemed necessary to prevent serious risks to the patient. Although restrictions on the use of ECT in such cases vary, most jurisdictions provide for use of the treatment involuntarily following proper legal review. Whenever ECT is used, but particularly when it is used without the patient's consent, one must weigh the risk-benefit ratio carefully.

Pre-ECT Evaluation All patients treated with ECT require careful psychiatric and medical histories and a thorough physical examination. The psychiatric history should include sufficient information to make a clear DSM-IV diagnosis, document prior response to pharmacological and psychotherapeutic interventions, describe any prior treatment with ECT (including response to treatment and adverse effects), and discuss the indications for ECT. The medical history and physical examination should focus on any documented medical problems. Of particular importance is any prior history of neurological, cardiorespiratory, or gastrointestinal disorders that might impinge on the patient's ability to tolerate general anesthesia or the ECT procedure. The past medical history should also include a description of prior surgeries, including any difficulties with anesthetic medications in the patient or the patient's family. A careful oral examination is also needed, since severe dental problems may necessitate adjustments in the procedure to protect the patient's teeth.

The pre-ECT laboratory evaluation need not be extensive but should follow guidelines for outpatient surgical procedures. Emphasis in the laboratory evaluation should be placed on any disorders identified in the initial history and physical examination. Minimal laboratory tests include a complete blood count, serum electrolytes, and electrocardiogram (ECG). Older patients and those with a history of cardiorespiratory disorders, should have a chest x-ray. Spinal xrays are not required for ECT but should be considered for patients with a history of significant back problems. Neuroimaging studies are not routine prior to ECT. Rather, these tests should be reserved for patients with suspicious neurological histories and physical examinations, particularly those with focal neurological findings on examination. Other laboratory studies should be based on the history and physical examination.

ECT Anesthesia. In most settings, a team of at least three individuals is involved in the administration of ECT: a psychiatrist, an anesthesiologist or nurse anesthetist, and a nursing assistant. Depending on the size of the ECT service, other personnel involved might include staff performing pre-ECT patient evaluation and staff assisting with recovery from treatment. Because ECT is administered under general anesthesia and involves a generalized seizure, patients should have nothing to eat or drink for at least 6 hours prior to the procedure. This precaution greatly reduces the risk of aspiration during treatment. Minor exceptions to this rule can be made when, for example, the benefits of administering cardiovascular medications or agents that diminish gastric acid secretion prior to treatment are greater than the extremely low risk of aspiration associated with a sip of water necessary to give medication.

Standards developed for administration of anesthesia in outpatient surgical settings are generally appropriate for ECT. These standards include regimens for pre-ECT evaluation, anesthetic care, and postoperative recovery. ECT is typically administered in either a specialized treatment area or in an operating room setting. In either case, facilities must be available to manage medical emergencies (particularly cardiac events) and allow the patient to recover from the procedure. Prior to treatment, all patients must be evaluated by the person performing anesthesia to assess independently the risks of anesthesia and potential problems in managing the patient's airway. Consultation with the anesthesia provider may also suggest ways to maximize therapeutic benefits of ECT (e.g., choice of anesthetic drug) and to diminish adverse effects of treatment (e.g., use of analgesics, antiemetics, or both).

At the time of treatment, an intravenous catheter is inserted into a peripheral vein to provide access for medications and (if required) fluids. Patients are typically connected to several monitors including an ECG, two-lead EEG, and pulse oximeter. Respiratory support during ECT is almost always provided via ventilation mask. Prior to administering the anesthetic agent, the patient's mouth is inspected to remove any foreign objects and dentures. Patients are usually preoxygenated prior to anesthetic induction using 100 percent oxygen by mask; exceptions can be made if the patient suffers intolerable anxiety from having a ventilation mask over the face. Oxygen is administered throughout the procedure until recovery of sustained respiratory effort occurs. The routine use of oxygen prevents problems with hypoxia and diminishes cognitive impairment from treatment and risk of cardiac complications.

Two or three medications are typically used for the ECT procedure (Table 31.31-4). The information provided in the table offers guidance regarding medication administration, but each ECT practice should individualize medication usage to reflect the experience of providers. Because the passage of the electrical stimulus can produce asystole lasting 6 to 12 seconds, many patients are treated with an anticholinergic drug. Atropine is a typical agent, administered at doses of 0.4 to 1.0 mg intravenously immediately before stimulation. Individuals with substantial oral secretions (e.g., tobacco smokers) can be given atropine intramuscularly 30 to 60 minutes before the procedure. Advantages of atropine include its effectiveness as an anticholinergic and low cost. Disadvantages include increased heart rate, which can compound the tachycardia that typically accompanies an ECT-induced seizure. Additionally, atropine has CNS effects and is associated with memory impairment and delirium. The latter problems can be prevented by using a peripherally acting anticholinergic agent such as glycopyrrolate (Robinul; 0.2 to 0.4 mg intravenously), although patients may not tolerate the prolonged drying effect of this agent. Because anticholinergic-induced tachycardia can increase cardiovascular risks of ECT, the decision to use these agents is best made on a case-by-case basis. In our practice, patients with resting heart rates above about 90 beats per minute are unlikely to be treated with anticholinergics unless, for example, they are also taking medications that promote bradyarrhythmias (e.g., b-adrenergic receptor antagonists, verapamil [Isoptin], digoxin [Lanoxin]).

Drug	Dose
Anticholinergics	
Atropine	0.4–1.0 mg IV or IM
Glycopyrrolate	0.2–0.4 mg IV or IM
Anesthetics	
Methohexital	0.5–1.0 mg/kg IV
Thiopental	1.5–2.5 mg/kg IV
Etomidate	0.1–0.3 mg/kg IV
Alfentanil	0.2–0.3 μg/kg IV
Ketamine	0.5–1.0 mg/kg IV
Propofol	0.75–1.5 mg/kg IV
Midazolam	0.15–0.3 mg/kg IV
Muscle Relaxants	
Depolarizing	
Succinylcholine	0.75–1.5 mg/kg IV
Nondepolarizing	
Mivacurium	0.1–0.2 mg/kg IV
Atracurium	0.3–0.4 mg/kg IV
Antihypertensives	
Esmolol	0.05–0.1 mg/kg IV
Labetalol	0.04–0.2 mg/kg IV
Nifedipine	10–30 mg PO

Table 31.31-4 Medications Used in the Administration of ECT

Anesthetic agents are given because they tend to obliterate memory of the procedure. Intravenous anesthetics with rapid onset and brief duration of action are the agents of choice for ECT; inhalational anesthetics play little role in administration of the treatments. Methohexital (Brevital; about 1 mg/kg intravenously), a short-acting barbiturate, is the most commonly used ECT anesthetic; it has a rapid onset and short (about 10 minutes) duration of action. Advantages include ease of use, low incidence of adverse effects, and low cost. Potential problems include respiratory depression, risk in patients with porphyria, and laryngospasm at low doses. Thiopental (Pentothal), a barbiturate anesthetic commonly used for induction prior to surgical procedures, appears to carry significantly greater risk of ECG abnormalities during ECT than methohexital. Since other adverse effects of thiopental are similar to those seen with methohexital, methohexital is the agent of choice. Other intravenous anesthetics that can be used for ECT include etomidate, alfentanil, ketamine, and propofol. Among these, etomidate is particularly interesting because it has few cardiovascular adverse effects and perhaps less effect on seizure induction than barbiturates. Alfentanil and other short-acting opioids may prolong seizures but require concurrent administration of an amnestic agent (e.g., barbiturates such as methohexital) to perform effectively as anesthetics. Furthermore, opioids are notorious suppressants of respiratory effort, an effect that can be reversed with antagonists such as naloxone. Ketamine also has less effect on seizure induction but tends to worsen ECT-induced blood pressure and heart rate changes and, in adults, is associated with psychotomimetic symptoms that would be particularly detrimental in psychiatric patients. Propofol has strong anticonvulsant properties that may diminish its usefulness for ECT anesthesia. The benzodiazepines (e.g., midazolam [Versed]) are to be avoided because of their deleterious effects on seizure induction. Etomidate is probably the anesthetic agent to choose if a barbiturate such as methohexital is undesirable.

Routine use of muscle relaxants during ECT has virtually eliminated fractures of long bones and vertebrae. After the patient has been anesthetized, a blood pressure cuff or tourniquet is placed on an extremity (usually the right ankle) and inflated to exceed the systolic blood pressure. A short-acting muscle relaxant is injected intravenously. The blood pressure cuff isolates the limb from the muscle relaxant and allows monitoring of motor seizure activity. Succinylcholine (Anectine; about 1 mg/kg, intravenously), a depolarizing muscle relaxant, is the drug of choice for ECT. This drug has a rapid onset (about 1 to 2 minutes) and short (less than 10 minutes) duration of action that is almost ideal for ECT. Advantages include ease of use and low cost. Adverse effects of succinylcholine include muscle soreness (due to fasciculations), increased extracellular potassium (due to depolarization of the neuromuscular junction), and risk of prolonged apnea in patients with pseudocholinesterase deficiency. Risk of hyperkalemia is greatest in patients with recent trauma (fractures and burns) and in those with neuromuscular disorders. Patients with neuromuscular disorders are also at risk for developing malignant hyperthermia following succinylcholine use. For these patients, a nondepolarizing muscle relaxant is a more appropriate choice. Alternatives include atracurium (Tracrium) and mivacurium (Mivacron). For patients who experience recurrent intolerable muscle soreness from succinylcholine, pretreatment with a low dose of a nondepolarizing agent (e.g., mivacurium, 1 mg intravenously) can be beneficial.

Following injection of the muscle relaxant, a bite block is placed in the patient's mouth to protect teeth and tongue. The ECT stimulus is then applied via electrodes placed either bitemporally (bilateral ECT) or over the nondominant hemisphere (unilateral ECT). A bite block is required because passage of electrical current directly stimulates jaw muscles and causes teeth clenching. Since this problem cannot be prevented by use of muscle relaxants, patients should be warned before treatment that some risk of damage to the teeth is associated with the procedure, particularly in patients with poor baseline dentition. Following the electrical stimulus and seizure induction, the bite block is removed, and oxygenation via mask is continued until the patient resumes spontaneous and sustained respirations.

An ECT seizure usually lasts between 30 and 90 seconds; the observed motor seizure is typically shorter than the EEG seizure. Brief seizures (less than 25 seconds) can be followed by restimulation at a higher charge during the same session if anesthetic conditions permit. Prolonged-ECT seizures are defined as those lasting more than 180 seconds on EEG. Prolonged seizures are terminated by an intravenous anticonvulsant such as a barbiturate (methohexital, 30 to 50 mg) or a benzodiazepine (diazepam [Valium], 5 to 10; lorazepam [Ativan], 1 to 2 mg). Following the end of the seizure and full recovery of respirations, the patient is taken to the recovery area where blood pressure, pulse, ECG, and oxygen saturation are monitored until the patient is fully alert and able to ambulate. This typically takes about 30 minutes.

During each ECT treatment there are marked increases in blood pressure and pulse rate. Most patients tolerated these changes well, but hemodynamic changes may predispose patients with underlying cardiovascular illnesses to episodes of myocardial ischemia or rate-dependent arrhythmias. In the ECT area, marked increases in pulse and blood pressure can be dampened by judicious use of esmolol (Brevibloc; 0.2 mg/kg, intravenously), a short-acting b-adrenergic receptor antagonist, or labetalol (Trandate; 5 to 20 mg intravenously), a combined b- and a-adrenergic antagonist. These agents can be administered either before or after electrical stimulation. At higher doses, both agents have been associated with increases in seizure threshold, and they may increase poststimulus asystole in patients not treated with an anticholinergic drug. Thus, poststimulus administration of esmolol and labetalol may be preferred for ECT. Cardiovascular changes induced by ECT are brief and time limited, so the briefer duration of action may make esmolol the preferred agent. However, both esmolol and labetalol may produce bradycardia that persists beyond the treatment period. Esmolol and labetalol tend to be effective for ECT-induced increased heart rate, but in some patients are less effective for increased blood pressure. For patients who exhibit marked changes in blood pressure, premedication with nifedipine (Procardia; 10 to 30 mg orally about 30 minutes prior to treatment) can be useful. Other medications (e.g., nitroglycerin) may also be useful.

Electrode Placement Typically, one of two electrode placements is used for ECT: unilateral, nondominant hemisphere placement or bilateral placement. The electrodes are usually either hand-held devices or metal plates contained in a band that is affixed to the patient's head. Hand-held electrodes are easier to position, but the position may change as pressure is applied to form a good electrical contact. Several varieties of unilateral placement have been described, but most practitioners prefer, and most research supports, a temporoparietal (d'Elia) position. For all right-handed patients, the electrodes are placed over the right cerebral hemisphere. Most (more than 60 percent) of left-handed patients are either left hemisphere dominant for language or have mixed dominance, so a right hemisphere placement is appropriate for these patients as well. For bilateral treatments, electrodes are usually positioned bitemporally; other placements are experimental. Prior to positioning the electrodes, the skin must be carefully prepared to improve electrical contact and diminish interelectrode impedance. This is accomplished by cleansing the electrode area with a saline-soaked pad and coating the electrodes with a conducting gel.

When the electrical dose is taken into consideration and electrical charges that are more than 2.5 times the seizure threshold are used for unilateral treatments, both unilateral and bilateral ECT are effective in treating psychiatric disorders. Nondominant hemisphere electrode placements are the preferred initial mode of treatment for most patients, because this placement tends to produce less memory impairment than bilateral stimulus. Exceptions to this approach may include patients who have a history of poor response to prior courses of nondominant hemisphere treatment, a history of positive prior response to bilateral ECT, or extremely severe symptoms. When a patient is to be treated with bilateral ECT, the reasons for this selection should be clearly documented in the medical record.

For reasons that are not clear, some patients do not respond to unilateral treatments. If a patient fails to respond after four to eight unilateral treatments using an electrical dose that is 2.5 to 5.0 times the seizure threshold, several options are open to the treating psychiatrist. If possible, the electrical dose can be increased to more than five times threshold. If the patient fails to respond to this form of stimulation, electrode placement should be changed to bilateral using a minimally suprathreshold electrical dose. Failure to respond to low-charge bilateral stimulation should prompt a change to high-charge bilateral treatments. In all cases, a decision to increase electrical charge, switch to bilateral treatments, or both should be made after carefully considering the patient's cognitive status and after discussion with the patient of the risks and possible benefits of the change in treatment. A patient should not be considered an ECT failure until a course of high-charge bilateral ECT has been administered. Additionally, failure to respond to a prior course of ECT does not necessarily predict failure to respond to ECT at later times, particularly during different episodes of the disorder.

ECT Course An average ECT seizures lasts from 30 to 90 seconds. ECT has anticonvulsant properties, and over a course of treatments, seizure threshold increases and seizure duration decreases. Seizures lasting less than 25 seconds are considered less therapeutic than longer seizures yet are associated with the risks and

adverse effects of longer seizures. When seizures routinely last less than 25 seconds, several approaches can be use to lengthen them. First, vigorous hyperventilation prior to and during the seizure can lengthen seizures in some patients by diminishing carbon dioxide levels. Second, any medications that raise seizure threshold and that can be withheld safely should be discontinued; these include benzodiazepines, antidepressants, and anticonvulsants given for psychiatric indications. Third, consideration should be given to the dose and type of anesthetic drug. High doses of barbiturates clearly have anticonvulsant effects. Thus, either lowering the dose of barbiturate or changing the anesthetic to etomidate or ketamine can lengthen seizures in some patients. Alternatively, the dose of barbiturate can be significantly lowered (to 20 to 30 mg) and alfentanil (0.25 µg/kg) added to the regimen. Fourth, intravenous administration of caffeine (250 to 1000 mg) significantly prolongs seizure activity in most patients. Theophylline has effects similar to those of caffeine but has been associated with status epilepticus during ECT.

Sustained improvement in psychiatric symptoms rarely occurs with a single ECT treatment. Most, if not all, patients require a course of repeated treatments. A typical course of ECT consists of 6 to 12 treatments administered two or three times per week over a period of several weeks until improvement in target clinical symptoms reaches a plateau. There have been several attempts to speed this course of treatment by inducing multiple seizures in succession at a single treatment session (referred to as “multiple-monitored ECT”). There is little evidence that these multiple treatments enhance the benefits of ECT, but they seem to be associated with significantly greater memory impairment and confusion, particularly in elderly patients. In an effort to prolong the duration of improvement following ECT, some practitioners have administered prolonged courses of treatment (20 to 40 treatments). There is no evidence that prolonged courses of treatment enhance clinical benefit. In the past, prolonged courses of treatment were used to induce a state of cognitive impairment (so-called regressive ECT). This form of treatment has no place in modern ECT practice, since it has no clear therapeutic advantage and is associated with severe cognitive impairment. Fixed courses of treatment for all patients are inappropriate, and decisions about discontinuing ECT should be made on the bases of clinical response and adverse effects of treatment.

The benefits of ECT are time limited. Following a successful course of ECT, an effective maintenance strategy must be implemented for each patient. This typically involves aggressive pharmacological treatment using medications that the patient has not failed in the past and psychotherapy to facilitate psychosocial rehabilitation. ECT can also be used for maintenance treatment. Because risk of relapse following ECT is highest in the first 6 to 8 weeks following a successful course, maintenance treatments are usually administered once a week for the first 2 months. Treatment frequency is then gradually decreased, aiming at one treatment a month. After 6 to 12 months of maintenance ECT, treatments are usually discontinued, and the patient continues taking psychotropic medications. During the maintenance ECT period, patients are commonly treated with appropriate psychotropic medications.

CONTRAINDICATIONS TO ECT

There are no absolute contraindications to ECT. Previously, the presence of a brain tumor was viewed as an absolute contraindication to treatment because increases in cerebral blood flow and intracranial pressure that accompany seizures increase the risk of brain herniation, neurological decompensation, and death. However, numerous reports have described successful use of ECT to treat psychiatric disorders in patients with CNS tumors. At present, the presence of any CNS tumor must be viewed as significantly increasing the risk of ECT. Patients at greatest risk are those with large CNS lesions, evidence of increased intracranial pressure, evidence of midline shift on neuroimaging studies, or neurological examinations that show clear focal deficits. Patients with small lesions in silent regions of the CNS who lack the findings described above are at lower risk. Because changes in intracerebral pressure are related to changes in cerebral blood flow, pressor responses to ECT must be managed carefully in patients with CNS tumors. Use of steroids may diminish local swelling in the tumor area and decrease risks associated with ECT. In all patients with CNS tumors, the decision to use ECT should be made carefully in collaboration with neurologists and neurosurgeons.

Patients who have had neurosurgical procedures or who have had skull fractures may also be at increased risk for complications from ECT because of bony defects in the region of the surgery or fracture. These defects provide a low-resistance pathway for current to enter the CNS more directly during electrical stimulation, thus increasing risk of electrolytic brain injury. In these patients, ECT electrodes should not be placed directly over regions where the skull has been significantly compromised.

Other factors that increase the risk of complications from ECT include a recent myocardial infarction or stroke, particularly when ECT is administered within 4 to 6 weeks of the event. These patients are at increased risk from general anesthesia alone. Similarly, patients with uncompensated congestive heart failure are at increased risk of complications from the treatment. In all of these cases, close interaction between the treating psychiatrist and the patient's cardiologist or neurologist may suggest management that decreases risk.

ADVERSE EFFECTS AND RISKS

Cardiovascular Effects of ECT Significant changes in hemodynamic function occur during each ECT treatment. Immediately following the electrical stimulus, a period of increased parasympathetic tone produces profound bradycardia and asystole that can last several seconds. This initial asystole may be more pronounced with subconvulsive stimuli, particularly in patients treated with medica tions that slow the heart rate (e.g., b-adrenergic receptor antagonists). The initial bradycardia can be diminished by pretreatment with anticholinergic agents (atropine, glycopyrrolate). During the ECT-induced seizure, there are marked increases in heart rate (up to 140 to 160 beats per minute) and blood pressure (often up to 220 to 260/120 to 140 mm Hg). These increases in heart rate and blood pressure can last for 20 minutes or longer following the seizure and are believed to result from the release of catecholamines during the generalized seizure. The increase in heart rate may be enhanced by pretreatment with anticholinergic agents. For this reason, many ECT practitioners determine the need for anticholinergics on a treatment-by-treatment and case-by-case basis. Hemodynamic changes can be dampened by judicious use of b-adrenergic receptor antagonists (esmolol, labetalol) at the time of treatment and by premedication with short-acting calcium channel blockers such as nifedipine. Following the ECT seizure, some patients develop bradycardia, which can last for several minutes. The mechanisms responsible for the postictal bradycardia are uncertain, but the slowing can be overcome by anticholinergic drugs.

Changes in hemodynamic function during ECT render patients with cardiovascular illnesses susceptible to episodes of myocardial ischemia and arrhythmias. Although in most cases, ECT-induced ECG changes are time limited and do not require specific interventions, some patients may develop more-malignant changes that require immediate attention. Thus equipment and medications for cardiac emergencies must be readily available in the ECT treatment room, and the ECT staff must be familiar with appropriate interventions for cardiac emergencies.

Death ECT is a medical procedure that involves general anesthesia. As a consequence it carries a small but definite risk of death. Furthermore, ECT is often used to treat psychiatric disorders in patients with severe medical illnesses. Although definitions of ECT-related deaths vary, the incidence of a death occurring within 24 hours of a treatment appears to be about 1 in every 25,000 treatments. This incidence does not different significantly from the incidence of death in patients exposed to general anesthesia alone. Most often, cause of death is a cardiovascular complication, including myocardial infarction, myocardial rupture, or ventricular arrhythmia. Other causes include brain herniation (particularly in patients with large CNS tumors) and respiratory complications, including aspiration. Given the cardiovascular changes that occur with ECT, it is perhaps surprising that ruptured aneurysms are rare following ECT. Despite risk of death and cardiovascular changes associated with the treatment, ECT has been used as a treatment for more than 50 years and is generally a very safe procedure. Furthermore, untreated severe psychiatric disorders carry significant morbidity and mortality risks from suicide and deterioration in physical health. All of these factors must be weighed when considering the use of ECT in severely ill individuals.

Cognitive Impairment Cognitive adverse effects of ECT show great individual variability. For example, some patients have little recollection of the ECT procedure while others can describe in detail all events up to the time they lose consciousness. The reasons for this variability are not certain.

Most patients experience a period of postictal and postanesthetic confusion that lasts about 30 minutes, although the duration can (rarely) extend to hours. During this time, some patients (roughly 5 percent) may become severely agitated and require restraint and sedation. Preferred agents for this purpose include benzodiazepines (e.g., lorazepam, 1 to 2 mg intravenously, or diazepam, 5 to 10 mg intravenously) or antipsychotic medications (e.g., haloperidol [Haldol], 5–10 mg intramuscularly). Factors that contribute to postictal confusion include frequency and number of ECT treatments, electrical dose, anesthetic agents used, and concomitant medications, including anticholinergic drugs and other CNS-active agents. Age and medical status may also contribute, but severe bouts of postictal confusion can occur in young, healthy persons. Patients who have a documented history of significant difficulties during the recovery period may benefit from prophylactic treatment with a benzodiazepine (e.g., 5 to 10 mg of diazepam intravenously) following termination of the seizure. These patients should also receive intensive nursing intervention in the recovery room.

Memory loss, a major adverse effect of ECT, has both retrograde and anterograde components. Because of the repeated treatments, memory is characteristically worse for events occurring during the ECT course (anterograde amnesia). Most patients also experience retrograde amnesia that is usually worse for events occurring in the weeks prior to treatment. Typically, severity and duration of amnesia diminish as ECT administration becomes more remote. Some patients report difficulties with memory for more-distant events, including specific problems with autobiographical memories. These problems are often confounded by the fact that memory can be impaired by episodes of depression and other treatments used for depression. ECT-induced memory problems usually improve within 6 to 8 weeks following a

course of treatment and coincide with the period during which the EEG shows significant slowing. Some patients report more-sustained difficulties with memory, lasting months, but persistent problems with memory formation are often difficult to demonstrate systematically, and interpretation can be confounded by recurrence of psychiatric symptoms.

As with postictal confusion, several variables contribute to memory impairment, including frequency and number of treatments, electrical charge used to induce seizures, and perhaps the drugs used for anesthesia. Electrode placement is possibly the greatest contributor to ECT-induced memory problems. Systematic studies clearly demonstrate that bilateral treatments are associated with significantly greater verbal memory impairment than nondominant hemisphere unilateral treatments. For this reason alone, unilateral electrode placement is considered the treatment of first choice for most patients referred for ECT.

Memory impairment is an adverse effect of ECT and has nothing to do with clinical benefits of the treatment. A number of attempts to prevent memory deficits have used pharmacological approaches, but none of these has had significant success or impact on clinical practice. Consequently, cognitive impairment remains a major concern in patients treated with ECT.

Brain Damage The concern that ECT may induce structural damage to the CNS is motivated by ECT-associated cognitive impairment. Furthermore, prolonged seizures in animals and humans can produce neuronal injury. Presently no convincing evidence indicates that either ECT or intermittent brief seizures, such as those induced during ECT, produce structural damage to the brain. The brain damage that occurs during status epilepticus is particularly irrelevant because this form of damage takes more than 20 minutes of continuous seizure activity to become manifest and often occurs in the context of hypoxia. ECT seizures rarely exceed 3 minutes and occur under conditions in which patients are well oxygenated. Perhaps the best clinical evidence against ECT-induced CNS damage is derived from magnetic resonance imaging (MRI) studies of the brain performed by C. Edward Coffey and colleagues.

Spontaneous Seizures The repeated induction of generalized seizures during a course of ECT led to concerns that the treatment may increase the risk of spontaneous seizures, perhaps via a kindling effect. The incidence of spontaneous seizures in patients treated with ECT appears to be about 0.1 to 0.5 percent, similar to the incidence of spontaneous seizures in the general population. Some of these patients may have had underlying seizure disorders, but it remains possible that rare patients have a spontaneous seizure following ECT. Whether this becomes a recurrent seizure disorder is less certain.

Other Adverse Effects of ECT Fractures often accompanied treatments in the early days of ECT. With routine use of muscle relaxants, fractures of long bones or vertebrae should not occur. However, some patients may break teeth or experience back pain because of contractions during the procedure. Muscle soreness may occur in some individuals but often results from the effects of muscle depolarization by succinylcholine and is most likely to be particularly troublesome after the first session in a series. This soreness can be treated with mild analgesics, including nonsteroidal anti-inflammatory drugs (NSAIDs). A significant minority of patients experience nausea, vomiting, and headaches following an ECT treatment. Nausea and vomiting can be prevented by treatment with antiemetics at the time of ECT (e.g., metoclopramide [Reglan], 10 mg intravenously, or prochlorperazine [Compazine], 10 mg intravenously; ondansetron [Zofran] is an acceptable alternative if adverse effects preclude use of dopamine receptor antagonists).

ECT can be associated with headaches, although this effect is usually readily manageable. Headaches often respond to NSAIDs given in the ECT recovery period. In patients with severe headaches, pretreatment with ketorolac (Toradol) (30 to 60 mg intravenously), NSAID approved for brief parenteral use, can be helpful. Acetaminophen (Tylenol), tramadol (Ultram), propoxyphene (Darvon) and more potent analgesia provided by opioids can be used individually or in various combinations (e.g., pretreatment with ketorolac and postseizure management with acetaminophen-propoxyphene) to manage more intractable headache. ECT can induce migrainous headache and related symptoms; sumatriptan (Imitrex) (6 mg subcutaneously or 25 mg orally) may be a useful addition to the agents described above. Ergot compounds can exacerbate cardiovascular changes observed during ECT and probably should not be a component of ECT pretreatment.

ECT AND PSYCHOTROPIC MEDICATIONS

The combined use of psychotropic medications and ECT does not appear to enhance the clinical benefits of ECT. However, in some settings, particularly outpatients undergoing maintenance ECT, it is likely that patients will be treated with a combination of medications and ECT. One concern is the risk of adverse interactions between psychotropic medications, adverse effects of ECT, or vice versa. Clear evidence of drug/ECT interactions is lacking for most medications, but it may be prudent to avoid combined use. For example, some evidence suggests that lithium may have adverse effects when combined with ECT, leading to greater confusion and possibly increasing the risk of spontaneous seizures. These findings have been disputed in the literature, but careful consideration of the clinical situation will usually encourage discontinuing lithium use in the period preceding ECT. Additionally, some evidence suggests that lithium may interfere with pseudocholinesterase, the enzyme that degrades succinylcholine; thus, lithium may be associated with prolonged muscle paralysis during ECT. There may be increased risks of combining ECT with irreversible monoamine oxidase inhibitors (MAOIs), particularly problems with blood pressure management and perhaps with pseudocholinesterase inhibition, but this is also controversial. Some studies indicate that benzodiazepines diminish the effectiveness of unilateral ECT, but this may result from effects on seizure threshold that can be corrected by titration of the electrical dose. On theoretical grounds, it may be wise to avoid agents with significant anticholinergic effects (e.g., tricyclic drugs and phenothiazines) because of potential problems with cognitive impairment, but data strongly supporting this contention are lacking. Certain medications (bupropion [Wellbutrin], clozapine [Clozaril], amoxapine [Asendin], and maprotiline [Ludiomil] may prolong ECT seizures, but this is not well documented. Tricyclic drugs and low-potency phenothiazines might be expected to produce similar problems, but no evidence supports this. Problems will other medications are mostly recounted in case reports and anecdotal experiences.

Despite the unclear literature, avoiding the combined use of ECT with psychotropic medications to the extent possible seems most prudent. Patients with marked anxiety may require treatment with low doses of shorter-acting benzodiazepines (e.g., lorazepam, alprazolam [Xanax]) may be necessary. If patients require a sedative-hypnotic, zolpidem (Ambien) or chloral hydrate (Noctec) would be reasonable choices. For severely agitated psychotic patients, high-potency neuroleptics antipsychotics (e.g., haloperidol, thiothixene [Navane]) are useful.

TRANSCRANIAL MAGNETIC STIMULATION

ECT has multiple effects on brain function that are responsible for both its therapeutic and adverse actions. If changes in only certain regions of the CNS are required for therapeutic benefits, it may be possible to develop stimulation paradigms that target these areas. Such treatments could have great advantages in avoiding many of the unwanted effects of ECT, perhaps including cognitive impairment. Transcranial magnetic stimulation (TMS) is one such treatment. In neurology, TMS has been developed as a way to stimulate the CNS noninvasively by application of a focal magnetic field over regions of the cortex. Refinements of magnetic stimulators, including the development of stimulators capable of discharging at frequencies up to 60 Hz (referred to as rapid-rate TMS [rTMS]) have allowed focal stimulation of the CNS to estimate motor thresholds and determine hemispheric language dominance. Interestingly, rTMS was found to benefit some patients with Parkinson's disease, and some Parkinson's disease patients exhibited improved mood following rTMS. Additionally, subjects exposed to rTMS for purposes of determining hemispheric language dominance exhibited affective responses following stimulation of the left frontal cortex.

These observations suggest that rTMS may have therapeutic potential in psychiatry and may allow focal stimulation of areas most involved in affective states. While experience with rTMS in psychiatry is limited, some evidence suggests that depending on the placement of the magnetic coil, rTMS can improve or worsen affective state. In one of the best studies to date, left dorsolateral prefrontal cortex stimulation significantly improved depression ratings in 11 of 17 patients with psychotic major depression. rTMS appears to be well tolerated and does not require general anesthesia. Seizures may be a side effect in some patients but do not appear to be required for therapeutic effects.

TMS is performed using a high-speed magnetic stimulator that generates a 1.5 to 2.5 Tesla field for brief periods. This field is similar to that used for nuclear magnetic resonance imaging. rTMS stimulus is delivered at frequencies of 10 to 60 Hz using a figure-8 shaped coil that is placed over the desired region of the skull and continuously cooled with water to prevent overheating. Patients and staff typically wear earplugs because of the noise generated by the stimulator. Stimulation is typically given several times per session and is repeated over several days to weeks. At present, optimal stimulation patterns for rTMS in psychiatric disorders are not known.

ROLE OF ECT

More than 50 years after it was developed, ECT remains an important, effective, and safe treatment for a variety of neuropsychiatric disorders. Major depression is presently the most common indication for the treatment. Despite the fact that the treatment is usually reserved for patients who fail to respond to psychotropic medications, ECT remains effective in this population. ECT may be a life-saving intervention for some patients. The invasiveness of the procedure and the major adverse effects of memory loss and confusion are limiting variables in the use of ECT. However, cognitive adverse effects of ECT clearly have nothing to do with

therapeutic benefits. Most major innovations in ECT technique over the past 20 years have sought to diminish cognitive effects while maintaining benefits. New developments in ECT technique and perhaps the development of rTMS as a therapeutic tool offer the hope that this form of treatment will find better acceptance among psychiatrists and patients. Further developments in understanding the neurobiology of major psychiatric disorders will only help in this regard.

SUGGESTED CROSS-REFERENCES

Basic electrophysiology is discussed in Section 1.9, and applied electrophysiology in Section 1.14. Biology of memory is covered in Section 3.4 Medical assessment and laboratory testing in psychiatry are covered in Section 7.7. Chapter 12 discusses schizophrenia, and Chapter 13 discusses mood disorders. Section 51.3d covers mood disorders in the elderly, and Section 51.4g covers the use of ECT in older persons. Transcranial magnetic stimulation also is discussed in Section 31.33.

31.32 NEUROSURGICAL TREATMENTS

SCOTT L. RAUCH, M.D. AND G. REES COSGROVE, M.D., F.R.C.S.(C)

Neurosurgical treatment of psychiatric disease has a long and checkered history. Crude freehand “psychosurgery,” such as prefrontal lobotomy, was widely and indiscriminately used to treat severe psychiatric disease during an era that predated modern psycho-pharmacology. Those primitive operations yielded modest reductions in symptoms but were accompanied by unacceptable adverse effects. Unfortunately, many people still associate neurosurgical treatment of psychiatric disease with the techniques and practices of that bygone era. Over the past 35 years neurosurgical techniques have evolved that differ substantially from early psychosurgical interventions. First, accurate, precise, and reproducible placement of lesions in specific target areas is performed using advanced magnetic resonance imaging (MRI)-guided stereotactic methods. Second, strict criteria for patient selection are observed, and the process of determining appropriate candidacy has been formalized. Currently, surgical intervention is predominantly reserved for patients with severe, incapacitating major depressive disorder or obsessive-compulsive disorder who have failed an exhaustive array of other available treatments. Surgery is not approved unless a multidisciplinary committee reaches consensus regarding its appropriateness for a given candidate and the patient renders informed consent. Third, although a large body of clinical data indicates the efficacy and safety of modern neurosurgical interventions, major centers providing these treatments continue to gather information prospectively. In the context of smaller, more precisely placed lesions and better-established selection criteria, modern psychiatric neurosurgery yields substantial improvement in approximately 25 to 70 percent of cases, with drastically reduced morbidity and mortality.

HISTORY

Trephination, as performed by ancient civilizations, probably represents the earliest form of surgical intervention for psychiatric disease. In 1891 the first formal report of neurosurgical treatment in psychiatry was published, describing bilateral cortical excisions in demented and depressed patients, which yielded mixed results. During the ensuing four decades, little progress was made in this arena. In 1935 John Fulton and Charles Jacobsen presented their research on primate behavior following frontal cortical ablation. They observed that lobectomized chimpanzees showed reduced “experimental neurosis” and were less fearful, while retaining an ability to perform complex tasks. Egaz Moniz (Fig. 31.32-1), a renowned Portuguese neurologist, was in attendance at Fulton's lecture. Prompted by these findings in primates, Moniz pioneered prefrontal leukotomy in collaboration with his neurosurgical colleague Almeida Lima. First by using pure alcohol injections and subsequently by mechanical means with a leucotome, Moniz and Lima performed “psychosurgery” on 20 severely ill institutionalized patients; 14 were said to have exhibited worthwhile improvement. In an era of overflowing asylums and few effective treatments for chronic debilitating psychiatric illness, this mode of therapy was initially enthusiastically embraced. In fact, Moniz was awarded the 1949 Nobel Prize in Medicine and Physiology for this contribution. From the mid-1930s until the emergence of the phenothiazines in the mid-1950s, there was a global proliferation of psychosurgical techniques and practices. Walter Freeman was perhaps the most zealous promoter of psychosurgery in the United States. Pioneering a series of freehand procedures to achieve prefrontal lobotomy (i.e., severing the white matter connections between the prefrontal cortex and the rest of the brain), Freeman and neurosurgeon James Watts reported on their first 200 cases by 1942. Although the benefits of the surgery were highlighted, others acknowledged a significant complication rate, including frontal lobe syndrome, seizures, and even deaths. At its peak, this brand of psychosurgery was being performed on approximately 5000 patients per year in the United States alone. A review of the results of 10,365 prefrontal lobotomies performed from 1942 to 1954 in Britain concluded that while 70 percent showed improvement, adverse events included 6 percent mortality, plus 1 percent with seizures and 1.5 percent with disinhibition syndromes. Widespread reports of blunted personality and socially inappropriate behavior also surfaced. In the late 1940s and early 1950s, recognition of these risks prompted attempts to develop modified surgical procedures that might yield better results. However, with the introduction of chlorpromazine (Thorazine) in 1954, satisfactory medical management of psychiatric illness became possible for the first time. Thus, despite the advent of stereotactic neurosurgical techniques in the 1950s and a continued high prevalence of severe treatment-refractory psychiatric disease, psychosurgery was all but abandoned in favor of nonsurgical therapies. Later, as the limitations of antipsychotic drugs and electroconvulsive treatment became known, there was a resurgence of interest in psychiatric neurosurgery at a few academic medical centers in the 1960s. Hence, refinement of stereotactic methods and emerging theories regarding the role of the limbic system in emotion shaped a new age of neurosurgical treatments for psychiatric disease. The pioneers of these contemporary procedures faced harsh opposition from political groups, as well as the populace, who equated psychosurgery with crude and indiscriminately applied operations of an earlier era. Political and social pressure dissuaded all but a handful of neurosurgeons from offering these treatments in the 1960s and 1970s. Gradually, over the past two decades, research and education regarding modern neurosurgery has led to its legitimacy as an acceptable treatment modality for severe, intractable psychiatric disease—now in the context of more-refined procedures as well as better-defined indications, risks, and potential benefits.

FIGURE 31.32-1 Egas Moniz. (Courtesy of New York Academy of Medicine.)

SURGICAL APPROACHES

Although numerous approaches have been tried, four neurosurgical procedures have evolved as the safest and most effective for treating psychiatric disorders. All four entail bilateral lesions and are currently performed using modern stereotactic methods (Fig. 31.32-2).

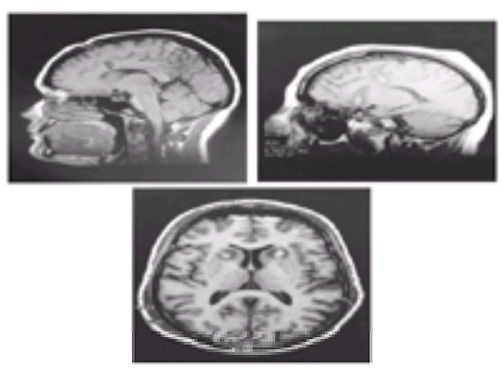

FIGURE 31.32-2 Appearance of psychiatric neurosurgical lesions by postoperative T_1-weighted MRI. **A**, Sagittal view depicting an anterior cingulotomy lesion. **B**, Sagittal view depicting the lesions of limbic leukotomy (i.e., anterior cingulotomy plus subcaudate tractotomy). **C**, Transaxial view depicting anterior capsulotomy lesions.

Subcaudate Tractotomy Subcaudate tractotomy was introduced by Geoffrey Knight in Great Britain in 1964 as one of the first attempts to limit adverse effects by restricting lesion size. By targeting the substantia innominata (just inferior to the head of the caudate nucleus), the goal was to interrupt white matter tracts connecting orbitofrontal cortex and subcortical structures. The surgery involved placement of radioactive yttrium-90 seeds at the desired centroid, yielding lesion volumes of approximately 2 cubic centimeters on each side. Indications for subcaudate tractotomy are major depressive disorder, obsessive-compulsive disorder, and other severe anxiety disorders.

Anterior Cingulotomy Fulton was the first to propose that the anterior cingulum might represent an appropriate target for treatment of psychiatric disease. While the first cingulotomies were performed for intractable pain, it was noted that the best results were in patients with comorbid anxiety or depressive conditions. H. Thomas Ballantine, Jr., and colleagues subsequently demonstrated the safety of anterior cingulotomy and studied its efficacy for a broad range of psychiatric indications. Since 1962 the group at Massachusetts General Hospital has performed nearly 1000 of these procedures, and it remains the most commonly used neurosurgical treatment for psychiatric disease in North America. The surgery is conducted under local anesthesia and two or three approximately 1.0 cubic centimeter lesions are made on each side by thermocoagulation through bilateral burr holes. The target is within the anterior cingulate cortex (Brodmann areas 24 and 32), at the margin of the white matter bundle known as the cingulum. Originally, lesion placement was determined by ventriculography; however, since 1991 anterior cingulotomy has been conducted via MRI-guidance. This group has always emphasized making the smallest possible lesion; consequently, up to 40 percent of patients return several months following the first operation for a second procedure to extend the first set of lesions. The indications for anterior cingulotomy include major depressive disorder, and obsessive-compulsive disorder.

Limbic Leukotomy Limbic leukotomy was introduced by Desmond Kelly and colleagues in England in 1973. The procedure combines the targets of subcaudate tractotomy and anterior cingulotomy. The lesions have typically been made via thermocoagulation or with a cryoprobe. Historically, the precise placement of the lesions was guided by intraoperative stimulation; pronounced autonomic responses were believed to designate the optimal lesion site. The indications for limbic leukotomy include major depression, obsessive-compulsive disorder, and other severe anxiety disorders.

Anterior Capsulotomy Anterior capsulotomy was first performed in France; however, Lars Leksell and colleagues popularized the procedure in Sweden. Anterior capsulotomy remains the most commonly used surgical treatment for psychiatric disease in Scandinavia. The procedure involves small lesions placed within the anterior one-third of the anterior limb of the internal capsule at the level of the intercommissural plane, thereby interrupting fibers of passage from prefrontal cortex to subcortical nuclei. Anterior capsulotomy was originally performed via thermocoagulation; more recently the lesions have been made noninvasively using a radiosurgical device known as the *gamma knife*. The relative advantages and disadvantages of this stereotactic radiosurgical approach remain undetermined. Indications for anterior capsulotomy include major depressive disorder, obsessive-compulsive disorder, and other severe anxiety disorders.

PATIENT SELECTION

Indications and Contraindications Although limited reports have suggested efficacy across a broad range of psychiatric conditions, the best-established indications for contemporary psychiatric neurosurgery are major depressive disorder and obsessive-compulsive disorder. In evaluating candidates several factors are considered:

1. **Primary diagnosis.** The patient must meet clinical criteria for the diagnostic indication, and this disorder should be a primary cause of the patient's illness.
2. **Severity.** The patient must have chronic, severe, and debilitating illness; duration of the primary illness must exceed 1 year and typically exceeds 5 years. Severity is gauged on standardized instruments (e.g., patients with obsessive-compulsive disorder typically have Yale-Brown Obsessive-Compulsive Scale scores of 25 or above; patients with depression typically have Beck Depression Inventory scores of 30 or above), while debility should be indicated by a low level of functioning (e.g., a Global Assessment of Functioning score £ 50) and a poor quality of life.
3. **Adequacy of previous treatment.** Patients must have already undergone an exhaustive array of other available treatments.
4. **Psychiatric comorbidity.** Appropriate treatment must have been rendered for any comorbid psychiatric disorder; the presence of psychoactive substance use or personality disorders are considered strong relative contraindications.
5. **Medical comorbidity and surgical fitness.** Structural brain lesions or significant central nervous system injuries are strong contraindications. Medical conditions that increase neurosurgical risks (e.g., cardiopulmonary disease) and age above 65 years are relative contraindications. A history of past seizures is a risk factor for perioperative seizures and must be weighed in the overall risk-benefit assessment.
6. **Access to postoperative care.** Patients must have access to adequate postoperative care, including a psychiatrist (typically the referring physician) who will accept responsibility for managing them after discharge. Arrangements for postoperative care (e.g., intensive behavior therapy) should be confirmed ahead of time.
7. **Informed consent.** Under no circumstances should psychiatric neurosurgery be performed on patients against their will. The patient must be able and willing to render an informed consent. In rare instances these procedures are performed with assent of the patient and formal consent from a legal guardian. In this context, age less than 18 years also represents a strong contraindication.

Multidisciplinary Case Review The process of assessing candidacy differs somewhat from center to center and between nations as governed by law. Across centers, however, there is consensus that decisions regarding candidacy must be made after thorough review of the patient's case, taking into account the written record, current clinical examination, and formal referral from the patient's treating psychiatrist. In Boston, Stockholm, and London, the decision is typically made by an interdisciplinary committee; in Britain, psychosurgery requires additional formal approval from the Mental Health Act Commission.

PREOPERATIVE WORKUP

In addition to a multidisciplinary clinical evaluation and formalized case review, the preoperative workup for psychiatric neurosurgery includes standard blood and urine laboratory tests, an electrocardiogram, and specialized tests of brain structure and function. A comprehensive preoperative assessment should include brain MRI, an electroencephalogram, and psychometric testing.

POSTOPERATIVE CARE

Immediate postoperative care includes the standard medical and surgical considerations following any stereotactic neurosurgical procedure. Special attention is paid to signs or symptoms of potential surgical complications, including infection, hemorrhage, seizures, or altered mental status. A postoperative MRI should be obtained to document the placement and extent of lesions. Intensive postoperative psychiatric treatment is recommended, since the efficacy of the surgery may rely on some synergy between the neurosurgical intervention itself and enhanced response to pharmacological or behavioral therapies. Although dosages of psychotropic medications may be reduced during the immediate perioperative period, the medication regimen should be readjusted as tolerated postoperatively. In the case of obsessive-compulsive disorder, intensive behavior therapy should be initiated as soon as possible, preferably within the first month postoperatively.

DESIGN AND INTERPRETATION OF CLINICAL STUDIES

One must appreciate the inherent challenges surrounding research in this domain. First, the population in question is very heterogeneous, has high rates of comorbidity, and is relatively small (the major psychiatric neurosurgical centers now treat 10 to 30 new patients per year). These factors limit statistical power and complicate the quantification of efficacy and adverse-effect rates. Second, the major academic centers each have their own surgery of preference and use somewhat different measures to assess treatment response. Consequently, it is difficult to contrast or combine data across these different groups. Third, determining the cause of postoperative improvement is often confounded by exposure to other new therapies as they emerge. Fourth, the surgical equivalent of placebo-controlled trials has not been possible, because the inherent risks associated with surgical incisions and craniotomy make sham neurosurgical procedures unethical. With the advent of new radiosurgical techniques, sham-controlled studies of neurosurgical treatments may now be feasible.

The initial literature on modern psychiatric neurosurgery suffered several additional limitations. Some of the first case series entailed retrospective designs and did not include rigorous clinical evaluations with valid or reliable standardized instruments for assessing diagnosis and outcome. More recently, the major centers have instituted protocols under which high-quality data are gathered prospectively. Further progress is still needed regarding blind evaluation, identification of optimal controls, and standardization of dependent measures across groups. Nonetheless, the best available data indicate that contemporary psychiatric neurosurgery is effective in 25 to 70 percent of patients, with a modest rate of adverse effects. Current data do not, however, provide compelling evidence that any one of the four modern operations outlined is clearly superior to the others.

TREATMENT OUTCOME

For all four contemporary procedures, outcome cannot be fairly assessed in less than 3 to 6 postoperative months. Most clinical reports have used the Pippard Postoperative Rating Scale or a similar measure of global improvement. The Pippard Scale rates outcomes as follows: (1) symptom free, (2) much improved, (3) slightly improved, (4) unchanged, and (5) worse. Most studies consider categories 1 and 2 as significant improvement. Since most studies focus on one or another of the procedures, they are best reviewed according to surgical approach.

Outcome With Subcaudate Tractotomy In 1975 investigators reviewed results of subcaudate tractotomy in 208 patients with depression and obsessive-compulsive disorder over a mean 2.5-year follow-up period. Optimal data, including structured interviews, were available from a subset of 134 patients. Significant improvement was seen in 68 percent of patients with major depressive disorder, 50 percent of patients with obsessive-compulsive disorder, and 62.5 percent of patients with other anxiety disorders. Patients with schizophrenia, substance abuse, or personality disorders did poorly. Short-term adverse effects include transient headache and confusion or somnolence, which typically resolve in less than 1 week. Patients are usually ambulatory by the third postoperative day. Adverse effects include mild undesirable personality changes in 6.7 percent and seizures in 2.2 percent. Transient disinhibition syndromes were common. One patient died because of migration of an yttrium seed, and three others committed suicide. In 1994 a large-scale review of 1300 cases concluded that the procedure enables 40 to 60 percent of patients to lead normal or near normal lives, with a reduction in suicide rate to 1 percent versus 15 percent in a similarly affected control group with major mood disorders. There were no additional deaths in this series, and although the seizure rate was comparable to that in previous reports, the 1994 review did not find enduring personality changes. In addition, the investigators proposed predictors of positive response, including major depressive disorder, sudden onset of symptoms, emergence in the second half of life or peripartum, positive family history, and previous positive response to electroconvulsive therapy.

Outcome With Anterior Cingulotomy Ballantine and coworkers retrospectively reviewed 198 cases with mean follow-up of 8.6 years. They noted significant improvement in 62 percent of patients with affective disorders, 56 percent with obsessive-compulsive disorder, and 79 percent with other anxiety disorders. In 1995 a prospective report on 18 patients with obsessive-compulsive disorder was published. The investigators, using more-stringent criteria, found that 28 to 44 percent had responded favorably, with no serious long-term adverse effects. A subsequent report reviewed a series of 34 patients who underwent MRI-guided cingulotomy. Among patients with major depressive disorder, 60 percent responded favorably; among patients with bipolar I disorder, 40 percent responded favorably; and among patients with obsessive-compulsive disorder, 27 percent were classified as responders with another 27 percent categorized as possible responders. Short-term adverse effects include headache, nausea, and difficulty with urination; however, these typically resolve within 3 days. Patients are usually ambulatory within 12 hours following the operation and discharged on the third to fifth postoperative day. In the Massachusetts General Hospital experience of nearly 1000 anterior cingulotomies there have been no deaths and no infections; since the advent of MRI guidance, there have been no cases of stroke or hemorrhage. The incidence of seizure is from 1 to 5 percent—most often occurring in patients with a preexisting seizure history. Over the past 5 years the practice of treating patients who experience perioperative seizures with long-term anticonvulsant therapy has been discontinued, and no cases of multiple recurrent seizures have been seen. An independent analysis of 34 patients demonstrated no significant intellectual or behavioral impairments attributable to anterior cingulotomy; a subsequent study of 57 patients likewise found no evidence for lasting neurological or behavioral adverse effects.

Outcome With Limbic Leukotomy Kelly's group has published several reports, including an initial series of 66 patients studied prospectively with a mean follow-up of 16 months. They found significant improvement in 89 percent of patients with obsessive-compulsive disorder, 78 percent with major depressive disorder, and 66 percent with other anxiety disorders. In a separate report regarding 49 patients with obsessive-compulsive disorder, they noted that 84 percent were improved at 20 months follow-up. Short-term adverse effects include headache, lethargy, confusion, and lack of sphincter control, which may last from a few days to a few weeks. In particular, postoperative confusion commonly lasts at least several days, and patients are rarely discharged in less than 1 week. There were no seizures and no deaths; however, one patient suffered severe memory loss because of improper lesion placement, and enduring lethargy was present in 12 percent of patients.

Outcome With Anterior Capsulotomy Leksell and colleagues reported on their first 116 cases, noting a favorable response in 50 percent of those with obsessive-compulsive disorder and 48 percent of those with major depression. Other investigators conducted a prospective study of 35 patients with obsessive-compulsive disorder and observed that 70 percent had satisfactory outcomes. One review of the available literature on capsulotomy uncovered adequate data on 213 of 362 cases; of these, 64 percent were deemed to have shown significant benefit. Short-term adverse effects can include transient headache or incontinence. Postoperative confusion often lasts for up to 1 week. Recovery from gamma capsulotomy may be swifter and cause less discomfort, but adverse effects from radiation necrosis may be delayed for up to 8 to 12 months. Although patients are typically ambulatory in a matter of hours to days following the operation, length of hospital stay may be influenced by the duration of confusion. Investigators followed a cohort of 24 patients prospectively and observed one intracranial hemorrhage and one episode of seizure. Fatigue was present in 29 percent, 17 percent had poor memory, and 8 percent exhibited slovenliness. Weight gain is a common, enduring adverse effect, with a mean increase in mass of 10 percent. In other reports, up to 200 capsulotomy patients have been assessed via a variety of psychometric tests with no evidence of significant cognitive dysfunction or adverse personality changes. Although it can be difficult to discern from the published literature, apparent discrepancies in terms of efficacy and adverse effects in part reflect disparities in lesion size across different study cohorts. In some case series with larger capsulotomy lesions, reductions in symptoms were greater but came at the expense of more common and more-severe adverse effects; conversely, series involving smaller lesions yielded more-modest efficacy with a superior adverse effect profile.

Outcome Across Contemporary Neurosurgical Procedures Carefully selected psychiatric patients should significantly benefit, from contemporary neurosurgical treatment in 25 to 70 percent of cases, with at least 25 percent showing outstanding improvement. Response rates are marginally better for major affective disorders than for obsessive-compulsive disorder. While minor short-term adverse effects are common, severe or enduring adverse consequences are rare but include seizures in approximately 1 to 3 percent of cases. Although frontal syndromes, confusion, or subtle cognitive deficits can still be seen, they are influenced by lesion size as well as choice of surgical approach, and they are minimal in comparison with past procedures. Notably, overall cognitive function, as indicated by the standard intelligence quotient, is generally enhanced, which is attributed to the overriding beneficial effects of symptomatic improvement. Psychiatric neurosurgery likely reduces mortality as evidenced by data on comparative suicide rates. Nonetheless, patients who undergo and fail to benefit from these procedures are at particularly high risk for completed suicide. Therefore, as with any therapy, the potential risks and benefits of psychiatric neurosurgery must be weighed against the potential risks and benefits of foregoing this brand of treatment. Future research should help to identify predictors of response, enable further refinement of the procedures, and elucidate the mechanisms by which these surgeries produce their observed effects.

SUGGESTED CROSS-REFERENCES

Depressive disorders are discussed in Chapter 14 on mood disorders. Obsessive-compulsive disorder is discussed in Chapter 15 on anxiety disorders. The history of psychiatry is covered in Section 55.1.

31.33 OTHER BIOLOGICAL AND PHARMACOLOGICAL THERAPIES

CHARLES DEBATTISTA, M.D., D.M.H. AND ALAN F. SCHATZBERG, M.D.

Biological therapies for the treatment of mental disorders have been available since the dawn of civilization. Herbs, potions, and other treatments for emotional disturbance date back thousands of years. In the twentieth century, many new pharmacological and other biological therapies have been developed to treat psychiatric disorders. Some treatments such as insulin coma therapy have not survived. It remains to be seen whether newer interventions, such as rapid transcranial magnetic stimulation, will become important tools in modern psychiatric practice or be quickly dispatched to the vaults of history.

RAPID TRANSCRANIAL MAGNETIC STIMULATION

Rapid transcranial magnetic stimulation (rTMS) is a noninvasive technique for stimulating cells of the cerebral cortex. rTMS uses a magnet to allow focused electrical stimulation across the scalp and cranium without the pain associated with percutaneous electrical stimulation. rTMS was originally used to map cortical motor control and hemisphere dominance. Stimulating the motor cortex with rTMS results in a contralateral motor response. Likewise, stimulating Broca's area with rTMS has resulted in speech blockage. Currently, the potential use of rTMS for the treatment of neurological and psychiatric disorders is being explored actively.

In rTMS a powerful electrical current is passed through a small coil applied to the scalp. This current generates a focused magnetic field of 1.5 to 2 teslas that passes through the scalp and is largely unimpeded by bone or tissue. The magnetic field in turn depolarizes brain cells to a depth of 2 cm from the coil. Cortical interneurons are more likely to be stimulated than are cortical output cells because the interneurons tend to lie parallel to the brain surface. rTMS uses magnetic stimulators with multiple capacitors capable of generating very rapid pulses up to 60 Hz. Low-frequency pulses in the range of 1 Hz may have an inhibitory effect on cortical cells, while higher frequencies have an excitatory effect.

Some psychiatric conditions, such as major depression, may be characterized by hypoactive cortical areas. Functional imaging, including positron emission tomography (PET), has revealed a relative hypofrontality in some patients with major depression. It has been proposed that rTMS stimulation of these frontal areas would relieve symptoms.

rTMS is an experimental technique, and it currently has no approved psychiatric indications. At this time, the most studied psychiatric disorder in rTMS research is major depression. Several open-label and controlled studies have suggested that rTMS may be at least temporarily effective in both animal models of depression and patients with major depression. For example, in the forced swim test, in which rats quickly learn to give up swimming after repeated failures at escaping, they will swim longer after exposure to rTMS over the whole cortex. Other animal models of depression, such as apomorphine-induced stereotypy, are also effectively altered with rTMS.

A number of small, open-labeled studies have suggested that rTMS may be effective in some patients with treatment-resistant major depressive disorder as well as in those with milder major depressive disorder. More recently some small, randomized, placebo-controlled (sham) rTMS studies have suggested that the procedure may also be effective in psychotic depression. In addition, recent functional imaging studies have suggested that the baseline hypofrontality associated with major depressive disorder can be reversed with active treatment but not with a sham rTMS procedure. In addition to major depressive disorder, rTMS has shown some preliminary efficacy in obsessive-compulsive disorder and in posttraumatic stress disorder.

The application of rTMS to psychiatric conditions has lagged behind its neurological applications. rTMS has been used to map the motor cortex, help determine hemispheric dominance, and probe short-term memory. In some symptoms of Parkinson's disease, including bradykinesia, diminished reaction time has improved transiently with rTMS. Finally, rTMS has been used to help elucidate the pathophysiology of migraine headache, and some patients have had temporary symptom relief with rTMS.

PHOTOTHERAPY

Phototherapy (light therapy) was introduced in 1984 as a treatment for seasonal affective disorder (mood disorder with seasonal pattern). In this disorder, patients typically experience depression as the photo period of the day decreases with advancing winter. Women represent at least 75 percent of all patients with seasonal depression, and the mean age of presentation is 40. Patients rarely present over the age of 55 with seasonal affective disorder.

Phototherapy typically involves exposing the afflicted patient to bright light in the range of 1,500 to 10,000 lux or more, typically with a light box that sits on a table or desk. Patients sit in front of the box for approximately 1 to 2 hours before dawn each day, although some patients may also benefit from exposure after dusk. Alternatively, some manufacturers have developed light visors, with a light source built into the brim of the hat. These light visors allow mobility, but recent controlled studies have questioned the utility of this type of light exposure. Trials have typically lasted 1 week, but longer treatment durations may be associated with greater response.

Phototherapy tends to be well tolerated. Some patients have complained of irritability and headache. Ophthalmic damage was reported with earlier light boxes that emitted high-intensity light over long periods of exposure. Some investigators have implicated the concurrent use of tricyclic drugs or neuroleptic agents in ophthalmic damage associated with phototherapy. Newer light sources tend to use lower light intensities and come equipped with filters; patients are instructed not to look directly at the light source. As with any effective antidepressant, phototherapy has on rare occasions been implicated in switching some depressed patients into mania or hypomania.

Phototherapy is primarily indicated in the treatment of so-called seasonal depressions. Patients with more prominent hypersomnia as a feature of their seasonal depression may show more robust response to phototherapy. However, recent data suggest that phototherapy may benefit both other types of depression and other psychiatric disorders. For example, exposure to bright light has been suggested to reduce hospital stays in depressed patients, whether or not a seasonal component is evident. Also, case reports suggest that phototherapy may alleviate depression in immobile, terminally ill patients. Some preliminary data indicate phototherapy may benefit some patients with obsessive-compulsive disorder that has a seasonal variation.

In addition to seasonal depression, the other major indication for phototherapy may be in sleep disorders. Phototherapy has been used to decrease the irritability and diminished functioning associated with shift work. Sleep disorders in geriatric patients have reportedly improved with exposure to bright light during the day. Likewise, some evidence suggests that jet lag might be responsive to light therapy.

In mammals, the photo period of the day may significantly influence circadian cycles. For example, in some mammals a decreasing photo period stimulates hormonal events that precipitate hibernation.

Circadian rhythms are frequently disrupted in major depression, resulting in sleep disturbance and other symptoms. Exposure to light results in a phase advance that shifts the phase response curve earlier in the day. In addition, light suppresses the production of melatonin from the pineal gland at night. This hormone may affect

both mood and sleep cycles. The interplay of melatonin and the phase response curve in phototherapy is the focus of current investigation.

A number of controlled studies suggest that phototherapy is effective as monotherapy and as an adjunctive agent in the treatment of winter depressions. Studies have generally compared low-intensity light (<100 lux) with high-intensity light (>1500 lux). In general, patients with milder seasonal depressions appear more likely to respond to phototherapy treatment alone than do patients with more serious depression. Bipolar depression with a seasonal component frequently appears responsive to phototherapy, and these patients also appear to be more susceptible to light-induced mania.

Seasonal depressions often are characterized by the reverse neurovegetative symptoms of atypical depressions. However, studies of phototherapy in atypical depression without a seasonal component have failed to show benefit.

Research into the efficacy of phototherapy has been hindered by the lack of a placebo for bright light. Patients can differentiate low-intensity from high-intensity exposures.

ACUPUNCTURE AND ACUPRESSURE

Acupuncture originated in China about 5000 years ago and continues to be an important medical intervention in the East. America was first exposed to acupuncture by Chinese immigrants in the 1800s. The practice involves inserting fine needles at specific points in the body to relieve pain and other ailments. In the East, acupuncture is used to treat mental disturbances, including agitation, depression, insomnia, and anxiety states. Unfortunately, these indications have not been fully investigated in the West. The two indications for acupuncture that have been best studied in the West are pain management and the treatment of substance abuse.

Abundant data from both animal and human studies suggest that acupuncture can modulate pain responses. Clinically, acupuncture has been used to treat a variety of pain conditions including trigeminal neuralgia, neuropathies, chronic back pain, and headache. The analgesic effects of acupuncture appear to be at least partly mediated by endorphins and enkephalins. Multiple studies have reported that naloxone (Narcan) appears to block the analgesic effects of acupuncture.

A number of studies in the past 25 years suggest that acupuncture may be beneficial in the treatment of alcohol, cocaine, and opioid dependence. Studies in rats and humans suggest that acupuncture may limit narcotic withdrawal symptoms. Among alcoholic patients, acupuncture appears to improve the rate at which they complete detoxification programs and may reduce the frequency of alcohol cravings when used as a maintenance treatment.

Acupressure involves the application of tactile pressure (rather than the insertion of needles) in the same points used in acupuncture. Acupressure and acupuncture share a reported utility in the treatment of headaches, pain states, and possibly addiction. A number of recent studies have reported on the utility of acupressure in the treatment of nausea including postoperative nausea, nausea associated with chemotherapy, and hyperemesis gravidarum. Compared with pharmacological interventions, many patients reported equal benefit from acupressure.

SLEEP DEPRIVATION

Affective illness is characterized by sleep disturbance. Mania tends to be characterized by a decreased need for sleep, while depression may be associated with either hypersomnia or insomnia. Sleep deprivation may precipitate mania in bipolar I patients and temporarily relieve depression in unipolar patients. Approximately 60 percent of depressive disorder patients exhibit significant but transient benefit from total sleep deprivation. The positive results are typically reversed by the next night of sleep. The pathophysiology of sleep deprivation is not well understood; however, monaminergic transmission is reportedly enhanced by sleep deprivation. In animal studies, sleep deprivation resulted in substantial increases in both triiodothyronine (T_3) and thyroxine (T_4). Beta endorphin concentrations appear to be increased in patients who respond to sleep deprivation, but cortisol concentrations tend not to differ from those in nonresponders. Finally, sleep deprivation is associated in responders with increases in auditory evoked potentials (P300).

Several strategies have been used in an attempt to achieve a more sustained response to sleep deprivation. One method used serial total sleep deprivation with a day or two of normal sleep in between. This method does not achieve a sustained antidepressant response since the depression tends to return with normal sleep cycles. Another approach used phase delay in the time patients go to sleep each night, or partial sleep deprivation. In this method, patients may stay awake from 2 AM to 10 PM daily. Up to 50 percent of patients get same-day antidepressant effects from partial sleep deprivation, but this benefit also tends to wear off in time. However, in some reports serial partial sleep deprivation has successfully treated insomnia associated with depression. The third and probably most effective strategy combines sleep deprivation with pharmacological treatment of depression. A number of studies have suggested that total and partial sleep deprivation followed by immediate treatment with an antidepressant or lithium (Eskalith) sustains the antidepressant effects of sleep deprivation. Likewise, several recent reports have suggested that sleep deprivation accelerates the response to antidepressants including fluoxetine (Prozac) and nortriptyline (Aventyl, Pamelor). Sleep deprivation has also been noted to improve premenstrual dysphoria.

HERBS, VITAMINS, AND AMINO ACIDS

Nutritional status has long been deemed important in mental health, and certain, now rare, vitamin deficiencies can produce psychiatric symptoms. For example, severe niacin deficiency results in pellagra with its characteristic triad of skin lesions, gastrointestinal disorder, and psychiatric symptoms. The psychiatric symptoms include irritability and emotional instability progressing to severe depression progressing to disorientation, memory impairment, hallucinations, and paranoia. Folic acid deficiency is associated with depression and dementia, while B_{12} deficiency is associated with cognitive impairment, depression, and other affective symptoms. Severe malnutrition can result in apathy and emotional instability. Herbs of undefined safety and unsafe herbs are shown in Table 31.33-1.

Table 31.33-1 Safety Profiles of Herbs Sold for Brewing Teas

In 1968 the eminent chemist Linus Pauling coined the term “orthomolecular” to refer to the connection between the mind and nutrition. In his book *Orthomolecular Psychiatry* research articles were compiled supporting the notion that taking many times the recommended minimum daily dose of vitamins is useful in the treatment of schizophrenia and other psychiatric disorders. While some severe vitamin deficiencies may result in syndromes with a psychiatric component (i.e., niacin deficiency resulting in pellagra), empirical data and an American Psychiatric Association (APA) task force have failed to find evidence supporting the notion that schizophrenia and other disorders respond to vitamin therapies. However, that is not to say that vitamins and amino acids are of no importance in preserving mental health. Evidence indicates that severe vitamin deficiencies can result in psychiatric symptoms and that amino acid supplements may be pharmacologically useful in the treatment of some disorders. These are briefly reviewed below.

Thiamine, Vitamin B-12, and Folate In industrialized societies, severe vitamin deficiencies are rarely encountered except in certain populations. Those who are elderly, alcohol dependent, chronically ill, or who have certain types of gastrointestinal surgery are at greatest risk. Among the forms of vitamin deficiency most commonly encountered in the emergency room is acute thiamine depletion from alcohol dependence. While the chronic forms of thiamine deficiency that lead to

beriberi are rarely seen in the Western world, the fulminant depletion of already low stores of thiamine result in Wernicke's encephalopathy and Korsakoff's syndrome.

Wernicke's encephalopathy classically presents with the triad of ataxia, ophthalmoplegia, and mental confusion, but confusion and a staggering gait are perhaps most common. While Wernicke's encephalopathy is an acute process, Korsakoff's syndrome may be the permanent residue of this encephalopathy. Patients with Korsakoff's syndrome exhibit a well-circumscribed retrograde and anterograde amnesia that results from destruction of the mamillary bodies, and psychotic symptoms are also reported. Wernicke's encephalopathy is a medical emergency that responds to acute treatment with 50 mg of thiamine intravenously followed by 250-mg intramuscular injections daily until a normal diet is attained. The treatment of uncomplicated acute thiamine deficiencies usually involves 100 mg given orally 1 to 3 times per day.

Vitamin B_{12} deficiency or pernicious anemia is often seen in elderly adults, patients with gastric surgery, and malnourished depressed patients. The most typical psychiatric presentations include apathy, malaise, depressed mood, confusion, and memory deficits. B_{12} concentrations 150 mg/mL of serum are sometimes associated with these symptoms. B_{12} deficiency is a more common cause of reversible dementia and is typically assessed in dementia evaluations. The treatment of pernicious anemia usually involves daily intramuscular injections of 1000 mg of B_{12} for approximately 1 week followed by maintenance doses of 1000 mg every 1 to 2 months.

Folate deficiency has been associated with depression and dementia. Other psychiatric symptoms occasionally associated with depression include paranoia, psychosis, agitation, and confusion. The relationship of folate to depression has been debated over the years. Folate deficiency may be the consequence of anorexia in depressed patients and may also contribute to depression by interfering with the synthesis of norepinephrine and serotonin. Folate deficiency has been associated with anticonvulsant use (particularly phenytoin (Dilantin), primidone (Mysoline), and phenobarbital (Solfoton) and the sex steroids, including oral contraceptives and estrogen replacement. Perhaps the most common cause of folate deficiency is the malnourishment associated with alcoholism. Many folate deficiencies respond to 1 mg of folate orally per day; however, some more severe forms may require dosages of 5 mg up to three times a day.

Amino Acids Amino acids provide the substrate for neurotransmitters and have been used as adjunctive agents in the treatment of depression and sleep. L-Tryptophan (Fig. 31.33-1) was used for many years in this country and elsewhere to treat insomnia and augment standard antidepressants. L-Tryptophan, the precursor to serotonin, must be obtained from the diet. Patients who respond to serotonergic antidepressants may rapidly relapse into depression on a diet that is deficient in L-tryptophan. Interestingly, patients who respond to more-noradrenergic antidepressants appear less vulnerable to relapse with an L-tryptophan-free diet. In the 1970s and 1980s, l-tryptophan was used to augment standard antidepressants. It was part of the Newcastle cocktail for refractory depression, which included clomipramine (Anafranil) or phenelzine (Nardil), lithium, and L-tryptophan. A number of small studies have suggested that it did have some effect on augmenting antidepressants; however, it has little antidepressant effect of its own.

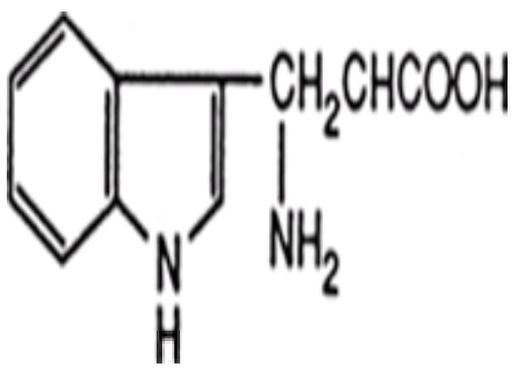

FIGURE 31.33-1 Molecular structure of L-tryptophan.

l-Tryptophan was also used as an over-the-counter treatment of insomnia in the United States. A number of studies suggested that l-tryptophan in doses of 1 to 4 grams before bedtime decreased sleep latency. l-Tryptophan has been unavailable in the United States since 1989, because of its association with the eosinophilia-myalgia syndrome, which may have been secondary to an impurity resulting from the processing of the compound.

Another amino acid that has been examined as an augmentor to antidepressants is phenylalanine. Phenylalanine is converted to tyrosine as a catecholamine precursor. Phenylalanine has been added to selegiline (Eldepryl) successfully in the treatment of some patients with refractory major depression. Tyrosine has been investigated as an augmentor to tricyclic drugs and may also have some mild antidepressant activity itself.

Herbs Over the years many herbs have been purported to affect mood and mental health. Homeopathic practitioners in many parts of the world, particularly Europe, use plant derivatives including belladonna, *Aconitum napellus*, and *argentum nitricum* (silver nitrate) to treat a variety of emotional maladies. Herbalists continue to recommend *Valeriana officinalis* (valerian) for insomnia, *Passiflora incarnata* (passion flower) for nervous unrest, and *Ginkgo biloba* (ginkgo) for memory problems and anxiety. Ginkgo is currently being investigated in the treatment of selective serotonin reuptake inhibitor (SSRI)-induced sexual dysfunction. However, few herbs have been subjected to any systematic investigation. One herb that has caught the attention of Western psychiatry recently is *Hypericum perforatum* (St. John's wort) for the treatment of major depressive disorders. St. John's wort has been used in folk medicine for hundreds of years and is still commonly used in Europe. In Germany, it is estimated that several million prescriptions for hypericum are obtained annually for the treatment of depression, anxiety, and sleep problems. Over 20 studies in the past 15 years have compared hypericum extracts with placebo and tricyclic drugs. A recent meta-analysis of these studies found that hypericum extracts were more effective than placebo and as effective as standard antidepressants in the treatment of mild-to-moderate depression. Furthermore, the hypericum-treated patients exhibited far fewer adverse effects than those taking standard antidepressants. The major problem with these studies has been the lack of rigor in the diagnosis of depression and the assessment of efficacy. Most of the trials were performed with private patients of internists, psychiatrists, and general practitioners.

ENDOCRINE THERAPIES

Hormones may act directly as neurotransmitters and also indirectly influence the activity of some neurotransmitters. For example, T_3 has numerous cortical receptors, and this thyroid hormone may also modulate central and peripheral noradrenergic activity. These actions may be the basis for liothyronine's (Cytomel) utility as an augmentor to antidepressants. In addition to thyroid hormone, the psychotropic effects of a number of other hormones remain under investigation.

Estrogen Estrogen has been used for many years to relieve menopausal symptoms and as hormone replacement therapy after menopause. Some evidence suggests that estrogens may have some antidepressant effects in postmenopausal women and that progesterone may be depressogenic. Estrogens appear to lower monoamine oxidase (MAO) concentrations and increase synaptic availability of monamines. In addition, estrogen displaces tryptophan from its albumin binding site and enhances the availability of this precursor to serotonin synthesis. Attempts to augment tricyclic drugs with estrogen have been mixed. Some studies have indicated that estradiol in dosages of 15 to 25 mg per day does augment tricyclic drug response in some women; other studies have failed to find any benefit. More-recent data suggest that estrogens modulate the effect of serotonin agonists. For example, estrogen appears to enhance the hormonal response of the serotonin agonist methylchlorophenyl piperazine (mCPP). In addition, preliminary data indicate that postmenopausal women who are on hormone replacement therapy are more likely to have a robust response to fluoxetine treatment for major depressive disorder than those who are not.

Dehydroepiandrosterone Dehydroepiandrosterone (DHEA), a precursor hormone for both estrogens and androgens, is available over the counter. Recent years have seen an interest in DHEA for improving cognition, depression, sex drive, and general well-being in elderly adults. Some reports suggest that DHEA in dosages of 50 to 100 mg per day increases the sense of physical and social well-being in women aged 40 to 70 years. Reports also exist of androgenic effects, including irreversible hirsutism, hair loss, voice deepening, and other undesirable sequelae. In addition, DHEA has at least a theoretical potential of enhancing tumor growth in people with latent, hormone-sensitive malignancies such as prostate, cervical, and breast cancer. Despite its significant popularity, there is a dearth of controlled data on the safety or efficacy of DHEA.

Melatonin Melatonin is another popular over-the-counter hormone used by many Americans on a regular basis for insomnia and jet lag. Melatonin is produced by the

pineal gland, and commercially available supplies are derived synthetically or from hog pineal glands. The hormone is released naturally by the pineal gland early in the sleep cycle and appears to contribute to natural sleep cycles. A number of small, brief studies have suggested that melatonin can act as a hypnotic in doses of 0.2 and 5 mg at night. Mostly anecdotal reports suggest that melatonin can also reduce the insomnia associated with jet lag. Some uncontrolled reports suggest that melatonin has mild antidepressant effects. However, because of its reciprocal relationship to b-adrenergic receptor activity, it may worsen depression in some patients. The long-term effects of melatonin use are unknown, and the efficacy of melatonin has been poorly studied at this time, given the widespread use of the drug.

Testosterone Testosterone derivatives are anabolic-androgenic steroids that appear to have psychotropic effects in both men and women. Testosterone is now given quite commonly to postmenopausal women to enhance libido, since this hormone appears to have significant effects on libido in both men and women. In hypogonadal men, testosterone may improve sexual dysfunction, mood, energy, muscle to fat ratio, and sex drive. High doses of testosterone derivatives are sometimes abused by bodybuilders, football players, and even teenagers trying to increase muscle bulk. Anabolic steroids have sometimes been associated with rage attacks, aggressive behavior, and untoward physical effects including accelerated atherosclerosis, testicular atrophy, alopecia, and enhanced tumor growth. Women who use testosterone at high doses also may experience irreversible virilization. Testosterone is now available in a transdermal patch and has been marketed fairly aggressively, resulting in a recent increase in prescriptions for both men and women.

OTHER PHARMACOLOGICAL STRATEGIES

Reboxetine In 1997, the first truly selective noradrenaline (norepinephrine) reuptake inhibitor (NRI), reboxetine, was introduced in Europe for the treatment of depression. Pharmacologically and chemically unrelated to tricyclics or SSRIs, reboxetine has significant affinity for the norepinephrine transporter, and little affinity for other neuroreceptors including serotonin, dopamine, histamine, muscarinic, and alpha adrenergic sites. Norepinephrine depletion studies suggest that while norepinephrine reuptake inhibition may improve all core symptoms of depression, norepinephrine regulation may be most closely correlated with patient improvements in energy, interest, concentration, agitation, helplessness, and hopelessness. Reboxetine, therefore, through its mechanism of action, may be useful for those depressed patients with either anergic symptoms or for those patients with comorbid anxiety.

Reboxetine is rapidly and extensively absorbed following oral administration. Maximal concentrations of 111 ng/mL are achieved within a mean of 2.4 hours after administration of a 4-mg tablet. The half-life of reboxetine is approximately 13 hours, and steady state levels are achieved within 5 days of dosing. Reboxetine is extensively metabolized after oral administration, primarily via cytochrome P450 (CYP) isoenzyme 3A4. Reboxetine does not inhibit the activity of cytochrome P450: CYP 1A2, CYP 2C9, CYP 2C19, and CYP 2E1. Reboxetine is a very weak inhibitor of CYP 2D6 and CYP 3A4, and based upon its low affinities for these enzymes, the potential for significant drug-drug interactions is minimal.

Area under the curve (AUC) and serum half-life values for reboxetine increase in elderly patients and in those with hepatic or renal insufficiency. A reduction in dose is warranted in these patients.

Reboxetine is an effective treatment for depression and is demonstrated effective long-term (one year) in preventing symptom relapse. Clinical studies have demonstrated efficacy for reboxetine as compared to imipramine, desipramine, and fluoxetine. In one study reboxetine demonstrated greater impact on patient-rated social functioning compared with fluoxetine. In a study of inpatients, reboxetine was also found to be significantly more effective than fluoxetine for patients with severe depression. A one-year maintenance study demonstrated the long-term effectiveness of reboxetine in preventing symptom relapse. One, double blind, placebo-controlled trial has demonstrated efficacy for reboxetine in the treatment of panic disorder. In this study, reboxetine-treated patients demonstrated significant reductions in weekly panic attacks, phobic sympton scores, and level of anticipatory anxiety.

Reboxetine is available in 4-mg functionally scored tablets. The initial dose for adults is 4 mg twice daily. For most patients, an increase in dose will not be necessary. However, if needed, the dose may be increased to a total of 10 mg/day in two doses after 3 weeks. In elderly patients or those with renal or hepatic impairment, therapy may be initiated at 2 mg (one-half tablet) one-half tablet) twice daily, and increased to a maximum of 6 mg/day in two doses after 3 weeks.

A variety of studies have demonstrated greater efficacy for norepinephrine-active compounds in the treatment of severe depression in comparison with SSRIs. While data is currently limited to one study, reboxetine may prove useful for patients with severe or treatment resistant depression. Depression in elderly patients is often characterized by lack of energy, impaired cognition, apathy, and agitation. Reboxetine appears to be effective and well tolerated in elderly patients at prescribed doses, offers minimal risk of drug interactions, and causes less agitation than placebo. In clinical tests, reboxetine does not appear to have a negative impact upon patient cognition.

As a result of the selectivity of reboxetine for norepinephrine, the product is generally well tolerated with a benign side effect profile. As compared with tricyclics, reboxetine has been associated with fewer reports of dry mouth, constipation, and other anticholinergic side effects. In addition, typical CNS side effects such as, agitation; anxiety; nervousness; and daytime somnolence; are reported less frequently by reboxetine-treated patients as compared to placebo-treated patients. A small percentage of patients reported sexual dysfunction on reboxetine therapy. The safety of reboxetine in overdose has been studied in animal models that suggest a very wide therapeutic margin for this product. Pharmacovigilance reports suggest safety in overdose for reboxetine, without a single death attributed solely to reboxetine overdosage. Unlike tricyclics, clinical pharmacology studies suggest that reboxetine does not prolong the QTc interval or impact significantly on cardiac conduction.

Bromocriptine and Levodopa Bromocriptine (Parlodel) (Fig. 31.33-2) is an ergot-derived dopamine agonist that has been used in medicine for many years as an adjunctive agent in the treatment of Parkinson's disease. Similarly, levodopa (Larodopa) (Fig. 31.33-3) is a dopamine agonist that has been a central treatment for Parkinson's for many years. Other uses for bromocriptine have included the treatment of hyperprolactin states including those associated with pregnancy and prolactinomas. Both levodopa and bromocriptine have proved useful in the treatment of restless leg syndrome and periodic leg movements. All dopamine agonists, including levodopa and bromocriptine, have been associated with producing psychotic symptoms, particularly in high doses and in elderly adults.

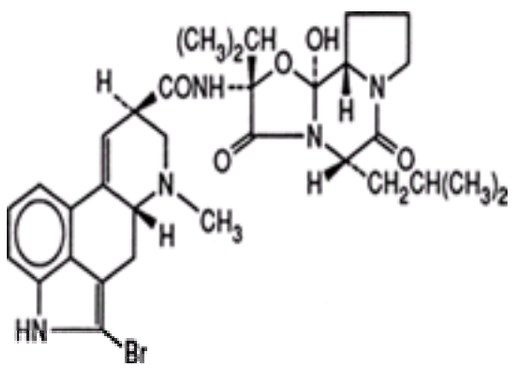

FIGURE 31.33-2 Molecular structure of bromocriptine.

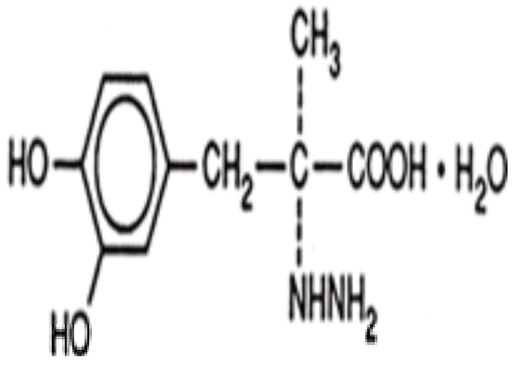

FIGURE 31.33-3 Molecular structure of levodopa.

In general psychiatry, bromocriptine has been used in the treatment of a variety of disorders. Bromocriptine has proved useful in treating neuroleptic malignant syndrome in many case studies. Antipsychotic- and head injury–induced akathisia has also responded to bromocriptine, although psychosis has also sometimes been induced in these populations. Some reports exist of bromocriptine helping with the negative symptoms of schizophrenia. Bromocriptine may also reverse the galactorrhea and amenorrhea associated with neuroleptic drug use. Recently, there has been an interest in the use of bromocriptine in addictive states, particularly cocaine dependence. The dopamine agonist properties of bromocriptine would appear to make it a rational choice for treating dependence to a dopamine agonist illicit drug. While some case reports have suggested that bromocriptine is efficacious in treating cocaine dependence, results of double-blind studies have generally been negative. Likewise, bromocriptine has not proved particularly useful in the treatment of alcoholism.

Fenfluramine and Dexfenfluramine Fenfluramine (Fig. 31.33-4) and dexfenfluramine are serotonin agonists that had been approved by the Food and Drug Administration as anorexiants. While fenfluramine has been available for many years, its popularity did not soar until reports of its success in the treatment of obesity when combined with the stimulant phentermine (Adipex, Zantryl) were widely reported in the popular media. In double-blind studies, both fenfluramine and dexfenfluramine were efficacious in the treatment of obesity. The drugs were approved for the treatment of significant or morbid obesity but quickly began to be used by many people with less-substantial weight difficulties. By 1996 16 million Americans were using one of these drugs. There were early reports of pulmonary hypertension associated with fenfluramine but the incidence was extremely low and did not significantly influence prescription practices. In 1997 a strong link was noted between the use of fenfluramine and valvular heart disease in young patients. All heart valves potentially involved in these patients were examined; the histopathology included plaque formation and fibrosis of the chordae. A number of patients required valve replacement surgery, and it was estimated that up to 25 percent of patients on fenfluramine or dexfenfluramine might have sustained some (although generally mild) valve damage. Thus these drugs were pulled from the American market in 1997, and many patients who had been on fenfluramine or dexfenfluramine were advised to obtain an echocardiogram.

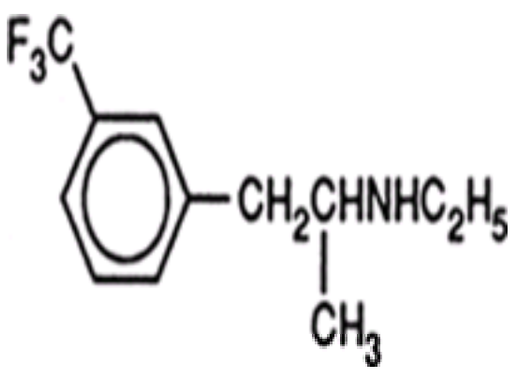

FIGURE 31.33-4 Molecular structure of fenfluramine.

In addition to their ill-fated use as anorexiants, fenfluramine and dexfenfluramine have had other uses in psychiatry. Perhaps most importantly, they have been used as chemical probes to evaluate the serotonin system and its relationship to the endocrine system. Case reports have suggested that fenfluramine may augment the anti–obsessive-compulsive and antidepressant effects of SSRIs. There have also been rare reports of serotonin syndrome associated with SSRI fenfluramine or dexfenfluramine combinations. Fenfluramine has been evaluated in the treatment of eating disorders such as bulimia nervosa and anorexia nervosa with inconsistent results. Results of recent studies of fenfluramine in the treatment of autistic disorder were negative.

Yohimbine Yohimbine (Yocon) (Fig. 31.33-5), an a_2-adrenergic receptor antagonist, has proved useful in the study of various anxiety disorders. In most animal models of anxiety, yohimbine is anxiogenic. In human studies, yohimbine has been used as a chemical probe to examine the biology of panic disorder and posttraumatic stress disorder. For example, intravenous yohimbine produces panic attacks in patients with a history of panic disorder at a significantly higher rate than in patients without such a history. Likewise, combat veterans with posttraumatic stress disorder who are exposed to oral or intravenous have a greater acoustic startle response than patients without posttraumatic stress disorder. In addition, some studies of combat veterans with posttraumatic stress disorder have demonstrated that yohimbine can precipitate an increase in core symptoms, including intrusive traumatic thoughts, emotional numbing, and grief.

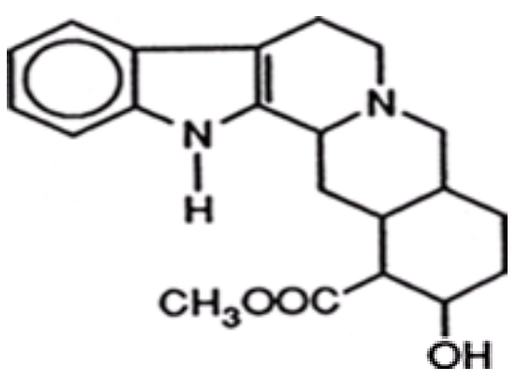

FIGURE 31.33-5 Molecular structure of yohimbine.

Yohimbine may also have therapeutic applications. For example, yohimbine appears efficacious in the treatment of some types of sexual dysfunction. Several case reports suggest that yohimbine can reverse the sexual dysfunction associated with the use of a serotonergic antidepressant. A number of placebo-controlled studies have examined the effects of yohimbine on various types of impotence. Yohimbine in combination with trazodone (Desyrel) has been effective in the treatment of psychogenic impotence. Some studies have also suggested that yohimbine may help mixed psychogenic and organic impotence while other studies have been negative.

The utility of yohimbine in other disorders remains to be seen. A few reports have suggested that yohimbine may be a useful strategy in the treatment of refractory depression but these reports have not been conclusive.

Dantrolene Dantrolene (Dantrium) is a direct-acting skeletal muscle relaxant. In contemporary clinical psychiatry, dantrolene is one of the potentially effective treatments for neuroleptic malignant syndrome, catatonia, and serotonin syndrome. Dantrolene is derived from hydantoin, as indicated in its molecular structure (Fig. 31.33-6). Dantrolene is structurally and pharmacologically unrelated to other skeletal muscle relaxants.

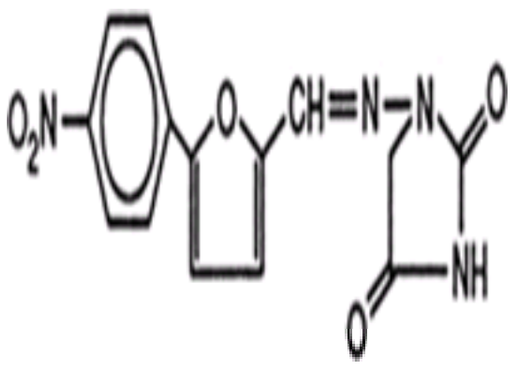

FIGURE 31.33-6 Molecular structure of dantrolene.

The skeletal muscle relaxant effect of dantrolene can cause muscle weakness and such symptoms as slurring of speech and drooling. Dantrolene also affects the gastrointestinal system (e.g., diarrhea) and the nervous system (e.g., headache and depression) and possibly toxic effects on hepatocytes, as indicated by an association with elevated liver function test results.

The primary psychiatric indication for intravenous dantrolene is muscle rigidity in neuroleptic malignant syndrome. Dantrolene is almost always used in conjunction with appropriate supportive measures and a dopamine receptor agonist (e.g., bromocriptine). Dantrolene has been used in efforts to treat other psychiatric conditions characterized by life-threatening muscle rigidity, such as catatonia and serotonin syndrome.

Because of its potential for severe adverse effects, dantrolene should not be used by psychiatric patients for any long-term treatment. Dantrolene should be used with caution by patients with hepatic, renal, and chronic lung diseases.

Disulfiram Disulfiram (Antabuse) is used to ensure abstinence in the treatment of alcohol dependence. Its main effect is to produce a rapid and violently unpleasant reaction in a person who ingests even a small amount of alcohol while taking disulfiram. Because of the risk of severe and even fatal disulfiram-alcohol reactions, disulfiram therapy is used less often today than previously.

The molecular structure of disulfiram is presented in Figure 31.33-7.

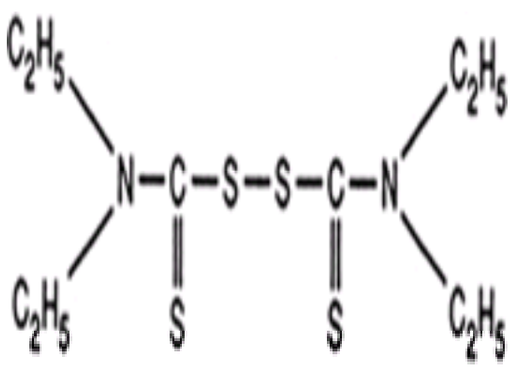

FIGURE 31.33-7 Molecular structure of disulfiram.

Disulfiram is an aldehyde dehydrogenase inhibitor that interferes with the metabolism of alcohol and produces a marked increase in blood acetaldehyde levels.

The treatment of alcohol dependence requires careful monitoring, since a patient can simply decide not to take the disulfiram; compliance with the medication should be checked if possible.

The intensity of the disulfiram-alcohol reaction varies with each patient. In extreme cases it is marked by respiratory depression, cardiovascular collapse, myocardial infarction, convulsions, and death. Most fatal reactions occur in patients who are taking more than 500 mg a day of disulfiram and who consume more than 3 ounces of alcohol.

The adverse effects of disulfiram in the absence of alcohol consumption include fatigue, dermatitis, impotence, optic neuritis, a variety of mental changes, acute polyneuropathy, and hepatic damage. A metabolite of disulfiram inhibits dopamine hydroxylase and thus potentially exacerbates psychosis in patients with psychotic disorders.

Drug-Assisted Interviewing The use of amobarbital (Amytal) and other sedative-hypnotic agents to facilitate interviewing in some patients has become uncommon but is still used in some settings. The primary indication for drug-assisted interviewing is ostensibly to recover repressed material in amnesiac patients and as a diagnostic probe in assessing conversion disorder, catatonia, confusion, and mutism. For example, if a patient is mute because of severe anxiety, the use of a sedative-hypnotic agent may facilitate gaining access to traumatic material. Catatonic patients anecdotally may become more activated when a hypnotic agent is administered. Confusion due to functional causes such as schizophrenia may improve with drug-assisted interviewing, while confusion due to organic causes may worsen. Despite the use of drug-assisted interviewing for over 60 years, there is very little evidence that interviewing with a sedative-hypnotic agent is any better than skillful interviewing without drugs. In some instances, memories are inhibited by the concurrent use of a sedative-hypnotic agent.

The amobarbital interview involves administering a 10 percent solution of sodium amobarbital at 0.5 to 1.0 mL per minute until mild sedation is achieved. Alternatively, intravenous diazepam (Valium) or lorazepam (Ativan) have been used as safer alternatives to barbiturates. Respiratory suppression is the most serious complication of drug-assisted interviewing, and the clinician must be prepared to take emergency measures as needed.

Given the risks of amytal interviews, drug-assisted interviewing using safer agents, such as benzodiazepines, has emerged as an alternative. Diazepam, lorazepam and other benzodiazepines have been used for this purpose. One of the most recent studies on drug-assisted interviewing used the very short-acting benzodiazepine midazolam (Versed) and a pulse oximeter to decrease the risk of respiratory suppression. Patients are treated with midazolam, 1 mg/mL given up to every minute depending on the levels of sedation observed and oxygen saturation. In addition to having a wider therapeutic index than barbiturates, benzodiazepines have the added advantage of having an effective antagonist available, flumazenil (Romazicon), which can quickly reverse the effects if needed.

Placebos Pharmacologically inactive substances have long been known to sometimes produce significant clinical benefits. The belief that a compound is helpful may often result in a patient's deriving considerable benefit from taking a substance, whether it is known to be pharmacologically active or not. For many psychiatric disorders, including mild-to-moderate depression and some anxiety disorders, well over 30 percent of patients can have significant improvement or a remission of symptoms on a placebo. For other conditions such as schizophrenia, manic episodes, and psychotic depression, the placebo response rate is very low. While suggestion is undoubtedly important in the efficacy of placebos (and active drugs), placebos may produce biological effects. For example, placebo-induced analgesia may sometimes be blocked by naloxone, which suggests that endorphins may mediate the analgesia derived from taking a placebo. It is conceivable that placebos may also stimulate endogenous anxiolytic and antidepressant factors, resulting in clinical improvement in patients with depression and anxiety disorders.

Just as placebos may produce benefit, they may also have adverse effects. In many studies, some adverse effects are likely to be more common with placebos than with the active drug. Some patients will not tolerate placebos despite the fact that they are supposedly inert. It is easy to discount such patients as being overly

suggestible. However, if beneficial endogenous factors may be stimulated by placebos, perhaps toxic endogenous factors may also be produced.

There are relatively few instances in modern medicine in which placebos should be routinely used. Clinical drug investigations are the clearest indication for the use of a placebo. However, even in pharmacological studies, the use of placebos sometimes presents an ethical dilemma. While placebo controls represent the gold standard in determining the safety and pharmacological efficacy of a given compound, the health of some patients may be jeopardized by being given placebo when there are known effective interventions. Psychotic patients sometimes decompensate on placebos, and placebo-treated depressed patients sometimes need to be hospitalized. However, without a placebo control in the early investigation of a new psychotropic agent, questions cannot be satisfactorily answered about the safety and efficacy of the drug.

Placebos are also routinely used in the detoxification of patients dependent on pain medications. This is often done in the form of pain cocktails in which the percentage of active drug is reduced with the patient being blind to the rate or extent of the reduction. The patient receives the same amount and type of liquid each time, although the composition of the cocktail may change daily. Patients are informed ahead of time, however, that the cocktail may be altered to contain the lowest amount of active drug they can tolerate. Some pain patients have been able to discontinue taking their narcotics and muscle relaxants altogether by being treated with a cocktail that no longer contains active drug.

Prudence is needed in contemplating the use of a placebo in clinical practice. Treating a patient with a placebo without consent can seriously undermine a patient's confidence in the physician if, and when, it is discovered.

TREATMENTS OF HISTORICAL SIGNIFICANCE

Chemical Convulsive Therapies Convulsive therapies for the treatment of serious psychiatric disorders date back hundreds of years, with the Swiss physician Paracelsus reportedly giving camphor by mouth to induce seizures and treat lunacy in the sixteenth century. Several European manuscripts from the 1700s describe the benefits of camphor-induced seizures for the treatment of mania and other forms of insanity. These manuscripts were largely forgotten until the work of Ladislas von Meduna in the 1930s. Von Meduna had experimented with intramuscular camphor monobromide, caffeine, strychnine, brucine, and other compounds before settling on pentylenetetrazol as a more reliable convulsant for the treatment of dementia precox. Pentylenetetrazol was more soluble than many other compounds and also had a quicker onset of action. Meduna typically used an initial dose of 5 mL of a 10 percent solution of pentylenetetrazol, followed by additional doses every minute if convulsions were not achieved. The major drawbacks of these chemical convulsions is that seizures sometimes did not occur, and patients would experience significant preictal discomfort including nausea and anxiety and thus, tend to decline further treatment. In the late 1930s and early 1940s, chemical convulsive therapy was replaced by the considerably more reliable electroconvulsive therapy (ECT).

Coma-Inducing Therapies. Insulin coma therapy emerged approximately the same time in the 1930s as electroconvulsive therapy. As von Meduna observed that epilepsy and dementia praecox were incompatible, Manfred Sakel observed that dementia praecox patients who went into a coma tended to come out less symptomatic. The treatment involved using incrementally higher doses of intramuscular insulin until the patient became comatose. Comas were initially terminated with glucagon after approximately 15 minutes, but an attempt was made to increase subsequent comas to a maximum of 60 minutes. Patients often required 60 or more treatments before results were seen. Complications including arrythmias and laryngeal spasms were not uncommon, and insulin coma therapy had a fatality rate of at least 1 percent and in some samples was considerably higher. The danger of the procedure and a controlled study in 1962 that suggested that it was no more effective than a similar period of unconsciousness induced by barbiturates hastened the demise of the procedure. However, some patients clearly appeared to respond to insulin coma therapy who did not respond to other available treatments.

Variations of insulin coma therapy included atropine coma therapy used briefly in the 1950s. Atropine in dosages of up to 200 mg a day was given to induce comas lasting 6 to 8 hours. If the patient did not wake up spontaneously, the coma was aborted by intramuscular physostigmine (Antilirium). As with insulin coma therapy, atropine coma therapy was said to be effective for the treatment of schizophrenia and mania. The most serious complications were hyperthermia and rhabdomyolysis. By the late 1950s, coma therapies had been all but abandoned for safer treatments, including ECT and effective antipsychotic drugs.

Continuous Sleep Therapy In the 1930s, therapies that altered consciousness for extended periods by seizure or coma were thought to be effective in the treatment of psychosis. Even earlier, psychosis was treated by inducing a state of continuous sleep for 10 days or more. Continuous sleep therapy was introduced for the treatment of psychosis into the early 1920s. This intervention originally involved the use of barbiturates to keep patients asleep 20 hours or more a day with brief interruptions for the patient to eat and use the bathroom. Complications of barbiturate-induced continuous sleep included allergic reactions, seizures on withdrawal, and respiratory depression ending in death. Later the combination of chlorpromazine (Thorazine) with benzodiazepines and other hypnotics was used to keep patients asleep for therapeutic purposes. Although there are some reports of improvement in anxiety states, obsessive-compulsive disorder, and schizophrenia, no controlled data are available to support these claims. Given the significant morbidity and clear lack of efficacy of this method, it was largely abandoned in the United States by the 1960s.

Hallucinogen Therapy. Many cultures have used hallucinogens, including mescaline, psilocybin, and ergots, for thousands of years to gain spiritual and personal insight. Lysergic acid diethylamide (LSD) was synthesized in the 1930s and was marketed to psychiatrists and other practitioners in the late 1940s under the trade name Desylid as a tool for understanding psychosis and for facilitating psychotherapy. Using LSD reportedly helped patients capture repressed memories and deal with anxiety, and it allowed patients to gain insight through an analysis of the primary process induced by the hallucinogen. Oral doses of 150 to 250 µg were administered occasionally by psychiatrists throughout the 1950s and early 1960s to facilitate psychotherapy with some patients. In the 1960s Timothy Leary advocated the wide spread use of hallucinogens, but the drugs were outlawed as class I controlled substances in 1965.

While no longer used for therapeutic purposes in this country, LSD has fulfilled part of its early promise as a probe for psychosis. Our more recent understanding of the pharmacology of LSD and its affinity to serotonin (5-hydroxytryptamine [5-HT]) type 2 (5-HT $_2$) receptors has supported the interest in developing serotonin-dopamine antagonists (atypical antipsychotics) with the 5-HT $_2$-receptor blocking properties.

Detoxification Therapies. The notion that some mental disorders may be related to a toxin of some sort is very old. Various methods have been used to combat potential toxins suspected to be included in the etiology of psychosis. More recent attempts to deal with suspected toxins include the use of blood transfusions in the 1940s and 1950s and hemodialysis in the 1970s. A few case reports in the late 1970s suggested that hemodialysis was an effective short-term and maintenance treatment in some schizophrenic patients. Patients were dialyzed daily until improvement was seen and were then maintained with dialysis every 2 to 8 weeks. Several patients were said to recover with hemodialysis and to relapse when the treatments were stopped. The investigators presumed a leucine-containing endorphin was the responsible toxin, but they (and other investigators) were unable to replicate their initial findings. Thus, hemodialysis joined blood transfusions and other detoxification therapies in the annals of psychiatric history.

CHAPTER 32. CHILD PSYCHIATRY

32.1 INTRODUCTION AND OVERVIEW

CAROLY S. PATAKI, M.D.

HISTORY

Over the last few decades, child and adolescent psychiatry has emerged as an academic discipline that covers a wide range of related topics from the development of the cortex, to the public health implications of childhood disorders. Child psychiatry began with the child guidance service delivery system. The goals of this system were to evaluate and provide psychiatric therapeutic interventions to children with psychiatric disorders. Although no psychiatrists were formally trained in child and adolescent psychiatry, a multidisciplinary team performed the evaluations and provided recommendations. That system developed from the historic Commonwealth Child Guidance Clinics of the 1920s, which endeavored to provide services to emotionally disturbed children and their families. The services rendered typically included family interventions by a social worker, some form of psychological testing administered by a psychologist, and psychodynamically based play therapy by a psychiatrist. Scientific study of childhood psychiatric disorders was not a part of the child guidance mission.

In 1946 the American Association of Psychiatric Clinics for Children was established, using the Commonwealth Child Guidance Clinics as a base for training. In 1953 an organization of medical practitioners was formed, the American Academy of Child Psychiatry. In 1959 the academy was legitimized as a medical subspecialty group with the establishment of board certification under the American Board of Psychiatry and Neurology.

EMPIRICAL MODEL FOR THE STUDY OF CHILD AND ADOLESCENT PSYCHOPATHOLOGY

Dennis Cantwell (1939–1997), was instrumental in the field of child and adolescent psychiatry by promoting an empirical model for the study of psychopathological disorders of childhood and adolescence. This was a novel direction for the field to take, given its history and the tradition of a psychoanalytic framework. The starting point for the empirical method was the recognition and classification of clinical phenomenology of child and adolescent psychiatric disorders.

PHENOMENOLOGY AND CLASSIFICATION

The clinical phenomenology of a psychiatric disorder comprises the essential core features, associated features, and relevant subtypes of the disorder. Once the essential features of a psychiatric disorder are identified, its natural history can be followed over time. Given the overlap of behavioral and mood symptoms in a variety of different childhood and adolescent disorders, defining the boundary between one disorder and another can be challenging. Additionally, within the more severely psychiatrically impaired child and adolescent populations, comorbidity is the rule rather than the exception.

Both categorical and dimensional approaches are useful in describing psychiatric syndromes in childhood and adolescence. The *Diagnostic and Statistical Manual of Mental Disorders* (DSM) uses categorical criteria to identify the clusters of symptoms that present together in multiple cases. This basis of identifying the clinical phenomenology of psychiatric syndromes and classifying them into reliable disorders facilitates meaningful investigation of many areas of child and adolescent psychiatry.

DEVELOPMENTAL PERSPECTIVE

Onset of a psychiatric disorder is a challenging concept in child and adolescent psychiatry, since it is difficult to pinpoint reliable landmarks for many of the disorders. Defining onset of a disorder by a single symptom might lead to inclusion of a heterogeneous group of disorders, whereas inclusion of only a rigid set of symptoms may exclude important subtypes. Age at onset of a disorder is an important scientific variable because it can give important etiological clues. Thus, age of onset can differentiate genetically determined disorders from those occurring sporadically and can separate cases of the same disorder that result from different genes. Earlier age of onset of some disorders (e.g., depressive disorders) have been associated with increased probability of depressive disorders in relatives.

Clinical Markers of Psychiatric Disorders Investigators are faced with the problem of finding reliable clinical indicators of disorders, while keeping in mind that the clinical emergence of symptoms is not necessarily correlated with the beginning of the pathological process.

Onset The investigation of age at onset of a disorder leads into studies of models of delayed onset of illnesses. Both developmental and genetic mechanisms of delayed onset of disease processes within the human body are applicable to psychiatric diseases. The following examples of delayed onset of disease shed light on potential future studies of the psychiatric disorders. Degeneration is a model of delayed onset of disease that characterizes diseases such as Alzheimer's disease and Parkinson's disease; that is, gradual loss of target neurons over time results in a predictable behavioral and neurological deficit. Developmental failure (i.e., a lack of physiological development within the nervous system at the appropriate time), is another model of disease process. Although most of the pervasive developmental disorders of childhood do not appear to have a delayed onset, a deficit of brain function and aberrant brain function seem to characterize these disorders.

Vulnerability Another theory of delayed onset of a disorder, the two-hit model, was first proposed in relation to the genetics of retinoblastoma. Essentially, the emergence disease is related to a genetic vulnerability triggered by exposure to a second event that might be environmental. For example, the rate of bipolar disorders increases markedly during adolescence, is maximal in young adulthood, and then gradually diminishes. One model to explain the emergence of a disorder with this distribution is a genetic predisposition (first hit) for the disorder and a second exposure, such as an adverse life event (second hit) that results in the emergence of the disorder.

Genetic anticipation is defined as the emergence of more-severe forms of a genetic disorder in successive generations. This mechanism has been shown to contribute to the severity of pathology in a number of genetic disorders that are caused by mutations of deoxyribonucleic acid (DNA) triplet repeat nucleotide sequences. Increases in repeat patterns of three nucleotides, (e.g., GACGACGAC) increase the length of DNA sequences and result in pathological genes. Triplet repeat expansion has been shown to be the mechanism of a number of genetic disorders including Huntington's disease and fragile X syndrome. Anticipation has been suggested as a possible explanation for increasingly severe psychopathology in successive generations in psychiatric disorders. Future investigation of possible molecular bases of anticipation in psychiatric disorders, such as the increased density of genetic triplet repeat expansions shown in Huntington's disease and fragile X mental retardation, is on the horizon.

NEUROBIOLOGY

The early development of the brain is an area of research that is of increasing interest to child psychiatrists. Developmental biologists have identified a critical period for the acquisition of various cognitive and motor skills. Environmental factors including exposure to alcohol, drugs, or infections may alter brain development during critical periods of nervous system growth and development and thus change later skills potentials. For example, differentiation of neurons and their migration to their proper places are critical for making necessary synaptic connections. Recent research on the acquisition of language has shown that early neuronal activity can influence the organization of the brain. Functional magnetic resonance imaging scans have determined the spatial relationship of language centers in children who have first and second languages. Children who learn first and second languages early in life have evidence of changes in both language centers in the same cortical region, whereas when a second language is acquired in adult life, the new language center is not represented in the same cortical region as the first language. Studies such as this are crucial for ultimate understanding of both cognitive and behavioral function and dysfunction. Moreover, an understanding of the critical

periods of brain development may drastically alter our understanding of early childhood behavior and its influence on later function.

In addition to the timely birth and migration of neurons to their final cortical destinations, interneuronal synaptic connections must develop for the acquisition of important skills. Finally, during development multiple neurons will die, and the brain will go on to function quite well. These various maturational steps are believed to be mediated by growth factors that send signals from the surface of a neuron into a cell.

Advances in genetics and neuroscience have opened up doors within child and adolescent psychiatry to the understanding of single-gene disorders, such as fragile X syndrome and more complex neuropsychiatric phenotypes. Disruptions of brain development may account for some of the more common disorders seen by child and adolescent psychiatrists, such as dyslexia. Overall, the broader our understanding of neurobiology and neuroscience of the brain, the greater our chance of comprehending the complex behavior of children and adolescents.

RISK AND PROTECTIVE FACTORS

Risk factors include all variables that increase the probability that a given child or adolescent will develop psychopathology. Protective factors decrease the risk of developing psychopathology. Demographics, psychosocial factors, biological factors, genetics, family environment, and external environment interact to produce risk and protection from psychiatric disorders. Rarely can a single risk factor account for the entire variance between the emergence or inhibition of a psychiatric disorder. Thus, the study of psychiatric risk is complicated and multifactorial. Risk factors often studied for influence on the emergence of psychiatric disorders among children and adolescents include family history of psychiatric disorders, social class, intellectual function, adverse life events, temperamental factors, and the quality of family and peer relationships. Developmental delays, child maltreatment, and high levels of family conflict increase the risk of psychiatric disorder. Protective factors that have been identified and studied include individual temperamental predisposition, positive family relationship, and other attributes of the external environment.

TYPES OF INTERVENTIONS

Interventions that can be investigated for efficacy include clinical interventions, targeted interventions, and universal interventions. Intervention studies may be the most important component of an empirical model of study within child and adolescent psychiatry.

Clinical interventions are those in which a family with a child or adolescent who has been identified as having a psychiatric problem seeks treatment. Psychosocial, psychopharmacological, and other environmental interventions can be compared with a placebo condition and with each other. Such efficacy studies are necessary to substantiate the benefit of the treatments. Because close to one half of families who begin psychiatric treatment terminate prematurely, the nature and delivery of the treatments also merit investigation.

Targeted interventions are those designed for children who have been identified as having an increased risk of a psychiatric disorder but whose families are not seeking treatment. Children can be identified either by an external factor such as a family characteristic (e.g., drug-addicted parent, family receiving state assistance) or through a behavior (e.g., defiance or aggression in the classroom). Thus, a child can be monitored or receive some psychosocial intervention on the basis of the risk factor, in some cases correlated with an already existing psychiatric disorder and in other cases preempting the emergence of a psychiatric disorder. The difficulty with these interventions is that sometimes interventions may not be wanted by the families or the threshold for identification is not correlated with a clinically relevant behavior.

Universal interventions are received by all children and families within a particular geographical distribution. They may occur throughout a targeted school or community or on a citywide, statewide, or national basis. This prevention strategy, also termed *primary prevention*, obviously reaches more children than any other method of intervention, but questions arise about the benefit and need of the intervention for the population at large as well as the cost-benefit ratio.

Much study of the risk factors and etiology of psychopathology is needed to develop the most effective combination of prevention strategies for children and adolescents. Interventions in child and adolescent psychiatric disorders will continue to be influenced by genetics, family environment, adverse life events, biological factors, and behavioral genetic studies. The goals within child and adolescent psychiatry are to diminish risk factors and enhance protective factors to prevent the emergence of psychiatric disorders in this population.

SUGGESTED CROSS-REFERENCES

In-depth reviews of the following areas of child and adolescent psychiatry can be found in Chapter 32, Chapter 33, Chapter 34, Chapter 35, Chapter 36, Chapter 37, Chapter 38, Chapter 39, Chapter 40, Chapter 41, Chapter 42, Chapter 43, Chapter 44, Chapter 45, Chapter 46, Chapter 47, Chapter 48 and Chapter 49. Chapter 32 details normal child and adolescent development; Chapter 33 discusses the psychiatric examination of the infant, child, and adolescent. Chapter 34 covers mental retardation; Chapter 35 ,Chapter 36 and Chapter 37 detail learning disorders, motor skills disorders, and communication disorders. Chapter 38 reviews the pervasive developmental disorders; Chapter 39, the attention-deficit disorders; and Chapter 40, the disruptive behavior disorders. Chapter 41 covers feeding and eating disorders of infancy and early childhood. Chapter 42 covers tic disorders; Chapter 43, elimination disorders; Chapter 44 details stereotypic movement disorders and other disorders of infancy, childhood, and adolescence and reactive attachment disorder of infancy or early childhood. Chapter 45 discusses mood disorders; Chapter 46 reviews anxiety disorders of childhood, including separation anxiety disorder, obsessive-compulsive disorder, and selective mutism. Chapter 47 discusses schizophrenia with childhood onset. Chapter 48 details psychiatric therapies, including individual psychotherapy, short-term pshildhood, including separation anxiety disorder, obsessive-compulsive disorder, and selective mutism. Chapter 47 discusses schizophrenia with childhood onset. Chapter 48 details psychiatric therapies, including individual psychotherapy, short-term psychotherapy, cognitive and behavioral therapies, group psychotherapy, pharmacotherapy, residential and inpatient treatment, community-based treatments, partial hospital and ambulatory services, and psychiatric treatment of adolescents. Chapter 49 includes special areas of interest within child and adolescent psychiatry including psychiatric aspects of day care; adoption; foster care; physical abuse, sexual abuse and neglect of children; children's reaction to illness, hospitalization, and surgery; psychiatric sequelae of human immunodeficiency virus (HIV) and acquired immune deficiency syndrome (AIDS); childhood or antisocial behavior; borderline intellectual function and academic problems; dissociative disorders; posttraumatic stress disorder; gender identity and sexual issues; identity problem and borderline disorders; adolescent substance abuse; forensic child psychiatry; ethical issues in child psychiatry; school consultation; and psychiatric prevention in children.

32.2 NORMAL CHILD DEVELOPMENT

MAUREEN FULCHIERO GORDON, M.D.

A growing, multidisciplinary body of developmental information encourages contemporary psychiatry to evaluate child development and its principles from an integrative perspective. Such an approach emphasizes certain essential elements of development: its inherent genetic predispositions, its interactive qualities, its repetitive patterns, and its transactional processes. An integrative approach considers such concepts as the “tutoring” of development. It focuses upon newer areas of research, particularly those involving temperamental and moral development, and stresses the independence and interdependence of separate areas of growth. The concept of normality, as it relates to development, frames the dynamic process.

Just as the developmental process necessarily incorporates change and continuity, an integrative approach to the study of development does not diminish any prior knowledge of child development. It allows instead an opportunity for the integration of the various biological, psychoanalytic, learning, psychosocial, and interactive theories into a coherent view of a growing and developing child. This approach is especially important for psychiatrists who are trying to understand the period from conception to the end of middle childhood, when development is the most substantial, dramatic, and fundamentally important. An integrative approach perceives infants and children as active participants in their move toward competence. It is a dynamic model of growth that is multidimensional and constantly evolving (Fig. 32.2-1). It incorporates the most recent biotechnical evidence to offer specific mechanisms that confirm development's essential interactive nature.

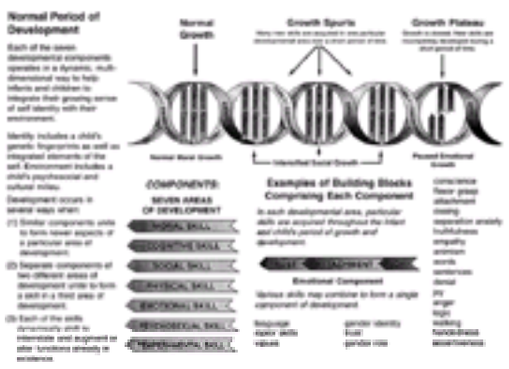

FIGURE 32.2-1 A transactional model of normal child development. The transactional model is aimed at helping to demonstrate the dynamic nature of the developmental process. This model, inspired by DNA's structure, describes an integrated approach to the normal development of infants and children. It represents the essential way in which a child's identity interacts with the child's environment to support the developmental process. In this view, identity represents a child's genetic prints as well as components that compose a child's sense of identity. Family environment represents the psychosocial milieu that surrounds the child. Development occurs when various components of behavior, supported by the child's identity and milieu, come together to form a completed set of maturational skills in each of the seven developmental areas. In contrast to the more traditional linear or branching model, this interactive schematic helps one see how development in one area may continually influence past or future growth in each of the other separate developmental lines. It demonstrates the active, dynamic independence and interdependence of development as well as its interactive nature. (© 1997, M. Gordon, M.D.)

SIGNIFICANT THEMES UNDERLYING CHILD DEVELOPMENT

The various theories contain certain important themes that help psychiatrists understand the complexity and consistency of children's growing experiences. These principles offer explanations for the transformation of simple collections of cells into 11-year-old children who can respond and interact with their world. There are at least four recurring and significant themes.

Development as Inherent in Nature Genetic predispositions are the foundation for any consideration of development's inherent nature. Developmentalists refer to this internally generated, exquisitely programed part of a child's development as organismic growth. Genetics dictates species-specific developmental potentials. Children, however, have their own special, genetically motivated patterns and ranges that shape their individual differences.

Only recently have developmentalists identified genes that are associated with behavioral traits and syndromes. Replacing the imprecision of genetic inferences—as obtained from twin studies—with the clarity of information derived from specifically identified genes is just one example of the enormous potential contribution of this new information to the study of child development. It has been suggested that contemporary developmentalists will have to learn to use newly found deoxyribonucleic acid (DNA) markers to answer questions about developmental interactions between nature and nurture, including psychosocial and physical environmental risks and influences, comorbidities, and genetically influenced, revised concepts of normality.

Development as Transactional in Nature The transactional quality of development, which is an interplay of nature and nurture, forms the basis of most current thinking and research. Mechanistic factors from conception on are quickly interwoven with the child's environmental and behavioral circumstances to alter an infant's growth patterns. The practice of tutoring is a transactionally derived principle. Developmental tutoring recognizes that children interact with their environment even before birth in ways that significantly stimulate or inhibit potential. A mother's ingested folic acid helps her fetus avoid the risk of spina bifida. A carefully designed mobile lets an infant engage in activities that are visually and auditorily stimulating. Jungle gyms stimulate physical development and coordination. Play dates allow an 8-year-old child to advance social and moral skills.

Transactional research and views have opened up new considerations for child developmentalists. The developmental entity, temperament, was differentiated as the result of observations made during transactionally oriented studies called longitudinal studies. The practice of interconnecting various theories has promoted a new emphasis to be placed upon other developmental areas, such as moral development, which is significantly influenced by cognitive, social, and gender issues.

Normality in Development The concept of normalcy is often implied in development; yet, as used in this arena, it has different connotations. *Normality* may mean freedom from pathology. In this context (but not without opposition), labeling a child as normal with respect to developmental maturity is a common practice. Normality may simply refer to statistics or it may reflect what is acceptable culturally. In the near future, normality may involve a comparison of genetic profiles. In transactional theory, the cultural concept, once having limited validity because of its changing norms, has taken on new importance. In child psychiatry *normality* conveys a continuum with various periods of rapid change. This concept of normalcy is important for understanding a critical, transactional principle: a child's development operates as a two-way street of regression and progression (Fig. 32.2-2). Typically occurring before growth spurts, environmental or internal changes can create a stress that causes developmental skills in a particular area to be lost. This phenomenon is called normal regression. Just before an infant makes an exciting quantum leap in growth, for example, it is common for parents to describe their child as particularly irritable or cranky. From a transactional viewpoint normal regression does not impede progression in other areas. A child can continue working socially on peer relations, for example, while regressing cognitively by resisting school assignments. This is in contradistinction to abnormal, or neurotic, regression. Neurotic regression creates a self-perpetuating psychosocial isolation—a break between individuals and their environments—that impedes further development in other areas. A neglected 5-year-old who is emotionally regressed will have trouble developing social empathy, applying temperamentally assertive skills, and cognitively refining problem-solving tools.

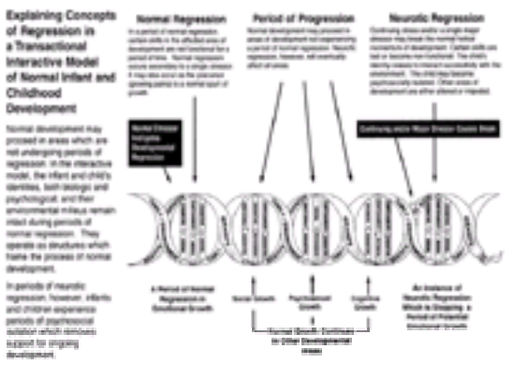

FIGURE 32.2-2 A transactional model of regression in normal infant and child development. Diagrammatic demonstration of how a transactional view of normal development can explain the concepts of normal regression, progression, and neurotic regression in normal child development. A transactional, dynamic model is used to explain how normal regression may occur yet not inhibit further development. It shows the sequence of normal development, called progression, and demonstrates how continued stress may actually separate the two supports a child must maintain to sustain and continue development. When enough stress occurs, psychosocial isolation results. In the process, children (identity) become separated from their psychosocial milieu (family-environment), *neurotic regression*. The model shows how disruptive this type of regression (as opposed to normal regression) can be to the entire developmental process.

Distinct Areas of Development To study child development, growth is often differentiated into distinct developmental areas. Each area is considered to mature independently, yet they interact in ways that ultimately change the outcome of each separate event. Developmentalists term this the *interdependence and independence of development*. Normal healthy development exists when there is significant harmony between both the level attained and the separate areas or lines. When infants and children do not mature in quantitative ways in each or all of these areas they are said to have *developmental delays. Developmental disorders*, on the other hand, involve behavior that differs qualitatively from the norm. These disorders are differentiated from *discontinuous development*, which refers to new ways of reacting at particular periods called *stages*. Child development has seven significant areas to be considered: physical, temperamental, cognitive, social, emotional, moral, and psychosexual.

THEORIES OF DEVELOPMENT

Theories help psychiatrists understand how a single cell grows into a complex child who has all the skills necessary to enter adolescence. By incorporating major developmental themes, theories help explain principles of development and create guidelines for translating concepts into practical applications. Theories help psychiatrists predict behavior in children and often explain the significance of their observations. Psychiatrists can test hypotheses that pinpoint factors that influence development. Understanding the significant theories in each of the seven major developmental areas is a valuable tool for the psychiatrist attempting to integrate the wealth of developmental knowledge of infants and children.

Physical Development of Infants and Children Human physical development is directed at helping infants and children perceive and negotiate with their external world. During infancy and early childhood there is enormous physical growth, including changes in overall body growth, size, shape, body composition, and structures. By the time children end the period of infancy, at about 2 years of age, their heights have reached half of their adult height potential; their weight has quadrupled; and they have acquired skills that help them to function in their external worlds. Especially important, however, is the astounding maturation that occurs in the central nervous system (CNS). This development allows children to acquire several paramount skills: motor abilities, perceptual abilities and pathways, and language (Table 32.2-1). This particular part of physical development uses much of the developmental energy of infants and smaller children. Most often the play of infants and young children involves practicing new physical skills or demonstrating competence with others.

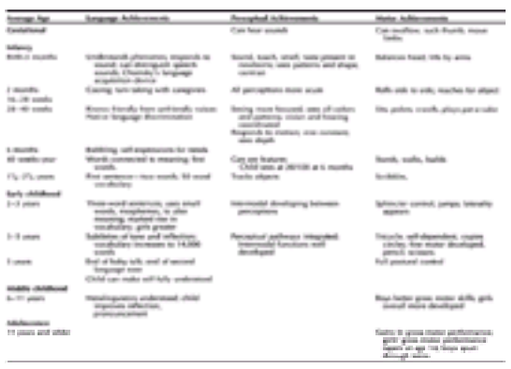

Table 32.2-1 Physical Development—Maturation of the Central Nervous System: Comparing Language, Perception, and Motor Skills

As with other areas of development, physical development is motivated by multiple pushes toward growth. Biological influences, for example, are mediated by the body's hormones: the pituitary monitors hormonal effects upon all tissues; sex hormones regulate sexual maturational changes; thyroxine influences brain and overall body development; adrenaline and neurotransmitters alter CNS maturation in particular and may influence overall development in general. This significant process begins long before birth. By the end of the first intrauterine month, a fetus has grown up to 10,000 times its size at conception and has a heartbeat and the beginnings of several organs. By the second month, a fetus has all its organs. By the fourth month it has human qualities, including the ability to breathe, suck, squint, hear, swallow, urinate, and move.

Even at this earliest of human stages, environmental factors interact with the organic to serve as tutors of growth. Maternal drug and alcohol use and maternal emotional issues, including stress, significantly affect outcome for the developing fetus. Cocaine, for example, increases norepinephrine and serotonin concentrations at the cellular level. In recent survey, newborns whose mothers had untreated prenatal depression showed lower birth weights and less alert behavior than newborns whose mothers had been treated with selective serotonin reuptake inhibitors (SSRIs). Proper nutrition, appropriate caregiving, and adequate stimulation allow maximal physical growth; illness, malnutrition, inadequate stimulation, and emotional deprivation can inhibit growth potential.

Sociological trends also alter physical growth patterns between generations and geographical regions. In economically deprived nations children often grow more slowly and reach maturity at much lower heights than their predecessors. In the United States, on the other hand, California children are rated on height scales that are calibrated 2 inches above the norm.

The enormous physical growth in infancy and childhood helps to magnify growth patterns, some of which are not exclusive to this area. Development is not a simple linear process. Growth in all areas occurs in spurts, which are followed by plateaus of much slower development. In one study, infants grew up to ½ inch a day and then did not grow taller for as long as 5 weeks. In older children, the plateau between spurts widens, but the pattern remains the same. Growth spurts are characteristically preceded by a regressive phenomenon, colloquially termed *growing pains*.

Unique to physical growth, however, is a pattern of universal direction, both a *cephalocaudad direction*—an infant's head is largest at birth and gradually becomes smaller in relation to the extremities and trunk and a *proximodistal direction*—growth extends from the center of the body and moves outward to the extremities, the lower extremities, and then the hands. These directions continue and reverse only when adolescence has begun. Development is also affected by sex. The growth rate for males lags behind that of females until both reach maturity. Girls between the ages of 3 and 10 typically spurt physically 6 months to 1 year ahead of boys. Even in the fetal stage, gender influences the rate of growth. By 20 weeks following conception, male fetuses are already 2 weeks behind female fetuses in development. Growth in children physically is *asynchronous*—various parts of the body spurt at different rates and at different times. In infants, for example, heads

and chests mature much more rapidly than the extremities. The brain, sexual organs, bladder, lymphatic organs, and individual tissues differ in both times of peak growth as well as appearance of growth spurts. Body composition changes as well. The fat composition of the body, for example, increases until the tenth month and then diminishes until adolescence.

Recording Physical Growth—Growth Curves Versus Milestones The various ways in which growth is recorded reflects physical development's patterns and principles. *Distance curves* are used to monitor an individual child's annual physical progress by charting a child's specific height and weight and comparing them with those of a sample of children at each chronological age. Results on such curves demonstrate, for example, the difference between growth patterns of boys and girls. *Velocity curves*, on the other hand, show the average annual growth for an infant or child. Data from velocity curves show growth spurts for an individual child. Milestones are based upon comparisons between children and convey a normal range of expectancy for acquiring various skills. One commonly used milestone-based tool is the Denver Developmental Screening Test devised to screen children from 1 month to 6 years of age in selected areas of development, such as language. Another measuring instrument popular with child psychiatrists and pediatricians is Berry Brazelton's Neonatal Behavioral Assessment Scale.

Physical Development of the Central Nervous System In infants and children, CNS maturation allows the development of a child's motor skills, perceptual patterns, and language. Thus, children eventually master their physical environment; take in essential information; and communicate their needs, wants, and feelings to those with whom they relate. The importance of CNS development makes it worthwhile to look closely at various theories that describe its principles.

Biological theorists describe the development of the CNS as a gene-regulated, orderly appearance of certain morphological structures, brain development, and synaptic maturation. They emphasize milestones for rating the timing of cell proliferation, differentiation, and maturation. One of their major contributions to understanding children's growth is the introduction of important terminology. They describe *critical periods*, which refer to increased activity in certain parts of the system within a short, specified period of time. Such periods suggest windows of opportunity for maximal growth in that area as well as times of particular vulnerability. The latter developmental phenomena, called selective vulnerability, explain why certain areas are damaged by harmful agents at particular times. This principle is used to explain the appearance of certain pathology, such as perceptual problems. Rubella, for example, causes the greatest damage to the fetus' auditory and cardiac system if it is contracted by the mother prior to the eleventh week of pregnancy, when the most fundamental development in those particular organs is occurring. Critical periods are sometimes used in reference to other areas of development as well. Biologists also refer to *plasticity*, the concept that the brain can compensate, within limits, by forming alternative pathways when toxic events damage part of its functions.

Environmentally oriented developmentalists emphasize the importance of a second category of regulators that include externally influenced and dependent factors. Illness, toxins, X-rays, drugs, and even therapeutic interventions can alter brain structure and chemistry. This schema can explain normal alterations in development as well as neuropathology. External assaults are most damaging during critical vulnerable periods and are most effective in restoring function at those same times.

New and exciting biotechnical research, however, has discovered processes that integrate much of the information previously used to describe development from gestation through middle childhood. This work demonstrates that although the brain's full supply of neurons is present at birth, critical neural pathways that depend upon environmental stimulation for their maintenance and development—shape and reform the original morphology. From the third gestational week, when neural tube development enters a rapid phase of proliferation, an infant must interact with the environment to generate the forces that will cause hundreds of thousand of proliferating neurons to shape structures and pathways. Identification of the genes and the mechanisms that accomplish this bridge between nature and nurture is the first solid evidence for the validity of a transactional theory of development. Biotechnical sophistication has resulted in identifying over 50,000 genes that use environmental stimuli to reshape the nervous system. One group includes morphology-inducing genes, such as the “hedgehog gene,” which encode proteins that create interneurons responsible for neural structural changes. A second group of genes, which includes the cyclic adenosine monophosphate (cAMP) response-element binding protein (CREB), encode electrical stimuli that translate environmental responses into new synaptic pathways. Together, these groups of genes actually determine whether there is proliferation or destruction of neural synapses and pathways.

Practical implications of this mechanism for explaining child development are enormous. During the first 10 years of life a child's nervous system most actively interrelates with environmental stimuli through gene-induced neural synapses. The first 3 years, in particular, when the bulk of neural synapses are formed, are crucial. At age 2, a child has twice the number of adult synapses. A child's brain, which begins to develop during the first gestational month, becomes proportionately the largest organ in the child's body, as it reaches 95 percent of its adult size by age 5. After age 10 the brain becomes actively involved in destroying weakly formed synapses. Such findings reinforce the critical importance of early childhood development. Peak times of synapse formation for each skill help explain the mechanism of critical periods. Biotechnically explained mechanisms shed new light on the ways in which environmental factors, including “tutoring,” can affect development of the CNS. During the period of most active synapse formation, a child's repeated experiences stimulate neural pathways. Such pathways interact with genetically controlled enzymes and other proteins to create neural synapses. The synapses in turn actually form parts of the brain responsible for special functions: motor development, perceptual development, and language. Understimulated pathways atrophy the parts of the brain that correspond to unused pathways. Newer and safer techniques for evaluating brain morphology, such as magnetic resonance imagery (MRI), delineate gross morphological changes that may parallel the synaptic changes. For example, MRI studies verify that between the ages of 3 and 18 years, the corpus callosum—composed of white matter or myelinated matter—increases approximately 1.8 percent in size while the brain's gray matter decreases.

CNS MATURATION AND MOTORIC GROWTH Motor activity, which allows children to begin exerting control over their environment, results from similar, specific patterns of brain synaptic maturation. By the time children reach age 2, they have trillions of new synapses available for their motor work. Children engaged in physical play are actually stimulating structures in the brain that are responsible for motor balance and coordination. Simple actions, such as a baby's reaching for a rattle, activate the vast motor-neural network, and the brain in turn responds to such activity. The cerebellum, a major part of the motoric brain, reacts by myelinating to its full maturity by the time a child is 4 years old. It is no coincidence that gross motor skills peak in 4-year-old children.

In general, motor development in children is extremely important because it allows them to acquire two of the most fundamentally important functional human skills: locomotion and handedness. *Locomotion*, the ability to navigate the environment, progresses as synaptic connections grow through stimulation initiated by children's repeated motor behaviors. In this way, infants progress from their struggle with simple movements (e.g., chin lifting at 20 weeks) to full postural control at 5 years (Table 32.2-1). In the same way, *handedness*, the ability to reach and grasp objects, begins as a simple reflex at age 1 month, progresses to a full grasp response at 1 year, and at 3 years shifts from gross to fine motor control that shows high dexterity. As part of this development, laterality also makes its appearance. *Laterality*, the asymmetric functioning of a paired faculty, is observable in a child's preference in using each of several organs: eyes, feet, visual fields, and hands.

CNS MATURATION AND PERCEPTUAL DEVELOPMENT To process their world, infants and children must develop their perceptions. Theorists who endorse nature over nurture are encouraged by the presence of well-developed perceptions, except for vision, in newborns. Even in utero, a fetus can hear sounds, and 3-day-old infants can recognize their mother's voice. By age 2, auditory perception has reached adult levels. Taste and odor are well perceived even by newborns, who show a preference for sweet milk and can identify their mothers by odor. Newborns have well-developed sense of touch and can discriminate between reassuring and threatening sensations.

Visual perception, however, is not well developed at birth and confirms the developmental principle that nature and nurture must operate together for optimal maturation. At birth an infant's visual acuity is only 20/800, but at 8 months it can range from 20/200 to 20/70. In the 6 months after birth, an infant's visual cortex changes enormously. As many as 18,000 new visual synapses can potentially form in that time. The number of synapses is predicated not only on genetic priming of electrical impulses, but also on environmental visual feedback that stimulates certain synapses and prevents the atrophying of others. Functionally, the new synapses are responsible for the appearance of depth perception, better visual acuity, perceptual organization, and eye-hand coordination. In addition, visual acuity is significantly affected by environmental factors such as diet. In one recent study prompted by current cultural concerns with fat content of foods, researchers determined that infants who were breast-fed milk, which contains higher levels of certain fatty acids, had acquired better visual acuity at both 3 months and 6 months of age than those given milk with lower fatty acid compositions (i.e., commercial formula milk or evaporated milk).

As a child matures, perceptions in all areas become intermodal or interrelated. By age 6, perceptions must continue to be differentiated and interrelated so that a child can perform tasks expected in the academic environment. Perceptual difficulty is often diagnosed when tasks require interrelated perceptions. According to biotechnical theories of synaptic peak formation, however, it would be valuable if such perceptual intermodal difficulties, including dyslexias, could be identified much earlier—at the peak of perceptual formation at age 3. For example, children treated for strabismus before the age of 2 have no permanent binocular visual damage (Table 32.2-1).

CNS MATURATION AND THE ACQUISITION OF LANGUAGE Developmentally, *language* refers to the ability to communicate as well as the capacity to use symbolic thought in the speech process. *Speech* refers to the ability to produce sounds and words. In addition to sound, language involves syntax (the rules of language) and semantics (the vocabulary). Developmental theorists generally concede that language maturation proceeds along a schema with a particular set of rules. Infants' prelinguistic development starts as early as a few hours after birth. An infant's language at age 18 months reflects a tendency to rely upon sound, a

telegraphic style of omitting insignificant words, and a significant development of receptive, as opposed to expressive, language. As children mature into early school age and middle childhood, language develops with less reliance upon sound and more emphasis upon semantics, grammar, and an understanding of metalinguistics, that is, the ability to perceive language as a system apart from themselves. The importance of this area of maturation to a child's overall development cannot be overstressed. In many studies, infants who are blind, for example, have demonstrated the auditory ability to recognize their mothers' voices, but suffer from lacking eye-to-eye contact. On follow-up, severe language difficulties, and serious social and emotional delays were found in the same infants (Table 32.2-1).

In language acquisition, as in much of development, widely divergent theories have made valuable contributions to understanding the process of growth. Noam Chomsky, for example, advocates a nativist language theory. He uses his observation that children create self-coined words to prove the presence of a *language acquisition device* that innately permits children to speak a universally grammatically correct language. Behaviorists, on the other hand, suggest that language is learned by association. They note that 2- to 3-month-old infants shape their localizations in response to their parents' special ways of speaking to them, a language termed *parentese*.

A biotechnically proven, transactional approach to language development, however, seems to be the only explanation that accounts for both overall patterns and individual differences. The complex neural synaptic connections between genetically regulated brain formations controlling language, and neural connections peripherally, explain language acquisition as well as its sensitive periods of acquisition. Infants and children have the most-sensitive, receptive language skills and ability to recognize speech until neural language synapses slow their growth markedly at ages 5 to 6. Between the ages of 1½ to 6 years, children learn approximately five to nine new words daily. After age 6, as synaptic formation rate slows, children have more difficulty learning a new language. Although children older than 6 years of age have more difficulty learning a new language, they remain equally responsive to the acquisition of new vocabulary at any age. As with other areas of development, children play active roles in language acquisition, especially during this peak period of neuronal stimulation and synapse formation. Children stimulate new language pathways by several widely used vocabulary-building strategies: inferring the meaning of a new word by its context, deriving the meaning of a novel word by comparing it with a familiar verb in the same sentence, and retrieving the meaning when presented with the same word a second time.

Temperamental Development Temperamental development involves the maturation of traits that allow children to respond to new situations, tasks, and opportunities. Parents frequently comment colloquially upon a child's temperament: “Where did this child of mine come from?” Usually such comments stem from parents' acknowledgments that they do not recognize a particular child's traits as familiar to their own experiences.

Principles of Temperamental Development Each child is born with specific temperamental patterns of behavioral response. These traits can be discerned throughout the child's life span. As with other developmental areas, temperamental traits can be stimulated or inhibited by external factors, including family interactions, cultural and environmental influences, and social interactions. Using inhibition as a focus for distinguishing temperament, Jerome Kagan shows that certain children are irritable and fearful in new situations regardless of a parent's sensitivity and support. Kagan's work also demonstrates the internal consistency and continuity of temperament up to a point. On follow-up, temperament remained the same until a child reached 5½ years. Sometime near the 7½ year mark however, environment begins to shape such traits. Unlike other areas of development, temperamental traits have especially strong negative and positive connotations, which magnify the influence of sociocultural influences upon a child's growing experience. Temperamental development can significantly affect other areas of growth. In the parent-child relationship, temperamental traits are particularly relevant for emotional growth. The compatibility of traits between children and their parents is termed a *goodness of fit*. A good fit results in parents behaving with more sensitivity and positive interactions with their children.

Unlike other areas of development, temperament has been considered a separate area of study only since the work of Stella Chess and Alexander Thomas in the 1970s. In the New York Longitudinal Study, Chess and Thomas found that temperamental traits in children could be identified from infancy and at least through adolescence. The results strongly indicate that temperament has a genetic base but that such traits are significantly altered by environmental factors, including family and sociocultural situations. Successful attempts to identify specific genetic markers involving temperament have bolstered both the genetic foundations as well as transactional aspects of temperamental development. In two separate studies, certain alleles of *DRD4*, a dopamine receptor gene, and the temperamental trait labeled novelty seeking, have shown strong association. In addition, the same *DRD4* alleles frequently occur in those with attention-deficit/hyperactivity disorder, which reinforces the transaction concept of comorbidity.

Assessment of Temperament The relative newness of this area of study results in the lack of uniformity among those who describe temperament. Chess and Thomas for example, categorize temperament into three general clusters based upon a continuum of ease with which a child approaches the environment. The “easy child” typifies 40 percent of the population; the “difficult child,” 10 percent of the population; and the “slow-to-warm-up child,” 15 percent of the population. The remaining 35 percent of children do not fall into any particular grouping. Within these broad categories are nine specifically described traits: activity level, rhythmicity, approach/withdrawal, adaptability to change, threshold of sensitivity response, mood, emotional expression, attention span, and distractibility. The Carey Infant Temperament Questionnaire, based upon the Chess and Thomas model, uses family interviews to rate temperament for 4- to 8-month-olds and for 1- to 3-year olds.

The Clinical Assessment of Temperamental Development focuses on a task-orientation approach that incorporates the negative and positive aspects of temperamental traits. In this system, eight temperament traits and their opposites are listed and categorized by their presentation at significant chronological ages and in each gender: goal-directed and non-goal-directed temperament, deliberate or impulsive; active or passive, assertive or nonassertive, verbal or nonverbal, and receptive or rejecting. Information for assessing such traits comes from clinical observation of each child. A 3-year-old child who is observed to move into another child's space without permission, for example, is given a highly aggressive rating. A 5-year-old child who is easily distracted yet moves consistently toward a goal is rated impulsive but goal-directed (Table 32.2-2).

Thomas and Chess		Carey	
Dimension	Description	Trait	Description
Activity level	% of time spent in activities	Verbal/Nonverbal	Utterances, including words but not cognitive quality
Distractibility	Degree to which stimuli are allowed to alter behavior	Goal-directed/nongoals	Degree to which a child thinks in terms of goals
Adaptability	Ease moving into change	Assertive/nonassertive	Expresses effectively needs
Attention span	Amount of time spent on attending	Active/passive	Degree of movement
Intensity	Energy level	Aggressive/Nonaggressive	Ease of crossing into another's space without permission
Threshold of responsiveness	Intensity required for response	Deliberate/impulsive	Time spent doing tasks, not necessarily goal-directed
Quality of mood	Positive compared to amount negative behavior	Resistance/acceptance	Attitude toward change
Rhythmicity	Regulation of functions		
Approach/withdrawal	Response to new situations		

Table 32.2-2 Two Models of Temperament—Newborn to 6 Years

In addition, measurements of temperament have been attempted by drawing correlations between observable traits and laboratory measurements of physiological criteria. For example, 12-week-old infants can be assessed for positive and negative traits on the basis of cardiac vagal tone, which is measured as the amplitude of respiratory sinus arrhythmias. Infants who show higher baseline cardiac vagal tone rate higher on assessments of temperamentally negative traits; infants with low cardiac tone show a higher incidence of positive temperamental traits such as goal-directedness and ease in being soothed.

Practical Implication of Temperamental Development In general, traits that coincide with a child's chronologically determined developmental tasks are the most significant because they frequently determine how children are received and perceived. Even before birth, temperament influences a child's reception. Expectant mothers often relate to their unborn child's trait unwittingly. One mother describes a temperamentally active fetus: “He's going to be a football player! His kicks are so hard.” Another mother exclaims: “She's never going to let me rest.” Newborns who are assertive cry with energy and receive attention much more emotionally. Parents respond according to their own personalities (“My child is feisty,” “My child is never satisfied”). In early childhood, other traits come into play. A temperamentally verbal child often appears “bright” (“My child asks a lot of questions”). The cognitive maturity of a less-verbal child is frequently underestimated. As childhood progresses, the traits that determine school success predominate. A child who is temperamentally deliberate and goal-directed functions well in the traditional school setting. An impulsive, non-goal-directed child may be mislabeled as having an attention problem or characterized as unmotivated. Temperamental qualities may alter behavior in critical ways. Verbal temperaments in children are a major factor in recognizing the need for psychiatric treatment. As a child matures, temperamental qualities can have critical long-lasting consequences. Preadolescent suicidal children who have verbal temperaments, for example, have been shown to receive timely and more adequate psychiatric treatment for their serious problems than their temperamentally nonverbal counterparts, whose verbal reticence makes

recognition of their suicidality much less likely.

Cognitive Development Children must find ways to understand, to remember, to solve problems, and to organize their environment. Cognitive development in children includes all the processes that lead to maturation of their mental activity: a fetus associating sound with its mother; a newborn learning to suck with the help of a guiding hand; a toddler tinkering with a toy; a 5-year-old putting together a six-piece puzzle; a 10-year-old's questioning the reason for an illness. Explanations for the enormous range of cognitive maturation that can occur within a child's first decade are widely divergent. Two theories—those of Jean Piaget and Leon Vygotsky—present opposing views of cognitive maturation. A third theoretical framework is favored by many contemporary researchers, an information-processing framework. An adequate explanation for cognition incorporates all three theories (Table 32.2-3).

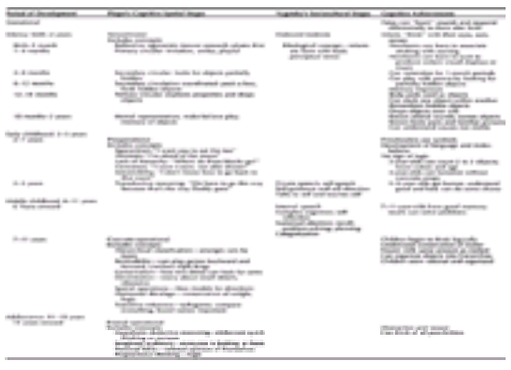

Table 32.2-3 Theories and Skills of Cognitive Development in Infants and Children

Biological Approach to Cognitive Development Piaget explains cognitive maturation by use of a biological model that focuses upon *schemes* (i.e., organized ways for children's developing brains to make sense of their experiences). To structure such schemes, children use two complementary processes: assimilation and accommodation. According to Piaget, cognitive growth occurs in stages, which are always in fixed order (invariant). Overall, cognitive maturity is defined by a child's increasingly refined ability to conceptualize space, both internally and externally. In the first stage, the *sensorimotor stage*, from birth to 2 years, infants use body senses and activity to explore their environment. In the process of exploration, infants learn to anticipate an experience by internally constructing a model of each of their own experiences. Cognitive growth results in forming new skills, such as object permanence (i.e., the ability to remember an object once it is out of sight). Children discover that objects can be assimilated into an experience they have already encountered: a top spins, a mobile makes music, apple juice tastes sweet, hot food burns. Infants begin to play or practice cognitive skills with games like peek-a-boo. Eventually, infants discover that each experience does not necessarily assimilate with the same function. By adjusting to this newer function, accommodating, infants broaden their cognitive development. Piaget asserts that infants and children have the cognitive challenge of internally constructing new schemes to fit old and new experiences into a universally uniform reality. Piaget's schemes are thought of in absolute terms. During the second stage, the preoperational phase, from ages 2 to 7, children become intuitive, anticipating experiences with consequences. Children in the preoperational phase think symbolically but illogically and with egocentricity and a distinct inability to perceive self from others in their environment. Preoperational processes combine to create a child's inner world populated with the creations of magical thinking. A stuffed kitty becomes a ferocious tiger, a darkened room is transformed into a dungeon, and the shadow of a swaying tree's bough conjures up monsters with unlimited powers. From ages 7 to 11, children enter a *concrete operational phase* that involves an ability to think logically and in an organized fashion. The magical woes of the younger child are replaced by a more realistic set of concerns that are stimulated by a new-found conception of cause and effect. Between the ages of 8 and 13, children normally spend some of their time worrying about such issues as school success, health and dying, and social relationships. At the end of this stage, at age 11, children develop the capacity to think abstractly. By adolescence, formal operations appear as abstract thought and the interesting imaginary-audience phenomenon, which joins egocentrism and the capacity to abstract to torment adolescents into thinking that the entire world can watch whatever they are doing in public. In the Piagetian schema, language becomes important as a tool only after a child is capable of hypothetical thought. However, some criticism of this theory of cognition exists. Many researchers who feel that certain social contexts obscure valid cognitive assessments argue that much younger children can display logic.

Sociocultural Schema for Cognitive Development In direct opposition to Piaget, Vygotsky uses a sociocultural framework to describe cognitive maturation. According to Vygotsky, an infant has a basic instinctive cognition that includes some basic memory and perceptual capacity. Until the age of 2, children simply develop this primitive cognition by interacting with their environment. After age 2, however, Vygotsky conceives cognitive maturity as children's acquisition of skills, which in turn mold their mental representations. Both tangible and intangible tools, from computers to social strategies, help children make the translation. For Vygotsky, however, language is the essential tool for cognitive maturation. Cognition is developed by children's social dialogues, (cooperative conversation with others), which are incorporated internally into private speech. Private speech, once internalized, is then used by children as a support, or scaffolding, to guide them through new learning. The motivation for cognitive development is created by a *zone of proximal development*, which is the distance between children's actual developmental levels and their potentials for tasks that can only be accomplished with adult help. Critics of Vygotsky's explanation for cognition argue that he eliminates the biological line of cognition. Others assert that language cannot be primary for cognition. Cognition develops in cultures and families that do not emphasize language. Children who can learn primarily by observation raise questions about Vygotsky's claims as well.

Information-Processing Model Explaining Cognitive Development A third model for understanding cognition relies upon a computer-like metaphor to explain cognitive maturation. According to this model, children use four strategies to develop cognition: taking in information from their environment, encoding the information into a symbolic mental system, recording it into a meaningful effective model for knowing their environment, and finally decoding it so that task solutions are possible. The processing strategies have been compared with software for the brain's hard drive system. This model is often used as a research tool for understanding cognition, memory, and perception. Short-term memory, which holds a certain amount of information until it is processed, is the center of this system. Detractors of this theory have argued that selective attention must be present and that it drives the cognitive process. They reason that prelinguistic children could not use this process for cognitive development because they do not have the required attention. Recent work, however, has confirmed that prelinguistic children do, indeed, have the capacity for selective attention as well as explicit memory. By using display training, researchers have demonstrated that not only can 3-month-old infants have their attention selectively directed toward objects, but such selection also increases their memories of these objects.

Possible Mechanism for an Integrated Cognitive Theory Over the last decade, many researchers have tended to agree that genetic influence is a major factor in dictating cognitive development; in fact, most researchers assert that over half of the cognitive ability within an individual may be determined by heredity. From birth, heredity exerts its influence upon cognitive development until it reaches its maximum effect during the midteens. Recent identification of the mechanism of operation of the *CREB* amplifier gene, however, has reinforced the concept that acquisition of cognition requires the interrelation of genetic, biological, and environmental factors. To assist in learning, the gene depends upon several elements: a child's repetition of cognitive tasks in the environment; interaction with certain neuronal synapses; and the individual child's DNA decoding. In particular, the *CREB* gene appears to be essential to develop pathways that allow learning and long-term memory—an element important to all the cognitive theories. In addition to the *CREB* gene, a single gene more closely connected to general cognitive ability has been identified; thus researchers can trace more directly the cognitive maturation process and observe the interplay between this specific gene and environmental factors.

Measurement of Cognitive Development Measuring cognition and intelligence have in the past been viewed as synonymous. Several contemporary developmentalists, however, have attempted to redefine the concept of intelligence in transactional terms—to include environmental factors and such other aspects of development as emotional and social maturation as part of a broader intelligence quotient. As the concepts are questioned, so are the measuring tools, especially standardized testing. Many clinicians have begun to rely upon clinical assessments based upon Piaget's work to assess cognition. Advantages include their ability to remove cultural influences; they can also adapt cognitive assessments to everyday situations that a child faces.

Social Development Once children have formed a sense of themselves, they can think about and interpret their experiences in other situations. The process by which children develop a sense of themselves and then relate that knowledge to their experience of others constitutes social development. Social maturation begins from birth when infants' cries tell others: “I'm hungry” or “I'm lonely.” It operates meaningfully in the small child's world; for example, when a 3-year-old gleefully shouts: “Throw the ball again, Daddy” or “I'm a great kicker!” Social maturation involves a shift away from adult orientation, when children depend upon adults for their needs, to a peer orientation in which children make friends their focus (e.g., “I don't want to go to the store with you, Mom. Can I take my friend Sarah with us at least?”).

There are four distinct phases in the social maturation process: a period of attachment, during which children develop a sense of self; a period of self-understanding

that allows children to analyze their own makeups; a period of perspective taking, during which children apply their self-knowledge to adults and peers; and a period of true friendships and peer orientation. Certain theories better explain social development at particular chronological stages. Attachment theories best describe the first phase of socialization—the development of self (Table 32.2-4).

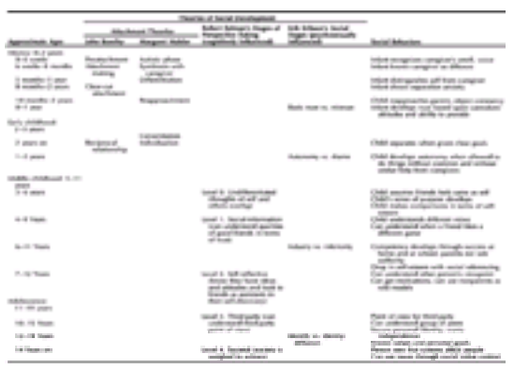

Table 32.2-4 Theories of Social Development and Skills in Infants and Children

Theories of Infant Socialization—Attachment Theories To begin to feel a sense of themselves, infants must first attach over a period of time to a parenting person who feeds, bathes, holds, and plays with them. Without this attachment, children have literally failed to thrive. More commonly, children with inadequate or faulty forms of attachment fail to develop the whole sense of themselves that is prerequisite to having good social relationships. Children of antisocial mothers who cannot empathize with their children's autonomy tend to form avoidant styles that persist as poor adult relationships in adulthood. John Bowlby, who coined the word “attachment,” describes the process in four phases. A baby experiences a preattachment phase during the first 6 weeks of life. With appropriate caregiving, infants are able to prefer one particular person and begin the attachment-making phase, which ends at approximately 8 months. A phase of clear-cut attachment follows. After age 2 years, children who have securely attached have learned three things about themselves and others: trust (i.e., people can be counted on to be there for them), reciprocity (i.e., people take turns interacting), and effectance (i.e., their behavior produces some kind of result in the parenting person).

Using psychoanalytic theory, Margaret Mahler proposes a more complex sequence whereby an infant arrives at some basic sense of self. According to her theory a child's ability to separate and individuate as a person is important. From ages 0 to 2 months, the infant exists in an autistic phase. Through a process of symbiosis, occurring during ages 2 to 5 months, an infant first becomes attached through an intense interaction with a mothering person. From 5 to 12 months, a child begins *differentiation* that is, having a sense of self as different from the parent. From 12 to 18 months, the differentiated infant practices separation. At 18 to 24 months a socially successful infant is free to leave and reapproach the parental person. Individuality and the beginning of object constancy follow. Indications of successful, normal attachment are the infant's ability to use the mothering figure for security and trust.

The father's role (along with the culturally changing maternal role) raises questions about a child's ability to attach to the father as primary parent. Most researchers recognize that attachment of a primary caregiver—whether mother or father—is essential for developing an internal working model for future relationships. *Engrossment* is the term used to describe the father's initial attachment to his child. Recent research describes the critical role that a father plays, not only in the social development of his children, but also in other areas, including cognition and moral development. Specifically, children reared in single-parent households with the mothers as heads have dramatically different social relationships with peers and with other adults, including teachers, when warm and positive social interactions are maintained with their nonresidential fathers. Results of this study show that peers perceive such children as making better friends, and teachers perceive them as having fewer behavioral problems and showing better academic performance than children who have inadequate relationships with their fathers. Daughters show an even higher correlation between adequate father-child relationships and acquiring socially positive developmental skills. Daughters with close attachments to their fathers, whether living in the same household or apart, develop higher levels of critical thinking and cause-and-effect-processing cognitive skills than daughters who are not involved with their fathers.

Behaviorists attempt to describe attachment as a series of learned behaviors. Drive-reduction models stress feeding habits between caregiver and child as stimulating and shaping the attachment. Operant conditioning models stress the need for a reciprocal responsiveness between the child and caregiver for attachment and separation to occur. As in others areas of development, incorporating elements of each theory gives a more complete explanation for the universal phenomenon of social maturation, which requires bonding before social maturation can proceed.

Measuring Social Interaction In addition to information derived from clinical observations, several tools are available to assess basic social interaction skills as a measure of social maturation. *The Ghuman-Folstein Screen for Social Interaction* (SSI) is one such tool. It is a questionnaire designed to measure preschool children's capacity for basic social interaction skills in a variety of contexts. It is most valid and reliable for assessing children from 24 months to 5 years of age and is especially helpful when a relatively quick assessment of children is required (e.g., school consultations, medical-clinical situations, and social intervention programs).

CONSEQUENCES OF ABNORMAL ATTACHMENTS Many studies have attempted to correlate attachment, a child's sense of self, and future behavior. In toddlers between the ages of 12 and 37 months, for example, feeding problems such as infantile anorexia and picky eating are significantly more frequent in children with faulty attachments than in those with secure attachments. Further cognitive and emotional development suffers when attachment is inadequate or faulty. Disruptive school behavior, poor social interactions, and a lack of appropriate long-term relationships correlate with inadequate attachment. On the other hand, children who have experienced secure attachments show high cooperation, enthusiasm, self-esteem, problem-solving ability, and normal relationships.

Socialization in the Childhood Years A child who adequately attaches and differentiates develops a strong sense of self. This rudimentary sense of self-discrimination continues to grow, and in midchildhood, children who have developed a strong self-sense can move ahead into successful peer relationships. Three skills are generally considered essential for children to take the next social step with peers: people perception (i.e., the ability to size up others), intention taking (i.e., the ability to understand motives), and perspective taking (i.e., the capacity to understand what others think and feel). Perspective taking stems from Piagetian concepts and is considered to be motivated by a child's active need to interpret experience.

Robert Selman has devised a system of perspective taking that incorporates all three elements in a child's movement toward a peer orientation. In this system children aged 3 to 6 years are placed at *level 0*, a level of undifferentiated perspective, during which they cannot separate their own needs from those of their peers. At ages 4 to 9 years, children advance to *level 1*, a social-informational stage; following which they can understand that friends have qualities that make them trustworthy or not. At *level 3*, from 7 to 12 years, children become self-reflective. They know that they have ideas and attitudes and consider friends as assistants in the process of self-discovery. By this stage, peers have replaced adults as the source of children's emotional intimacy (Table 32.2-5).

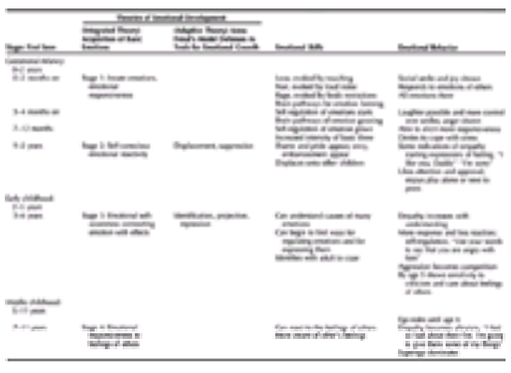

Table 32.2-5 Emotional Development: Theories of Emotional Development and Emotional Skills

Social maturation has been described by other theorists who share a child's sense of self in relation to their environment as their chief focus. Social cognition theory offers a studied approach to socialization on the basis of a recognition of self. From birth to 2 years of age, social cognitionists believe that children engage in learning self-recognition. Infants as young as 5 months can discriminate their images and sounds from those of peers, dolls, and adults. The work of cognitionists shows that from 2 to 4 years of age, children learn how to translate their sense of self and their desires into actions. From ages 3 to 5 years, children discover how to use their self-concept to relate to their environment. From age 5 onward, social comparisons are made in terms of the child's self-esteem. At age 10, as the result of social referencing, children actually drop in self-esteem. From age 8 onward, children learn about their attributes, which lead them to have a sense of master-orientation versus learned helplessness. Finally, from age 11 onward, a true identity is formed. Erik Erikson uses identity formation as the central focus for his own social model as well. According to his schema, children are driven toward the formation of identity in adolescence by first developing a sense of self based upon the perceptions of their ability to function independently and successfully in their social environment. James Youniss offers a model of social interaction that emphasizes social development based upon peer structure and status. He perceives social maturation as proceeding along two tracks. Peer relations develop through a sharing of mutual goals and behavior. Peers enable a child to develop a sense of equality, awareness, cooperation, intimacy, and of being able to cope with differences. Child-adult relationships, which allow internal controls to develop, are based upon reciprocity and authority conveyed through nurturing, modeling, setting rules, explanations, and discipline.

Emotional Development Emotional development can be seen as the literal acquisition of emotions. Children must develop the ability to recognize and use their emotions appropriately. They must also become successful in a complex maturation process that entails learning to become emotionally responsive rather than emotionally reactive to internal experiences of emotion. In addition, children must learn to use their emotional repertoire to handle the inherent anxiety and stresses that are universal to the human condition. Emotional maturation can be understood as the acquisition of coping defenses in infancy and childhood. In infants and children, emotional maturation is best understood by theories that incorporate all of these elements.

Theories of Emotional Development Several approaches help explain how infants and children acquire emotions. Behaviorists and social learning theorists explain emotions as developing secondary to either stimulation or classical conditioning. John Watson postulates a theory of three innate emotions that states that emotions are available and are easily stimulated from birth: fear is evoked by loud noises or loss of support, rage is stimulated by body restrictions, and love is aroused by touching. Others postulate that operant conditioning stimulates emotions. However, none of these theories adequately explains the appearance of spontaneous emotion in older children.

A second group of theorists, cognitive developmentalists such as Donald Hebb, postulate that emotions are simply the byproduct of the cognitive process. In the discrepancy theory of emotional development, Hebb postulates that emotional learning results when children attempt to rectify the discrepancy between a previously learned experience and a new one. This theory does not explain why old situations can be interesting and new ones boring or why some children react differently than others to the same situation. Three-year-old boys, for example, cry more spontaneously in new situations than girls of the same age. A group of children who experience the same event display a wide range of reactions. For example, children can either laugh or cry at a circus clown's performance, scream or smile at a tiger's growling in its home at the zoo, and giggle or moan at an animated elephant's escape from its captor.

The functionalist theories of emotional development—including Anna Freud's defense model and the adaptation of emotional acquisition—transactionally combine previous theories of emotional development with a new, more pragmatic formulation. The functionalist's premise is that emotions are acquired inherently to help children adapt to their world. They are applied through a learned practice that derives from cognitive and social maturation, called *social referencing* (infant's use of parents for cues as to how to react). Functionalists believe that emotional maturity is contingent upon acquiring defense mechanisms for coping with the inevitable anxiety and stress of life. Emotional maturity is quantitatively based upon the number of available emotional defenses acquired successfully by the child. Such defenses include denial, repression, sublimation, regression, projection, reaction formation, substitution, rationalization, compensation, and escape.

Recently, researchers used the most advanced biotechnical equipment to document a series of complex interactions for explaining emotional maturation. Their work appears to integrate the previous theories into a transactional, biological, sociological, interactive formulation. They suggest that emotional maturation—predicated upon genetic predispositions, environmental exposure, and behavioral repetition—occurs through the development of complex interactive pathways within a child's brain. They postulate, for example, that the persistent and pervasive anxiety of children who are neglected or abused as infants stems from the enormous stimulation and subsequent high degree of development of those particular brain synapses.

Proposed Model of Emotional Behavioral Milestones Incorporating aspects of all three theoretical models, a four-stage model for the emotional development of infants and children can be proposed. First in the developmental process must come *acquisition of basic emotions*—those learned directly or inferred from facial expressions, including happiness, anger, sadness, and fear. Throughout the first year, an infant's emotions grow as they are stimulated and rewarded. Smiles, for example, are simple reflexes at birth. By 5 to 6 months, however, smiles or laughs can be elicited when a parent makes a familiar motion that the child anticipates as funny. Appearing at the end of the second year are the second-stage emotions, the *self-conscious emotions*, which arise from injury to, or enhancement of, the sense of self: shame, envy, pride, embarrassment, and guilt. The third stage involves the development of *emotional self-regulation*—strategies to adjust emotion to a comfortable level of intensity. This phase begins as early as 2 to 4 months but increases markedly in middle childhood. Certain patterns corroborate this view of emotional maturation. For example, irritability and temper tantrums diminish progressively with age as children learn to respond rather than react to situations. Crying diminishes in childhood, and worry becomes a common weekly experience for 70 percent of middle-school-age children. Fears diminish with age, but different fears arise at different times in relation to varying life circumstances. Moodiness and unhappiness normally increase toward the end of childhood and into adolescence. Finally, emotional maturity is reached at a fourth stage, when true *empathy* (i.e., the capacity to respond to the emotions of others) is attained. Empathy is a major underlying theme that supports each of the stages of maturation. Rudimentary empathy occurs at age 1 with the development of some self-awareness. Children with a basic level of empathy understand the expression “I'm sorry.” Empathic capacities of children continue to mature until the age of 5, when children can apply their own experiences with feeling to something that they see happening to another. An empathic child can show support: “I'm sorry you didn't get invited to the party.” Finally, by late childhood, empathy develops into *altruism*—empathy directed toward strangers and people with different life experiences (“I'm going to volunteer in a nursing home. So many older people have no one to visit them”).

Psychosexual Development Psychosexual development involves the process of infants and children learning to view themselves and others in terms of gender. It includes aspects of sexual, physical maturation. Three stages describe psychosexual maturation in children: the development of *gender identity*, the formation of a concept of behavior related to their own gender identity (*gender roles*), and the formation of children's attractions to a particular gender in others (*gender relationships*). Psychosexual developmental principles are best explained by integrating several distinctly different theories: a biological explanation, a cognitive-developmental system, a social learning premise, and traditional psychoanalytic theories.

In infants and children physical sexual maturation proceeds in stages. Even before birth there are distinct biological, genetic, and hormonally driven physical changes. In the first 3 months of fetal development, the presence of a Y chromosome and fetal androgens produces masculinization and inhibits feminization. Without a Y chromosome, ovaries form at 12 weeks. Very little sexual physical development occurs until late childhood. In boys, puberty occurs between the ages of 11 and 16 1/2 years; in girls, it generally occurs between the ages of 8 and 16 1/2 years. The current trend is toward earlier sexual physical maturation. It has been speculated that environmental factors, such as hormones in food and better nutrition, may be responsible for such changes.

From infancy onward, however, most psychosexual maturation focuses upon the psychological stages of sexual development. *Gender identity*—a child's perception of the self as either male or female—begins at 3 to 4 years. Two thirds of 3- to 7-year-olds know their own sex, based upon cues such as clothing and hair. There is a large range of individual difference in the timing of gender identity. Gender identity generally appears earlier in girls than in boys. Sociocultural factors can influence the timing as well. Changing gender identity, however, is very difficult after age 4. Gender roles tend to appear at approximately the same ages. By ages 3 to 4 years, most boys show masculine preferences in choices of activities, toys, and peers. Studies show that gender role appears, especially in boys, as early as age 2, even before gender identity, with gender-labeling. A 2-year-old can say, “He is a boy.” A 3-year-old can identify herself: “I am a girl.” Gender role is refined through early childhood so that by early school years a child has a sense of gender stability as well: “I will always be a girl.” From the early school years to adolescence, gender role is further developed to include gender consistency: “I know I'm a girl even if my haircut looks like my brother's.” Behaviors that are labeled clearly masculine or feminine are relatively fixed by ages 4 to 5. Gender stereotyping is well set by age 5. Gender relationships have certain patterns. Infant boys and girls can engage in genital manipulation, but between ages 2 to 5 years, genital interest and sex play increases markedly. In spite of the use of the term *latency*, children between the ages of 5 and puberty have an ongoing interest in sex. Masturbation normally increases during this period. Heterosexual play rises from 5 percent in 5-year-olds to 33 percent in 8-year-olds and 66 percent in 13-year-olds. The cause of gender preference in relationships is currently quite controversial. Homosexual play in early childhood is considered transient and generally does not indicate adult sexual orientation.

Four significant areas of theory explain psychosexual development in infants and children. No single school of thought accounts for the complexity of sexual

development; each theory offers a piece of the psychosexual puzzle. The biological theory of psychosexual development argues that sex differences are established in the brain early in life and that sex-typed behaviors, gender identity, general sex object choice, and sexual mechanisms are all neurobiologically determined. However, this approach fails to account for any significant environmental influences. The cognitive-development theory of psychosexual development links such development to cognition, concluding that gender identity is constructed from an awareness of physical reality and that sexual behavior is determined by the child's self-image. A failure to explain individual difference, sexual preference, or the existence of sex-typing behavior prior to a development of gender constancy makes this theory incomplete. Social learning theories of psychosexual development suggest that sexuality is determined by identification with the same-sex parent. Social theorists emphasize the importance of differential reinforcing of sex-type behavior as the basis for psychosexual development. This theory is inconsistent when children's behavior fails to resemble that of their same-sex parent. The psychoanalytic theory of psychosexual development has changed significantly since Freud's initial schema. His theory, however, has both historical significance and relevance for social, emotional, and moral development. The basis of Freud's schema is that children move through a series of stages during which a conflict between their biological drives and social expectations is confronted. Inherent in his theory is the concept of the critical role that ages 0 to 5 play in personality development. Freud suggests that psychosexual development occurs in five stages. Birth to 1 year is a period of oral gratification, used by the infant's *ego*—the conscious part of the personality—to direct the *id*, which is the inherent biological instinct. From ages 1 to 3 children's egos redirect their ids in anal terms. From ages 3 to 6, the id impulses of children are transferred to the genitals. From ages 6 to 11, sexual instincts cool down or become latent while the superego develops in relation to peers. Arguments against the Freudian explanation include a progressive increase of sexual activity during the latent period as well as difficulties with incomplete explanations for gender behavior, especially in terms of roles (Table 32.2-6).

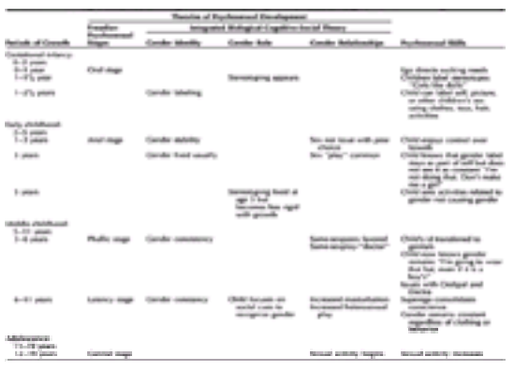

Table 32.2-6 Psychosexual Development: Theories of Psychosexual Development and Psychosexual Skills

Moral Development In developmental terms, moral maturation refers to children's acquisition of internal standards that guide their observable actions or behavior. Infants have only a rudimentary awareness of the effects of their responses on others. They know that smiling makes their parents hug them. Small children can understand that sometimes they do things that make their parents concerned. A 3-year-old can say: “My daddy gets upset when I say yucky words.” However, by the time children enter adolescence, they should have acquired enough moral skills to be able to make decisions on the basis of something other than fear of punishment. They are already able to understand rules in terms of a sense of fairness. At this point, external restrictions are replaced by *conscience*, a person's inner ability to make decisions regarding concepts of right and wrong. In certain cultures elaborate rituals mark the acquisition of conscience. Transactional thinking has catapulted this area of development to its important position in the developmental schema. As with other areas, various explanations are offered to help understand the moral developmental process.

Ethologists suggest that moral principles are innate and universal in origin. They suggest that moral principles are inherited by humans as a species and are developed through social experiences. Such theorists see moral development as adaptive.

Cognitive developmentalists, such as Piaget and Lawrence Kohlberg, suggest that moral maturation is an active process of acquiring a moral sense through a set of cognitively derived constructions that operate in conflictual situations. In Piaget's schema, morality is formed in two stages. Heteronomous morality develops as children are able to see rules as being fixed and dictated by authority, a period also called “the morality of constraint.” A child's behavior is determined by physical consequences and rules are considered unchangeable; motives are not related to intention, actual consequences rule intention. Justice is a concept that is meted out as punishment by some supernatural agent in response to the child's misbehavior. Autonomous morality, or the morality of cooperation, forms as children see rules as flexible and people-dictated rather than absolute. In this second stage, children are able to see morality as linked to intentions, not consequences, and are able to see that moral punishment can be modified by circumstances. In the latter stage, incidents such as illness are no longer connected to punishment for bad behavior in the child's mind. Justice becomes a more abstract consequence and goal. Kohlberg elaborates upon Piagetian views by dividing the moral maturation of children into three levels. At the preschool and early childhood level, morality is based on a system of rewards and punishment meted out by authority figures. In a later phase, beginning after age 6, relativism and social approval are important enforcers. In the middle childhood to preteen years, morality is based on a system of laws that overrides simple approval. The framework for both Piagetian moral development and Kohlberg's form lies in cognitive growth and understanding.

Social theorists, on the other hand, stress that a child's morality is learned when adult models offer instructive examples in their interactions with children. Helpfulness, generosity, and altruism are learned and reinforced by positive feedback. Punishment tends to preclude the development of a conscience. Social theorists explain that negative experiences make the child more stressed and less amenable to adopting any part of the parental directive.

Psychoanalytic theories also stress the importance of the environment on the child. Classical psychoanalytic theory suggests that the conscience is actually a superego that arises from repressed hostility held toward a parent following the resolution of the Oedipal and Electra issues. Guilt and self-punishment occur when a child behaves in a way that is contradictory to internalized parental values. More-modern psychoanalytic theory stresses conscience development as the growth of a superego—arising out of a positive identification with parental values rather than over guilt.

More recent approaches to explain moral development are the gender-based theories. Carol Gilligan asserts that male and female morality develop along different tracks. Women's moral development ends in compassion and an ethics of caring, whereas men's morality culminates in a moral system dominated by the ethics of justice and the assertion of rights (Table 32.2-7).

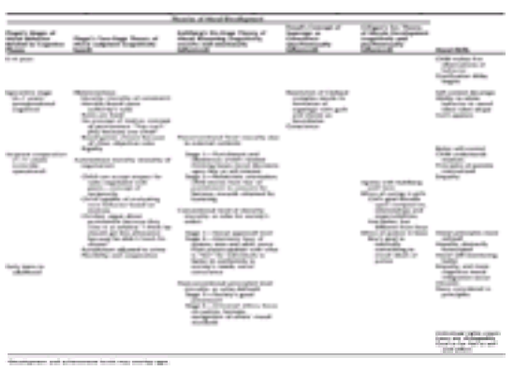

Table 32.2-7 Moral Developmental Theories and Achievements*

Integrated Approach to Moral Development Attempts have been made to formulate a system of moral development that integrates aspects of cognitive, social, and moral maturation. One approach uses the concept of moral volition to frame the moral developmental process. In this system, children mature morally by applying their growing cognitive understanding and social ability to a process of integrating intent and autonomy with the development of conscience—a process that involves five stages of conceptualization: the morality of restraint, morality of mastery, morality of virtuous striving, idealization, and individual responsibility. According to this

view, children can better see their own behavior as independent from their conscience as they progress through the five stages; consequently, they can take full responsibility for their behavior by the time they reach the last two levels of moral development.

DSM-IV CHANGES IN DEVELOPMENT AND THEIR IMPLICATIONS FOR THE FUTURE

Recent significant changes in developmental thinking, as reflected in the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV), hint at the direction in which developmental research and clinical observation might be leading psychiatry. Atypical development, maturation that quantitatively or qualitatively differs from normal development, is defined with more emphasis upon process, communication, and the integration of various elements of development. Certain language and motor developmental disorders, for example, are differentiated in a more detailed way in DSM-IV and have been moved from Axis II to Axis I categories. DSM-IV models rely upon developmental process concepts. Learning disorders, for example, are regrouped with principles of developmental theory in evidence.

SUGGESTED CROSS-REFERENCES

The contributions of the psychological sciences are discussed in Chapter 3. Classic psychoanalytic theory and Erikson's developmental theory are discussed in Section 6.1 on psychoanalysis and Section 6.2 on Erikson, respectively. Normal adolescent development is reviewed in Section 32.3, and normal adult development in Chapter 50. Principles of examination are discussed in Chapter 33, and clinical syndromes observed in children are reviewed in Chapter 35, Chapter 36, Chapter 37, Chapter 38, Chapter 39, Chapter 40, Chapter 41, Chapter 42, Chapter 43, Chapter 44 and Chapter 45. Treatment modalities specific to children are discussed in Chapter 48, and special areas of interest in child psychiatry are discussed in Chapter 49.

32.3 NORMAL ADOLESCENCE

NANCY S. COTTON, PH.D.

Adolescence is a developmental period of dramatic change. Healthy integration of these changes stems from facilitating dialogues between teenagers and the people involved, in the contexts in which they develop. Adults are always on the outside of childhood development; however in this developmental stage, being on the outside can lead to more misunderstandings, distortions, inaccurate readings, and just plain ignorance of what a teenager is trying to understand, do, feel, or be.

What is a teenager trying to do with the behaviors, feelings, and interests adults observe? What is the response from individual adults and peers in the child's historical, cultural, socioeconomic, and geographical context? The adult response to the outside is largely shaped by adult expectations and understanding of what should happen in adolescence and adult feelings about what is happening. These feelings can be intense and range from delight, admiration, and interest to disapproval, dislike, disgust, and fear. Accurate understanding of what should, will, and may happen in adolescence shapes the nature and quality of the dialogue that occurs between an adolescent and family, peers, and society.

DEFINITION

Adolescence refers to the long transitional developmental period between childhood and adulthood and to a maturational developmental process involving major physical, psychological, cognitive, and social transformations. The onset of adolescence is marked by puberty, which is primarily a physical, maturational, hormonal, and growth process. Physical changes and expanding cognitive abilities initiate broader psychological and social changes shaped by the cultural, socioeconomic, and historical context in which adolescence occurs. The concept of a transitional period between childhood and young adulthood is a modern invention; earlier, childhood was directly followed by adult status, marked by puberty.

Earlier views of adolescence described normal adolescence as a time of universal and extreme internal and external turmoil and stress marked by marked emotional reactivity, volatile behavioral unpredictability, dramatic separations from family ties, and severe disruptions in the personal sense of self, leading to separation and autonomy. These extremes were expected and considered normal and necessary for subsequent healthy adult development. However, empirical studies in the last 20 years have described normal adolescence as a time of reordering, realignment, and transformation leading to physical and cognitive development, relational transformations, and psychological differentiation, interdependence, and greater selfcoherence. Daniel Offer found that only about 10 to 20 percent of adolescents experienced severe emotional disturbance or dramatic disruptions in family relationships and self-concepts.

Studies of adolescent development reveal both continuity and metamorphosis—moving forward toward maturity and reaching backward toward childhood for familiarity and grounding. Adolescent development is shaped differently by gender, including sexuality, sources of self-esteem, relationship needs, paths of separating from parents, and the psychological impact of timing of physical development. Rigid schedules of phases of development and categorizations of typical behaviors have been deemphasized and viewed as generic blueprints of adolescence. Normal adolescence can only be seen and understood by studying individual paths of adjustment, with particular attention to their contexts.

Adolescent development is best understood as a dialogue between teenagers and their total environment. Descriptions of adolescent development that ignore the nature of the participants and the characteristics of this dialogue can be inaccurate and deceptive. Perhaps the older views emphasizing the inevitability of adolescent turmoil and psychopathology resulted from a failure to recognize the power of this dialogue to steer development in positive or negative directions.

STAGES OF ADOLESCENCE

Joseph Noshpitz, Robert King, John Schowalter, and David Elkind provide “outsider” reviews of the adolescence. Adolescence is usually divided into phases of early (12 to 14 years), middle (14 to 17 years), and late adolescence (17 to 19 years) described in terms of physical, cognitive, psychological, and social changes; developmental tasks; typical and pathological behaviors and feelings; and healthy outcome measures for each task. These summaries also list parenting tasks, typical parental behavior, and acceptable and unhelpful or pathological responses by parents to adolescent behavior and feelings.

Research describes late childhood and early adolescence as the period of major developmental shifts in all domains, with smaller changes occurring in middle and late adolescence. Although separate developmental lines are usually constructed for each area, actual development involves the mutually influential interplay of all developmental changes. Thus, teenagers who exhibit low-level decision-making in real life situations because of constraints derived from a range of personal and social forces can exhibit higher-order thinking during discussions of hypothetical situations. Physical, cognitive, and psychological changes combine to form a complex web that becomes increasingly difficult to unravel.

Physical Changes Brain maturation and hormonal growth set off major physical changes in early adolescence with a growth spurt and the appearance of secondary sex characteristics. At about 10 years of age, girls show dramatic increases in their height and weight. Boys begin their growth spurt about 2 years later. This is why the average 12- or 13-year-old girl is likely to be heavier and taller than the average boy of this age. Boys grow most rapidly during the thirteenth year, when they may grow as much as 4 or 6 inches in height.

Secondary sex characteristics begin to appear about a year after the onset of the growth spurt. These changes are charted by J.M. Tanner's five-stage scale of pubertal maturity, which traces changes in pubic hair and breast development in girls and pubic hair and genital development in boys. Menarche, beginning around the age of 12 or 13 years, occurs after the growth spurt has peaked. A wide range of factors influence the great variability in the onset and rate of physical changes, including gender, nutrition, body type, stress, ethnicity, geography, and climate.

The body changes in almost every area. The nose and mouth widen, the nose becomes longer and more prominent, and the jaw juts out. The chin is the last facial feature to increase in size. Body hair darkens and lengthens for both girls and boys. Sweat glands, inoperative in childhood, become active, leading to secretions that cause body odor. Voice quality changes. Complexion and acne problems begin to appear. Endurance and strength increases.

Cognitive Changes Cognitive development in adolescence builds the foundation for a more differentiated, multileveled, abstract, subtle, and complex view of self, others, and society. From early adolescence on, adolescents acquire formal or abstract thought, information-processing skills, a knowledge base, and decision-making strategies. Emerging adolescent thinking tends to involve abstract rather than concrete descriptions; to entertain future or ideal possibilities; to become self-reflective and self-aware; to become multidimensional rather limited to a single issue; and to become relative rather than absolute in the conception of knowledge.

These developing abilities have enormous practical impact. Teenagers can integrate concrete experiences, inferences, possible scenarios, historical facts, and remembered experiences into an abstract generalization (e.g. a new perception of self, parents, or a peer as reliable or trustworthy). Self-reflection can create new dimensions of the self involving higher-order personal or moral categorizations. Abstractions can represent possible situations or ideal situations that stimulate new feelings of hope or despair. A teenager can be inspired by the “what ifs” if they suggest a better life and despair if they suggest a dismal future.

Thoughts about ideal adults, parents, friends, or worlds can lead to complex emotional reactions. The ability to separate one's thinking from that of others enhances the capacity for perspective taking and interpersonal empathy. These new capacities lead to preoccupation with the self, extended periods of private introspection,

self-consciousness, and (in some cases) inaccurate application. Elkind describes this as “the imaginary audience” problem in which adolescents falsely assume that others are as preoccupied with their behavior and appearance as they are themselves.

Teenagers learn to process information more efficiently and develop selective attention, better short- and long-term memory, and organizational strategies. Appreciation of multileveled realities leads to more complex understanding of causality in academic, personal, and interpersonal matters. Investigators of adolescent thought are careful to point out that many of these new thinking capacities benefit academic pursuits and theoretical discussions but are not typical of everyday thinking, in which issues are more influenced by psychological and affective pressures. The development and use of new thinking is influenced by personality, gender, culture, and social class to create individual pathways, as in all areas of development.

INDIVIDUAL PATHWAYS THROUGH PHASES

Empirical studies of adolescence reveal multiple adaptive pathways for negotiating the biological, cognitive, psychological, and social transitions of this developmental period. This research leads to the study of individual differences and deemphasizes a unitary picture of adolescence with predictable sequences and phases and typical profiles. Adolescents themselves would certainly agree that “teenagers don't come in neatly wrapped boxes.”

Individual adaptations are shaped by variables within the individual (individual differences), variables in the individual's environment (context), transactions between individual differences and context (the dialogue), and the fit of individual milestones to normative or expected growth curves (timing). Longitudinal research and empirically derived profiles of adolescents show more variability than conformity in development. In their longitudinal study of psychiatrically hospitalized adolescents Stuart Hauser and colleagues reported that some of these adolescents went on to function exceptionally well because of adaptive ego functioning marked by capacities for self-reflection, self-efficacy or agency, self-complexity, persistence and ambition, and positive self-esteem. Their research identifies multiple paths of adolescent development characterized by arrested ego development, steady conformity, progressive ego development, and accelerated ego development. Ego development traces the evolution of meanings that the teenager imposes upon inner experiences and perceptions of people and events. This research concludes that healthy adolescence results from healthy ego development that generates an extensive and flexible repertoire of responses to the normal vicissitudes of living and facilitates a healthy balance of autonomy and involvement with others.

In adolescence, a person is male or female first and an adolescent second. Timing, gender, and match are the crucial variables in whether early puberty is a positive or negative experience. Early maturation appears to benefit boys who are taller and stronger and perceived as more sexually attractive than their late-maturing peers. Since boys measure positive self-esteem by athletic and academic prowess, early-maturing boys also benefit psychologically. Early-maturing girls must cope with sexual advances from boys at an earlier age and a longer awkward period when they are taller and heavier than boys as well as hair growth, body odor, and changes in facial bones and features before their peers. Early-maturing girls have poorer body images and engage in smoking, drinking, and sexual activity at earlier ages than their late-maturing peers. The differences in gender reactions to puberty are in part influenced by adult and societal attitudes that increase expectations for early maturers and decrease expectations for late maturers. Mary Pipher's popular book on adolescent girls and William Pollack's book on boys describe the gender-specific struggles and socialization challenges of adolescents and their parents.

CONTEXT

Individual pathways are constructed and shaped by sex and gender, socioeconomic status, historical context, parental education, culture, race, ethnicity, religious affiliation, sexual orientation, and geographic location. These variables provide positive or negative possibilities, guidelines, and resources to shape the consequences and meanings of change. Socioeconomic class mediates exposure to the entire catalogue of ills in society. Poor, urban youths measure significantly lower on perceived life chances than privileged youths, which places them at greater risk for troubles in adolescence.

The predominant value system of the culture or community can also shape development regardless of socioeconomic status, as noted in adolescent adaptations in privileged boarding-school and poor, urban gang cultures. Immigrant parents from some cultures frequently influence children with their high expectations for educational achievement. Children from financially privileged backgrounds can experience unreachable expectations or “benign” neglect.

Adolescent development is affected by the historical era. Today, children living in isolated, culturally homogeneous communities (e.g., rural or elite) are exposed to broader worlds via television, newspapers and computers and can interact with this world through the Internet. Guiding and supportive social structures such as the traditional family or religious institutions are currently in transition. American adolescents are growing up in a world with fewer rules—a much less predictable, unstable, larger, more unfamiliar world. The sexual practices of the 1990s adolescent have been shaped by changes in adult practices, the individual choice of partner, and premarital sexual relations. Modern teenagers are most likely to die in a substance-abuse-related automobile accident, by suicide, or by violence.

Membership in a marginalized community has always been a risk factor in development, but the interaction of culture and socioeconomic factors can change the context for the developing teen. Teenagers from diverse cultures or with alternative sexual orientations whose families have sufficient economic resources to choose tolerant living and educational communities can be shielded from the destructiveness of hostile and judgmental communities. Relatively normal adolescent development is possible for teenagers with major learning and language disabilities, mental illnesses, or retardation or physical disabilities given sufficient social or familial economic resources, sophisticated treatment, educated and understanding parents, effective school systems, and safe and attractive living spaces and communities.

Accounts of adolescents have been based on narrow samples of white, middle-class, urban, Western-European adolescents growing up in conventional family structures consisting of one or two heterosexual parents raising their biological children, born to them during their twenties and thirties. Barbara Okun has described successful variants on conventional family formats created by older, adoptive, homosexual, and multiracial families.

PARENT-CHILD DIALOGUE

When the point of adolescent development was separation and autonomy, there was relatively little research on normal parent-child relationships. Lawrence Steinberg describes more-complex parent-child roles in which parents and teenagers actively participate in the mutual and reciprocal process of redefining the relationship. The result is a realignment in which parents and adolescents maintain close ties and resolve differences through mature cooperative negotiation and mutual respect. Reaching this point involves inevitable perturbations (rather than storms) along the way.

The quality of the conflict-resolution strategies shapes the nature and outcome of the dialogue. Conflict starts with behaviors that deviate from expectations. Children and parents argue more at the onset of puberty, continue to squabble throughout adolescence, and begin to resolve differences more easily in late adolescence. Parents and children argue more often about such issues as curfews, chores, schoolwork, and personal hair and clothing styles than about conflicting value and political systems. Parent-child conflicts yield positive outcomes when they are temporary, take place in the context of warm close relationships, and proceed with mature conflict resolution strategies that end in negotiated compromises.

Jenny was a responsible 16-year-old who remained home for the weekend to attend practice for the Latin club's annual theater night. Her parents and younger sister went on an annual ski trip with old friends in another state. When her parents returned home it was obvious that Jenny had given a party. Her parents were furious with their daughter's betrayal of their trust in her and horrified by the condition of their house. Several months of strained relationships ensued, marked by initial parental blowups; constant parental monitoring (including picking up and dropping off Jenny at school); calling the parents of other children known to have attended the party; indefinite weekend grounding; and frequent, intense, emotional monologues.

Jenny was appropriately ashamed of her actions and shocked in retrospect about her poor judgment and inconsiderate behavior. Throughout the punishment period she began to wonder how she could have thought the evening was worth it. She mourned the loss of her parents' trust and respect. Although she was humiliated by the supervision and rejected by some of her friends who were furious about her parents contacting their parents, Jenny “took her punishment” because she felt that she deserved it.

The third Saturday night following the party, Jenny was watching television with her mother. They were laughing and Jenny found herself crying and then weeping uncontrollably. Her mother spontaneously hugged her for the first time since the incident. Finally, Jenny could say, “Will it ever be the same? I can't stand this feeling. I'm such a failure.” Her mother was shocked by the intensity and depth of her feelings and her words. Both parents wanted Jenny to experience guilt and regret over her actions—“to learn from her mistake”—but something was going wrong. Her mother told Jenny, “Things will never be the same. But things do not always need to be this bad. We need to figure this out together. Your Dad and I do not think that you're a failure. In fact we felt we were the failures. But we all need to learn from this and rebuild our relationship. It will take some time. I'm still pretty mad and frightened by all this. But I know I love you so much, Jenny. I always have and I always will. That's going to get us through this.”

This began a new dialogue and realigned the relationship between this basically healthy teenager and her parents who had a history of love and caring and being able to speak sincerely to each other. The new dialogue was based on a new-found respect for the unpredictability of feelings, thoughts, and actions in adolescence that necessitates less emphasis on global parental trust and global adolescent “goodness and reliability” and more emphasis on dialogue and anticipation of challenges to existing capacities.

The inevitable bumps along the road may result in negative outcomes when they become pervasive, occur with a backdrop of shaky emotional relationships, involve parents or children who may be temperamentally or psychiatrically more vulnerable, and escalate regularly to devaluing and hostile interactions that end in withdrawal or disengagement. Constructive conflict resolution contributes to adolescent identity formation and the development of social-cognitive skills, relatively advanced reasoning, and ego. Ineffectively managed and continuously high levels of unresolved conflict are associated with psychosocial problems during adolescence.

From the Adult Side Constructive parent-adolescent engagement is shaped to a large extent by parental responses to teenagers' legitimate, but often annoying or anxiety-provoking, efforts to make sense of the internal and external changes that confront them. Studies have identified certain parental and familial factors associated with effective management of parent-adolescent tensions: the affective quality of the preadolescent relationship, parental expectations and assumptions about adolescence and their adolescent in particular, parenting style, and parental ego functioning.

Adolescent development is better in a parent-child relationship characterized by secure attachments, well-worn styles of discussion, supportive communication, and adaptive strategies for conflict resolution. Steinberg points out that stepparent-adolescent relationships are particularly vulnerable because they lack the relational context to prevent low-level bickering from escalating into dysfunctional discord or abuse.

Hauser and colleagues describe parents with more-mature ego development as more prepared to engage in, and respond to, the adolescent dialogue. These parents have greater self-awareness and appreciation of individual differences, leading to more curiosity, reasoning, and joint searches for solutions in their family discussions. A more reasoned approach to adolescent experimentation with style, rule breaking, and questioning of society can help clarify values, prioritize concerns, and effect compromises.

More-mature ego functioning may buffer increased feelings of inadequacy around parenting, greater anxiety, negative midlife self-evaluations, and greater marital tension reported in parents of early adolescents. These parents also start the dialogue with more-adaptive responses to the adolescent's emotional distancing, body changes, increased questioning of family rules and conventions, different tastes in clothes and music, and search for privacy and extrafamily relationships. Parental developmental also shapes their response to the dialogue. Middle-age parents may be confronting diminished physical attractiveness and life opportunities while their adolescent's physical development is in bloom and life opportunities are opening up.

Parents with mature ego functioning are more able to use the authoritative parenting style described by Diana Baumrind and her colleagues and associated with more-successful adolescent psychosocial development as measured by social competence, self-reliance, school performance, and self-esteem. Authoritative parents provide a supportive framework in which adolescents can stretch and grow. Authoritative parenting balances limit setting and negotiating, values autonomous expression and disciplined conformity, and provides emotional responsiveness through love, acceptance, empathy and mature conflict-resolution strategies. These qualities create a family environment that encourages and uses mature conflict-resolution strategies grounded in warmth and caring, including discussion, negotiation, self-expression, and respectful interactions during the most heated debates. The dialogue needed in adolescence was nurtured and modeled throughout childhood and can now be used.

As their children mature, parents recall and reexperience their own childhoods. This can be deeply troubling when they have had painful childhoods, even for parents with mature ego functioning.

Susan arrived for her first appointment red-eyed and anxious. She had called about her 13-year-old son. She described the escalation in fighting over the past 3 months. Sean and she had always been close. This had been important because he had always been “uptight” in spite of his general success with friends, school, and athletics. In addition to starting a psychological evaluation of Sean, an additional source of stress in this relationship emerged. Susan's mother had died when she was 12 years old. As the oldest of seven children, she assumed her mother's role in housekeeping and childcare. Her devastated father worked diligently to provide financially for the family but remained emotionally unavailable. Susan realized that she was working hard to give Sean the kind of adolescence that she had missed and yearned for. She resented the fact that Sean was so ungrateful for his opportunity to participate in athletics and after-school activities while her high school years had been filled with household chores and childcare. Her resentment had been largely unconscious before her treatment. In addition she realized how hurt she was when Sean blocked her vicarious enjoyment of his adolescent experience in his efforts to lessen his dependence on his relationship with his mother. Her broader awareness of her multiple feelings about Sean's development allowed her to tolerate and then transform their frequent battles. They agreed on Sean's legitimate need to be more independent of her and they were able to recover some of the pleasure that they had always had in each others company.

Stereotypic parental expectations and assumptions can severely hamper the dialogue. American culture stereotypes teenagers as victims, rebels, victimizers, or sophisticated young adults, and stereotypes inevitably distort interpersonal interactions. Parents can become too controlling after the first missed curfew; too judgmental after a drunken episode or too devaluing after a drop in school grades if they fail to put these behaviors in the context of their child's ongoing development and see them as signs of the child fitting their most feared stereotype.

If the interpersonal dialogue between a developing adolescent and caring adults deteriorates, negative stereotypes are more likely to dominate the person-to-person interactions. Adults plead with adolescents to change their style to avoid the negative images, and adolescents respond by requesting that adults stop oversimplifying and being emotional about their harmless experimentation with their “surfaces.” In the 1960s reasonable adults could panic over long hair on a boy; in the 1990s adults are undone by tattoos and body piercings. Negative stereotypes also function as mirrors held up to adolescents by their parents, and the teenager may accept the adult assumptions and interpretations about their behaviors, ideas, or dress.

Table 32.3-1 lists guidelines for the parent side of the dialogue.

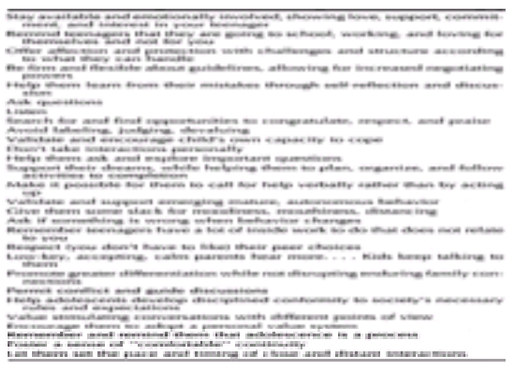

Table 32.3-1 Guidelines for the Parent Side of the Dialogue

From the Adolescent Side Table 32.3-2 summarizes the major life questions posed by a focus group of primarily white, middle-class adolescents. The list mirrors the process of self development, moving from “Who I am” to questions about measuring up, likability, and attractiveness.

Table 32.3-2 The Big Questions: Working Through What?*

Journey to Self Versus Rebellion Adults can miss the teenager's absorption in these bigger questions if they overlook the arenas in which they ask them or if they interpret the teenagers' lifestyle choices only in terms of the parent-child relationship. Adolescent fashion, behaviors, and tastes are not merely “rebellious” alternatives to parental values and behaviors. Teenagers are learning and making serious life choices when they do the varied and sometimes extreme things they do. Girls and boys do these things differently as do daughters and sons, sisters and brothers, firstborns and later borns. Individuals create different pathways.

Adults see the outside (e.g., struggles over schoolwork despair over a bad haircut, a rebuff from a peer). What appears to be a banal concern to an adult can be a crucial life experience for a developing teen. For the teenager they are explorations into who I have been, am, or could be. They are also badges of membership in some peer groups and nonmembership in others.

Carol had always been able to depend upon her 13-year-old son, Darien to pick up his younger sister after school on Tuesdays and take her to gymnastics. She received a hysterical call from Cheryl who was left at school. In the evening, Darien was initially angry when confronted by his mother. He told her, “Anyway, I needed to go with the kids. I can't be taking care of my little sister all the time.” As the evening wore on and Carol and Darien became less emotional, he apologized and told her, “Josh had never asked me over before. I couldn't not go. What if he never asked me again?” Carol could finally see the situation the way that Darien did and was able to help him think of other ways to juggle his responsibilities in the future.

Cognitive Development and Social Context The questions asked are partially determined by maturing cognitive skills and social context in early, middle, and late adolescence. Questions and order of importance of topics change drastically in focus groups of socioeconomically or culturally diverse youth. Nothing separates urban, poor teenagers from their economically privileged peers as much as their proximity to daily violence and the smells, sights, and sounds of poverty, which make the question not who you are or what you will be but whether you will be.

In less dramatic and compromising contexts, teenagers are primarily focused on self-development, which often leads to periods of intense self-absorption. The famous emotional volatility of adolescence is the external evidence of the challenging work within. The stable self-images created and supported in the middle-school years by parents and other nurturing adults are reexamined by the teenager and put to a test: Is this still me? Will this be me? Do I want this to be me? Is it likeable, worthwhile, attractive to me, peers, adults?

Psychological Milestones of Self-Development Susan Harter has mapped out the milestones of the self-development process: generation of components of the self; differentiation and exploration of these components; valuing of some parts and devaluing of others (self-esteem regulation); dropping of undesirable and development of valued parts; reconciling of contradictory self images; and integration of self components. During this process the adolescent moves from creating a self portrait to exploring broader societal roles in terms of gender, occupation, religion, and political identities.

Identity Formation Erik Erikson has called adolescence the developmental period of identity versus identity confusion, as the teenager works through being or not being oneself and issues of sharing oneself. Even in normal adolescence, self-discovery involves discomfort, confusion, anxiety, and unhappiness in the short run. Early adolescence is particularly marked by the negative emotions caused by the inner reworking of the self. The positive outcome of this process, in later adolescence, is the development of “the real me” or a clear, integrated, realistic, internalized sense of an acceptable self (positive self-esteem) perceived as acceptable to society. The healthy adolescent identity is not the final self, but the basis for the continued search for meaningful identity in the future.

Erikson describes the normative process of identity formation as moving through a period of exploration of alternative selves (identity diffusion) toward a period of choice, commitment, and consolidation. Maladaptive attempts at identity formation can avoid or get stuck in the process by premature commitment (foreclosure) or failure to commit (identity diffusion). Teenagers who foreclose the process adopt identities prescribed by parents or other authority figures without ever experiencing tension or exploring options. Although diffusion is developmentally appropriate in early adolescence, in later adolescence and young adulthood it represents a maladaptive inability to seek decisions and make commitments. Pathological outcomes in identity formation lead to turning against the self (e.g., depression, eating disorders, and suicidality) or turning against others or society (e.g., delinquent behaviors).

Components of the Self The components of the self come from all domains including physical, academic, athletic, social, artistic, and moral, which are gradually sorted into the more important and less important parts of the self. In early adolescence the self is defined by relatively concrete self-descriptions of the social and behavioral exterior, physical attractiveness, athletic ability, popularity. The late adolescent self-portrait is defined by the psychological interior, a composite of beliefs, emotions, motives, wishes, and attitudes. Developing abstract capacities for self-reflection and reflection on the thoughts of others, teenagers create personal narratives about themselves and use the imaginary audience of others to validate and evaluate themselves.

Self-Esteem Development Self-esteem is positively regulated when teenagers approve their competence in domains that they value. The search for self also incorporates evaluations from others (“the looking glass–self”) such as parents, other adults in authority, individual peers, and peer groups. Thus self-esteem regulation consists of a general sense of liking oneself as a person, global self-esteem, and domain-specific self-esteem, based on how adequate adolescents feel in the areas they consider important.

Researchers have found that global self-esteem depends heavily on what others think—individual adults and peers as well as society as a whole. Studies of African-American youths with positive self-esteem found that the positive support of their family and members of the African-American community filtered out destructive racist messages from the white community. Pipher's discussion of developing adolescent girls emphasizes the destructive role of sociocultural messages to developing girls. Physical appearance consistently correlates most highly with global self-esteem, followed closely by peer and parental acceptance, and then scholastic, athletic, and behavioral competence. Early teenage girls are more vulnerable to comparisons with cultural standards of the ideal female as an ultrathin person, subsuming her personal assertiveness, competence, and individuality under the desire to please others. Adolescent girls' self-development also needs supportive, affirming subcultures to buffer the "girl-hurting isms," such as sexism, consumerism, and "lookism."

Although parent and adult feedback remain essential to the process of self-understanding, adolescents begin to look more and more to their peers for validation and approval. Peer pressure is probably better understood as "self-pressure" to meet the expectations and win the approval of the selected peer group. When teenagers pick a peer group with behaviors and values more similar to those of their parents, the teenagers and parents have a more harmonious journey. Selection of the peer group depends upon who the teenagers are trying to be or think they can be. Teenagers with ability in academics, athletics, or the arts who can function well in those arenas are accepted by these peer groups. If teenagers are rejected by more-competent peer groups, they seek out groups who will accept and validate their level of competence. Self-development and self-esteem regulation depend upon feedback from peer groups and close friends. The feedback from close friends is often discounted in favor of the perceived objectivity of the greater peer group.

Early, Middle, and Late Adolescent Self-Development The course of self-development is most tortuous in early and middle adolescence when self-esteem is at a low point. Teenagers are exploring multiple, often contradictory, selves based upon fragments of childhood selves and the diversity of possible selves generated by their capacity to imagine ideal or future selves. The comforts of a more cohesive and continuous self need to be delayed for a genuine attempt at integrating new selves. The "quality of the dialogue" is seriously threatened. From the outside, parents watch their athletic child give up sports, their kind daughter become critical, their trustworthy child throw a party while they are away for the weekend, or their studious child fall off the honor roll. Parents' responses are less helpful if they take these exploratory choices as personal affronts, treat them as final decisions on identity, cannot explore the choices with the teenager, refuse to set firm boundaries and flexible guidelines around dangerous and safe choices, or fail to validate and respect the power of this process. Everyone must remember that a process is going on and that learning takes place through mistake making.

Ken and Stacey called the clinician about their 14-year-old daughter, Kim. They described escalating fighting, Kim's apparent abandonment of her previous friends and field hockey, and her demands to quit band. Ken and Stacey were well-respected professionals in their community, married happily for 20 years after meeting in college, and articulate and caring parents. They described Kim as a challenge since early childhood, with a quick temper, bossy with friends, irritable doing family activities and routines, academically bright, and testy with some (not all) teachers. "If a teacher gets Kim, she or he likes her and Kim likes the teacher and does well in that class. When Kim feels unliked by a teacher, she becomes sullen, talks back, and doesn't perform academically as well as she could." Ken and Stacey feared that they were losing control over Kim. She had run away from home the previous weekend when they refused to let her stay out later than her curfew. Ken had followed her along a dark country road until she had finally agreed to walk home.

The dialogue in this family had seriously broken down. Kim's angry declaration of her rights to be independent were met by parental rules and standards that they believed to be reasonable for a child her age. Kim was escalating her position from words to actions.

Kim refused to come to see the clinician. She agreed to come only when it was suggested that the psychologist needed to meet her because her parents wanted to work on being better parents for her. She could provide her view of how they functioned as parents. The most striking moment in her first meeting was when Kim said, "So you don't think I'm the monster."

The clinical work with this child and her parents took the form of shuttle diplomacy. The clinician suggested that the problem was in the quality of the dialogue not in "problem parents" or a "problem child." They were all reaching out to each other and frightening each other. Kim had given her mother a book on adolescent girls to help her mother understand her. The book contained examples of severe eating disorders, drug addiction, and identity breakdowns. When Kim asked her mother theoretically what she would do if a child of hers tried alcohol or marijuana, Stacey said she would send her to drug and alcohol treatment. It was obvious that both parents and child were trying desperately to connect with each other. In separate clinical sessions, the clinician tried to help them identify ineffective ways of responding to each other or of bringing up situations. Kim learned that her provocative and combative style was defeating her sincere wish to be understood and respected. Stacey learned that her inability to discuss risky behaviors or more flexible rules was closing off conversation and encouraging deception and an overreliance on Kim's new and older friends, who were experimenting with parental limits and drugs and alcohol. Ken learned that he intimidated his daughter with his definitive stances, articulated clearly with suppressed emotion. When he felt most hurt by his daughter, she was usually feeling most attacked by her father.

A new emphasis on building respect and trust, rather than assuming that these qualities were automatically present, helped to refocus the dialogue. Kim was able to refine her asking skills and take responsibility for her deceptions. Stacey was able to listen to her daughter's concerns and try to understand her, rather than try to fix or protect. Kim's father became less reactive to her provocative remarks, which were often pointed personality critiques of his shortcomings. In the space provided by some peaceful dialogue, parents and adolescent noticed small ways in which they cared for each other. Diplomacy and restraint, coupled with a willingness to compromise (more compliance by Kim and more flexibility by her parents) brought more harmony to their relationship. This, in turn, facilitated Kim's reengagement in more-positive developmental pursuits (e.g. academics and athletics) and her parents' return to their more-mature conflict resolution strategies.

Kim's parents were amazed when they received a call from her on a Friday night, before her curfew. She asked if they could pick her up from a party. She instructed them to wait three houses down from the party. Without asking any questions, Ken drove to pick her up. Kim did not want to give details. She simply told her father, "That's not me anymore."

Discovering the true self in middle adolescence involves choosing between the differentiated and valued parts of the self, adopting some and rejecting others. The feedback from self-evaluations, based upon social comparisons and the feedback from adults and peers, partially determines what is kept and what is shed. Later stages of self-development involve the integration of parts of self, based upon what feels compatible and feasible. More-mature ego development allows higher-order integration of more-complex portraits of the self, just as less developed ego skills simplify self-knowledge. Healthier teenagers can see how they can be both smart and dumb, kind and mean, capable and incompetent, lovable or unpopular depending upon the context.

In older adolescence, integration of past, current, and future selves involves reconciling and coordinating conflicting insights into self-knowledge and self-acceptance. Older adolescents will refuse to participate in an activity with reasons such as "That's not me."

The late adolescent version of the real me is a more stable, comfortable sense of self with continuity to childhood identities and confidence in newer competencies and roles. Although life choices for career and religious and political identities may not be made, the process of identity formation up to this point has developed the skills to make those choices and the self-confidence to face those decisions with less anxiety and confusion than the junior high school student brought to the challenges of early adolescence.

Views From Inside Young-adult literature provides a unique opportunity to listen to the inner voice of adolescence. These stories can show adults how it looks and feels from within.

Many of these stories are written as journals or narratives: *Dear Nobody* is about a pregnant teen; *Ironman* is about an angry teen learning how to be heard and how to listen; *Ruby* and *Sees Behind Trees* place adolescent development in other cultures; *Deliver Us from Evie, Bad Boy*, or *A Boy's Own Story* reveal different experiences growing up gay; *Imitate the Tiger* explores the development of alcoholism in a football player. Gang life with conflicting loyalties to self, friends, and society is the subject of *The Outsiders* and *That Was Then, This is Now* and *A Way Out of No Way* collects stories of black childhoods. Holden Caufield in *Catcher in the Rye* became the archetypal angst-filled teenager of the 1950s and is the hero for a 1996 teenager in *Bottom Drawer* who finds relief from his troubled relationship with his stepfather via the Internet.

SUGGESTED CROSS-REFERENCES

The ideas of Jean Piaget are explained in Section 3.2 and of Erik Erikson in Section 6.2. Normal human sexuality is discussed in Section 19.1, eating disorders are

discussed in Chapter 20, normal child development is outlined in 32.2, family therapy in Section 30.5 and Section 48.5, mood disorders and suicide in Chapter 45, and psychiatric treatment of adolescents in Section 48.10.

CHAPTER 33. PSYCHIATRIC EXAMINATION OF THE INFANT, CHILD, AND ADOLESCENT

ROBERT A. KING, M.D., MARY E. SCHWAB-STONE, M.D. , BRADLEY S. PETERSON, M.D. , AND ARMIN PAUL THIES, H.D.

Psychiatric assessment of the child or adolescent is undertaken for a variety of purposes including outpatient office or clinic evaluation to determine the need for treatment; emergency room assessment of safety issues and need for hospitalization; consultation to pediatric, school, or legal services; as a component of family or other mode of treatment; and for research purposes. While the structure and style of the assessment will vary to some extent depending on the purpose and setting, certain elements are common to all.

Core features of the clinical diagnostic assessment of the child are identification of the reasons for referral; evaluation of the nature and extent of the child's emotional or behavioral difficulties or both; and determination of factors in the child, family, and environment that cause, exacerbate, or potentially ameliorate those difficulties. While information gathering and differential diagnosis are the primary aims of such assessment, the evaluation process should also facilitate the development of an alliance with the clinician around understanding the child's difficulties and pursuing the treatment recommendations that emerge from the evaluation.

Since decisions about intervention follow from evaluation, clinical assessment may rightly be regarded as a cornerstone of child and adolescent psychiatry. Clinical evaluation of the child or adolescent is both challenging and complex in that the clinician must draw upon multiple sources and a range of techniques for eliciting information on various aspects of the child's functioning. This information must then be integrated from multiple theoretical perspectives using the clinician's knowledge of both development and psychopathology to arrive at a diagnostic formulation that can guide treatment planning effectively.

The initial portion of this chapter focuses on the comprehensive clinical assessment of the child and adolescent; subsequent sections discuss more-specialized types of assessment, such as the assessment of infants and adolescents, psychological testing, laboratory assessment, and clinical research assessment instruments.

CLINICAL INTERVIEW OF THE CHILD

The psychiatric assessment of the child requires a comprehensive approach that evaluates the child's developmental progress in various domains and positive adaptive capacities, as well as the presence of the pathognomonic symptoms of specific disorders. A developmental approach to the assessment of the child is essential because children differ from adults in certain key respects.

Distinctive Features of Childhood Psychopathology First, psychiatric disturbances in children often consist of a lack of developmental progress in one or more domains, rather than the presence of specific symptoms that are pathognomonic of adult disorders. For example, a nursery school child's failure to develop useful social language or interactions or a school-aged child's inability to meet the developmental expectation of separating from parents and settling into the school day may prompt the parent, school, or both to request an assessment.

Second, the child's developmental status may affect the clinical presentation of various syndromes. For example, in children, depression often presents with irritability and somatic complaints, while excessive guilt or depressive delusions are rare.

Third, development brings expectable periods in which distressing emotions or impairing behavior may occur as part of a normal transition, for example, the separation anxiety of a child starting preschool or the oppositionality of the adolescent.

In many cases clinical conditions represent severe forms of symptoms found in milder form in nonreferred children. Fears, tantrums, moodiness, or restlessness are relatively common in childhood and occur transiently at different stages. Assessment may be sought by concerned parents needing guidance on how to understand and manage these developmental manifestations. Thus, the clinician must judge whether the behavior is likely to resolve with time and without substantial deleterious impact on the child or family or whether, instead, the level of distress, compromised functioning, or symptom persistence indicates the need for clinical intervention.

To distinguish transient or normative difficulties from those that are more clinically worrisome, the evaluator must possess a solid knowledge of both normal and abnormal child development. This developmental frame of reference includes an understanding of what behaviors can be expected normally in children of different ages, the time frame within which various behaviors normally wax and wane, and the natural history of psychiatric disturbances at different stages in development, including knowledge of the ages at which particular syndromes are more or less likely to present.

Another difference in the adult and child psychiatric assessment is that many children coming to clinical attention have difficulties that cannot be neatly subsumed under the rubric of a single diagnostic label. Thus, comorbidity is usually not the exception but the rule in childhood disorders. Even in epidemiological studies of children and adolescents, as many as half of those who meet diagnostic criteria for one disorder also meet criteria for at least another disorder. This high rate of comorbidity, found even in nonreferred populations, may have several sources. Many traditional nosological entities draw their definition from clinical experience with adults; although childhood analogues clearly exist, the appropriate descriptive boundaries may not be the same. Furthermore, impairing symptoms in childhood tend to have a ramifying effect by interfering with the ongoing acquisition of key developmental skills in multiple areas. Finally, regardless of whether the origins of a given form of childhood psychopathology lie in biological factors, family or social environment, or an interaction between these realms, these pathogenic forces often produce symptomatic difficulties that cut across many diagnostic lines.

Distinctive Aspects of Child Assessment Save for patients brought involuntarily for evaluation, most adults coming for psychiatric assessment acknowledge, at least implicitly, some degree of self-perceived distress and wish for help, no matter how ambivalent the wish may be. In contrast, for most children, the responsibility for initiating and following through with a psychiatric evaluation lies with the parents. In many cases, children's behavior is a greater source of distress to others—parents, teachers, peers—than to the children themselves. Other children, even while acknowledging distress, view the locus of the troubles as purely external, and hence see little need for evaluation, even if they comprehend the process. In any event, the lack of any stated wish for help or active role in seeking the evaluation colors the child assessment process from the start. As a result, explicit attention must be paid to assessing the child's view of the problem and to cultivating the child's engagement in the process.

A related aspect of the child psychiatric assessment involves the need for the clinician to assess and accommodate to limitations in the child's ability to reflect, conceptualize, and report experiences and internal states. These capacities emerge only gradually with maturation and are influenced by both normal and pathological factors. Thus, the clinician's communication must be attuned to the child's developmental level and may require play, stories, drawing, and other alternative modes of interaction in addition to direct discourse.

Context and the Need for Multiple Informants Even more so than for an adult, the child's functioning and psychological well-being are strongly related to the social context—the family, school, and community settings—in which the child lives and develops. Thus, to evaluate the nature and severity of the child's psychiatric status, information is needed about the child's relationship to, and functioning in, these diverse settings. The fit of the child and social environment can be appraised from what parents say about their relationships with the child and from the child's direct report, as well as from play and drawings; however, direct observation of the content and tone of parent-child interactions in the office setting also provides much useful additional data. In some cases, a home visit may provide invaluable information.

It is also important to gather information on the child's functioning in school, a task that often requires speaking with the child's teacher or guidance counselor, in addition to reviewing school reports and educational assessments. Here too, direct classroom observation can provide invaluable in vivo information. For children

involved with child welfare, juvenile justice, or other institutional systems, information from caseworkers, probation officers, and institutional caretakers is essential.

Special Types of Assessment The main emphasis of this chapter is on the assessment of children and adolescents, especially those capable of participating verbally in the assessment process. Because developmental considerations shape the evaluation process, infant and toddlers on one hand and adolescents on the other require specific modifications of the general approach outlined in this chapter (see sections below on these age groups). Nonverbal or language-impaired children, such as those with pervasive developmental disorders or mental retardation, also require specialized assessment techniques.

Although the prototype for clinical assessment of the child is the office consultation or clinic visit, evaluations occur in a variety of settings including schools, pediatric wards, residential treatment centers, detention centers, and hospital emergency rooms. Procedures necessarily vary with the setting and reasons for carrying out the assessment. The following general model for the outpatient evaluation can be adapted to fit more-specific clinical situations. More-specialized types of evaluation are discussed in a separate section below.

Preliminary Contact In the initial phone call to the clinician or clinic intake office it is helpful to gather some basic information about the nature of the chief complaint; to set the time, date, and place of the first appointment; and, if relevant, to discuss issues of fee or insurance coverage.

During the evaluation the clinician will want to see the parents alone, the child alone, and the parents and child together. The order in which these should be done and the corollary issue of who will attend the first meeting should be discussed at the initial contact. This decision is usually made with reference to the child's age. When evaluating a young child, the parents are often seen first, without the child. This allows the clinician to obtain a history and to discuss how to prepare the child for the evaluation. On the other hand, the adolescent should usually be included in the initial interview so that the youngster does not identify the clinician as an agent of the parents, which may interfere with the adolescent's willingness to talk with the clinician and impair the formation of a treatment alliance. If children or adolescents are to attend the initial appointment, the clinician should discuss in the initial call how they are to be prepared for the appointment.

In the initial phone contact the issue of which adults will attend should also be discussed. When the family is intact, the presence of both parents is optimal. When this is not the case, the clinician and parent should discuss whether a noncustodial parent, stepparent, or other adult should be present.

Parent Interview In the initial parent interview the clinician seeks to understand the parents' view of the problems that have led to the referral, including the nature of the child's current difficulties; the explicit and implicit reasons for the timing of the referral; and the impact of the child's difficulties on the parents, individually and as a couple, as well as on the well-being and functioning of the family as a whole. A detailed history of the child's development and a review of family medical and psychiatric disorders are obtained. Finally, the clinician seeks to understand how the family is functioning in their community and cultural setting. This includes a careful appraisal of the strengths of both the child and the family, in addition to the history of the presenting symptoms and areas of impairment.

Child's Current Difficulties and Reasons for Referral In child psychiatry, referrals are usually initiated by the parent or parents rather than the child. Similarly, parents are key in determining whether a recommendation for treatment is followed. Over and above the need to gather information about the child's symptoms and functioning, the parent interview provides an opportunity to develop an alliance with the parents around the goals of identifying and helping the child's difficulties. Success of this process requires understanding the parents' expectations and concerns regarding the evaluation and its outcome. How these issues are addressed will depend on the nature of the child's problems and the parents' knowledge of and previous experience with psychiatric evaluations and treatment. Attention to the parents' view of the evaluation process allows the clinician to address unrealistic fears or excessive expectations about what can be accomplished in a given time and to reduce family stress when parental anxiety is too high.

In taking a history of the current problem, the clinician obtains a detailed picture of the parents' current emotional and behavioral concerns about the child. Parents should be asked to describe specific instances of the child's problematic behavior, frequency, intensity, duration, circumstances in which the behavior occurs, their responses, and the child's responses to it. The extent to which the symptoms cause functional impairment is ascertained by asking about the level of the child's distress, interference with social and academic activities, impact on ongoing development, and the effect of the child's behavior on others. The clinician should also inquire directly about behaviors or symptoms not reported by the parents but known to be commonly associated with the presenting problem or with disorders that the presenting problem may suggest. Thus one goal of the initial parent interview is to develop a detailed picture of the presenting problems, their course, their effect on functioning and on the family, and what has been tried to help alleviate them.

The clinician is also interested in the implicit and explicit reasons why the child has been brought for help at this particular moment. Often the reason lies in an escalation of troublesome behavior or in the deleterious impact of a deficit emerging into sharper relief (e.g., a learning disability or attention deficit becoming more apparent as the child faces the increased demands of a new grade). In other cases, the child's behavior may not have changed, but some change within the family or loss of compensatory support may have made it impossible for the parents to tolerate or ignore previously bearable behavior. These iatropic factors (factors propelling families to seek clinical attention) are often complex. In surveys of the general child population, rates of diagnosable psychiatric disorder (defined as meeting both diagnostic and impairment criteria) approach 20 percent, yet the number of children actively seeking or receiving clinical services is far lower. Perceived barriers to services alone do not account for this low rate of seeking help.

Throughout the history taking, the clinician strives to understand the meaning and function of the symptoms in relation to the factors in the child and environment that influence them. A given symptom (e.g., a period of anxiety, theft, or hallucinations) may have quite different meanings, functions, and clinical implications in different children. Thus, detailed information on precipitating circumstances, behavioral concomitants, and consequences and alleviating factors is needed, much as is the case in taking a medical history. However, this information must be interpreted within the broader developmental and family contexts in which the symptoms occur; thus while gathering history, the clinician simultaneously takes in information about these contextual elements. History taking and diagnostic formulation are not distinct processes; during the interview process clinicians continually formulate and test tentative hypotheses that guide further questions and the diagnostic possibilities under consideration.

To understand the child's presenting problems, developmental status, and family and social context, the clinician must learn about the child's strengths, interests, talents, and areas of adequate or superior adjustment. Such information is essential for a full diagnostic understanding of the child and helps the clinician appraise the child's overall adjustment and functioning. Moreover, in planning for treatment, factors that may help counterbalance or remediate the child's vulnerabilities must be identified. Finally, the clinician's appreciation and discussion of the child's strengths and areas of good functioning provides support and reassurance at a time when the child's problems and limitations have been the parents' major focus of attention.

The parent interview should also cover the practical and administrative aspects of the diagnostic assessment, including discussion of fees, scheduling, confidentiality, and permission to obtain information from school personnel and other clinicians. If the child was not included in the initial interview, the clinician should discuss appropriate preparation of the child for a meeting.

Developmental History The developmental history is a detailed accounting of the child's development across physical, cognitive, linguistic, social, and emotional domains. One task of this part of the parent interview is to ascertain the timing and sequence of developmental events from pregnancy to the present. Parents vary in their ability to provide precise information on the timing of specific milestones; however, an adequate sense of the course of development can often be obtained by having the parents compare the patient's progress in a particular domain with that of siblings. Asking parents about the timing of changes in the family, such as moves or other memorable life events, may help provide a chronological framework for remembering features of the child's development. Besides gathering descriptive information about the child's development, this part of the interview often allows one to tap the emotional aspects of the parent-child relationship by querying the parents' hopes, worries, expectations, and life circumstances in relation to different developmental events.

It is useful to conceptualize the child's past and current development, in the following domains.

COGNITIVE AND ACADEMIC DEVELOPMENT The child's pattern of cognitive strengths and weakness should be traced from early childhood, including verbal and attentional skills. While academic performance is important (including areas of particular strength and weakness), important information about aspects of emotional and social development also flows naturally from the discussion of how the child progressed from one school year to the next. Thus, in tracking cognitive development and academic success, ask about the child's ability to separate from parents and to attend school regularly, interpersonal relationships with peers and teachers, motivation to learn, ability to function independently, tolerance for frustration and delay of gratification, attitudes toward authority, ability to accept criticism, etc. A grade-by-grade history of the schools attended can be obtained during this part of the interview, as well as the reasons for any changes. Retentions, the reasons for them, and the child's reaction at the time and subsequently should be noted. When the child's behavior or progress at school is among the reasons for the psychiatric evaluation, one should obtain permission to communicate with the child's teachers, counselors, or other school personnel and to review the school records, including

results of standardized tests.

FAMILY RELATIONSHIPS The parent interview should include assessment of how the child relates to each family member and how the child fits into the overall family system. The child's reactions to major family changes should be noted (e.g., deaths; birth of siblings; marital separation, divorce, or remarriage; and changes in caretaking arrangements, custody, or visitation), as well as parental responses to those reactions. Ask about compliance with family rules and standards as well as consequences when the child does not comply (i.e., usual mode of discipline or limit setting) and the child's response to such interventions.

PEER RELATIONSHIPS The clinician should gather information about how the child relates to peers, including the number of friends, preferences regarding age and gender of friends, and any major changes in peer group; the child's satisfaction with these relationships; their relative stability; activities and interests shared with peers; and parents' feelings about the child's close peers or lack thereof. The parents' perspective on the child's social skills and deficits should be assessed, including their sense about any difficulties the child has in this domain. For adolescents, this part of the history includes issues such as the capacity for intimate relationships, romantic interests, sexual activity, and concerns over sexual orientation.

PHYSICAL DEVELOPMENT AND MEDICAL HISTORY Assessment includes fine and gross motor development, toilet training and its lapses, eating behavior and attitudes, and sleep patterns. Precocious development or delays in physical growth or pubertal maturation should be noted. In this context, parents should be asked systematically about medication, illnesses, hospitalizations, operations, episodes of loss of consciousness, seizures, head injury, or other serious injuries, as well as the child's reactions to these and their impact on subsequent health and activities. Inquiry about tics, difficulties with hearing or vision, lead exposure, and other specific conditions may be suggested by the clinical presentation. When necessary, medical reports should be obtained and reviewed.

EMOTIONAL DEVELOPMENT AND TEMPERAMENT While some of these topics will have been covered in taking the history of the presenting problems, the clinician should fill in gaps with a systematic review. This domain of assessment includes the child's present and past mood and capacity for affect regulation, anxieties, and ability to adapt to changes and situations that are new, challenging, or frustrating. Prevailing mood as perceived by the parents should be assessed, and if the child has shown depressive symptoms, including irritability, the clinician should ask specifically about suicidal ideation, gestures, or attempts. Worries, fears, and other manifestations of anxiety should be covered and the level of any distress and impairment explored. The generalized or specific nature of symptoms, situational evokers, historical precipitant, and impact on the child are relevant. Unusual fears, excessive shyness or withdrawal, and obsessive or compulsive symptoms are also important.

The child's capacity to regulate aggression falls within this domain and should be reviewed. Ask about circumstances in which the child becomes angry or aggressive, the mode of expressing anger (i.e., verbal, physical, or both), the impact on others, and the child's reaction to and processing of such feelings and behavior. In this context the clinician seeks to evaluate how the child manages aggression, and whether the child is too aggressive, or too fearful of his or her own anger or that of others. Specific aggressive symptoms, (e.g., bullying, firesetting, vandalism, or cruelty to animals) should also be sought.

DEVELOPMENT OF CONSCIENCE AND VALUES The clinician should assess the development of conscience to gauge whether it is too harsh, lax, or overly focused on particular issues. The effectiveness of conscience in helping the child conform to family and societal expectations is important. Religious or ethical concerns and their concordance with those of the family can be addressed in this phase of history taking. The family's expectations with regard to the child's values and future life choices should be ascertained from the parents' perspective, and areas of potential discord noted.

INTERESTS, HOBBIES, TALENTS, AND AVOCATIONS Although this line of inquiry is also pursued with the child, it is useful to obtain the parents' perspectives on the child's interests and activities and to assess the parents' approval, involvement, and support for them. Indications of parent-child conflict should be probed and may provide useful information about the relationship. The presenting difficulties may have affected the child's ability to focus on or engage in previously enjoyable areas of interest or activity such as sports or music.

The quantity and type of TV programs, movies, and videos a child is permitted to watch provides information on both the child's interests and the quality of parental limit setting.

UNUSUAL CIRCUMSTANCES The clinician should assess the child's exposure to unusual or traumatic circumstances such as sexual or physical abuse, family or community violence, natural disaster, or armed conflict. If a history of such exposure exists, the child's immediate and subsequent reactions and the nature of the response from parents or other adults should be assessed.

Family and Community Background Children develop in the contexts of the family and community, and these provide opportunities and challenges that influence and shape the course of that development. The clinician should gain a picture of the child's functioning in these contexts and their influences on the child. While the clinician will learn a great deal about these areas from taking the history of the presenting problem and the developmental history, direct questioning may also be needed.

PARENTS The clinician should assess the parents as individuals and as a couple, including strengths, weaknesses, and areas of conflict or difficulty. If the child resides with someone other than the parents (e.g., a relative or foster parent) obtain information on the history and circumstances of that relationship, including how the child came to be in that adult's care. Determine what the child's previous experiences were with the parents and the nature of the bond with them. The clinician should similarly assess the current caregivers and their parenting relationship with the child.

If the child is adopted, obtain information on the circumstances, the parents' feelings and expectations about the adoption, the age at adoption, the child's adjustment at the time and subsequently, and how the child and family members currently view the fact of the adoption. Review how the adoption has been discussed with the child and any concerns or questions about the biological parents.

When taking the developmental history it is often natural to inquire about the parents' feelings and involvement with the child at different stages. Parents' past attitudes and behavior are likely to reflect on their responses in the current situation, hence, one wants to know how they felt about past difficulties, and what they have done to help and support the child. The parents' individual views on the causes of the child's difficulties, and the extent to which they agree or disagree on this and other aspects of the child's care and management affect how they will respond to the clinician's recommendations. Information on the parents' own backgrounds and histories with their families of origin will help the clinician to understand and work with their responses to their child.

Ask about the parents' ethnic and religious backgrounds. They may be a source of shared identification and values to be imparted to the child or a source of conflict between the parents or between the adolescent and the parents. A clinician should be sufficiently familiar with the culture and language of the family to understand the child's and family's situation in that context.

The parents' education and occupation may bear on how they understand and respond to the evaluation. How knowledgeable and worried they are may depend on their past experiences and familiarity with psychiatric issues. Financial resources and insurance coverage should be ascertained because this may be a source of stress or worry and may pose practical limitations to the treatment options available to the family.

The clinician should gain an understanding of how the family system functions, with whom the child lives, and the nature of relationships between household members and the child. Explore boundaries and alliances within the family and the child's affinities and conflictual relationships with parents, siblings, and other household members. Assess family communication and problem solving, including how issues of separation or disagreement are handled. The emotional tone of the family (e.g., tense, anxious, critical, warm, supportive) can be ascertained by observing interactions and by direct inquiry. Stresses on the family as a whole or individual members (e.g., moves, migration, illness, accidents, job loss, legal difficulties) should also be addressed.

COMMUNITY The clinician should understand the community or neighborhood in which the family lives and their feelings and identification with it. Information on the family's involvement with civic, community, and religious activities (and the extent to which the child participates) should be ascertained. The clinician will also want to know about issues of safety and adversity (e.g., poverty, poor housing, high rates of crime or urban violence) in the neighborhood. In some communities, mental health resources are viewed positively; in others their use is stigmatized, which may adversely affect the child. These issues should be assessed and understood because they may affect how and where the child receives any indicated treatment.

Family Medical and Psychiatric History A careful family medical and psychiatric history is needed to identify any medical or psychiatric disorders with potential genetic or environmental implications for the child. Among those to be routinely considered are psychotic disorders, mood disorders, anxiety disorders, tic and

obsessive-compulsive spectrum disorders, alcohol or substance use disorders, attention-deficit disorders, learning disorders, and antisocial personality disorder as well as metabolic and neurological disorders. The impact of any family members' symptoms, hospitalizations, or incarcerations should be probed, with particular reference to the child.

Special Issues in the Parent Interview

INFORMANT DIFFERENCES While parents' concerns usually play a major role in initiating the evaluation, parents may perceive the child's problems differently and may disagree about their severity and the need for treatment. Parents' accounts of the child's difficulties and of various aspects of the developmental history may not agree completely with each other or with those of the child, teachers, or records of past events. To note these discrepancies is not to denigrate the reliability of parents as informants, but rather to emphasize the necessity of multiple informants.

Informants provide differing accounts of children's problems for a number of reasons. Thus, discrepancies should be noted and regarded as potentially useful data regarding what they reflect about the clinical situation. Informants may interact with the child in different settings that vary in the extent to which the child expresses disturbing feelings and problematic behavior. This is commonly true for behaviors expressed most dramatically in settings that challenge the child in vulnerable areas (e.g., the school's demand that a child with attention-deficit/hyperactivity disorder sit still and pay attention). Information about such situation-specific symptoms is best provided by those who spend the most time with the child in that setting. These different perspectives on the child's behavior may also have led to tension between informants who see the child discrepantly. (This is often true with divorced or separated parents whose child may show quite different behavior in the context of each parent's home). The clinician should be aware of these different perspectives and the feelings they generate so that the focus is maintained on evaluating and providing services for the child, with adults working together rather than at cross purposes.

Another reason for discrepant reporting involves differences in how the informants evaluate the child's behavior. Observers may judge the same behavior by differing standards or expectations for many reasons. The clinician's appreciation of the informant's psychology or cultural background will be useful for understanding and working with such differences. For example, when one parent is overly worried about the child having a serious disorder and the other is too ready to chalk up symptoms as something the child will “just grow out of,” the clinician must navigate carefully to allow both parents to move to a reasonable middle ground that will best serve the child's needs. In such instances, understanding each parent's defensive style will help the clinician avoid appearing to collude with one parent and alienating the other.

Discrepant reporting also results from differences between informants in their willingness or ability to report their views to the clinician. For example, parents may be quick to report a behavior that they find disturbing or annoying, while a child may be unable to describe the problematic behavior verbally, or may not appreciate the level of disturbance it creates for others, or may not report it because of feelings of shame or fear of being blamed or punished.

Generally speaking, both methodologic studies and clinical experience suggest that parents are more likely than children to report disruptive or externalizing behaviors such as restlessness, impulsiveness, oppositionality, or aggression. Conversely, children may be more likely to report anxious or depressive feelings and symptoms (including suicidal thoughts and acts) of which the parents may be unaware. Because children may be immature in their capacity to report information, such as frequency and duration of symptoms, parents are usually more accurate informants about chronological details. The child, however, may be the only source of information on events such as sexual abuse, exposure to violence, or behavior that occurred in peer contexts. Generally children become more reliable reporters of specific symptoms with age, with prepubertal children tending to be less reliable reporters of symptoms than their parents.

Mothers and fathers also differ in their experiences with their children, depending on the child's age and gender, shared interests, parental availability, and the respective temperaments and personalities of the parents and child. Although mothers have been reported to be more reliable informants than fathers, in practice it is wisest, both for gathering the fullest information possible and for fostering an alliance with the parents, to involve both parents from the outset. When appropriate, other informants such as siblings, grandparents, or child caregivers, may be called on to contribute information, but only after the implications for the family system and the child's specific relationships with household members are carefully thought out.

Parents and teachers may view the nature and severity of the child's difficulties differently because of the situation-specific nature of some presentations. When present both at home and at school, symptoms such as hyperactivity and inattention may carry a different clinical significance and prognosis than those noted in only one (but not both) setting. Parents and teachers may also differ in their appraisals of the child's behaviors. For example, a stressed and preoccupied mother may be oblivious to her child's behavior while an observant teacher with years of experience with similar-aged children may readily identify the child as distressed or disruptive.

For the clinician conducting the assessment, the issue is not which informant is “right” but how to understand the differences in viewpoint most effectively for the patient's benefit. Thus, eliciting and synthesizing information from multiple informants is a critical aspect of the clinical evaluation of children and adolescents.

INTERVIEW TECHNIQUES WITH PARENTS The clinician should use a variety of interview techniques to elicit information from parents. The type and quality of information obtained is in part determined by the methods used and the clinician's skill and comfort in using them. A series of empirical studies confirm that systematic factual information and details about onset and timing of symptoms are generally most easily elicited by specific and direct questions, while an understanding of feelings and relationships in the family is usually gained most effectively by means of more open-ended, indirect questioning strategies.

In the initial interview, parents should have the opportunity to tell their story in their own way. For rapport to develop they must feel that they have been able to express their concerns in their own words and were heard and empathically understood. An open-ended beginning also avoids narrowing down too quickly on a single aspect of the child's situation and conveys the clinician's interest in many different aspects of the child's situation. Subsequent probing can clarify details and help shape the clinician's understanding of diagnostic and potential treatment issues.

Parents are most likely to be nondefensive and comfortable about sharing personal information when they feel that the clinician is trustworthy, interested, understanding, and nonjudgmental. Clinicians must thus convey respect and empathy and avoid seeming aloof or excessively familiar. They should discuss the child's and family's situation in a natural way, using words and concepts that the parents can understand. The range of questions and the tone of the inquiry will convey the clinician's interest in the whole child (including strengths, interests and talents) and an appreciation that the child is not merely the repository of a set of symptoms.

EXPECTATIONS AND ANXIETIES Parents may hold strong preconceived ideas about the nature of their child's problem and the kind of help needed. Because of the extensive coverage of issues relating to psychotropic medications in the popular press, many parents have drawn their own conclusions about the appropriateness of medications both in general and in relation to their child's needs. For example, parents may arrive convinced that their child needs fluoxetine (Prozac) or that methylphenidate (Ritalin) is an addicting and inherently harmful drug.

Preconceptions or parental anxiety or conflict may also be played out around the issue of blame for the child's problems. In such situations, a parent may maneuver to have the clinician arbitrate or to agree that the teacher, school, or other parent is responsible for the child's behavior and distress. The clinician should be alert to such situations and handle them without making either parent feel defensive or discounted. If ignored, such hidden or overt agendas can have a deleterious effect on the assessment process and the likelihood that treatment recommendations will be accepted.

Parents may bring other entrenched, preconceived agendas to the clinical evaluation process. A parent may insist that the evaluation will confirm that the child has been abused (e.g., by an ex-spouse) or does not have a psychiatric problem but a medical one. Alternatively, the parent may demand that the clinician agree that there is nothing wrong with the child. In such instances, clinicians must explain carefully and clearly that they will conduct a thorough assessment and provide thoughtful professional advice, adding that the assessment must be done openly, without preordained conclusions. This may not satisfy some parents, and some situations may simply not be workable.

Bringing a child for psychiatric evaluation is a charged and emotionally difficult step for nearly all parents, and it is only taken after much worry and disappointment that home remedies or school-based adjustments have not sufficed. Our children are the repositories of our dearest hopes (and often our darkest fears) for ourselves. Although a parent may rationally conclude that seeking consultation is reasonable and necessary, admitting that one's child (or oneself) needs help is always painful. Submitting one's child and one's parenting to professional scrutiny stirs many anxieties, as well as positive expectations of help, even in the most enlightened parents.

Parents often bring unspoken anxieties about the child's possible diagnosis or prognosis to the evaluation. These anxieties may be based in the parent's own personal or family experience with psychiatric disturbance or may derive from accounts in the popular media. For example, is the child's uneven development a sign of

autism or retardation? Do the facial grimaces mean the child is developing a disabling tic disorder? Is the child's moodiness a harbinger of a serious depression or suicide? Other parental anxieties may be guilty ones. Is failed parental rearing or transmitted heredity somehow to blame for the child's difficulties? Is the child fated to share the parent's (or other relative's) own painful struggle with depression, anxiety, or psychosis? Does the parent' relationship to the child seem to recapitulate some distressing aspect of the parent's own early family experience?

The clinician must be aware of such parental anxieties and remain alert for hints of them as the evaluation progresses; some parents are too anxious or ashamed to be forthcoming about them. By and large, it is best to have these concerns aired, even if they cannot be settled at the initial stage of the evaluation and perhaps will not be settled for some time. When such anxieties are revealed or suggested indirectly, the clinician must express an interest in them with sensitivity. Respect and concern for these anxieties can be conveyed without dismissing them or providing premature or unfounded reassurance. The clinician may need to acknowledge the limits of knowledge about cause or prognosis in individual cases. Parents often seek psychiatric assessment after years of worry, having been given wellmeaning (but inappropriate) reassurances that the child would grow out of it. Frank discussion of these issues may provide some relief to the parents, albeit perhaps not definitive answers to their questions.

PREPARATION OF THE CHILD At some point in the initial interview, the clinician and parents should discuss the preparation of the child for his or her first appointment. Children have many reactions to a first visit to the psychiatric clinician, and parents must anticipate their child's possible reaction and prepare their own response. Children may feel anxious because they cannot envision what will transpire or because the evaluation may feel like a punishment. Some children fear that the assessment will reveal some profound or irremediable problem (this may be projected on to the clinician or parent with the reproach “You think I'm crazy”). Many younger children fear shots or having to get undressed for a physical examination. In most cases, the child is probably aware of many of the parental or school concerns that have led to the evaluation and may feel a sense of relief (which can nevertheless coexist with anxiety) about the possibility of getting some help. The child's anxiety or defensiveness may be reduced if the purpose of the visit is put in supportive (rather than pejorative or accusatory) terms. The parents might be encouraged to tell the child something like, “We know you've been having a hard time at school (or feeling upset and sad, or having trouble with friends), so we are going to see Dr.——, who is used to helping kids with that sort of problem and can maybe figure out what would help.” For younger children, explanatory terms such as a “feelings doctor” or a “talking doctor” who helps children with problems and worries may be useful. The parents must give permission and encourage children to tell the clinician about their concerns, even those that might seem to involve private family matters not otherwise spoken about.

Child Interview In the child interview the clinician directly assesses the child's psychological functioning, developmental status across different domains, and perceptions and experiences of the presenting problems. Like the parent interview, the child interview also provides an important opportunity to establish rapport. Such rapport will reduce the level of stress experienced by the child during the assessment process, enhance the child's engagement and willingness to share information, and facilitate the child's cooperation with subsequent recommendations for intervention. Thus, from the outset, the clinician should convey empathy and interest in understanding and helping the child.

There has been debate regarding the reliability, validity, and clinical utility of various approaches to the child interview, but it is generally agreed that the direct child interview is an essential component of a comprehensive clinical child assessment. It provides both observational data and diagnostic and historical information that is not accessible from other sources. In particular, information about feelings and moods, level of distress, and the child's view of significant events is essential for a full diagnostic understanding of the child's problems. For their own reasons, parents may not understand or fully appreciate the importance of these issues, or the child or adolescent may not have divulged them. The child may be guarding important information, such as secrets about abuse, sexual or antisocial activities, suicide attempts, pathological patterns of eating, or collusive family dynamics. Certain symptoms such as compulsions, premonitory urges, obsessive or suicidal thoughts, or hallucinations may be apparent only to the child. Other symptoms may escape or mislead the untrained eye; detection of tics or a thought disorder may require direct clinical observation.

There are many varieties of child interviews, depending on the nature of the presenting problem, the clinical setting, and the purpose of the assessment. Thus the scope, focus, duration, setting, and predominant techniques used will vary, depending on whether the assessment is an emergency department evaluation of a suicidal threat, a pediatric ward consultation of a regressed or uncooperative child, a forensic custody evaluation, an investigation of alleged child abuse, or the evaluation of a child who is academically underachieving, anxious, or manifesting tics.

The clinician approaches the child interview with a developmentally based understanding of child and adolescent functioning and psychopathology. Within this framework, the clinician expects to obtain information relevant to the diagnostic questions raised by the presenting problems, and so will systematically review the major domains of symptomatology. The order and manner of conducting the child interview vary with the child's age and developmental status, the nature of the presenting problems, the setting and context, and the clinician's style. The constant elements in the interview process are the orienting framework chosen and the clinician's clinical skill in engaging and eliciting relevant data from children of varying ages and capacities, with diverse problems and concerns. Some data may emerge spontaneously; some require questioning or other deliberate means of eliciting information.

Components of the Child Interview The components of the child interview are often conceptualized under two broad headings: history taking and the mental status examination. *History taking* involves inquiry into the significant areas of the child's life and functioning, past and present, including the presenting problem. The *mental status examination* consists of an assessment and description of the child's appearance and functioning as manifested in the interview. While these aspects of the child interview can be conceptually distinguished, they usually proceed concurrently. For example, the interviewer may ask a specific question such as who lives at home with the child or how the child gets along with a sibling or a teacher. From a history-taking point of view, the child's response provides some information about these facts, as well as how the child feels about them. While the child's response is thus of interest for the historical information it reveals, the child is also providing the clinician with data relevant to the mental status examination (e.g., how the child conceptualizes the response; how fluent the child is; how readily the child engages; how confiding or suspicious the child is toward the interviewer). Similarly, while engaging a young child in play with figures or puppets, the clinician can simultaneously gather information for the mental status examination (e.g., speech, relatedness, conceptual skills) and inferential data about the child's feelings, fantasies, and conflicts.

Several distinctive characteristics of clinical work with children bear on the manner of conducting the child interview and mental status examination and on interpreting the data they yield. The focus of both history taking and the mental status examination of the child is developmental, that is, it seeks to describe the child's current presentation in various domains and to compare the child's functioning in these areas with that expected for the child's age and phase of development. Another distinctive aspect of the child interview involves the child's potential lability and propensity to react in more immature ways when tired, sick, anxious, or stressed by an unfamiliar situation. While one can sometimes gather sufficient information for an assessment from a single interview, usually more than one interview is needed to assess the child's optimal or characteristic level of functioning.

Mental Status Examination For the mental status examination, the child psychiatrist observes and assesses the following areas.

Physical appearance—including physical development, presence of minor congenital anomalies, style of hair and dress, cleanliness, and other indicators of the quality of self-care or parental attentiveness (or its lack) to the child's physical appearance and hygiene.

Manner of relating to examiner and parents—including ease of separation, how confiding or guarded the child seems toward the clinician, eagerness to please or impress, flirtatious behavior, readiness to make excuses or minimize, passive withholding, or open defiance. The child's behavior toward the examiner is compared with that observed or reported toward the parents or other adults. Reactions to the clinician's physical appearance, gender, or ethnicity (especially if different from that of the child) should be noted.

Affect—the child's predominant mood and range of emotion during the interview and appropriateness of mood.

Coping mechanisms—as manifested toward the clinician, expressed in play, or described by the child in relation to important others; age-appropriateness of the child's dependent longings, sexual interests and impulses, and aggressive feelings with respect to intensity, object, and mode of expression; child's control or modulation of such urges (e.g., finding alternative or socially permissible means of satisfying them); strategies used for coping when anxious or frustrated.

Orientation to time, place, person:—whether children are accurately aware of the date, where they are, and who they are. This can be evaluated by asking the child “What is the year? season? date? day? month?” or “Where are we?” (Name of building, town, state, country).

Motor behavior including activity level—coordination, presence of unusual postures or motor patterns (e.g., tics, compulsions, or stereotypies, such as hand flapping or

twirling).

Quality of thinking and perception—including presence of hallucinations, delusions, thought disorder, flight of ideas, and adequacy of hearing and vision.

Speech and language—including reading and writing. Articulation, inflection, pitch, rhythm and fluency of the child's speech; richness, limitation, or idiosyncratic aspects of vocabulary and syntax; presence of echolalia or persistent neologisms; misuse of pronouns and gender; delayed or deviant social use of language; and lack of accompanying nonverbal communicative behavior (e.g., lack of facial expression or eye contact with interlocutor). When evidence of delays or problems in these realms exists, formal speech and language evaluation by a qualified specialist may be warranted. Some of the instruments used are shown in Table 33-1.

Table 33-1 Language and Speech Tests

Overall intelligence and fund of knowledge—capacity for classification, abstraction, and inference appropriate to age; counting, alphabet, days of the week, months of year, reading, writing, computational abilities; geographical and historical facts.

Attention, concentration, impulsivity—level of attention to an activity or topic of discussion, degree to which child jumps from activity to activity; need for physical limits; distractability (e.g., by outside noises).

Memory—immediate short- and long-term memory (e.g., repeat three items and recall at 5 and 30 minutes).

Neurologic Functioning—fluctuating alertness, tremor, nystagmus, choreiform movements, abnormal gait, neurological soft signs, cerebral dominance (preferred hand, foot, eye, ear); testing for neurological soft signs can be incorporated in a game-like fashion (e.g., ball throwing, walking on a line, heel-to-toe walking, evidence of hand overflow when walking on outside of feet, and timing 20 repetitions of finger tapping, successive finger tapping, alternating pronation-supination of the hand are reliable components of the revised Neurological Examination for Subtle Signs [NESS]).

Judgment and insight—especially concerning the presenting problem; this is most usefully judged after the child has had the opportunity to develop some rapport with the clinician, as the child's initial impulse may be deny or minimize the parents' presenting concerns.

Preferred modes of communication—Is the child open to talking directly about the presenting problems and the significant aspects of his or her life or is the child more comfortable with indirect modes of expression such as play or drawing?

Reliable detailed assessment of a child's speech and language capacities, intelligence, academic attainment, attentional and executive functioning, and memory requires standardized psychometric testing (see section on psychological testing below). Some simple tasks, such as those used in the Mini-Mental State Examination (as adapted for children by R.A. Ouvrier and colleagues (Table 33-2) can be incorporated in a game-like fashion into the interview of the child to provide a rough screen of higher mental functions such as orientation, attention, memory, language, and constructional ability.

Orientation		Score	Points
1. What is the	year?	_____	1
	[season]?	_____	1
	date?	_____	1
	day?	_____	1
	month?	_____	1
2. Where are we?	Country	_____	1
	State or territory	_____	1
	Town or city	_____	1
	Hospital or school	_____	1
	Floor or address	_____	1
Registration			
3. Name three objects, taking one second to say each. Then ask the patient all three after you have said them. Give 1 point for each correct answer. Repeat the answers until patient learns all three.			3
Attention and Calculation			
4. Serial sevens. Give one point for each correct answer. Stop after five answers.			5
5. Spell WORLD backwards.			5
Recall			
6. Ask for names of three objects learned in Q.3. Give one point for each correct answer.			3
Language			
7. Point to a pencil and a watch. Have the patient name them as you point.			2
8. Have the patient repeat "No ifs, ands or buts."			1
9. Have the patient follow a three-stage command: "Take a piece of paper in your right hand. Fold the paper in half. Put the paper on the floor."			3
10. Have the patient read and obey the following: "CLOSE YOUR EYES." (Write in in large letters.)			1
11. Have the patient write a sentence of his or her choice. (That sentence should contain a subject and an object, and should make sense. Ignore spelling errors when scoring.)			1
12. Have the patient copy the design printed below. (Give one point if all sides and angles are present and if the intersecting sides form a four-sided figure.)			1

Table 33-2 Mini-Mental State Examination for Children

Although the clinician should usually evaluate all areas of the mental status assessment, the emphasis and detail given to the different elements varies with the presenting problem and the type of assessment. For example, in an agitated, potentially delirious child on a pediatric ward, particular attention is paid to the child's orientation, alertness, memory, verbal coherence, neurological functioning, and the possible presence of hallucinations.

Child Interview Techniques A range of techniques is used in the psychiatric interview of the child or adolescent. The choice and timing of techniques depends on the child's developmental, cognitive, and linguistic level; the emotional difficulty of the issue being addressed; and the degree of rapport between child and clinician. Being able to gauge the potential utility of a technique at a particular moment and feeling comfortable with shifting from one technique to another as the occasion demands are important skills for those conducting child and adolescent clinical assessments.

PLAY TECHNIQUES Children under 7 years of age have limited capacities to verbally recount their feelings or interpersonal interactions. For these younger children as well as a number of older ones, play is a useful adjunct to direct questioning and discussion and is often a less challenging mode for the child. Some children find it easier to communicate in displacement; thus, imaginative play with puppets, small figures, or the interviewer can provide useful inferential material about the child's concerns, perceptions, and characteristic modes of regulating affects and impulses.

The skilled interviewer can facilitate the child's engagement in play, without prematurely introducing speculations or reactions that might distort or cut short the presentation of certain types of material. During the course of play, the clinician follows the sequences of play content, noting themes that emerge, points at which a child backs away from the story line or shifts to a new sequence or activity, and situations in which the child gets stuck or falls into a repetitive loop. To facilitate the play component of an interview, the interview room should have a supply of human and animal figures or dolls and appropriate props. These should be relatively simple, since elaborate toys can become distractions rather than serve as vehicles for the expression of the child's fantasies. Stock characters (such as Barbie or Disney characters) may impose their own specific story lines and thus limit access to the child's own concerns.

Not only is the content of the child's play a rich source of information, careful observation of the form of play also provides important information for the mental status examination. During imaginative play, the clinician can observe the child's coordination and motor capacities, speech and language development, attention span,

readiness to engage the interviewer, capacity for complex thought, and affective state. Absence of imaginative play or limited, concrete, noninteractive play may indicate a pervasive developmental disorder.

Games such as cards or board games are also useful for putting the child at ease and developing rapport. These provide opportunities to observe the degree of the child's engagement in and enjoyment of the shared activity; how the child manages competition, including reactions to winning or losing; or whether the child is prone to cheating. Some play activities (e.g., throwing a ball back and forth or easy card games such as war) are simple enough to permit ongoing conversation, while helping to discharge tension and diminish the pressures of the interview situation. As with toys, elaborate games (e.g., chess) should be avoided; games that demand much cognitive energy and concentration usually preclude discussion of issues relevant to the assessment and may become a means of avoiding issues involved with the child's difficulties.

PROJECTIVE TECHNIQUES In addition to imaginative play, projective techniques often help provide an indirect picture of concerns that the child may be reluctant or unable to report directly. These techniques can help the child feel more comfortable with the clinician, are often experienced as fun, and may provide access to concerns that are important to the diagnostic formulation.

One commonly used technique is picture drawing. The child can be asked to draw a picture, leaving the choice of subject up to the child or, alternatively be given a specific request (e.g., draw a person or the child's family doing something). When the picture is finished or nearly so, it is helpful to compliment the child's effort and express interest in what is happening in the drawing. The child's elaboration provides information that may not be readily apparent from the drawing itself. Both the content and form of the drawing offer a window on the child's emotional concerns and aspects of intellectual and visuomotor development. For example, the relative size and placement or omission of family members in a family drawing may be important nonverbal indicators of the child's perceptions or feelings about the family. Aggressive or sexual themes may be reflected more readily in drawings than in words. Self-image may be indicated through depictions of the child as nonhuman, grotesque, inconsequential, or of the opposite gender. The clinician should become familiar with the developmental progression and norms for human figure details, such as limbs, joints, facial features, and clothing, which can provide a useful rough estimate of intellectual maturity. Various systems have been developed for systematically assessing the cognitive and emotional aspects of children's drawings. Also, the child's behavior and speech while drawing may yield useful information (e.g., throwing the picture away unfinished and saying that it is no good).

Frequently used verbal projective techniques are asking what animal the child would most or least like to be or whom the child would pick to take along to a desert island. It is useful to ask what the child would do with three magic wishes; if elaboration is needed, the clinician can explain that the wishes could be to have anything, to have the world be any way, or to change oneself in any way. Children's responses are often revealing. Some may needily or impulsively wish for material possessions, such as a videogame or a million dollars. Other responses may reveal longings to change distressing circumstances, such as “for my mom and dad to get back together again,” “not to have tics anymore or get teased about them,” or “to have a dad who doesn't yell at me all the time.” Still other children appear uncomfortable wishing for something for themselves, preferring instead seemingly altruistic responses, such as “no more poverty or wars.” Children's responses can be used as the starting point for further exploration. For example, the child who wishes for “a big house and lots of money,” may be asked who else would live there and what they would do. Children who wish for “no more fighting in the world” can be asked if there are some particular fights that they would especially like to stop.

Some interactive imaginative techniques useful to interviewers comfortable with them provide elements of playing a game, which may appeal to the child. The squiggle drawing game developed by Donald Winnicott consists of the clinician drawing a curvy line and asking the child to turn it into a picture of something; the child then draws a curvy line that the therapist elaborates, and so on, taking turns. The Despert fables are a series of incomplete affectively evocative stories that the child is asked to complete.

Asking the child to tell about a dream or a book, movie, or television program can provide information about the child's interests and preoccupations. (If the clinician is familiar with the plot, the distortions the child may introduce can be informative regarding the child's cognitive and emotional style.) Inquiring about what the child would like to do for a living when grown up can provide insight into the child's aspirations, values, and concerns as well as those of the family.

DIRECT QUESTIONING Direct questioning about the current problems and other aspects of the child's life requires tact, attention to the child's level of cognitive and linguistic development, and regard for the impact of the questions on the child's self-esteem. The goal of such discussion is to determine how children see their world and functioning in it, including attachments and antipathies, pleasures and anxieties, and strengths and weakness, which may include difficulties that led to the evaluation.

It is important to phrase questions in language that is appropriate to the child's developmental level and verbal capacities. Children may become confused or made more anxious by technical words or abstract or complicated questions. Closed questions often yield little information. For example, “Do you get along OK with your brother?” may bring forth a simple “yes” or “no,” while open-ended or descriptive questions are more likely to elicit a richer picture of how a child thinks and feels (e.g., “What sort of guy is your brother?” or “Tell me about your last play-date with Danny.”) Some usefully evocative questions include “What sorts of things make you mad (or make you feel afraid)?” “What is your saddest (or happiest) memory?” “What do you like to daydream about?” If it is important to establish the order or duration of events, school-aged children will do better if the questions are anchored to markers in their own lives (e.g., “Did that happen before or after your birthday?” or “Have you had trouble with that since school got out?”) Several empirical studies by Michael Rutter and colleagues have examined the effects of various interview styles on the information elicited from children and parents.

Although direct questions are often needed to initiate or focus discussion, settling into a direct question format may constrict the interview process and give children the impression that the clinician just wants to hear the facts and is not so interested in their own feelings and experiences. Young children frequently respond in a manner they believe to be socially desirable, while older children are often reluctant to acknowledge, even to themselves, feelings of sadness or vulnerability. Clinicians should convey, by demeanor and tone of voice, their interest in the child's real feelings.

When discussion of feelings seems difficult for the child, it may be useful for the clinician to acknowledge the link between a situation and the child's affective response (“Some kids might have felt mad if that happened to them; how about you?”). However, the clinician must avoid leading a child who is not yet well known by assuming experiences or feelings. Probing a bland, equivocal response may prove useful; for example, in response to “Okay, I guess,” the clinician may say, “Sounds like you're not quite sure.”

The assessment should convey respect for the child and protect the child's self-esteem. Many children feel ashamed or guilty about the difficulties that have brought them to the evaluation. When the clinician conveys a nonjudgmental understanding, using language that suggests that the difficulties are problems to be helped rather than transgressions, the child is more likely to be forthcoming. The child has come to the evaluation because of problems, but one should also talk with the child about strengths. For example, in inquiring about school, it may be useful to say, “Tell me the parts of school you like best” before asking “Are there subjects (classmates, teachers) that give you trouble?” or “What are the rough spots at school?” It may be better to ask the socially isolated child “Do you sometimes have trouble making or keeping friends as much as you'd like?” then “What do you think the trouble is?,” rather than “Do you have any friends?” (especially if the truthful answer to this question is “no”).

Structure and Sequence of the Child Interview When interviewing the child, the clinician has in mind an overall map of the functional and historical areas to be covered; however, the format and sequence of any given interview is responsive to the individual child, the presenting problems, the unfolding pattern of the interview, and the clinician's personal style. For example, in every assessment, the clinician should ask about the cardinal symptoms of depression, anxiety, and disruptive behavior disorders, but when, how, and in what order this is done, varies from one interview to another.

BEGINNING THE INTERVIEW There are various ways to start the interview. The one chosen should be comfortable for both clinician and child and set the stage for a productive interchange. Many clinicians prefer not to address the presenting problems at the very outset. Some clinicians, for example, remain quiet and let the child look about the room and begin playing or talking without prompting or guidance. This approach imposes a minimum amount of structure; the clinician can see how the child reacts to both the materials present in the playroom and to the clinician. It also provides information about how the child handles the situational anxiety that is often evoked by the first meeting with the clinician. However, this unstructured approach may leave many children disoriented and uncomfortably uncertain as to the clinician's goals and intentions. Other clinicians are more direct in attempting to place the child at ease and begin by inviting the child to explore the available play materials (“What looks interesting?”). Others open the interview by inquiring about neutral or pleasurable topics (“Tell me about what you like to do for fun?”). The clinician must read the child's cues regarding level of comfort and urgency in deciding when to address the problems that led to the evaluation. Some children will prefer to first talk about nonthreatening topics, while others expect to get down to business and talk about their problems right away.

Although it may be useful to establish some initial rapport around neutral or interesting topics, most children understand that they have not come for a conventional

social encounter. Hence, relatively early in the interview it is useful to ask what the child's ideas are about the purpose of the meeting. It is usually best to do this in a matter-of-fact manner by asking, “What did your mom and dad tell you [or what do you know] about why they wanted you to come and see me today?” If the child has already met with the clinician together with the parents as part of an earlier contact, the clinician will have asked something similar at that time and may have heard about the child's view of the presenting problem and its history. If so, the clinician can follow up by saying, “Last time, mostly your mom and dad said what they thought about things. Today, we have a chance to talk more about how things look to you. Are there any things we talked about then that we should talk about today?” Asking what the child knows or thinks about the purpose of the evaluation shows the clinician's interest in the child's view of the situation and allows the clinician to hear how the child describes or assumes responsibility for the problem (or repudiates it as someone else's concern). Asking for the child's view up front, before the child has become deeply engaged or focused on some aspect of the interview process, allows the clinician to address misapprehensions. It also provides an opportunity for the clinician to explain, in terms that can be understood and potentially acknowledged by the child, the issues (at least as the clinician understands them) that have prompted the assessment.

ASSESSMENT OF MAJOR REALMS OF FUNCTIONING Throughout the assessment, the clinician elicits and assimilates information to develop a picture of the child's functioning in the realms of family, school, peers, and recreation. Discussion of the presenting problem will reveal information, particularly with respect to impairments, in these domains; however, additional discussion of the child's experiences in these areas enhances the picture of the child's life and level of adaptation. It is often useful to begin exploration of each of these realms by asking for objective facts (e.g., “Who lives at home with you?” “Whom do you like to play with [or hang out with?]” “What school do you go to? What grade are you in?” or “What do you like to do for fun?”). This can be followed up with probes for more subjective views: “How do people in your family get along? Are there any problems at home? things people fight about? or things you get in trouble for?, or things people at home do that you don't like?).” This approach is intended to open up discussion of the major realms of functioning, not to simply elicit rote responses.

It is often helpful to begin by inquiring about the child's recreational activities (“What do you like to do for fun?”). This allows the clinician to learn about the child's interests, preoccupations, and talents and may provide a less threatening or problematic starting point than the areas of peer and academic functioning. Family functioning can be approached by asking who lives at home, how the child gets along with each person, and how family members get along with each other. One can also inquire more specifically “What do you like to do with your dad [or other relative]?” or “What is your brother like?” In the case of nontraditional family structures or families of divorce or separation, the clinician may inquire about the history of the current arrangement and what sort of relationship is maintained with the noncustodial parent.

INQUIRY ABOUT PSYCHOPATHOLOGICAL SYMPTOMS Just as a medical evaluation includes a review of key symptoms in the major systems, the child psychiatric evaluation should include a set of questions that screen for symptoms of common or major disorders. The family or child may not see a link between one behavior or area of distress and another and may not volunteer symptoms that seem unrelated to the presenting problem. Comorbidity is relatively common in children with psychiatric disorders; thus, the child psychiatric clinician must routinely question across the major areas of psychopathology. Using developmentally appropriate language, this inquiry should cover depressive symptoms (e.g., low self-esteem, anhedonia, and suicidal ideation or behavior); excessive anxiety or fears; obsessions and compulsions; hallucinations and delusions; and antisocial behaviors. For example, one should ask “Do you feel sad or grumpy a lot of the time? Do you often feel like crying?” If the answer is positive, one can follow up concerning persistence (“Does that last for more than a few minutes?”), frequency (“Does that usually happen every week [or most days?”]) and context (“What sorts of things make you feel that way?”). To inquire about suicidal ideation, one can begin by asking, “Do you ever feel that life is so hard, you wish you weren't alive (or would be better off dead)?” following up with the more explicit “Have you ever tried to hurt yourself (or done anything to try to make yourself dead?)” Exposure to potentially traumatic experiences should be routinely covered and developmentally appropriate language should be used (e.g., “Have any really scary things ever happened to you?”).

MENTAL STATUS EXAMINATION Throughout the clinical interview the clinician observes and notes information relevant to the domains of the mental status examination. Some abnormalities or deficits may be evident through this process; however, other areas will require direct examination, which can usually be incorporated in a playful way into the clinical interview. While intensive developmental, psychometric, language, and neurological assessment usually cannot be subsumed within the clinical interview, a brief semistructured evaluation requires only about 5 to 10 minutes and provides useful information. This generally involves drawing; copying a design; simple tests of orientation, recall, general knowledge, and language (e.g., naming three objects; repeating a phrase such as “No ifs, ands, or buts”; a three-stage command such as “Take a piece of paper in your right hand, fold the paper in half, put the paper on the floor”; a writing sample [such as asking the child to write a sentence of their choice]; and a brief screen of neurological soft signs).

CLOSING THE INTERVIEW In winding up the interview, the clinician can check for concerns that have not been covered and also signal that the interview is coming to a close by asking, “We've talked about a lot of things; are there any other things that would be important for me to know about you?” Similarly, one may ask, “I've asked you a lot of questions; do you have any questions you want to ask me?” The clinician should also give the child a general idea of what will be done with all the information the child has shared and some sense of what will happen next. For example, one may explain “I'm going to think over what I've heard from you and your folks and meet again with them [and you] to talk about what might help with .... Are there any particular things I should be sure to mention?” If the clinician already has a sense of what interventions might be helpful, this may be tentatively broached with the child, keeping in mind the parents' right to hear and decide on those recommendations.

SPECIAL ISSUES IN THE ASSESSMENT OF ADOLESCENTS

The clinical assessment of adolescents requires familiarity with the distinctive dynamics of adolescents and their characteristic patterns of managing conflicts, anxiety, and interactions with adults.

The adolescent's attitude towards the evaluation has important implications for how the assessment process unfolds. In contrast to the adult patient (who usually takes the responsibility and initiative for seeking help) and to the child patient (who is simply brought by parents), many adolescents are cautiously ambiguous as to whether there is a problem with which they want help or whether they are merely passively complying with their parents' initiative.

One important initial decision concerns who is to be seen in the initial interview: the parents, the adolescent, or all together. Seeing adolescents alone first has the advantage of emphasizing their active participation in the process and underlines the clinician's interest in their perspective; on the other hand, it may mean that crucial elements of the history are not available to the assessor. Furthermore, some embattled youngsters may protest that they are being identified as the patient or bearer of a problem that they feel resides in their parents or in the family as a whole. The clinician may to need to explain explicitly that the evaluation is not a judicial proceeding to assess blame, but rather an attempt to understand what the problems are.

In some cases, when the adolescent balks at being seen at all the clinician may need to meet with the parents alone to facilitate the youngster's participation in the evaluation. Regardless of when the adolescent is seen, the parents should at some point be seen alone to explain their concerns about the child, to obtain a full developmental and family history, and to hear about aspects of their spousal and parenting relationship that may be clinically significant but that may not be appropriate to discuss initially in the adolescent's presence.

Meeting with both the adolescent and parents together is usually helpful. This provides an opportunity to explore how family members interact, their convergences or divergences of perspective, them, and their capacity to work together therapeutically. Such conjoint interviews usually require active structuring by the clinician so that the purpose is framed as an occasion to talk together. Without such active intervention, the family session can easily deteriorate into an adversarial proceeding in which the parents complain about the adolescent, who in turn retreats into hostile or guarded silence.

Confidentiality The assessment of adolescents often raises complex issues of confidentiality. Although the parents and the adolescent must know that the adolescent's communications will be kept confidential, they must all understand from the onset that this does not extend to situations that pose a clear danger to the patient or others. For example, if the adolescent reveals significant suicidal ideation or a recent suicide attempt of which the parents are unaware, parents must be informed for the youngster's safety. Having made clear that the parents need to know, the task is then to negotiate whether the adolescent prefers to tell the parents directly or to have the clinician inform them. It is usually best to have the adolescent undertake this responsibility, but sometimes after discussion with the youngster, the clinician must be the one to speak with the parents, preferably in the adolescent's presence. Less clear-cut situations in which the adolescent reveals problematic, but not imminently dangerous, antisocial or sexual behavior or substance use must be decided on an individual basis. Treatment may not be possible without some confidentiality; on the other hand, confidentiality must not become collusion.

Developmental Issues Adolescents' usual strong push toward autonomy is often linked to a wariness of feeling vulnerable, dependent, or controlled. Tolerating feelings of ambivalence, guilt, or other painful affects or internal conflicts does not come easily to adolescents. In addition, adolescents are prone to externalize their concern or embarrassment over self-perceived shortcomings or difficulties. As a result, even adolescents who consciously desire help often approach a clinical

assessment with the fear that revealing what they perceive as shameful weaknesses will leave them vulnerable to criticism, control, or regressive dependency. Fear of acknowledging vulnerability or dependency may result in bland denials of any problems or insistence that “I can handle it by myself” or “I don't need a shrink; I can talk about my problems with my friends.” Externalizing their conflicted feelings about autonomy versus dependence, adolescents may fluctuate between grievances about parental overprotectiveness and complaints about perceived lack of care. Reversal of affect and counterphobic defenses may mask anxiety, shame, or other painful affects. The skilled clinician learns to look beyond surface behavior and to notice when an adolescent “doth protest too much.”

Although many adolescents seem intolerant of self-reflection, an unrealistic belief in the omnipotence of thought often helps support denial and avoidance. Even when confronted with a pattern of long-standing maladaptive behaviors, the adolescent may insist “I can stop any time I really want to” or “I don't do that any more” (i.e., not since Saturday).

The lability of adolescents' moods and their truncated time perspective often make it useful to extend the evaluation over time to distinguish the transient issues from those that are more enduring.

Technical Issues in the Adolescent Interview Interviewing adolescents requires tact, flexibility, a sense of humor, and clinicians who have come to terms with their own adolescent issues. Condescension, sarcasm, competitiveness, or excessive passivity on the part of the interviewer are likely to result in failure. On the other hand, although conveying a genuine interest in the youngster is essential, seductiveness, overfamiliarity, or the failure to maintain an adult role are likely to frighten the adolescent. The interviewer should resist the temptation to be too “with-it” or too “cool”— nothing is more dated than last year's slang. Because adolescents can so easily feel defensive, criticized, or embarrassed, the interviewer must learn to talk frankly, yet tactfully, about areas of apparent difficulty. Many embattled adolescents see adults as either for them or against them; hence, the clinician needs to convey a genuine empathic interest in the adolescent's view of a situation without implying collusive, uncritical acceptance of it or entering into an adversarial dispute.

The general observation that it is important to learn about youngsters' strengths and interests as well as their problems and vulnerabilities is especially true of adolescents. Without appearing squeamish or avoidant of the problem areas, the clinician should inquire about the adolescent's interests, hobbies, recreations, and friendships. Knowing about the areas of accomplishment, talent, and gratification is required for a full picture that includes the youngster's adaptive and compensatory strengths and assets. Furthermore, such an inquiry helps to facilitate rapport and conveys an interest in the adolescent as a whole person, rather than simply a bearer of problems. A too-exclusive focus on pathology puts many youngsters on the defensive, and an opportunity to talk about more-neutral areas or those of greater mastery or confidence helps the adolescent feel less on the spot. Instead of the interviewer straining to demonstrate familiarity with the latest band or winning team, letting adolescents teach one about the details of their interests lets the youngsters enjoy a sense of mastery, control, and a degree of parity with the adult interviewer that helps put them at ease. Indeed, what has been called the constructive use of ignorance is often a useful technical element of the adolescent interview. This consists of being able to ask about some missing piece in the story or about some puzzling impasse with an ingenuous curiosity that invites the adolescent's self-reflection.

Although interviewing and taking the history of the adolescent cover the same general areas outlined above, certain domains are of particular salience with the adolescent. These relate to the core developmental tasks of adolescence: developing increased autonomy and individuation from parents, taking over the tasks of physical self-care; developing a satisfying, realistic body image in the face of pubertal changes; mastering burgeoning sexual and aggressive impulses; consolidating an identity including ethical values and vocational goals, developing a network of satisfying peer relations; and, in later adolescence, a capacity for romantic intimacy with an appropriate partner (Table 33-3 and Table 33-4).

1. Gradual development as an independent individual
2. Mental evolvement of a satisfying, realistic body image
3. Appropriate control and expression of sexual drives
4. Expansion of relationships outside the home
5. Implementation of a realistic plan to achieve social and economic stability
6. Transition from concrete to abstract conceptualization
7. Integration of a value system applicable to life events

Table 33-3 Developmental Growth Tasks of Adolescence

Tasks	Early: 10 to 13 Years	Middle: 14 to 16 Years	Late: 17 Years and Older
1. Independence	Emotionally breaks from parents and prefers friends to family	Ambivalence about separation	Integration of independence issues
2. Body image	Adjustment to pubescent changes	"Trying on" different images to find real self	Integration of a satisfying body image with personality
3. Sexual drives	Sexual curiosity; occasional masturbation	Sexual experimentation; opposite sex viewed as sex object	Beginning of intimacy and caring
4. Relationships	Unisexual peer group; adult crushes	Begin heterosexual peer group; multiple adult role models	Individual relationships more important than peer group
5. Career plans	Vague and even unrealistic plans		Specific goals and specific steps to implement them
6. Conceptualization	Concrete thinking	Fascinated by new capacity for thinking	Ability to abstract
7. Value system	Drop in superego; testing of moral system of parents	Self-centered	Idealism; rigid concepts of right and wrong; other oriented; asceticism

Table 33-4 Growth Tasks by Developmental Phase

In the realm of values, ideals, and aspirations, the clinician should explore the adolescent's values and the models whom the adolescent wishes to emulate or reject. To what extent do these values complement or conflict with those of the parents? What expectations and aspirations (realistic or not) does the adolescent have concerning the future?

The world of peers and friends should also be explored with adolescents. With whom do they “hang out?” What crowd do they see themselves part of? How do they get along with peers, what do they do for fun? Asking teenagers to describe a close friend provides a chance to learn how they think about people and relationships and to assess their capacity for empathy.

The topic of friends leads naturally to the topic of romantic and sexual interests and relationships. Exploration of this area requires tact, and the clinician cannot always be sure of receiving a candid response. Nonetheless, as with questions concerning depression or substance use, the clinician's tone can convey the sense that the inquiry into these sensitive areas is motivated by a genuine and legitimate wish to understand the adolescent. One can begin by asking whether the teenager dates and whether there is anyone of either sex with whom the youngster is close? If so, who are they, and what attracted the adolescent to them? Are the adolescent's interests reciprocated? How has the relationship gone? Does the teenager note any recurrent patterns in terms of the type of person to whom he or she is attracted or how such relationships have unfolded in the past? Have any of the teenager's relationships developed into sexual ones? Has the adolescent had other sexual experiences? (Here one must be open to hearing about possible episodes of sexual abuse or concerns about sexual orientation.)

Because of the high prevalence of depression, suicidal ideation, and even suicide attempts in the general population, specific inquiry about these areas as outlined above is particularly important. The clinician should also inquire matter-of-factly about whether the adolescent smokes, drinks, or uses drugs illicitly, and, if so, with what frequency, in what amounts, in what contexts, and with what consequences.

ASSESSMENT OF INFANTS AND TODDLERS

The assessment of infants and toddlers poses special challenges for the clinician. First, the evaluation of young children requires specific and detailed familiarity with the cognitive, linguistic, motor, and adaptive developmental landmarks of 1 month to 6 years of age, as well as the specialized techniques needed to assess these competencies. Second, although direct observation of the child is an important source of data, the preverbal or limited verbal capacities of the child severely restrict the historical material that can be obtained from the direct interview of the child. Third (and perhaps most important), infants and young children cannot be assessed, diagnosed, or treated apart from their caregiving environment, which includes not only the parents, but also other members of the extended family and day-care and other care providers.

The developmental tasks of infancy include achieving physiological homeostasis, developing stability of state and learning to negotiate transitions between states, organizing basic physiological rhythms of wakefulness and feeding; coping with novel stimuli; perceiving coherent patterns of experience; mastering simple sensorimotor schema; establishing a specific and secure relationship with a caretaker; maintaining a positive affective tone; developing expressive and receptive channels of communication (including vocalizations and facial and gestural cues); and forming schemas of causality, intentionality, object permanence, and affect. The older infant or toddler must grapple with the regulation and socialization of bodily functions (e.g., eating, toileting, sleep), learning to concentrate and regulate shared attention, more-complex forms of imitation and acquiring the capacity for imaginative play, the challenge of socialization (including development of more-complex forms of social perception, communication, and empathy and negotiating conflicts of will with caregivers and peers), control of negative mood and aggression, and formation of core gender identity. Development can proceed at a different pace in each area and may go awry in any or all of them.

The goal of the developmental assessment of infants and toddlers is to depict functional capacities in each of these areas, the relationship between the various domains of development, their ability to adapt, and the range of coping strategies they use in doing so, as well as the caregiving environment as it impinges on them, the quality of caregiving interactions, and the impact of their developmental status on the caregiver. As with older children, the purpose of the assessment is to define what, if any, interventions are necessary, while at the same time helping to form an alliance with the parents that will facilitate implementation of any recommendations that may come out of the assessment.

The most common referral problems for infants and toddlers involve:

1. Developmental delays (e.g., specific delays such as delayed, absent, or deviant motor or speech development or general delays in multiple areas of development).
2. Psychophysiological dysregulation (fussy behavior, disturbances of sleep or feeding, rumination, eczema, self-stimulatory behaviors [head-banging, rocking], failure to thrive).
3. Behavioral disturbances (excessive tantrums, excessive negativism, aggression, hyperactivity).
4. Disturbed social development (lack of apparent awareness of or interest in others, response to abuse, neglect or multiple placements or repeated or prolonged separations).
5. Medical or genetic problems (e.g., prematurity, genetic syndromes).
6. Exposure to domestic or urban violence, sequelae of trauma.

Because so many aspects of early development are interdependent, the significance of difficulties in one functional domain cannot be understood without reference to the child's developmental status in other areas. For example, speech, language, and hearing difficulties profoundly affect personal and social development. Assessment of motor or adaptive competency that involves interaction with the caregiver or assessor will be affected by disturbances in relatedness and hence yield findings that appear erratic or uneven. Infants and toddlers are particularly sensitive to environmental stresses, which may delay the appearance of phase-appropriate skills or lead to transient regressions.

Technical Issues in the Development of the Infant and Young Child The assessment of the young child usually requires several sessions. In addition to sessions spent with the parents alone to gather history and to present the results of the assessment, familiar adults must be present during the assessment of the child; this is necessary both to place the child at ease in the assessor's presence and to permit direct observation of child and caregiver interaction. Furthermore, the behavior of infants and young children is highly state dependent (and sensitive to fatigue or illness), and one usually needs to see the child on more than one occasion to have a sufficient sample of characteristic behavior.

The general principles of history taking from the parents and assessment of the caregiving environment follow those outlined above. However, particular emphasis is given to the parental perception of the pregnancy—whether the conception was planned or came at a good time in the life of the family, and what the impact of the child's arrival was on the parents individually and on the family as a whole. The history should explore parental (and grandparental) expectations for the child, the meaning the child has for them, whom the infant reminds them of, and what they perceive as the child's best and worst traits.

The developmental history for the young child includes prenatal, perinatal, and postnatal complications, including maternal illness, medication and substance use, and neonatal status. In addition to the areas outlined above, assessment of the child's behavioral organization should include the regulation of physiological state, alertness, and activity patterns. Children's ability to console themselves and to adapt to new situations and their response to separations are also key areas of evaluation. The history should also include the history of child-care arrangements (nannies, relatives, out of home day-care) and the child's reaction to any changes in these arrangements.

The child's mastery of various gross motor, fine motor, language, adaptive, and personal-social milestones should be systematically assessed, both by history and in the direct evaluation of the child. In taking such a history, the assessor may be aided by a variety of screening instruments, such as Vineland Adaptive Behavior Scales. It is useful to inquire about the timing of the child's mastery of these milestones relative to any siblings.

Within the first few months of life, children begin to manifest distinctive and often enduring behavioral styles or temperament. Table 33-5 shows the nine temperamental categories and three distinctive constellations of temperament as defined by Stella Chess and Alexander Thomas. The goodness of fit, or degree of consonance between the child's temperament and the parents' expectations or demands of the child, is an important predictor of future development.

Table 33-5 Temperament Categories

Particularly salient aspects of the parental interview include a detailed history of the parents' own childhoods and history of care, out-of-home placement, separations, and experience in their families of origin. The impact of the child on each parent and their marital relationship should be assessed as well as the appropriateness and degree of congruity in their respective expectations of the child.

Adequate caregiving for the young child requires a delicate balance between gratification, comfort, support, and frustration appropriate to the child's developmental phase. It is important to hear (and observe) which aspects of parenting and which features of the child's behavior the parent feels most comfortable with or most

challenged by. The clinician should assess the parents' overall level of psychological functioning; the parental difficulties that adversely affect a young child's development do not always involve such gross failures as serious neglect or abuse, but may involve problems more difficult to identify such as persistent maternal depression. To help obtain a concrete picture of the parent, child, and their interaction, it is useful to ask for a detailed description of a day in the life of the child. In addition to providing data regarding the child's capacities, responses, and temporal organization, such a description provides clues to the parents' attunement and affective responses to the various elements of the child's behavior.

Although much of the clinical observation is focused on the child's behavior and capacities, direct observation of the parent-child relationship is essential. Inviting the family to interact in the play room as they usually would at home allows observation of their interaction in unstructured parent-child or family play; assigning various structured tasks may also be useful. Observing the child in interaction with each parent separately helps reveal relationship-specific patterns of behavior. Among the dimensions of parental behavior to be assessed are the ability to engage the child (both verbally and nonverbally); the quality and affective tone of this engagement; the parent's attunement to the child's cues; parental vigilance, protectiveness, and limit setting; the parent's facilitation or restriction of autonomous play by the child; thematic content; and the degree of mutual pleasure during play. Although instruments for formally assessing parental responsivity and parent–young child interaction, such as the Home Observation for Measurement of Environment (HOME) and the Parent-Child Early Relational Assessment (PCERA) are used primarily for research purposes, familiarity with the various facets of such instruments is clinically useful.

Observation and Examination of the Infant and Toddler The direct examination of the young child draws on three levels of observation: the child's response to structured assessment items during formal testing, the child's response to other interactions with the assessor and the assessment environment, and the interactions of the child and parent.

Structured Assessment Instruments A variety of instruments exists for the structured assessment of infants and young children, and each has somewhat different goals, theoretical orientation, and psychometric properties. These instruments do not yield diagnoses; they detail the child's development in various areas relative to a normative population. For example, the Denver Developmental Screening Test (Denver II) is suitable for screening use by pediatricians or trained paraprofessionals to help identify children with significant motor, social, or language delays who need fuller evaluation. Population-specific norms are also available for assessing children from families of various ethnic or educational backgrounds. The Bayley Scales of Infant Development II, which are administered by a trained assessor, can be used to assess children 1 to 42 months of age; they include a mental scale (assessing information processing, habituation, memory, language, social skills, and cognitive strategies); a motor scale assessing gross and fine motor skills; and a Behavior Rating Scale for assessing qualitative aspects of the child's behavior during the assessment. This well-standardized instrument yields standard scores for a Mental Development Index and Psychomotor Development Index.

Although tests such as the Bayley Scales may show good reliability and concurrent validity, their ability to predict later performance on Intelligence Quotient (I.Q.) assessments or later adaptive functioning is highly variable. Among the reasons for this weakness of prediction are the intervening effects of social and family environment and the heavy emphasis infant tests place on perceptual and motor skills that may have relatively little to do with information-processing capacities.

The mental status examination of the infant and young child may be organized using a schema such that shown in Table 33-6.

Table 33-6 Infant and Toddler Mental Status Exam by Anne L. Benham, M.D.

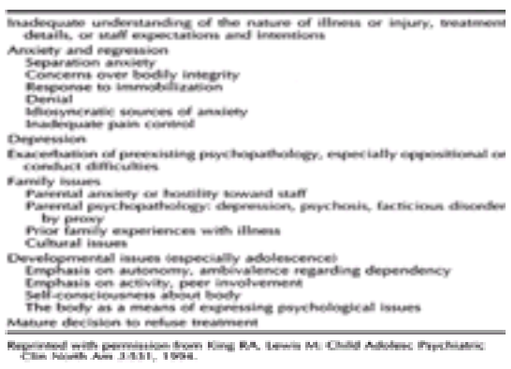
Diagnostic Formulation of the Assessment of Infants and Young Children Although mental retardation, autism, and other pervasive developmental disorders can be at least tentatively diagnosed in infants and toddlers, the most widely used official diagnostic systems—the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) and the 10th revision of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10)—generally lack a developmental perspective and diagnostic criteria or categories suitable for infants and young children. The Zero to Three/National Center for Clinical Infant Programs's *Diagnostic Classification of Mental Health and Development Disorder of Infancy and Early Childhood* provides a diagnostic schema for this age group that is intended to complement DSM-IV. This new schema is still under development, and the nosological approach to this developmental epoch remains an area of ongoing research and debate.

The appropriate outcome of a thorough clinical assessment of the young child thus extends far beyond an attempt at a specific categorical diagnosis. The diagnostic formulation should provide a detailed picture of the strengths and weaknesses in the child's social, emotional, cognitive, linguistic, motor, and perceptual development, the quality of the child's temperament, attachment, and regulatory capacities; hypotheses regarding the etiology of the child's difficulties; and potential exacerbating or risk factors and protective or ameliorative factors in the child and family. This formulation, which should be shared with the family in a comprehensible and usable form, ought to provide the basis for recommendations regarding intervention or further assessment.

SPECIAL TYPES OF ASSESSMENT

This chapter describes the comprehensive clinical assessment of the child. Although the clinician must be aware of the many facets of history taking, interview, and observation described herein, certain clinical settings or tasks may call for a narrower focus of inquiry or distinctive emphasis for the evaluation. For example, an urgent situation may require therapeutic intervention before a comprehensive assessment can be completed; in such cases the immediate evaluation focuses on defining the crisis and selecting the most suitable immediate intervention. Thus, the emergency room or crisis center evaluation focuses on precipitants and extent of the current decompensation, predisposing vulnerabilities, the exacerbating factors impinging on the child and family and the ameliorative resources available to them, the risk of danger to self or others, and other issues germane to making an immediate disposition (including assessing the potential need for hospitalization). Evaluation of suicidal ideation, threats, or attempts or aggressive outbursts are perhaps the most common clinical context for such urgent evaluations (Table 33-7). Children exposed to acute trauma (e.g., natural catastrophe or violence) are often screened outside the traditional clinic setting, in a combination of emergency assessment and crisis intervention. The noncompliant, acutely agitated, or delirious child in the pediatric setting raises yet a different set of assessment issues (Table 33-8).

Table 33-7 Questions to Ask in the Evaluation of Suicidal Risk in Children



Inadequate understanding of the nature of illness or injury, treatment details, or staff expectations and intentions
Anxiety and regression
Separation anxiety
Concerns over bodily integrity
Response to immobilization
Denial
Idiosyncratic sources of anxiety
Inadequate pain control
Depression
Exacerbation of preexisting psychopathology, especially oppositional or conduct difficulties
Family issues
Parental anxiety or hostility toward staff
Parental psychopathology: depression, psychosis, factitious disorder by proxy
Prior family experiences with illness
Cultural issues
Developmental issues (especially adolescence)
Emphasis on autonomy, ambivalence regarding dependency
Emphasis on activity, peer involvement
Self-consciousness about body
The body as a means of expressing psychological issues
Mature decision to refuse treatment

Table 33-8 Differential Psychosocial Diagnosis of the Uncooperative Patient

Various specialized consultative purposes also require distinctive techniques or procedures or specific areas of inquiry. For example, forensic evaluations raise special issues of role definition, confidentiality, and privilege and require familiarity with the legal issues involved. Clinicians must be clear about whether they are serving as neutral impartial advocates for the best interests of the child at the behest of the court or as consultants to one party or another. Although the clinician treating or assessing the child for clinical purposes may have information valuable to a forensic evaluation, it is usually in the best interests of both the therapy and the legal proceedings for the evaluator to be someone other than the therapist.

The forensic evaluation of children or adolescents who may have been physically or sexually abused is a common form of forensic evaluation. In addition to assessing the child's competency and credibility, the examiner may also be asked for recommendations regarding whether the child should testify in court (and if so, how) and whether removal of the child or alleged perpetrator from the home is needed, as well as any therapeutic interventions that may be required. A forensic evaluation requires careful documentation of parent and child interviews. The suggestibility of younger children raises the danger of both false accusations and false denials and requires meticulous safeguards against repetitive, suggestive questioning.

Child custody evaluations also require careful definition of the assessor's role with all concerned; specific attention must be given to the best interests of the child in terms of continuity and stability of care, the quality of parent-child attachment and attunement, the child's stated preferences, the mental health of each parent, and the level of parental conflict and its impact on the child. Consultations for the juvenile court regarding youthful offenders or children in need of services and probate or commitment hearings represent other forms of forensic evaluation. Other specialized forms of evaluations include medication consultations and consultation to day-care centers, schools, or pediatric specialty clinics (e.g., pain or oncology clinics).

STANDARDIZED ASSESSMENT INSTRUMENTS FOR CHILDREN AND ADOLESCENTS

The past two decades have seen the development of a number of standardized interviews and rating scales that provide systematic methods for eliciting information about child psychiatric symptoms and for combining that information to yield categorical diagnoses or dimensional scores on statistically derived scales. The wave of interest in developing and testing methodologies was stimulated in large part by the rapid expansion of research activity in child and adolescent psychiatric disorders. This burgeoning research interest has confronted researchers with the need for assessment techniques that yield reliable and valid data.

There are a number of reasons why the development of measures to assess psychopathology in children is more challenging than the comparable task with adults. These challenges include (1) the need to incorporate an understanding of various aspects of development into the framing and wording of questions about symptoms and into the process of discriminating normative behavior from pathological behavior; (2) the necessity of conducting the assessment with both child and parent (and at times with the teacher), since often some kinds of information are uniquely reported by one or the other informant; (3) the importance and difficulty of integrating concepts of social context and adaptive functioning into a symptom-based assessment; (4) the lack of a readily available gold standard with which to compare the results from assessment methods in order to modify and improve them. Despite—or perhaps because of—these challenges, extensive research effort has been directed toward diagnostic assessment in child psychiatry; this effort has yielded a number of measures for use in clinical and epidemiological research. Some of the methods described below have found appropriate adjunctive roles in certain clinical settings.

Structured and Semistructured Interviews Available diagnostic interviews differ from each other in several respects. A fundamental one is the degree of structure that is built into the interview. Interviews range from highly structured instruments that specify the exact order and wording of all components to semistructured interviews that delineate the symptoms to be covered and suggest phrases that may be used but permit much latitude in the order and phrasing of questions. The degree of structure reflects the intended use of the interview, the type of interviewer who will administer it, and the cost of using it in a study.

On a continuum of structure, semistructured interviews resemble clinical interviews more closely than do structured interviews, but they nevertheless differ substantially in style and content from a true clinical assessment. Semistructured interviews are designed to be administered by interviewers with clinical training or with very intensive training in the assessment of symptoms covered by the measure (e.g., the Child and Adolescent Psychiatric Assessment). The flexible structure of the interview allows the clinically informed interviewer some freedom in the manner of inquiry and permits judgments about whether a reported behavior or expression of distress is of the quality and severity required to be considered a symptom. Some structure is needed to ensure that symptom inquiry is complete, and the interviewer is also required to make specified ratings that can be compared and aggregated across the sample. Interviews of this type include the many versions of the Child Schedule for Affective Disorders and Schizophrenia (K-SADS), the Child Assessment Schedule, (CAS), the Interview Schedule for Children (ISC), the Child and Adolescent Psychiatric Assessment (CAPA), and the recent forms of the Diagnostic Interview for Children and Adolescents (DICA). Semistructured interviews are more costly to administer than highly structured ones, but they are particularly appropriate for clinically based research in which subtle diagnostic distinctions may be critical for defining samples and where sample sizes are small enough to justify the expense of hiring interviewers trained to make these judgments.

Structured interviews, on the other hand, provide highly specified protocols that are particularly useful for epidemiological studies in which large sample sizes (i.e., in the thousands) require using many nonclinician interviewers. These studies investigate issues of prevalence of disorders, developmental patterns of psychopathology, psychosocial correlates, and risk and protective factors, topics that often require large samples to provide enough statistical power to examine study hypotheses. Because it is obviously unwise to have untrained interviewers make clinical distinctions and because using more highly trained interviewers becomes prohibitively expensive, considerable effort has been devoted to the development of highly structured techniques. In recent years, the bulk of this work has focused on writing and testing the Diagnostic Interview Schedule for Children (DISC), which has proceeded through several rounds of methodological testing in clinical and community samples.

Choosing the appropriate instrument for a particular purpose and interpreting results from child psychiatric studies that have used one or another diagnostic method require some understanding of a few key issues concerning the quality of the assessment method. Two critical properties in the evaluation of such instruments are validity and reliability. *Validity* is the extent to which an instrument measures what it purports to measure. There are various ways to conceptualize and assess validity. Child psychiatric diagnoses generated by a particular instrument are usually compared with those generated by an expert, or criterion, assessment. Statistical methods are then applied to quantify the degree of agreement on whether diagnoses are present or absent. In the methodological evaluation of the validity of an instrument, agreement is usually determined diagnosis by diagnosis, so that the instrument can be revised in areas of poor agreement with the criterion.

The *reliability* of an assessment method is often conceptualized as the extent to which the results of an assessment are repeatable. There are various types of reliability. *Interrater reliability* involves the stability of an assessment when it is administered by different raters (in this case, interviewers). *Test-retest reliability* reflects the stability of result over time (i.e. when a test is administered on two occasions separated by a period of time in which the degree of real change in the condition being measured is expected to be trivial). In child psychiatric assessment, the test is often administered twice, about 2 or 3 weeks apart. This interval is chosen to

minimize memory effects (i.e., the child or parent is not likely to remember, and thus repeat, precise responses to a great number of the questions previously asked). On the other hand, the relatively long duration of many child psychiatric conditions makes it more likely that changes between the first and second administration reflect unstable aspects of the assessment instrument than real changes in the disorder.

In addition to writing and testing the interview itself, developers of structured and semistructured diagnostic methods must determine how to use symptom information to yield diagnoses. While DSM-IV criteria determine the overall rules for defining a diagnosis, much detailed work goes into the decisions about the number of positive responses required to meet a DSM-IV symptom criterion. The specification of frequency and duration for behaviors also requires much fine tuning (e.g., contrast the number of times truant versus episodes of fire-setting for meeting DSM-IV symptom criteria). For some instruments (e.g., particularly highly structured interviews such as DISC), diagnoses are generated by having a computer count and combine the interview information according to a specified algorithm. For the semistructured instruments (e.g., K-SADS), the clinician performs this process. Depending on the instrument, information elicited from the child and parent may be combined to generate diagnoses, simulating clinical assessment. Alternatively, diagnoses may be generated for each informant separately, so that the investigator can explore issues of differential reporting (and perhaps awareness of) types of psychopathology, as well as different correlates for parent- and child-reported psychopathology. Recent research has placed increased emphasis on incorporating indicators of associated impairment, over and above the mere presence of symptomatology.

Used in a clinical setting, these interviews may be useful in prompting the clinician to inquire systematically about a broad array of symptoms and disorders, including those that may be clinically significant but are not part of the initial chief complaint.

Rating Scales A variety of checklist rating scales have been developed over recent years to assess symptomatology and various aspects of behavior and adaptive functioning. Different measures have been designed to be completed by parents, teachers, or children. These may focus on either a broad range of symptoms or a specific area (e.g., depression, anxiety). The development of each scale involves testing its reliability and validity and administering it to large and diverse samples to determine norms and clinically relevant cutoffs.

Probably the most widely used comprehensive symptom rating scale is the Child Behavior Checklist developed and extensively tested by Thomas Achenbach and Craig Edelbrock. It is a 118-item inventory of behavior and functioning that is filled out by the parent or primary caregiver. The component behavior and competency scales have age and gender group norms and clinically meaningful cutoffs. Companion forms exist for the teacher to fill out (Teacher Report Form [TRF]) and for the youth (Youth Self Report [YSR]). These measures provide a convenient way to screen for overall level of symptomatology, and when scored, they provide a profile of problem areas and competencies. The Child Behavior Checklist is stable over relatively brief intervals (i.e., good test-retest reliability) but also reflects changes resulting from treatment. The Child Behavior Checklist TRF and YSR have been widely used in epidemiological and clinical research and in many clinical settings and countries. These measures can be a useful clinical screening tool and an efficient way for clinics to gather uniform information for characterizing the populations served and changes in those groups over time.

The Behavior Assessment System for Children (BASC), developed by Cecil Reynolds and Randy Kamphaus, is a relatively new multimethod assessment for evaluating aspects of behavior and personality in children ages 4 to 18 years. It has five components including parent, teacher, and child self-reports, a structured developmental history, and a system for systematic collection of observed classroom behavior. A distinctive feature of the BASC is its emphasis on positive aspects of the child's adjustment in addition to rating symptoms and problem behaviors. An additional feature of this system is its coverage of problems related to school functioning, such as difficulties in social or study skills. Norms have been established for children by age, gender, and clinical status. This system has been designed for application in clinical, educational, research, and program evaluation contexts.

The Conners' Parent Rating Scale (CPRS) is a commonly used rating scale that collects systematic information from a parent on the child's conduct, activity level, attention, impulsiveness, and somatic complaints. The scale can be scored to reflect a child's symptom level on six component subclasses, including a general index of hyperactivity. Norms have been determined for boys and girls ages 3 to 17 years. The Conners' Teacher Rating Scale (CTRS) is a companion instrument completed by the child's teacher that can be a convenient means of collecting information on a child's behavior in the classroom. It is often a useful adjunct in evaluating and (particularly) monitoring children being treated with medication for attention-deficit/hyperactivity disorder. The CPRS and CTRS are well known and widely used. They have been revised and organized into a family of six instruments developed by Kieth Conners and colleagues, known as the Conners' Rating Scales–Revised (CRS-R). This family of instruments has scales of varying lengths for parent, teacher, and adolescent informants.

The Child Behavior Checklist and BASC families of rating scales are examples of assessment tools designed to collect information across a broad range of symptoms and competencies. The CRS-R focuses especially on disruptive behavior and symptoms of attention-deficit/hyperactivity disorder. More narrowly focused symptom rating scales have been developed to permit the quantitative assessment of specific symptom realms. Such symptom scales may be useful in quantifying the presenting severity of a symptom to establish a baseline against which response to a therapeutic intervention, such as medication, can be compared. A number of these scales are self-report measures. These have the advantages of providing an opportunity for the child to report on symptoms that might be difficult to conceptualize or verbalize. Sometimes parents or children (especially adolescents) are initially more willing to report an area of difficulty in the seemingly more anonymous context of a questionnaire than they are in a face-to-face interview. On the other hand, self-reports also carry the risk of the child misunderstanding some questions or feeling compelled to provide socially desirable responses rather than acknowledging behaviors and feelings that the child believes would be met with disapproval. With these potential limitations in mind, child self-report measures can provide useful adjunctive information in clinical settings or research studies.

Among the rating scales useful in clinical practice are a variety of scales for assessing the severity of depressive symptoms. One of the most widely used, the Children's Depression Inventory (CDI), developed by Maria Kovacs, is a self-report measure for assessing symptoms of depression in children aged 7 to 17 years. It was adapted from the well-known adult scale, the Beck Depression Inventory, and has seen considerable use in clinical and research settings. The Reynolds Adolescent Depression Scale (RADS) was designed specifically to assess depressive symptoms in adolescents and has been used in a range of populations. In addition to research applications, it may be particularly appropriate to screen for depression in schools or other such settings. The Children's Depression Rating Scale (Revised) of Elva Poznanski and Hartmut Mokros, modeled after the adult Hamilton Rating Scale for Depression, assesses 17 depressive symptom areas, based on a 20- to 30-minute, focused, semistructured interview; well standardized, it is useful as a sensitive and reliable screening instrument and severity measure of depression for children 6 years old and above.

Various rating scales for different types of anxiety symptoms, traits, and disorders are also available. For example, the Revised Children's Manifest Anxiety Scale (R-CMAS), developed by Cecil Reynolds and Bert Richmond, is a child self-report measure that assesses symptoms of anxiety (including physiological anxiety), worry, and oversensitivity, and social concerns and concentration. Children at the third-grade reading level or above can fill it out individually or by group administration, and it has been used with younger children by reading the items aloud. The Multidimensional Anxiety Scale for Children (MASC) is a self-report measure for children and adolescents aged 8 through 18 years that assesses symptoms of anxiety in the areas of physical symptomatology, social anxiety, harm/avoidance, and separation anxiety, as well as seven more-refined subdomains. Although relatively new, it is being used in a number of treatment studies to monitor response.

Instruments are available for assessing many different types of child and adolescent symptomatology, including symptoms of obsessive-compulsive disorder (the child version of the Leyton Obsessional Inventory by Carol Berg and coworkers and the Child Yale-Brown Obsessive-Compulsive Scale by Lawrence Scahill and coworkers); tic severity (Yale Global Tic Severity Scale by James Leckman and coworkers); eating disorders and related attitudes (Eating Disorder Inventory by David Garner and coworkers and Eating Attitudes Test by David Garner and Paul Garfinkel). For assessment of autism and related disorders there is the Autism Diagnostic Observation Schedule (ADOS), a play-based interview with standardized probes and ratings for various facets of social relatedness, communication, and repetitive behaviors; the revised Autism Diagnostic Interview (ADI-R) is a semistructured interview administered to parents regarding developmental milestones and assessment of these same facets.

Instruments also exist for assessing level of adaptive functioning and impairment, either globally or with respect to specific domains. The Children's Global Assessment Scale (C-GAS) by David Shaffer and coworkers provides a quantitative scale for the clinician's rating of overall impairment. The Columbia Impairment Scale by Hector and coworker Bird is a rating scale of impairment that taps four major areas of functioning: interpersonal relations, broad psychopathological domains, functioning in school or at a job, and use of leisure time. The Vineland Adaptive Behavior Scales provide a comprehensive framework for systematically recording and assessing the development of children with respect to various realms of adaptive functioning. The Social Adjustment Inventory for Children and Adolescents (SAICA) provides a semistructured interview format for assessing social functioning.

Various structured and semistructured formats for performing or recording portions of the child mental status examination have been developed. Some such as the child version of the Mini-Mental State Examination by R.A. Ouvrier and coworkers contain specific standardized items for screening cognitive functions. Other instruments, such as the Mental Health Assessment Form by Clarice Kestenbaum and Hector Bird, provide a format for organizing mental status data derived from a

semistructured clinical interview.

Limitations of Structured Measures in Clinical Assessment Interviews and scales such as those described above can at times be useful adjuncts in clinical assessment, if thoughtfully chosen and administered with sensitivity to their meaning in the overall process of the evaluation. For example, they can help ensure a comprehensive review of symptoms or provide a standardized baseline measure of severity for later determination of intervention efficacy. They cannot, however, replace an individualized child psychiatric interview nor be relied upon as the sole basis for establishing diagnoses or planning treatment. Most of the existing instruments were developed for use in research studies where data must be gathered from all subjects in a specified, uniform manner. Eliciting information for a clinical child assessment, on the other hand, requires comprehensive, detailed, and flexible inquiry and an empathic rapport with the parent and child. These elements cannot be provided by a standardized interview format alone. Furthermore, most standardized interview schedules are designed as symptom inventories and not the comprehensive assessment of feelings, personality style, coping mechanisms, situational context, and adaptive strengths that the clinical interview affords. Such factors may be as crucial to the clinical assessment and treatment planning as the presence or absence of a given pathognomonic symptom or categorical diagnosis.

The researcher interested in selecting measures for a study protocol must review carefully the existing measures in the area of interest and consider the psychometric characteristics of potential measures and the appropriateness of the measures for the study sample and the goals of the study. It is useful to begin by examining some up-to-date critical reviews of instruments.

PSYCHOLOGICAL AND NEUROPSYCHOLOGICAL ASSESSMENT

Psychological assessment using tests of personality and mental functioning can be a valuable part of the child psychiatric evaluation. Psychological evaluations provide a unique perspective on the child's condition by generating information complementary to that obtained from history, observation, and interview. With history and observation, such psychological data may clarify relationships among various etiological factors or help direct the selection of an appropriate intervention. Although partly inferential, the clinical information derived from projective tests of personality is less influenced by certain reporting biases (e.g., social desirability) than self-report. Psychological testing also provides data that are more quantitative than the qualitative information provided by the child's history, presenting complaints, and clinical presentation.

The quantitative character of test findings is more important in the assessment of cognitive abilities than in personality assessment, because the child's relative strengths and weaknesses in mental processing can be estimated only grossly from history taking and clinical observation. Such clinical estimates are also, necessarily, less accurate. The ability to discriminate meaningful differences among various domains of functioning helps to clarify the particular pattern or syndrome evidenced by the child. The assessment of cognitive functioning also reveals cognitive impairments that may underlie or influence the psychological condition under investigation (e.g., whether poor social judgment in a child with conduct disorder also results from a nonverbal learning disability). Furthermore, the manner in which any cognitive impairments or strengths interact with the child's psychological disorder can be delineated. Findings from tests of personality also identify important dynamics that affect the child's clinical condition.

Referral for Psychometric Assessment A referral for a psychometric assessment of the child is a request for a professional consultation from which an opinion regarding the referral questions can be expected. The referral for psychological examination is analogous to that made to a neurologist or radiologist, who use their assessment methods and particular expertise to contribute potentially valuable information that can then be considered, evaluated, and integrated into the psychiatric evaluation. Referrals are, therefore, best worded in terms of the information that is needed, the issue to be resolved, or the decisions that must be made, rather than requesting that specific tests be administered.

Referral questions can be broad in scope, such as requesting a second opinion regarding the child's condition from the unique perspective of psychological test findings. Requests for assistance in delineating differential diagnoses or in identifying idiosyncratic attributes of the child that may affect treatment are narrower referral questions that, nonetheless, still require relatively broader psychological examinations. In contrast, more narrowly focused questions, such as the adequacy of the child's reality testing, may permit more focused examinations. However, the extent to which psychological evaluations can be restricted to a narrowly defined referral question has a lower limit. Usually a critical mass of data is required to interpret test findings properly.

Referrals for psychological examination should be made to professionals who will use the appropriate instruments and can interpret the findings. Just as psychiatrists may specialize in the treatment of adult, child, or geriatric patients or develop a special expertise with certain disorders, psychologists develop specialized skills in assessing certain groups of children or syndromes.

While it is still best to state a referral question, referrals are frequently made for a particular kind of evaluation (e.g., psychological versus neuropsychological). A request for a psychological evaluation is commonly understood by the psychologist to mean assessment of personality and intelligence, with only a screening of achievement or other cognitive functioning unless specifically requested. In contrast, a request for a neuropsychological evaluation by a neuropsychologist is assumed to mean comprehensive assessment of cognitive functioning, including intelligence, complex mental processing, attention, memory, language, perception, and motor functioning, with only a screening of personality.

The primary purpose of neuropsychological evaluations is not to detect brain damage. Rather, comprehensive assessment of cognitive functioning, attention, memory, language, perception, and motor functioning permits the identification of deficits that cause academic, social, or developmental disabilities or that impede psychiatric treatment. Such assessments also identify the child's areas of strengths and weaknesses and help provide the basis for prescribing rehabilitative interventions that may be delivered as special education, occupational therapy, physical therapy, or vocational or cognitive rehabilitation. By parsing the psychological and cognitive impairments that contribute to the child's functional disability, such assessments also help to delineate the interaction between the child's psychological disorder and cognitive impairments. While neuropsychologists are familiar with the cognitive sequelae of various neurological conditions and can be particularly helpful in the assessment of children with neurological disorders, any child requiring a detailed assessment of cognitive functioning is appropriate for referral.

Psychological Test Batteries Table 33-9 contains a list of commonly used psychological measures for various domains of functioning. A comprehensive examination samples all of the domains, whereas a more focused evaluation selects a subset of domains. In the most general sense, a battery of tests consists merely of a collection of tests to measure a variety of mental functions. There are loosely defined batteries that are routinely administered in psychological examinations. For example, the psychological battery for a child often includes the Wechsler Intelligence Scale for Children–III (WISC-III) as the measure of intelligence. In addition, there may be a measure of achievement in basic linguistic skills and math, such as the Wide Range Achievement Test–3 (WRAT-3) or the Kaufman Test of Educational Achievement (K-TEA). A test of visuomotor integration or visual construction, such as the Beery-Buktenica Test of Visual Motor Integration (VMI) or the Bender Visual-Motor Gestalt Test, is also usually administered. Finally, a variety of personality tests and behavior rating scales is used.

Table 33-9 Commonly Used Child and Adolescent Psychological Assessment Instruments

Some published test batteries consist of measures of various mental functions that have been developed together and can usually be combined into composite or factor scores. For infants and preschool children, psychometric instruments primarily focus upon development, including motor, sensory, perceptual, and language development and the development of conceptual reasoning. Comprehensive developmental quotients are derived from many of these instruments. The revision of the

Bayley Scales of Infant Development and the Mullen Scales of Development are two notable examples. The Woodcock-Johnson Psychoeducational Battery and the Halstead-Reitan Neuropsychological Batteries are appropriate for school-aged children and examine a variety of smaller domains of functioning.

Personality Measures Personality tests for the young school age child consist primarily of projective tests of personality. Projective tests contrast with objective tests of personality in that projective tests use limited structure and ambiguous stimuli to which the child can respond in a virtually unlimited variety of ways. Perhaps the best known example of a projective technique is the Rorschach Inkblot test. Other projective tests commonly used for the young, school-age child include the Thematic Apperception Test (TAT) and the Children's Apperception Test (CAT), which both require that the child compose a story in response to a picture depicting a scene. A variety of tests administered to this age group require the child to draw, such as the Draw-A-Person Test, the House-Tree-Person Test (HTP), and the Kinetic Family Drawing (KFD). (Methods exist for scoring children's drawings to assess cognitive and visual motor development as well as affective content). For the most part, the interpretation of responses to projective tests of personality is inferential, that is, the meaning is not self-evident in the response. The inferences are based upon accumulated clinical experience reported in the literature, symbolic interpretation or analogous reasoning based upon a theory (e.g., psychoanalytic theory) and, to a much lesser extent, empirically established norms. The notable exception is the interpretation scores derived from the Exner Scoring System for the Rorschach, which have norms and have been extensively studied in empirical research.

Objective personality tests are usually more structured than are projective tests, in that the stimuli have limited ambiguity and only a select number of responses are permitted. In most objective measures, individuals are asked whether various statements are true or false for them. Perhaps the best known example of an objective test of personality is the Minnesota Multiphasic Personality Inventory, which is now in its second revision (MMPI-2) and is appropriate only for adults. Objective measures of personality for younger children are usually limited to behavior rating scales or structured reports by parents or caregivers. The Personality Inventory for Children (PIC) and the Behavior Assessment Scales for Children (BASC) are good examples of these measures. There are objective tests of personality available for adolescents in the format of the MMPI-2. The Minnesota Multiphasic Personality Inventory–Adolescent (MMPI-A), and the Million Adolescent Personality Inventory (MAPI) are two well-known examples. Both of these tests yield personality profiles based upon the relative deviations of scales that measure various psychological attributes.

Validity and Reliability While the validity and reliability of individual tests as measures of specific mental functions are established with group data, the reliability and validity of findings for the individual child is also a concern for the examining psychologist. Test batteries provide some advantages in determining the reliability and validity of individual test findings. An integrated battery provides some overlap in the testing of mental functions, permitting comparative assessment of the consistency of the child's performance across measures. In addition, if there is a theoretical or empirical basis for knowing that some mental abilities are associated with each other, then consistent findings across measures of those abilities strengthens the confidence in the findings for the individual child. Examinations that focus on a few mental functions by administering a limited number of tests do not permit detection of transient performance factors that may cause spurious scores. In addition, no test is a pure measure of the target variable; therefore, performance on a single test may be impeded by impairment of a mental function necessary for performing the task but which is not the function that the test purports to measure. If previous psychometric evaluations have been performed, the reliability of findings for the particular child can be estimated from the consistency of findings across examinations.

Finally, the assessment of children with motor, language, hearing, or visual impairments presents a special challenge. Every psychological measure requires a modality of perception, mental processing, and modality of expression. To assess children with impairments in any of these functions, tests are selected with forms of input and expression that avoid the obviously impaired functions. Children with pervasive disorders of mental processing require assessment methods appropriate for their level of functioning. In such cases, it is frequently more helpful to characterize the impairments in terms of criterion-referenced measures, which list abilities mastered, or in terms of the child's standing among children of the same diagnostic group.

Interpretation of Psychometric Findings The interpretation of psychometric findings is predicated upon standardized administration of the tests. In addition, the proper interpretation of psychometric findings generally requires knowledge of parametric and nonparametric statistics, mastery of the literature on test performance and test construction, familiarity with the construction and psychometric properties of the specific tests used, and knowledge of the literature on those instruments.

The results of psychological examination are often best integrated in a concluding discussion of the findings as they pertain to the referral question. The results of a neuropsychological examination are organized around a discussion of various functions with a concluding integration. The interpretation of test results includes consideration of the immediate context in which the tests were administered (e.g., performance factors such as fatigue, anxiety, rapport, level of cooperation, and motivation of the child). There are generally three levels of analysis for the test scores themselves: (1) symptoms, (2) levels of performance, and (3) syndromes or patterns. Syndrome analysis interprets scores within the context of the results of other measures and is the most powerful form of analysis in terms of the ability to extrapolate beyond the immediate test data. This capacity to extrapolate is based upon the known characteristics of children evidencing the syndrome. Finally, in testing children, one must bring a developmental perspective to the findings, so that future difficulties can be anticipated with the changes that occur as the child grows older.

Psychometric findings are communicated more easily if the clinician receiving them understands some basic principles of psychometrics. Most people cluster around some average score for most measures of mental abilities, and fewer persons score either very high or very low. The distribution approximates a binomial distribution in the form of an inverted U, known as the normal curve. Raw scores are frequently the number of correct responses during a test and are not usually reported. Percentile scores indicate the percentage of persons obtaining raw scores equal to or less than the raw score obtained by the individual. In the normal distribution, small changes in raw scores close to the average (where many people are grouped) result in relatively large shifts in the percentile rank, whereas large shifts in raw scores at either the high or low ends of the distribution may change the person's percentile rank very little.

To compensate for the variations in the rate of change of percentile scores and to make performance levels comparable across tests, raw scores are converted to standard, or deviation, scores that indicate the extent to which an individual deviates from the mean or average. By convention, the average standard score for most psychological tests is 100, and the standard deviation is set at 15. I.Q. scores are standard scores with these psychometric properties. By the use of standard scores, performance levels on measures of specific mental abilities can be compared with I.Q. Standard scores also give the best indication of significant differences among scores, because the ntervals between scores of the same magnitude are equal anywhere in the distribution. Statistical significance occurs when the probability is very low that a difference between scores could have occurred by chance, as the result of inherent error variance in the test. By convention, a level of .05 probability is set as the standard for statistical significance. Although two scores may differ, that does not mean that the difference is meaningful or has clinical significance. Many statistically significant differences occur frequently in the normal population. For example, a difference of 15 points between the Verbal and Performance I.Q. scores of the WISC-III is statistically significant, but a difference of 15 points is not necessarily clinically significant, because it occurs in 24.3 percent of the normal subjects used to standardize test. Of course, a difference of this magnitude could have clinical significance in a particular case, if the adverse effect of the difference was exacerbated by other factors.

Some tests for children allow calculating standard scores from either age norms or grade norms, for example, the Woodcock-Johnson Psychoeducational Battery and the Kaufman Tests of Educational Achievement. The difference between these two methods of calculation illustrates the importance of understanding test scores in relation to the normative reference group. A standard score based upon age norms compares the performance of the child with that of other children of the same age. A standard score based upon grade norms compares the child's performance with that of other children in the same grade. If the child has been retained in grade to compensate for learning problems, the standard score based upon grade norms will be artificially inflated, masking the extent of the child's impairment. On the other hand, an achievement score based upon grade norms will indicate how well the child has mastered the curriculum at that grade level. In general, grade scores and age scores should be interpreted cautiously, because their psychometric properties are poor and the implications of the scores vary across levels. Clinical decisions should not be based solely on these types of scores.

There has traditionally been a concern about reporting I.Q. scores, because people do not understand that the scores are not absolute and immutable. Reporting the standard error of measurement or confidence intervals helps others to realize that scores have inherent error and will vary to some extent over successive administrations of the test, even when the test is valid and reliable by present standards. The standard error of measurement is the standard deviation of the hypothetical distribution of scores obtained from repeated administrations of the test. For example, the Woodcock/Johnson Psychoeducational Battery provides standard error of measurement for its subtest scores. Confidence intervals are the range of scores believed to contain the true score at a specified level of probability. The WISC-III and K-TEA test manuals, for example, provide tables that specify confidence intervals for standard scores, at both 90 and 95 percent probability. Increasing levels of confidence require larger intervals.

Report of the Psychometric Findings Ordinarily, the child's parents are informed of the results of a psychological or neuropsychological evaluation. Because test scores are easily misinterpreted, reports of psychological test findings should not to be given to the child or parents unless a qualified professional is present to explain the findings and answer questions. It is helpful if the referring clinician indicates how such feedback is to be given. In many situations, especially if the findings could create distress for the child or family, the referring clinician may wish to provide the feedback. If a written report is desired, then a report can be written for the

family that does not include confusing technical information and is designed to minimize adverse effects of sensitive findings. In other cases, the referring clinician may choose to have the psychologist provide feedback. Alternatively, the referring clinician may decide to meet with the psychologist and the family so that the psychologist can explain any technical aspects of the evaluation and its findings, while the referring clinician can place the findings within the context and perspective of the overall assessment and treatment recommendations.

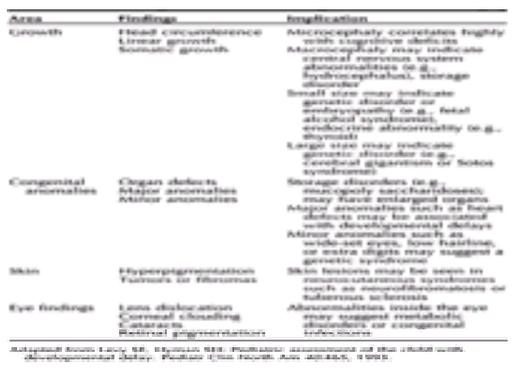
LABORATORY MEASURES

A burgeoning number of research studies applying new techniques of molecular genetics, neurobiology, functional and structural imaging, and neuroendocrinology are rapidly expanding our understanding of the pathogenesis of various childhood psychiatric disorders. This section, however, focuses on the practical use of various laboratory studies in the clinical assessment of the child presenting for psychiatric evaluation.

PEDIATRIC AND OTHER ADJUNCTIVE EVALUATIONS

Pediatric Evaluation Close collaboration with the child's pediatrician is usually an important component of any evaluation. The pediatrician is a valuable source of information about the child's developmental and medical history and can contribute a unique long-term perspective on the child and family.

A general pediatric examination is a useful adjunct to the psychiatric evaluation of a child. In addition to a general review of systems, the pediatrician should assess the child's current and past physical growth (head circumference, height, weight, pubertal status). Screening of hearing and vision, with more detailed testing as indicated, is important because deficits in these areas can manifest themselves in learning, language, and social delays or seeming inattention or oppositionality. For children with developmental difficulties, a careful history of perinatal risk factors is taken; the pediatric examination includes careful evaluation for major or minor congenital anomalies, dysmorphic features, dermatological abnormalities (hyperpigmentations, tubers, fibromas), or ophthamological findings (lens abnormalities, retinal pigmentation) (Table 33-10). History taking includes abnormal movements or absence spells suggesting seizures, abnormal postures, and tics. The physical examination notes difficulties in muscle tone and strength; asymmetrical, abnormal, or primitive reflexes; tremor; and gait or postural disturbances



Area	Findings	Implication
Growth	Head circumference Linear growth Somatic growth	Microcephaly correlates highly with cognitive deficits Microcephaly may indicate central nervous system abnormalities (e.g., hydrocephalus), storage disorder Small size may indicate genetic disorder or embryopathy (e.g., fetal alcohol syndrome), endocrine abnormality (e.g., thyroid) Large size may indicate genetic disorder (e.g., cerebral gigantism or Sotos syndrome)
Congenital anomalies	Organ defects Major anomalies Minor anomalies	Storage disorders (e.g., mucopolysaccharidoses) may have enlarged organs Major anomalies such as heart defects may be associated with developmental delays Minor anomalies such as wide-set eyes, low hairline, or extra digits may suggest a genetic syndrome
Skin	Hyperpigmentation Tumors or fibromas	Skin lesions may be seen in neurocutaneous syndromes such as neurofibromatosis or tuberous sclerosis
Eye findings	Lens dislocation Corneal clouding Cataracts Retinal pigmentation	Abnormalities inside the eye may suggest metabolic disorders or congenital infections

Table 33-10 Clues to Developmental Disability From the Physical Examination

The pediatric history and examination, in turn, help guide decisions about what further medical consultations (e.g., neurological, orthopaedic, audiometric, genetic) and which diagnostic tests (e.g., neuroimaging, laboratory tests, electroencephalogram) are likely to be informative.

Diagnostic Laboratory Tests The clinical utility and cost effectiveness of routine laboratory tests for children who present with psychiatric problems has not been thoroughly studied. Most guidelines for performing these tests for children have historically been developed using data from studies of adults. Adult studies generally suggest that routine laboratory tests are not clinically useful in such typical psychiatric settings as outpatient clinics and most inpatient units. Laboratory screening tests are of some use in psychiatric settings where patients are at high risk for medical illness, such as the emergency room, substance abuse treatment centers, acquired immune deficiency syndrome (AIDS) clinics, and geriatric clinics, as well as for patients who have new-onset psychosis, depression, or dementia. Similarly, routine screening laboratory measures are more likely to yield clinically significant information when clinical symptoms of physical illness are present.

The few studies of the use of routine laboratory tests in child psychiatry patient populations have yielded similar conclusions. One review of routine laboratory screenings (thyroid function tests, electroencephalograms [EEG], chest X-ray, chemistry panel, urinalysis, complete blood count, electrocardiogram, and rapid plasma reagin) in 100 consecutive adolescent inpatient admissions reported variable rates of abnormal values, depending on the specific test, but in only 1 of these 100 patients did the tests produce a change in diagnosis from functional to organic—and even then the diagnostic information proved to have little clinical relevance. Most laboratory abnormalities in this study were regarded as minor and did not indicate a need for clinical follow-up.

More-specialized diagnostic laboratory evaluations (EEG, computed tomography [CT], magnetic resonance imaging [MRI], or chromosomal analyses) also provide a relatively low yield of clinically useful information. In a study of 200 consecutive child psychiatric inpatients, these evaluations were done only when “clinically indicated”; despite their judicious use, the tests provided clinically relevant information in only 7 patients (3.5 percent of the total patient sample), or in 7 of 136 tests (5.1 percent of all tests performed). Chromosomal analyses proved to be the most informative of all these tests, yielding new medical diagnoses in 5 of 32 (15.6 percent selected children for whom they were performed. A study of 111 putatively high-risk inpatients with new-onset adolescent psychoses produced similar conclusions. In this population, routine endocrine and neuroimaging screening evaluations failed to provide any information of diagnostic utility in any patient (although inconsequential laboratory abnormalities were present in 15.4 percent of the neuroendocrine screens and 11 percent of the neuroimaging screening tests). More-specialized neuroimaging technologies, such as positron emission tomography (PET), single photon emission computerized tomography (SPECT), functional MRI (fMRI), and brain electrical activity mapping (BEAM) currently have no routine clinical or diagnostic utility in child and adolescent psychiatric populations.

Testing in Specific Childhood Disorders Certain child psychiatric patient populations may warrant specific diagnostic tests. Generally the pediatric history and physical examination guide the appropriate use of laboratory tests.

Mental Retardation and Pervasive Developmental Disorders In general, the more severe the child's disability, the greater the likelihood of an identifiable (albeit not necessarily treatable) cause. For example, one study found that a medical cause could be identified in 60 to 70 percent of children with severe mental retardation, versus only 35 to 55 percent of children with mild mental retardation. Chromosomal abnormalities, especially, trisomy 21 (Down syndrome) or fragile X syndrome, account for over half of cases of mental retardation.

The pediatric history and examination provide important clues. Loss of previously acquired developmental milestones or the presence of congenital anomalies, dysmorphic features, microcephaly or macrocephaly and other growth problems, abnormal skin pigmentation or lesions, and symptoms suggesting seizure activity or other neurological abnormality warrant more-detailed genetic, metabolic, or neurological evaluation (Table 33-10).

Autistic children have relatively high rates of mental retardation, seizure disorder (20 to 40 percent), and tuberous sclerosis (1 to 5 percent). Most experts would therefore still advocate a Wood's lamp examination to search for tubers, an EEG to exclude seizures, and chromosome analysis to exclude fragile X in children who display features of autism, retardation, or pervasive developmental disorder. Lead testing is also indicated in cases of mental retardation, since chronic lead ingestion due to pica can cause substantial retardation; conversely, many children with retardation or pervasive developmental disabilities from other causes indulge in pica and may accumulate a substantial lead burden.

Mood Disorders Common medical causes of mood disorders in child and adolescent psychiatric populations include substance abuse, infectious diseases (e.g., mononucleosis, Lyme disease, human immunodeficiency virus [HIV], and thyroid abnormalities). Rapid onset, severe fatigue, and a change in cognition suggest an organic basis for the mood disturbance. Routine thyroid function, infectious disease, and toxicology testing is probably indicated in this population.

Psychotic Disorders The patient's history and physical examination should guide the use of diagnostic tests beyond a general health screening battery. Cognitive decline, an altered level of consciousness, headache, an abnormal neurological examination, altered vital signs, leukocytosis, or new-onset seizure disorder are all

indications for further clinical and laboratory workup that may include examination of the cerebrospinal fluid.

Attention-Deficit/Hyperactivity Disorder Thyroid function abnormalities (particularly hypothyroidism) in attention-deficit/hyperactivity disorder were first reported in 5.4 percent of a group of 277 children with this disorder compared with reported rates in the general population below 1 percent. Matched control children were not included in this study, however, so the results were considered preliminary. In a subsequent study of 196 inpatient adolescents with attention-deficit/hyperactivity disorder who were routinely tested for thyroid function abnormalities, most of the observed abnormalities had normalized by the time of repeat testing 1 week later, and none of the adolescents actually required treatment for the abnormalities. Therefore routine thyroid testing is not currently indicated in children newly diagnosed with this disorder who do not have other signs or symptoms of thyroid dysfunction.

Tic and Obsessive-Compulsive Disorders History and physical examination differentiate tics and compulsive behaviors from other stereotypies and movement disorders such as choreoathetosis, myoclonus, ballismus, akathisia, and tremor. Once the diagnosis of a tic disorder or obsessive-compulsive disorder is made, further laboratory testing is generally not indicated. However, with an acute onset or acute exacerbation of symptoms or with chronic or recurrent pharyngitis, a throat culture and serological studies for group A b-hemolytic streptococcal (GABHS) infection, which include anti-deoxyribonuclease B and antistreptolysin O antibody titers, are probably warranted. Recently, GABHS has been postulated to initiate and sustain an autoimmune disorder due to cross-reactivity of GABHS and neuronal antigens, similar to the presumed cause of another movement disorder, Sydenham's chorea. The evidence for the role of GABHS in the cause of tic disorders and obsessive-compulsive disorder, however, is much less clear than it is in Sydenham's chorea.

Substance Use Disorders Substance abuse and dependence can cause a wide range of neuropsychiatric symptoms. The high prevalence of substance abuse in adolescent populations has prompted recommendations that toxicology screens be obtained for (1) all adolescents who have psychiatric symptoms or who exhibit acute behavioral changes; (2) high-risk adolescents, such as delinquents and runaways; and (3) adolescents who have recurrent accidents or unexplained somatic symptoms.

Sexually Transmitted Diseases Children and adolescents with a history of either sexual activity or sexual abuse who are being evaluated for depression or a change in cognitive function should be evaluated for sexually transmitted diseases, including HIV infection and syphilis.

DIAGNOSTIC FORMULATION AND RECOMMENDATIONS

In the diagnostic formulation the clinician attempts to integrate the data gathered through the assessment process into a coherent account of the child's difficulties, the factors that appear to have predisposed the child to develop the problem, the concomitants and consequences of the problem, and the factors that maintain the problem or might ameliorate it. It is not always possible to provide a complete formulation at the conclusion of the initial assessment; under such conditions, the best that the clinician may be able to provide is a differential diagnosis that can point toward the appropriate treatment options and the subsequent steps needed to establish a diagnosis.

One product of the assessment may be the assignment of a diagnosis of one or more categorical psychiatric disorders using the multiaxial diagnostic schema of DSM-IV or ICD-10. While these nosological systems have done much to standardize diagnostic practices and improve the quality of research, one must be aware of their clinical limitations as applied to children. Many children experience sufficient symptoms, distress, or impairment to be regarded as psychiatrically disturbed and to warrant therapeutic intervention without meeting the full criteria of a categorical psychiatric disorder. Furthermore, as currently conceptualized, the DSM-IV classification is descriptive and atheoretical; it specifies neither presumed etiology nor treatment for the various diagnostic categories. If the assessment process is to provide a picture of the child that suffices to guide intervention, the resulting diagnostic formulation must go beyond simply assigning a categorical psychiatric diagnosis (if one is warranted). As noted in the introduction, comorbidity is often the rule rather than the exception in childhood, and many children have complex patterns of developmental and behavioral difficulties that are not adequately captured by a list of multiple categorical diagnoses. Children who share a given categorical diagnosis may differ in crucial respects that influence current severity, natural history, and treatment response. Examples of potential risk (or exacerbating) factors and protective (or ameliorative factors) include intelligence, compensatory skills, family resources and supports, and vulnerabilities such as comorbid pathological personality traits or neurological impairments. When the DSM-IV or ICD-10 is being used, the full multiaxial diagnostic system must be used. In addition to Axis I (categorical psychiatric disorders), this includes specifying comorbid personality disorders and mental retardation (Axis II), general medical conditions (Axis III), level of psychosocial and environmental problems (Axis IV), and a global assessment of current functioning (Axis V).

The clinician's diagnostic formulation should thus supplement the assignment of any formal categorical diagnoses by attempting to identify, as far as possible, the potential causes, predisposing factors, and current determinants of the child's difficulties. On the basis of this information and the clinician's expertise regarding the various interventions available for the diverse forms of childhood psychopathology and developmental difficulties, the clinician formulates appropriate recommendations for treatment of the child's problems.

Communicating Findings and Recommendations Communicating the findings and recommendations that result from the assessment to the parents and child is an essential part of the evaluation process and may require one or more sessions. Depending on the problem and the child's age and level of comprehension, presenting the findings usually involves meeting with the child and parents, either separately or together.

Several principles must be observed to maximize the likelihood that the parents and child will hear, understand, and experience the clinician's findings and recommendations as helpful. First, the clinician must communicate a sense of the child as a whole person, with strengths and abilities as well as problems and vulnerabilities. This perspective conveys a sense of the clinician's appreciation and empathic understanding of the child, reduces defensiveness, and helps mitigate the fear that there will be only bad news.

The findings and recommendations will be most useful to the family and likely to be implemented if the interpretive session is a dialogue rather than a lecture. The clinician must use language comprehensible to the parents and child, avoid jargon, and keep technical terms to a minimum. When technical terms are necessary, they should be explained clearly so the parents and child understand them; terms that are merely descriptive to the clinician may hold frightening or negative connotations for the child or family. Allow ample opportunity for the parents and child to discuss the recommendations; this provides a chance to judge whether the clinician's formulation made sense to the family, to address any differences of opinion, and to explore the feasibility and acceptability of the recommendations offered. Remaining areas of uncertainty or ambiguity about the assessment or recommendations should be clearly noted and discussed.

If the assessment is a consultation requested by an agency, a school, or another clinician, the findings and recommendations should be communicated to the referring party in appropriate terms, after being discussed with the parents and child and with their consent. If further evaluation or treatment is indicated but is best done by someone else, the clinician should offer to assist in appropriate referral.

SUGGESTED CROSS-REFERENCES

General principles of the psychiatric interview, history, and mental status examination are presented in Section 7.1. The psychiatric report is discussed in Section 7.2, psychiatric rating scales in Section 7.8, and medical assessment and laboratory testing in Section 7.7. Theories of personality and psychopathology are discussed in Chapter 6. The normal development of children is in Section 32.2, and of adolescents in Section 32.3. Details regarding the personality assessment of children are found in Section 7.5. Treatment in child psychiatry is discussed in Chapter 48 and special areas of interest in child psychiatry in Chapter 49.

CHAPTER 34. MENTAL RETARDATION

BRYAN H. KING, M.D., ROBERT M. HODAPP, PH.D., AND ELISABETH M. DYKENS, PH.D.

HISTORY

Persons with mental retardation have long been of interest to Western societies. This interest has ranged from the overly positive to the overly negative, from the French expression *les enfants du bon Dieu* (God's children) to Martin Luther's exclamation that “The Devil sits where their souls should be.”

The field's modern history begins in the late eighteenth and early nineteenth centuries. At that time, Jean-Marc Itard attempted a natural experiment to educate Victor, a “wild child” discovered in the forests of Aveyron, France. Although Itard himself judged his work with Victor a failure, this renowned experiment marked the first time that anyone had considered the possibility that persons with disabilities could be educated. An overview of the history of this complex field should mention three interrelated topics: service delivery, research, and organizations.

Service Delivery Spurred by Itard's work, the French educator Edouard Seguin developed his physiological view of education in the mid-1800s. Seguin's education focused on children's development in three areas: activity, intelligence, and will. *Activity* involved muscular or physical education, including exercises and movement to “awaken” the child's body. *Intelligence* emphasized educating the senses. Children with mental retardation were taught to handle objects, discriminate musical and environmental sounds, taste and perform tongue movements for speaking, and visually discriminate forms, colors, and sizes. Such visual discriminations eventually led to drawing and writing. The final component of Seguin's educational program involved educating the *will*, a “moral education” akin to what one might call socialization. Throughout, Seguin wanted children with mental retardation to take their rightful place in the societies of their day. His views that children with mental retardation could be trained successfully fit well with the progressive, reform-minded spirit of the times.

Such optimism helped create the early training schools, the residential component of service delivery in mental retardation. First begun in 1848 in Massachusetts by Samuel Gridley Howe (the first public facility) and Hervey Wilbur (the first private facility), the late 1800s saw the creation of many such training schools. These schools were originally small and homelike, often housing only 8 to 10 residents. Residential schools had as their original goal the return of children to their families after a period of intervention. By 1890, 20 such residential schools had sprung up in 15 states.

Gradually, however, these residential schools became larger and less focused on education than on custodial care. To many superintendents, it was becoming clear that many residents could not return home. In addition, the isolated placement of most training schools allowed for the segregation, overcrowding, and abuses seen in later years. Such isolated placements also fostered a change in goals: from an original focus on a warm, homelike residence that might help children return to their communities, residential schools began to be seen as custodial institutions designed to keep persons with mental retardation away from society. During their peak usage, from 1950 until the late 1960s, institutions were home to approximately 1 per 1000 Americans.

Since the mid-1960s, many fewer persons with mental retardation have been institutionalized in the United States. This move toward deinstitutionalization has arisen from many sources. First, the overcrowding and neglect common in many large institutions came to light in various exposés during the late 1960s. Burton Blatt and Fred Kaplan's photographic exposé *Christmas in Purgatory* (reproduced in *Look* magazine), Geraldo Rivera's television reports, and Robert F. Kennedy's attacks on the Rome and Willowbrook institutions in New York all shocked the nation.

Normalization Other forces also led to deinstitutionalization. Probably the most important of these forces was the philosophy of “normalization,” the idea that individuals with mental retardation were entitled to a more normal lifestyle, including a culturally normal rhythm to the day (school or work, leisure-time, sleep), week (weekdays and weekends), and year (vacations, holidays). In 1972, Wolf Wolfensberger extended the idea of normalization to the service delivery system itself, calling on all residences, schools, and other services for persons with retardation to be as normative as possible. Parent and professional advocacy groups also fought hard for legislative and legal victories to decrease the size of large institutions.

Compared with institutions even 30 years ago, changes in U.S. residential institutions have been dramatic. Several states have closed their institutions, and remaining institutions have become much smaller. Typically, patients remaining in large or even medium-sized institutions are the most severely and profoundly impaired; many of these residents also have severe behavior problems or motor or sensory disabilities in addition to their severe or profound mental retardation. Overall, from 1967 to 1994, the total institutional population (defined as those in state-operated institutions with 16 or more residents) has decreased by almost two thirds, from 194,650 to 65,818.

Schooling is the other major service for persons with mental retardation. The move to school all American children began in the mid-1800s, and teachers and administrators soon discovered that a subset of children were having difficulty performing school lessons. As a result, classes for problem children began in many cities and towns in the late 1800s. In 1894 the first classes specifically for children with mental retardation were formed in Providence, Rhode Island. In rapid succession, special education classes were begun in Springfield, Massachusetts (1894), Chicago (1898), Boston (1899), New York (1901), Philadelphia (1901), and Los Angeles (1902).

Local school districts have historically held an ambivalent attitude toward special education classes. Often housed within the least desirable buildings and rooms, these classes were frequently furnished with sparse equipment and materials, and had few specially trained teachers. By 1968, Lloyd Dunn declared that most children with mental retardation could be “mainstreamed” in classes with nonretarded age-mates; he questioned the need for segregated special education classes for most children with mental retardation. Dunn's article took note of the Supreme Court's ruling that “separate could not be equal” in educational settings, that research had not shown that children with mild mental retardation learn better in special education classes than in regular classes, and that educational techniques had advanced sufficiently to allow the effective schooling of most children with retardation alongside other, typical children.

In both education and living settings then, the post-1970 era has witnessed the strong influence of mainstreaming, community living, and normalization. On the whole, such movements have proven beneficial, as persons with mental retardation increasingly take their rightful place within modern society. Many professionals do, however, question whether normalization has sometimes gone too far. Not every child with mental retardation may be able to be schooled optimally with typically developing age-mates, nor might every adult be able to live independently in the community. These issues continue to be hotly debated among professionals, families, and organizations associated with persons with mental retardation.

Research Like service delivery, the modern history of research also begins in the mid-nineteenth century. In 1838, Jean Esquirol differentiated mental retardation from mental illness and proposed several levels of mental retardation. Later in the century, various workers proposed different classification systems. Probably the best known was a system of “ethnic classifications” proposed by J. Langdon Down in 1866; hence the term “mongolism” for persons with Down syndrome, the type of retardation he first identified.

In addition to classifying persons with mental retardation, genetics plays an important historic role in retardation research. Early in this century, that role was mainly negative. Spurred by the rediscovery of Gregor Mendel's genetic findings, various workers attempted to show that mental retardation was inherited. Most notorious were Dugdale's (1877) study of the Jukes, and Henry Goddard's (1913) study of the Kallikaks. In both cases, families with multigenerational retardation were used to argue that mental retardation was inherited and that sterilization was necessary for the “preservation of the race.” Such eugenic scares led to court decrees and

sterilization laws in California and other states during the 1920s.

Also playing an important role in mental retardation research was the new science of psychological testing. Goddard, the research director at the Vineland (New Jersey) Training School, was the first to use Binet and Simon's intelligence quotient (I.Q.) tests in the United States. After testing Vineland residents over several years, Goddard concluded that “the vast majority of feeble-minded children are not changing and are not improving in their intelligence levels,” a finding that another leading worker, Walter Fernald, called “the most significant ... and the most discouraging that we have ever known.”

Since early in this century, research has progressed in both the behavioral and biomedical fields. Behaviorally, early and more recent work has allowed better diagnoses and classification. Beginning as early as the 1910s, psychologists invented tests of motor skills, nonverbal intelligence, achievement, adaptive behavior, and other skills. Following similar work with typically developing children, psychologists have recently learned much about the development of cognitive, linguistic, social, and adaptive skills in persons with mental retardation. In addition, many studies now examine the presence of psychiatric disorders in children and adults with mental retardation, and families, schools, group homes, and workshops have all received research attention. Much of this work has occurred from the 1960s to today, a time of strong, often federally supported, progress in mental retardation behavioral research.

Arguably the most important progress has occurred in the biomedical and genetic fields. As early as 1934, the Norwegian physician Asbjorn Folling hypothesized that several of his patients with retardation were unable to metabolize phenylalanine. Such insights later led to a dietary treatment of this inborn error of metabolism; the phenylalanine-free diet, though not perfect, has significantly limited phenylketonuria (PKU) as a cause of mental retardation is most industrialized countries. In addition, PKU can now be detected at birth by the Guthrie test, after which dietary treatments can be instituted. PKU remains one of the major success stories in mental retardation.

Modern genetics constitutes another success story in mental retardation research. In 1959 J. Lejeune, M. Gautier, and R. Turpin discovered that most cases of Down syndrome were due to a trisomy of chromosome 21. Fragile X syndrome, the second most common genetic cause of mental retardation, was discovered in 1969, and its cytogenetic diagnosis was refined in the mid-1970s. With the banding techniques of the 1970s and the molecular genetic techniques of the 1980s, exact causes are being described for many of the 750 different genetic disorders associated with mental retardation. The genetic—and, increasingly, the behavioral—characteristics of many of these disorders are now known.

Organizations The modern field of mental retardation is also a history of organizations. The first such organization was the Association of Medical Officers of American Institutions for Idiotic and Feeble-Minded Persons, begun in 1876. As the first professional group devoted exclusively to persons with mental retardation, the Association of Medical Officers was the forerunner to the American Association on Mental Retardation (AAMR), the field's most influential organization. Through its various journals and committees, AAMR has been at the forefront of research, policy, and legislative advances for persons with mental retardation.

In addition to AAMR, other groups have also played important roles, particularly concerning changes in federal policy toward persons with disabilities. The Council for Exceptional Children (CEC), begun in 1922, continues to champion the profession of special education and the education of all children with disabilities. The National Association for Retarded Citizens (NARC) is the main parental lobbying group. NARC was particularly influential in the passage of the Education for All Handicapped Children Act of 1975 (PL 94&142), the federal law that for the first time mandated the “free, appropriate public education” of all children with disabilities throughout the United States. Each of these groups was also influential in the passage of the Americans with Disabilities Act, federal legislation that took effect in 1992 and outlawed discrimination of persons with disabilities.

Federal agencies have also been influential. Begun during the presidency of Kennedy (who had a sister with mental retardation), the National Institutes of Child Health and Human Development (NICHD) have long supported disability research. Other federal programs, including the University Affiliated Facilities (UAFs), University Affiliated Programs (UAPs), and Mental Retardation Research Centers (MRRCs), have also played important roles in research and policy. Taken together, professional, parental, and federal organizations provide an important infrastructure to the mental retardation field.

DEFINITION

The struggle to define and classify mental retardation is long-lived. Esquirol (1843) is considered the first medical writer to have penned a definition, and his seminal characterization of mental retardation as a disorder of development instead of a disease is maintained in all modern definitions (which require an onset during childhood or adolescence). Writing over a century ago, Wilbur (1852) reasoned that mental retardation was defined primarily by deficits in social or moral reasoning. This line of thinking has also persisted over time and is now woven into contemporary controversies about the respective roles of social adaptation and intelligence in defining mental retardation. Such controversy is not entirely recent however. William White (1919) observed that “feeble-mindedness, even from the standpoint of an intelligence measuring scale, is a relative affair when expressed in the behaviour of an individual, and conduct which would be considered normal under certain conditions might well be open to inquiry, as possibly defective, under others.” Alfred Tredgold's (1922) presentation of the case of Gottfried Mind is also illustrative:

> Gottfried Mind was a cretin imbecile who was born at Berne in 1768, and died in the same city at the age of forty-six years. At an early age he showed considerable talent for drawing, and as it was obvious that he would never be able to earn his living in any ordinary occupation, his father's employer interested himself in providing young Gottfried with some training. He could neither read nor write, he had no idea of the value of money, his hands were remarkable for their large size and roughness, and his general appearance was so obviously indicative of mental defect that his walks through the city were usually to the accompaniment of a crowd of jeering children. In spite of all this his drawings and water-color sketches of not only cats, but of deer, rabbits, bears, and groups of children were so marvelously lifelike and so skillfully executed that he acquired a European fame. One of his pictures, indeed, of a cat and kittens was purchased by King George IV.

Thus, central to the struggle with how to conceptualize and understand mental retardation is the idea that something more than cognitive deficits or low I.Q. scores on intelligence tests is involved. Over the years, the American Psychiatric Association (APA) adopted definitions of mental retardation from the AAMR. Looking back to the revised third edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III-R) for example, the diagnosis of mental retardation is virtually identical to the previous AAMR definition. Most recently, however, the AAMR definition has diverged somewhat from that of the fourth edition of DSM (DSM-IV), thus generating some controversy. The cognitive and adaptive components of these definitions must be examined to understand the controversy.

Cognitive and Adaptive Functioning

Cognitive Functioning Both DSM-IV and the 10th revision of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) specify an I.Q. of 70 or less in their diagnostic criteria for mental retardation. I.Q. scores are presumably derived from standardized intelligence tests that meet appropriate psychometric criteria for reliability and validity. I.Q. tests that are commonly used to identify mental retardation are summarized in Table 34-1, along with each test's age range and cognitive domains. Though all are generally acceptable, diagnosticians should shy away from tests that tap a single domain (e.g., receptive vocabulary) in favor of more extensive batteries such as the Kaufman or Wechsler tests, as these rely on performance across multiple cognitive domains (Table 34-1).

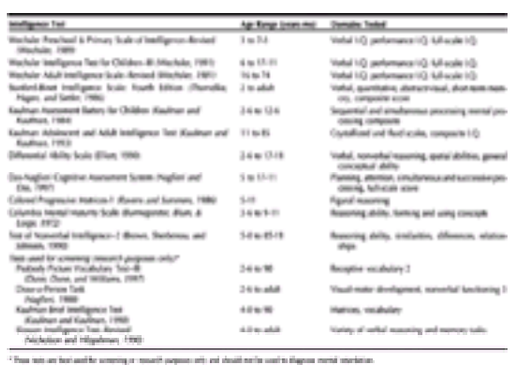

Table 34-1 I.Q. Tests for Diagnosing Mental Retardation

In many ways, administering I.Q. tests to persons with mental retardation is quite challenging, both in terms of the testing situation itself and in the choice of an appropriate I.Q. test. Since persons with mental retardation have increased risks of comorbid psychiatric or behavioral dysfunction, examiners need to ensure that difficulties such as hyperactivity or poor frustration tolerance do not impede optimal test performance. Even in persons without behavioral dysfunction, certain personality characteristics may interfere with testing. Many persons with mental retardation look to others for solutions to difficult problems and are quick to acquiesce or become easily discouraged by failure. Certain techniques minimize these problems, for example, ensuring that the examinee succeeds with easy tasks before administering hard tasks, or providing positive incentives for effort.

Challenges also emerge with individuals who are nonverbal, and several I.Q. tests now exist that do not rely on expressive language (Table 34-1). Persons with certain genetic syndromes (e.g., Williams syndrome, Down syndrome) also present unique test challenges as many display syndrome-specific profiles of cognitive strength and weakness that are not easily described by a global I.Q. score. Persons with mental retardation and co-occurring sensory or motor deficits also require adaptation to routine test procedures. Finally, examiners need to be extra cautious when testing individuals from minority groups. Sparked by a series of lawsuits in the 1970s (e.g., *Larry P. v W. Riles*), controversies still rage about test bias and the appropriateness of I.Q. testing in children from minority groups. Court rulings have come out both against and in favor of I.Q. tests. Most psychologists readily agree that testing persons from minority groups requires extra sensitivity to language and cultural issues as well as a multimethod test approach, especially when diagnosing persons with mild mental retardation.

Adaptive Functioning Based on his pioneering work at the Vineland Training School in Vineland, New Jersey, Edgar Doll (1935) was the first to develop a formal definition and measure of adaptive behavior. Two decades later, the AAMR officially included deficits in adaptive behavior in its definition of mental retardation. Since then, deficits in adaptive behavior have been formally included in all definitions of mental retardation. Though meanings vary, adaptive behavior is typically viewed as the performance of behaviors required for social and personal sufficiency.

Further, adaptive behavior is an inherently developmental and social construct. Adaptive behavior changes as children grow into adolescence and adulthood, and demands for social adaptation are also defined by expectations from others—from one's family, society, and culture. Adaptive skills typically change across various settings; one's adaptive performance on the job or at school may differ from one's performance with friends or at home. Measurements of adaptive behavior, then, need to have a developmental orientation, to be socially and culturally sensitive, and to represent the many settings in which people live, work, and play.

In contrast to Doll's time, many instruments now exist that measure adaptive behavior across multiple domains (e.g., community skills, personal grooming). Table 34-2 summarizes commonly used measures of adaptive behavior, their age ranges, and various domains. All are acceptable measures of adaptive behavior in persons with mental retardation, yet the Vineland probably enjoys the most widespread use. Although most of these measures are administered as interviews with parents or other care providers, some of the newer measures are given directly to persons with mental retardation. Central to all measures is the idea that adaptive behavior is measured by typical, everyday performance, not ability. If individuals with mental retardation can perform certain behaviors but for any reason do not routinely do so, then they necessarily have compromised adaptive functioning.

Measure	Age Range	Domains Tested
Vineland Adaptive Behavior Scales (Sparrow, Balla, and Cicchetti, 1984)	Birth to 18	Communication: receptive, expressive, written; daily living skills: personal, domestic; community; socialization: interpersonal relations, play and leisure; coping skills; motor skills: fine, gross
Scales of Independent Behavior–Revised (Bruininks, Woodcock, Weatherman, & Hill, 1996)	Birth to 80+	Motor: fine, gross; social interaction and communication: social interaction, language comprehension, language expression; personal living skills: eating and meal preparation, toileting, dressing; community, living skills: time and punctuality, money and value, work
AAMR Adaptive Behavior Scales (Lambert, Nihira, and Leland, 1993)	3 to 18–21	Independent functioning, physical development, economic activity, school
Kaufman Functional Academic Skills (Kaufman and Kaufman, 1994)	15 to 75+	Functional math and reading skills, administered directly to person
Street Survival Skills Questionnaire (Grieve-Volker and McCarron, 1993)	9 to 45+	Administered to person; basic concepts, functional signs, tools, health

Table 34-2 Common Measures of Adaptive Behavior

Definition Controversies

Cognition Versus Adaptation What, then, is so controversial about cognitive and adaptive functioning? One controversy lies in the relative importance of these domains in defining mental retardation. Some workers object to the equal role afforded to cognitive and adaptive deficits and argue that intelligence is more important to the definition of mental retardation than adaptive behavior. These workers consider low I.Q. the benchmark of mental retardation and view adaptive deficits as correlates or sequelae of low I.Q. Further, unlike adaptive behavior, intelligence has firm theoretical and empirical roots, evolving from Francis Galton's pioneering work on individual differences to a host of modern views of intelligence, ranging from Howard Gardner's “multiple intelligences” to Robert Sternberg's triarchic theory of intelligence. Critics of adaptive behavior, then, embrace the strong theoretical and empirical history of the intelligence field and question whether adaptive behavior has equally robust psychometric properties.

Yet persons who have low I.Q. scores do not necessarily show deficits in everyday behavior. Proponents of adaptive behavior argue that cognitive and adaptive functioning are generally unrelated, with dramatically different theoretical underpinnings and measurement techniques. Indeed, some studies of persons with mixed etiologies find nonsignificant correlations between cognitive and adaptive functioning. A disjuncture between I.Q. and adaptive behavior may be particularly apparent in those with mild mental retardation. Variable outcomes were seen, for example, in Robert Ross and colleagues' 40-year study of students with mild mental retardation followed into adulthood. As adults, some of these subjects were completely to partially independent and adapted quite well, whereas others were highly dependent and showed poor social adaptation. Robert Edgerton, who followed up 48 residents of a large institution after their discharge and integration into the community, observed that the I.Q. of any given individual said little about what to expect in the outside world, and even very low I.Q. was no sure indicator. His case of Fred Barnett (pseudonym) is illustrative.

> Fred was the product of an uncomplicated pregnancy and delivery. Developmental milestones were remarkable for walking at 17 months of age, but slowness to talk and stammering, unclear speech. He was described as a little slow, but at 5 years of age when verbal and learning delays became more obvious, the family became concerned. At age 6, Fred was injured in an automobile accident with resultant coma for 5 days. Hospital records at the time suggested the possibility of slight neurological injury, but his mother attributed all of Fred's subsequent problems to this accident. He was unable to keep up in school and fell into greater conflict with his younger siblings. At 10 years of age he dropped out of school, and 4 years later was admitted to the Developmental Center. I.Q. testing over the years consistently placed Fred in the moderate range (middle to lower 50s). While in the institution Fred was seldom in trouble and worked on the wards, in the kitchen, and occasionally as a messenger. After 3 years he was discharged to the community, where despite nearly continuous supervision from employers and social workers, he was said to be in frequent trouble. In virtually all of his multiple places of employment, primarily as a dishwasher, his reputation was highlighted by temper, aggression, profanity, and boorishness. He was also involved in several minor difficulties with police including several charges of vagrancy. On one occasion he took an employer's car without permission and drove it recklessly. Over time, his conduct became more competent, and at the age of 32 he presented as a robust-appearing man perpetually smoking a cigar who gave every appearance of “being a happy-go-lucky, easygoing, altogether happy man. There is nothing in his appearance to suggest that he is anything less than a normal man, and his speech is likewise unexceptionable... It is only upon much closer inspection that Fred's intellectual deficit becomes apparent. To the casual observer, he is an ordinary man, competent to live within the not too demanding constraints of his life circumstances.”

Other studies, however, find strong correlations between cognitive and adaptive behavior, especially in persons with moderate-to-profound mental retardation. Significant I.Q.-adaptive behavior correlations are seen in studies of persons with moderate mental retardation of mixed etiologies, as well as in studies of individuals with distinctive syndromes such as fragile X syndrome, Down syndrome, Prader-Willi syndrome and 5p- (or cri du chat) syndrome.

Thus, I.Q. may set an upper limit or ceiling to adaptive accomplishments, which resolves at least some of the controversy about the relative importance of these two constructs. If so, this limit may be more pronounced at the lower levels of intelligence, with increased variability in adaptive outcome found in persons with mild mental retardation. Though many still feel that adaptive behavior does not belong in the definition of mental retardation, virtually all workers agree that adaptive skills are

critical to the long-term adjustment and success of people with mental retardation.

AAMR's New Definition Controversies about how best to conceptualize mental retardation have recently been piqued by the AAMR's so-called new definition of mental retardation. The new definition does not view mental retardation as an inherent characteristic of people, but as an interaction between individuals and their environments. With this assumption, the new definition eliminates traditional nosology based on level of cognitive impairment (i.e., mild, moderate, severe, profound) and instead proposes four levels of environmental supports (intermittent, limited, extensive, pervasive) across 10 different adaptive domains (e.g., health and safety, self-care, leisure). Thus, instead of giving a person a diagnosis of “moderate mental retardation,” the new definition specifies that a person has intermittent needs for supports in health and safety, limited needs for supports in self-care, and so on, across 10 domains. Critics argue that this system is unwieldy, is more pertinent for practice than diagnosis, and represents a giant step backward for research as it leaves researchers without a meaningful way to classify subjects.

Two other features of the new definition have been hotly debated. The new definition extends the I.Q. criterion from “70 and below” to “70 or 75 and below,” opening up the possibility for a more lenient I.Q. cutoff point of 75. Although a 5-point increase seems small, the Gaussian, or bell-curve, I.Q. distribution makes this high-end change in the I.Q. cutoff point particularly important. Donald MacMillian and colleagues note that “Small shifts in the upper limit have substantial consequences for the percentage of the population eligible to be diagnosed with mental retardation. *Twice as many people are eligible when the cut-off is 75 and below than when it is 70 and below*.” Many critics thus predict that if followed, the new definition will increase the size of the population with mental retardation, including increases in the overrepresentation of several minority groups.

Many critics also deride the new definition's adaptive behavior criteria, which now specify that documented deficits must be seen in at least 2 of 10 adaptive domains. Factor-analytical studies of adaptive behavior provide no empirical support for 10 domains and instead reveal from 2 to 7 factors of adaptive behavior. Further, no single measure of adaptive behavior taps these 10 particular domains, which forces workers to mix domains across two or more different tests or to simply rely on their clinical judgment.

For all these reasons, then, the new 1992 AAMR definition has generated much controversy in the mental retardation field. The controversy has spread to the field of psychiatry as well. In particular, the new definition was published just in time to create a dilemma for the APA and the DSM-IV work group on childhood disorders. The crux of the dilemma was whether DSM-IV should adopt the new AAMR definition—if the work group followed this organizational tradition, DSM-IV would depart radically from DSM-III-R. The solution was in large part a compromise. DSM-IV and ICD-10 criteria retained the I.Q. cutoff point of 70 and the traditional level-of-impairment nosology yet adopted the AAMR's adaptive behavior criteria. While some practitioners have embraced the new AAMR definition, others (both practitioners and researchers) have rejected the new definition in favor of DSM-IV or other more empirically based models. Given the many criticisms of the new definition, its fate remains in doubt.

EPIDEMIOLOGY

According to some estimates, approximately 1 percent of the population has mental retardation. This 1 percent figure is cited by DSM-IV and is roughly the percentage found in most prevalence studies. Yet the widely cited 1 percent figure hides a variety of controversies within mental retardation. In particular, many have reasoned that mental retardation is more frequent—nearer to a 3 percent prevalence rate—while others question whether some categories of mental retardation are disappearing altogether. These controversies have enormous societal implications. Based on the current U.S. population, a difference of even 1 percent means that an extra 2.6 million Americans have mental retardation and may require services.

Two Groups of Individuals With Mental Retardation To understand the prevalence issue, one must consider who, historically, has been thought to make up the retarded population. Given a Gaussian, bell-curve distribution of intelligence, 2.28 percent of individuals should fall two or more standard deviations below the general population average of I.Q.-100, which translates into scores below 70 on most psychometric tests. Following the Gaussian distribution, most of these individuals should have an I.Q. just below 70, and increasingly fewer individuals should have an I.Q. below 55 or 40 (three or four standard deviations below the mean). The percentage of persons whose I.Q. is below 40 (4 standard deviations below the mean) should equal 0.00003, or roughly 7800 persons in the entire United States (0.00003 × 260 million).

As early as 1960, Harvey Dingman and George Tarjan realized that many more persons with severe and profound mental retardation exist than would be expected by a Gaussian distribution. The relatively large number of persons at the lowest I.Q. levels seems to be due to the many persons with clear organic causes for retardation. Most prevalence studies find that as one goes lower down the I.Q. spectrum, increasingly high percentages of individuals show one or more clear organic causes for their mental retardation. Earlier, Leta Hollingworth observed that “a small percentage of mental deficiency is due to disease of the nervous system ... research points to the conclusion that approximately 90 percent of the mentally subnormal are the products of inferior germ-plasm. The remainder are the victims of organic causes, and are in a true sense pathological cases.”

In 1967 Edward Zigler proposed that there are two groups of persons with mental retardation. Retardation in the first group was caused by the usual (and so far unidentified) factors that distinguish individuals across the normal range of intelligence. Researchers have variously referred to this group as having cultural-familial, familial, or nonspecific mental retardation. Many of these individuals come from poor, minority, and low educational backgrounds, and low I.Q. scores are also common in parents or siblings. Like variations across the entire I.Q. spectrum, some interplay of environmental and biological factors seems to be involved in this type of retardation.

Zigler referred to the second group as having “organic” mental retardation. The retardation of this group was caused by one of many different pre-, peri-, or postnatal causes. Over the years, increasing numbers of persons with organic mental retardation have been identified. Mental retardation has now been linked to approximately 750 different genetic causes, and other causes also exist. In all cases, however, these individuals have one or more organic insults associated with their mental retardation.

The 1 Percent Versus 3 Percent Issue By summing percentages of the two groups, most workers of the 1960's and 1970's concluded that approximately 3 percent of individuals have mental retardation. In the early 1970s, however, Jane Mercer criticized the 3 percent figure and concluded that only 1 percent of the U.S. population has mental retardation. Although the 1 percent versus 3 percent debate may ultimately be unresolvable, its details illustrate some of mental retardation's most complicated issues.

I.Q. as the Sole Criterion of Mental Retardation The 3 percent prevalence rate considers I.Q. the sole criterion for mental retardation. That is, persons with an I.Q. below 70 are considered to have mental retardation, those with an I.Q. of 70 or above do not. Even considerations of the excess of individuals at the lowest I.Q. levels are based solely on the Gaussian distribution of I.Q.

But I.Q. is not the sole criterion of mental retardation. To be considered to have mental retardation, a person must have an I.Q. below 70 as well as deficits in adaptive behavior. If the two are perfectly correlated—if every person with a below-70 I.Q. also has deficits in adaptive behavior—then a 3 percent figure becomes tenable. If the two correlate weakly or not at all, much lower prevalence rates hold. Although strong I.Q.-adaptive correlations have been found for some organic groups and for individuals with severe and profound mental retardation, lower correlations probably hold for children with mild mental retardation. Throughout the entire population of persons with mental retardation, a moderate, but by no means perfect, correlation probably exists between I.Q. and adaptive behavior. To the extent that the two are uncorrelated for persons with an I.Q. fall below 70, less than 3 percent of individuals have mental retardation.

In recent years two new twists to the I.Q.-adaptive issue have arisen. The first concerns the possible change in the I.Q. cut-off criterion itself, from an I.Q. of 70 to one of 75. Given the Gaussian distribution of I.Q., as many people have an I.Q. between 70 and 74 as have an I.Q. between 0 and 69. A second issue concerns the change in the AAMR definition's adaptive criteria, from “deficits in adaptive behavior” to inadequate functioning in 2 of 10 adaptive domains. In both instances, more persons become eligible for a diagnosis of mental retardation.

I.Q. Remains Constant The 3 percent prevalence rate also assumes that an individual's I.Q. remains relatively stable over time. This assumption seems justified in some ways, unjustified in others. Once children reach the late-preschool years, correlations between separate testings many years apart become fairly high, particularly in samples of children with disabilities. Indeed, across the entire I.Q. distribution, a median correlation of .77 has been shown between testings at age 4 and age 12. However, correlations between I.Q. scores during infancy and later I.Q. scores are essentially zero. That is, with the exception of infants with whose I.Q. scores are very-low, any baby's I.Q. score (e.g., “developmental quotient”—or D.Q.—on the Bayley) has little relation to that child's I.Q. during later childhood or adulthood.

Further, different groups may show different trajectories of I.Q. with development. Children with Down syndrome show their highest I.Q. (or D.Q.) scores during the first year of life, then decline in I.Q. over the early and middle childhood years. Boys with fragile X syndrome also decline in I.Q., but their declines seem to begin at approximately 10 to 15 years. Conversely, children with cerebral palsy (half of whom have mental retardation) remain remarkably stable in their I.Q. scores over time, much like groups with mixed or nonspecific etiologies of mental retardation. Thus, considering I.Q. alone, the age of the individual must be kept in mind when considering the prevalence rates of different degrees of mental retardation.

Identification Rates Are Equal Across a Range of Variables A related issue concerns identification rates. To receive a diagnosis of mental retardation, individuals must be brought to the attention of professionals, tested, and found to meet definitional criteria. But the workings of this process vary widely for a host of reasons.

The first concerns age. Nearly every study finds that prevalence rates are low during the years from birth to age 5 or 6, increase rapidly until the adolescent years, and decrease thereafter. As might be expected, the increased intellectual demands of school seem to be responsible for such discrepancies.

But increased intellectual demands are not the only school variable affecting prevalence rates. Schools also vary in their formal procedures for identifying children with problems such as mental retardation. In many schools, these processes begin when the classroom teacher calls the child to the attention of a student study team, a multidisciplinary group designed to help teachers handle difficult children. The team then decides on within-class changes that the teacher might try or refers the child for further evaluation. Unfortunately, researchers currently have only a general sense of why teachers refer children to student study teams, why rates vary so much from one school or district to another, or what percentage of children who meet criteria for referral to student study teams ultimately receive a diagnosis of mental retardation. Such variations undoubtedly affect mental retardation prevalence rates.

These diagnostic issues are further complicated by regional and local variations. Many more children receive mental retardation diagnoses in certain areas of the country than in others. Using percentages of children enrolled in special education services across the 50 states during 1993, only 3.2 per 1000 schoolchildren were identified as having mental retardation in New Jersey and 4.5 in California versus 31.4 in Alabama and 25.4 in Kentucky. Although many factors probably relate to these interstate differences, Philip Massey and Richard McDermott note that three account for most of the variance: the percentage of a state's population with less than a ninth-grade education, the median household income, and the percentage of births to teen mothers.

In addition to these demographic factors, policy variables are also important. Over the past 20 years, the number of children given a diagnosis of mental retardation has decreased markedly. This decrease arises from many sources. Particularly in California, the *Larry P. v. W. Riles* case lessened reliance on I.Q. tests for diagnosis, particularly with minority children. Many even consider the very term *mental retardation* stigmatizing. Partly as a result, fewer children who might otherwise be considered to have mild mental retardation (i.e., I.Q. scores from 55 to 69) are receiving a mental retardation diagnosis.

Where are all the children with mild mental retardation? Partly, it seems, these children now receive diagnoses of learning disabilities. According to U.S. Department of Education statistics, over the school years 1976–77 to 1992–93, there was a 41 percent decline in the percentage of children considered to have mentally retardation by U.S. schools, while the percentage of children considered to be learning disabled jumped 198 percent.

But the move from mental retardation to learning disabilities is not the total answer. Indeed, many children with an I.Q. score below 70 do not have a diagnosis or either mental retardation or learning disabilities. They do not receive the diagnosis of mental retardation because of fear of stigma and decreased reliance on I.Q. tests, and they do not receive a diagnosis of learning disabilities because they do not function two or more standard deviations worse on achievement tests than on I.Q. tests (the usual definition of learning disorders). To stop the underdiagnosis of these children, some workers have suggested abandoning the category of mild mental retardation in favor of a new diagnostic category that highlights this group of low-intelligence, low-achieving, and less-often-served children.

Equal Mortality Rates A final assumption of the 3 percent figure is that persons with mental retardation and those without have equal life spans. This assumption seems obviously incorrect, particularly for persons with more severe and profound mental retardation.

Several variables lower life expectancies. For example, many early deaths—sometimes for persons in their 20s and 30s—are related to ambulatory and respiratory problems. Etiology may also play a role. Specifically, children with Down syndrome continue to be prone to heart problems, leukemia, and (by age 35) the plaques and tangles of Alzheimer's disease. Similarly, children with Prader-Willi syndrome are prone to hyperphagia and obesity, and complications of obesity (e.g., diabetes, heart disease) remain the main cause of higher death rates for persons with Prader-Willi syndrome.

How many persons with mental retardation are there? No one can say for certain. Given a definition that features an I.Q. below 70 and deficits in adaptive behavior, the prevalence rate is probably below 3% but above 1%. If one adopts a cutoff below I.Q. 75, higher percentages might be obtained. At present, it seems best to conclude that although the 1% figure is cited by most studies and professional-organizations, several difficult (possibly unresolvable) issues complicate even the simple question of how many persons have mental retardation.

ETIOLOGY

As noted by Esquirol in 1845, intellectual disability is not a disease in and of itself, but the developmental consequence of some pathogenic process. In 1898 William Ireland could classify idiocy into ten categories on the basis of etiology including “genetous, microcephalic, eclampsic, epileptic, hydrocephalic, paralytic, cretinism, traumatic, inflammatory, and idiocy by deprivation.” More recently, the AAMR offered an admittedly partial listing that enumerated over 350 causes of mental retardation.

With advances in medicine generally and in molecular genetics in particular, new causes of mental retardation or the genetic causes of formerly unspecified syndromes are identified each year. John Opitz counts over 750 genetic causes of intellectual disability alone. Eleanor Feldman notes that some 95 mental retardation syndromes have been linked to the X chromosome. The most common causes of mental retardation are Down syndrome, fragile X syndrome (accounting for 40% of all X-linked retardation), and fetal alcohol syndrome. Together, these three conditions are responsible for about 30 percent of all identified cases of mental retardation. Recently, early childhood anemia has been identified as a risk for mild to moderate mental retardation.

In addition to new causes being identified, additional knowledge is accumulating about underlying mechanisms in causes previously known. In Down syndrome, for example, a critical region on chromosome 21 (*DSCR1*) has been described at the 21q22.1-q22.2 locus. The availability of molecular markers for this and flanking regions has enabled clinicians to confirm cases of Down syndrome in the context of subtle translocations and chromosomal abnormalities other than trisomy. At least 170 different mutations leading to phenylketonuria have been reported in the phenylalanine hydroxylase gene.

As clinicians approach the cause of mental retardation in a particular patient, it is helpful to work from a broad framework initially. For example, an initial distinction might be drawn between congenital and acquired causes. For the latter, the timing of the insult that led to retardation may be further broken down into perinatal or postnatal causes. Congenital causes might be divided into genetic disorders or developmental disorders of brain formation, or more specifically still into inborn errors of metabolism and so on.

The frequency with which mental retardation associates with a particular cause depends highly on the population surveyed. For example, persons drawn from institutional settings, where severe and profound mental retardation and visible congenital anomalies are seen more commonly, are more likely to have an identifiable chromosomal abnormality than are persons with mild disability residing in community settings. In other words, more severe presentations of mental retardation are likely to have an organic cause. Table 34-3 presents a classification scheme with associated frequency estimates for mental retardation etiopathogenesis.

Cause	Examples	Estimated Frequency (%)
Prenatal		
Genetic disorders		4–28
Chromosomal aberrations	Down syndrome	
Single gene mutations	Tuberous sclerosis, phenylketonuria and other metabolic disorders, fragile X syndrome	
Multifactorial	"Familial" mental retardation	
Malformation syndromes due to microdeletions	Prader-Willi, Williams, and Angelman syndromes	
Congenital malformations		7–17
Malformations of the central nervous system	Neural tube defects	
Multiple malformation syndromes	Cornelia de Lange syndrome	
Exposure		5–13
Maternal infections	Congenital rubella, HIV	
Teratogens	Fetal alcohol syndrome	
Toxemia, placental insufficiency	Prematurity	
Other	Radiation, trauma	
Perinatal		2–10
Infections	Meningitis	
Delivery problems	Asphyxia	
Other	Hyperbilirubinemia	
Postnatal		3–12
Infections	Encephalitis	
Toxins	Lead poisoning	
Other postnatal causes	Traumas, brain tumors	
Psychosocial problems	Poverty, psychotic illness	
Unknown		30–50

Table 34-3 Mental Retardation Causes

Animal Models Over the past 100 years, increased understanding of basic brain organization and function and some of the causes of intellectual disability has been derived from animal models. It is hoped that such modeling will help clarify underlying mechanisms and suggest potential treatments for mental retardation.

Rodent models have been described for Down syndrome, phenylketonuria, fragile X syndrome, Lesch-Nyhan syndrome, and prenatal exposure to alcohol or cocaine. Trisomy 16 mice, a potential Down syndrome model, demonstrate visual, spatial, and attendant learning deficits. Homologues of the single-minded gene in the fruit fly *Drosophila* have been identified in both man and mouse, and the human gene maps to the Down syndrome critical region. Likewise, the *Drosophila* minibrain gene appears to be associated with the Down syndrome critical region. Both of the genes in *Drosophila* are involved in brain development, and their study will suggest possible mechanisms underlying mental retardation in humans. The curly tail mouse has been a valuable model for the study of neural tube defects, and a number of agents derived from this paradigm will likely be evaluated for their potential to prevent neural tube defects in humans. A mouse model for the fragile X syndrome, in which the *FMR*-1 gene is molecularly knocked out, is remarkable in that like humans with the disorder, the knockout mice show macroorchidism, learning deficits, and hyperactivity. These models may help to unravel the physiological role of the FMR1 protein in humans.

Genetic Mental Retardation Syndromes and Behavioral Phenotypes New genetic technologies have played a key part in elucidating causes of mental retardation, and the study of intellectual disability has contributed to advancing the understanding of the genetics of disease more broadly. Largely as a result of research into mental retardation syndromes, primarily fragile X and Prader-Willi syndromes, novel genetic mechanisms have been identified that have led to collective rethinking of classic Mendelian principles.

These remarkable genetic advances have sparked renewed research interest in the behavioral features of persons with fragile X, Prader-Willi, and other genetic syndromes. In their review of behavioral aspects of chromosomal disorders, Seymour Kessler and Rudolf Moos, for example, discuss only five syndromes. Since then, the number of disorders for which a “behavioral phenotype” has been suggested has grown considerably. A good working definition of a *behavioral phenotype* was proposed by Elisabeth Dykens, namely, a syndrome in which the probability of the expression of certain behaviors or constellations of behaviors is greater than expected. Stereotyped hand movements, for example, have been described in many contexts, but a particular form of stereotyped hand wringing is almost invariably seen in Rett's syndrome. Hyperphagia and obesity are nonspecific symptoms, but without aggressive dietary intervention, the probability of an individual with Prader-Willi syndrome becoming obese is nearly 100 percent.

Table 34-4 provides a representative sample of syndromes for which behavioral phenotypes have been described, some only anecdotally, others with controlled studies. Though the study of behavioral phenotypes is in its beginning stages, this line of work holds much promise for both clinicians and researchers. Identified syndrome-specific behavioral patterns guide clinicians toward some diagnostic possibilities over others, and these behavioral profiles also guide intervention and treatment. From a research standpoint, phenotypic work advances the understanding of gene-brain-behavior relation. To illustrate these advantages, behavioral and genetic features are reviewed below in fragile X, Prader-Willi, and Down syndromes.

[illegible]	[illegible]	[illegible]

Table 34-4 Representative Sample of Mental Retardation Syndromes and Behavioral Phenotypes

Examples of Behavioral Phenotypes in Mental Retardation Syndromes

FRAGILE X SYNDROME Fragile X syndrome, the most common inherited cause of mental retardation, results in a wide range of learning and behavioral problems, with males being more often and severely affected than females. The recently discovered fragile X gene (*FMR*-1) represents a newly identified type of human disease, caused by amplification (or excessive repetition) of a three-nucleotide sequence (CGG) in deoxyribonucleic acid (DNA). Above a certain threshold of these triplet repeats (about 200), people are fully affected with the syndrome. Numbers of repeats between the normal threshold of 50, and below 200, are termed “premutations.” As many as 1 in 259 women in the general population may carry the premutation, with 1 in 4000 males and 1 in 8000 females being fully affected with the syndrome.

Many of the behavioral features in people with fragile X syndrome are a function of the number of CGG repeats and a cascade of subsequent effects. The number of repeats is related to the extent to which the *FMR*-1 gene is methylated and subsequently silenced, or blocked from transcription and translation. This, in turn, affects the amount of FMR-1 protein (FMR1P) produced, and the range of clinical expression in fragile X syndrome is associated with the amount of FMR1P. Fully affected, fully methylated males have no FMR1P, whereas high-functioning males, though rare, have some FMR1P. In females, only one X chromosome carries the *FMR*-1 gene; the other allows production of some FMR1P. Because all females have one X chromosome randomly inactivated in all cells, the degree of involvement in females with fragile X is related to the ratio of normally active X chromosomes to the total number of X chromosomes (active plus inactive). About half of fully affected females show mild-to-moderate mental retardation and half have average I.Q. scores. But even among those with average intelligence, up to 80 percent may show specific problems in planning, memory, and attention. Neuroimaging studies link performance on some of these cognitive tasks to the size of the posterior cerbellar vermis, which is smaller in males and females with fragile X syndrome than in controls.

FRAGILE X SYNDROME AND AUTISTIC DISORDER Reportedly, many fully affected males with fragile X syndrome show autistic-like symptoms such as language delay, echolalia, stereotypies, self-injurious behavior, perseveration, poor eye contact, and tactile defensiveness. Not surprisingly, then, early workers tried to associate fragile X syndrome with autism, spurred on by the possibility of a common genetic cause of autism. Yet highly variable prevalence rates were found in this work, primarily because of discrepancies in the diagnostic criteria for autistic disorder.

This flurry of research faded as new studies suggested that instead of autism per se, many males showed a willingness to interact with others that was coupled with social and performance anxiety and mutual gaze aversion. Controlled studies and meta-analyses now suggest that only about 5 percent of males with fragile X have autistic disorder. Most affected males can be placed on a spectrum of social anxiety, shyness, avoidance, and gaze aversion. While some of these boys have anxiety

disorders or pervasive developmental disorder not otherwise specified, others may simply display slow-to-warm temperament styles, including shyness or social withdrawal.

Similarly, many females with fragile X syndrome exhibit variable levels of social dysfunction, primarily shyness, gaze aversion, and social anxiety. Many of these women meet clinical criteria for schizotypal disorder, showing interpersonal discomfort and difficulties in communication and social relationships. Fully affected women (with more than 200 CGG repeats) are more likely to have schizotypal disorder or schizotypal features than women with a premutation or appropriately matched control women without a fragile X. Although shyness is thus a central feature of the fragile X behavioral phenotype, affected females may also have a higher risk of depression than non–fragile X mothers of developmentally delayed children.

In addition to these difficulties, hyperactivity and attention deficits are seen in the vast majority of boys and girls with fragile X syndrome. Attention-deficit/hyperactivity disorder symptoms are higher among fragile X boys than among control subjects, and girls with a fragile X have lower prevalence rates of attention-deficit/hyperactivity disorder than fragile X boys. Among adults, problems in attending and in sustaining effort have been found in the neuropsychological profiles of women who carry the *FMR-1* gene, which may contribute to problems in mathematics, abstract reasoning, and planning.

Fragile X syndrome thus involves vulnerabilities toward shyness, gaze aversion, social anxiety, avoidant disorders, schizotypal disorder, attention/deficit/hyperactivity disorder, pervasive personality disorder not otherwise specified and, more rarely, autistic disorder. These difficulties vary in severity but are typically found in persons across the I.Q. spectrum, from those with moderate mental retardation to those with mild learning disabilities.

PRADER-WILLI SYNDROME First identified 41 years ago, Prader-Willi syndrome affects about 1 in 15,000 births and is best known for its food-related characteristics. Babies invariably show hypotonia and pronounced feeding-sucking difficulties, while young children between 2 and 6 years of age develop hyperphagia and food-seeking behavior such as foraging and hoarding. Hyperphagia is probably associated with a hypothalamic abnormality resulting in a lack of satiety. Food preoccupations are lifelong, and without prolonged dietary management, affected individuals invariably become obese. Complications of obesity remain the leading cause of death in persons with this syndrome.

Prader-Willi syndrome is the first known human disease to show the effects of genomic imprinting, that is, genes being modified and expressed differently depending upon whether they are inherited from the mother or the father. About 70 percent of Prader-Willi syndrome cases are caused by a paternally derived deletion on the long arm of chromosome 15. The remaining cases are attributed to maternal uniparental disomy of chromosome 15, in which both members of the chromosome 15 pair come from the mother. In either case, the paternally derived contribution to this specific region of the genome is missing. When missing information in this same region of chromosome 15 is maternally derived, it results in a completely different and more severe developmental disorder, Angelman's syndrome.

Although people with Prader-Willi syndrome invariably obsess about food, a remarkably high proportion also show nonfood obsessions and compulsive behaviors. These nonfood symptoms include skin picking; hoarding; needing to tell, ask, or say things; and having concerns with symmetry, exactness, ordering, arranging, cleanliness, and sameness in daily routine. Often these symptoms are associated with distress or adaptive impairment, suggesting a marked risk of obsessive-compulsive disorder in this population. Indeed, the authors estimate that obsessive-compulsive disorder is many times more likely in persons with Prader-Willi syndrome than in the general population of persons with mental retardation.

In addition, even compared with others with mental retardation, children and adults with Prader-Willi syndrome display high rates of temper tantrums, aggression, stubbornness, underactivity, excessive daytime sleepiness, and emotional lability. Coupled with food seeking, these impulsive behaviors often lead those with Prader-Willi syndrome to need more-restrictive care than would be predicted by their mild levels of mental retardation.

Psychopathology may be associated with the derivation of the individual's Prader-Willi syndrome. Preliminary findings from ongoing work suggest some behavioral differences between cases due to paternal deletion and those due to maternal uniparental disomy. Patients with deletions may have a lower I.Q., especially verbal I.Q., and more frequent or severe problem behaviors such as skin picking, hoarding, temper tantrums, overeating, and social withdrawal. Although a dampening of symptom severity is suggested in many uniparental disomy patients, the authors also observe occasional patients with more-severe problems in uniparental disomy, primarily autistic-like features and relatively low I.Q. scores.

Many people with Prader-Willi syndrome then, are at increased risk for obsessive-compulsive, impulse control, and affective disorders. Yet even those who do not meet diagnostic criteria for these psychiatric disorders often show significant maladaptive behaviors that interfere with optimal adaptive functioning.

DOWN SYNDROME Occurring in approximately 1.2 of 1000 live births, Down syndrome is the most common chromosomal abnormality leading to mental retardation. It usually results from nondisjunction of chromosome 21. The syndrome has been the subject of considerable investigation.

Studies of children have revealed distinctive cognitive and linguistic profiles. Particular strengths have been noted in visual (versus auditory) processing. Language impairment can be extensive, with particular difficulty in expressive language, grammar, and pronunciation.

In contrast to the relative overall weakness in the cognitive arena, those with Down syndrome are often described as being particularly socially adept. However, studies of adaptive functioning suggest that these skills are not uniform, with communication scores trailing behind measures of daily living skills and socialization. The stereotype of a Down personality—happy, good tempered, affectionate, placid, and stubborn—has been difficult to verify.

Compared with others with mental retardation, persons with Down syndrome appear to suffer less often and less seriously from psychopathology. Adults with Down syndrome appear somewhat less prone to psychiatric disturbance than controls. This trend seems to extend to children and adolescents as well; rates of psychiatric and behavioral problems exceed those in the general population but are appreciably lower than those in other groups with mental retardation. Commonly noted problems include attention difficulties, impulsivity, hyperactivity, and aggression. In contrast to these problems, depression seems to be less common among children and adolescents than expected norms. Autism and pervasive developmental disorders appear to be relatively rare.

DIAGNOSIS AND CLINICAL FEATURES

Table 34-5 presents the DSM-IV diagnostic criteria for mental retardation, and Table 34-6 lists the ICD-10 criteria.

A. Significantly subaverage intellectual functioning: an IQ of approximately 70 or below on an individually administered IQ test (for infants, a clinical judgment of significantly subaverage intellectual functioning).
B. Concurrent deficits or impairments in present adaptive functioning (i.e., the person's effectiveness in meeting the standards expected for his or her age by his or her cultural group) in at least two of the following areas: communication, self-care, home living, social/interpersonal skills, use of community resources, self-direction, functional academic skills, work, leisure, health and safety.
C. The onset is before age 18 years.

Code based on degree of severity reflecting level of intellectual impairment:

Mild mental retardation: IQ level 50–55 to approximately 70
Moderate retardation: IQ level 35–40 to 50–55
Severe mental retardation: IQ level 20–25 to 35–40
Profound mental retardation: IQ level below 20 or 25
Mental retardation, severity unspecified: when there is a strong presumption of mental retardation but the person's intelligence is untestable by standard tests

Table 34-5 DSM-IV Diagnostic Criteria for Mental Retardation

Table 34-6 ICD-10 Diagnostic Criteria for Mental Retardation

Levels of Mental Retardation At present, the field lacks a classification system that reflects the remarkable diversity, strengths, and competencies of people with mental retardation. The new AAMR definition rejected traditional nosology because of its emphasis on deficits in people, yet it fell short of developing a successful alternative based on strengths or competencies. Until a viable new scheme is developed, it makes sense to use traditional nosology to describe persons with mental retardation.

Mild Mental Retardation Mild mental retardation (I.Q., 55 to 70) characterizes the largest group of persons with mental retardation, possibly as many as 85 percent of the total. These individuals appear similar to nonretarded individuals and often blend into the general population in the years before and after formal schooling. Many achieve academic skills at the sixth grade level or higher, and some graduate from high school. As adults, many of these individuals hold jobs, marry, and raise families—yet at times they may appear slow or need extra help negotiating life's problems and tasks.

Johnny is a 10-year-old boy with mild mental retardation. Although from birth his parents considered him somewhat “slow,” Johnny was not diagnosed with mild mental retardation until his early grade-school years. To this day, no clear diagnosis has been provided for Johnny's mild mental retardation. As measured by the Stanford-Binet IV, his I.Q. is 67, with no significant differences between his verbal and perceptual processing scores. Johnny does, however, show impulsivity and problems in attending. These attentional problems are apparent on his Stanford-Binet IV auditory short-term memory subtests and in his adaptive behavior. For example, he has difficulty waiting his turn at school and needs many prompts to follow through with directions from his teachers and parents.

Johnny's mental retardation first became apparent at the end of first grade. At that time, a student study team at his school worked with Johnny's classroom teacher and the resource room teacher to help Johnny improve his basic work organization skills and increase his attention span. At his parents' request, Johnny was also evaluated for attention-deficit/hyperactivity disorder by a local psychiatrist, who subsequently prescribed stimulant medication that seemed to help.

Traditionally, individuals with mild mental retardation were thought to show relatively few clear-cut organic causes for their delay. While this may still be the case, recent years have seen an increase in the number of people with genetic syndromes who function in the mild range. Examples include most people with Prader-Willi syndrome and some males and most females with fragile X syndrome.

A more striking characteristic, however, is that more people with mild mental retardation come from minority groups and low socioeconomic backgrounds than would be expected from their percentages in the general population. This overrepresentation of minority groups has been used to criticize I.Q. tests and to highlight the importance of both environmental-cultural and genetic influences on mental retardation.

Moderate Mental Retardation Moderate mental retardation (I.Q., 40 to 55) is seen in approximately 10 percent of those with mental retardation, including persons with more-impaired cognitive and adaptive functioning. Individuals with moderate mental retardation typically receive their diagnosis in their preschool years, and some show a clear organic cause for their delay. Persons with Down syndrome often function in this range, as do many adolescents and adults with fragile X syndrome. Most children with moderate mental retardation require special education services and achieve academic skills at the second to third grade level. Supportive services are needed throughout life. With proper supports, many live, work, and thrive in their local communities. A study by Ross and colleagues found that 20 percent of persons with an I.Q. from 40 to 49 lived independently, 60 percent were considered partially dependent, and 20 percent were totally dependent on others. Similarly, some individuals in this range are employed in the competitive job market and need minimal job supervision, whereas others require more extensive supervision on the job and may work in sheltered workshops or other, more segregated settings.

Harold is a 16-year old boy with moderate mental retardation. Diagnosed at birth with Down syndrome, Harold has been mainstreamed with same-aged peers throughout his schooling. Harold, whose I.Q. is 53, has some difficulties with articulation, and his language consists mainly of two- to four-word sentences. Recently, Harold was introduced to reading; he now can read 50 sight words. Although he can occasionally be stubborn and argumentative, Harold is well liked by his teachers and classmates, and his parents boast that Harold has been a charming, pleasant child from infancy on. In addition to attending his classes at the local high school, Harold serves as the assistant manager for his high school's cross-country team and actively participates in Special Olympics.

Severe Mental Retardation Severe mental retardation (I.Q. 25 to 40) occurs in about 3 to 4 percent of persons with mental retardation. Individuals at this level often have one or more organic causes for their delay, and many show concurrent motor, ambulatory, and neurological problems as well as poorly developed communication skills. Most persons with severe mental retardation require close supervision and specialized care throughout their lives. Some individuals learn to perform simple tasks or routines that facilitate their self-care or their ability to perform in a sheltered workshop or preworkshop-type setting.

Robert was born prematurely at 8 months, weighing 4 pounds 7 ounces. Because of hyperbilirubinemia and respiratory problems, Robert remained in the hospital for several weeks before going home. For the first 2 years of his life, his mother recalls that Robert was quite a “passive” baby who would seldom even make his needs known; he did not even cry when he was hungry or wet. Similarly, while Robert gave no indication that he enjoyed cuddling early on, neither did he indicate that he disliked it. At approximately 2 years of age, Robert was hospitalized with a very significant episode of chicken pox that apparently included pneumonia. During that illness, he also had at least one seizure, which prompted the initiation of phenobarbital (Solfoton) treatment. During that hospitalization, physicians observed Robert's developmental delays: he was not bowel or bladder trained and did not talk or walk independently. A subsequent evaluation yielded a diagnosis of severe-to-profound mental retardation. His mother recalls receiving a recommendation at this time to consider institutional placement for Robert, given the severity of his disabilities. She recalls that Robert continued to acquire skills, including bowel and bladder training at approximately 4 years of age, and that he began to speak some years later. He also began to change from a relatively placid child to one with more motor activity, and mother describes him as having been quite hyperactive and also as having exhibited insomnia. Robert was placed in a residential school setting at age 6. During this placement, Robert's medications were tapered and discontinued without incident, and through a behavioral modification program, his behaviors were significantly improved, which lead to a recommendation for discharge when Robert was ten. In the discharge summary, Robert was characterized as a young man who was very pleasant and cooperative, who enjoyed working with others and even enjoyed hugs. There were no reports of symptoms that might be regarded as autistic, either stereotypies or unusual preoccupations. Following his discharge from the institutional setting, Robert returned home and lived with his family until the age of 21, when he moved into a sponsored living situation with one other peer. Robert, now 37, is a handsome man who is quite particular about his appearance. He speaks in one- and two-word phrases and follows simple requests without difficulty. He does not consistently demonstrate good safety awareness and requires supervision when crossing streets. For approximately the last 5 years, Robert has been treated with carbamazepine (Tegretol) for staring spells. When carbamazepine treatment started, Robert was described as having become somewhat irritable. This adverse effect has since resolved, and he is doing well at the moment in all settings, both at his structured workshop and at home, with no problems with his sleep, appetite, or behavior.

Profound Mental Retardation Profound mental retardation (I.Q. of 25 or below) affects relatively few individuals (1 to 2 percent) and involves pervasive deficits in cognitive, motor, and communicative functioning. Impaired sensory-motor functioning is often seen from early childhood on, and most individuals require extensive

training to complete even the most rudimentary aspects of self-care such as eating and toileting. The vast majority of people with profound mental retardation have organic causes for their delay, and most require total supervision and care throughout life.

> Martha is a 24-year-old woman with profound mental retardation. Diagnosed from birth as having 5p syndrome, Martha's I.Q. is below testable limits, she walks only with difficulty, and she shows limited toileting and grooming skills. Martha is nonverbal but seems to understand simple commands and phrases. She is also extremely hyperactive and prone to irritability and temper tantrums, especially when going from one activity to another. Despite her difficulties, Martha shows an interest in others, has good eye contact, and is well liked by the residents and staff of her community-based group home. Martha attends a day-training program, where she is learning grooming and toileting, as well as basic visual-motor tasks.

Metabolic Testing The presence of certain clinical characteristics may prompt the focused use of metabolic studies to identify inborn errors of metabolism. A partial listing of signs and symptoms that might raise the suspicion of a metabolic disorder appears in Table 34-7. Testing in the presence of clinical suspicion might include plasma and urine amino and organic acid studies, acid-base balance determination, thyroid function tests, lysosomal enzyme analysis, plasma and urine carnitine analyses, and plasma very long chain fatty acid assays, among others. Because neonatal screening picks up phenylketonuria, hypothyroidism, and galactosemia, the yield for subsequent unselected screening for inborn metabolic disorders is extremely low. In general, in the absence of specific indications other than mere mental retardation, metabolic testing is likely to be of little diagnostic value.

Growth abnormality
Recurrent, unexplained illness
Seizures
Ataxia
Loss of psychomotor skills
Hypotonia
"Coarse" appearance
Eye abnormalities (cataracts, ophthalmoplegia, corneal clouding, retinal abnormality)
Recurrent somnolence/coma
Abnormal sexual differentiation
Arachnodactyly
Hepatosplenomegaly
Metabolic/lactic acidosis
Hyperuricemia
Hyperammonemia
Low cholesterol
Structural hair abnormalities
Unexplained deafness
Bone abnormalities (dysostosis, occipital horns, punctate calcifications)
Skin abnormalities (angiokeratoma, "orange-peel" skin, ichthyosis)

Table 34-7 Selected Clinical Findings and Laboratory Abnormalities That Increase Suspicion for Underlying Metabolic Disorder

DEVELOPMENTAL CONSIDERATIONS IN CHILDREN WITH MENTAL RETARDATION

Throughout the twentieth century children with retardation have been an ongoing topic of developmental research. Small groups of researchers have examined the development of various Piagetian cognitive domains, language, social skills, and even morality. By now, much is known about how children with mental retardation develop.

Besides providing basic milestones or natural histories, these studies help reveal the underlying processes of development. Over the past decade, researchers have begun to specify the ordering of development (sequences), the ways in which levels in certain areas relate to levels in other areas (cross-domain relations), and the points at which the speed of development (rate) changes. Such analyses have begun to be applied to children with different causes of mental retardation.

In addition, developmental analyses have been extended beyond children themselves. Many developmental psychologists examine mother-child interactions, family behaviors in families of different-aged children, and the child's ongoing interactions with peers, neighbors, and schools.

Child-Related Aspects of Development Following developmental psychology's study of normal children, researchers throughout this century have examined children with mental retardation. Such studies have focused in two main areas: development of children themselves and children's interactions with their surrounding environments.

Children with mental retardation are now known to traverse the same sequences of development as nonretarded children, but children with certain forms of mental retardation show intellectual strengths and weaknesses not generally found in those who are nonretarded. Children with mental retardation also show certain ages and tasks with particularly slowed development that seem to be related to specific types of mental retardation; the reasons for such slowing are little understood.

Mothers of children with mental retardation resemble mothers of typical children in shortening their speech, focusing on key words, and in other ways structuring the environment for their child's development. However, they seem much more didactic and intrusive. Families of children with mental retardation differ widely one from another. When the child with retardation shows less maladaptive behavior and when the mother's style of coping is more problem focused, parental and family stress seems to be lowered.

Sequences Normal children have a specific, possibly universal, order to their development. For example, in Piagetian cognitive development, children proceed from sensorimotor, to preoperational, to concrete operational, to formal operational thought. Even within these four larger stages, smaller orderings hold; within sensorimotor development, normal infants proceed in order through Piaget's six substages in each of several subdomains.

Do children with mental retardation also follow a so-called similar sequence in development? For almost 30 years, similar sequences have been found for a variety of children over many tasks. Similar sequences even hold for children with genetic or other organic causes for their retardation. The only possible exceptions include some children with uncontrollable seizures (which make accurate testing difficult) and some autistic children, who may show different orderings because of their particular disabilities on certain social tasks. Such sequences have been noted in many areas: in almost twenty Piagetian domains, in symbolic play, and in linguistic grammar and pragmatics. For almost all children and for a wide variety of behaviors, children with mental retardation and other children develop along similar sequences.

Cross-Domain Relations If children with retardation proceed in the same developmental ordering as other children, do they also show the even, or flat, profiles that groups of children without mental retardation show from one domain to another? Such a “similar structure” to development was proposed by Zigler in the late 1960s.

Unlike similar sequences—which hold for all children with mental retardation—cross-domain structures may differ, depending on which retarded group one considers. With a few exceptions, children with cultural-familial mental retardation do show even or near-even performance across various intellectual domains.

In contrast, children with different organic forms of mental retardation show specific intellectual strengths and weaknesses. For example, three separate groups are weaker in sequential (i.e., bit-by-bit, serial) processing than in simultaneous (i.e., Gestalt, holistic) processing or achievement abilities. Such sequential deficits are found in boys with fragile X syndrome, children with Prader-Willi syndrome, and children with Smith-Magenis syndrome. Children with Down syndrome may have particular weaknesses in expressive (versus receptive) communication and special problems in grammatical abilities. Children with Williams syndrome show extra deficits in visuospatial processing skills, and some subsets of these children show heightened abilities in language. Different causes of mental retardation thus result in different characteristic intellectual strengths and weaknesses.

Rates A further issue concerns children's rates of development. By definition, children with mental retardation develop at slower rates than other children. Nonspecific or mixed groups show reasonably steady rates of development, evinced by stable a I.Q. after the early childhood years. Children with other types of mental retardation, however, may have periods of speeded or slowed development.

Times of speeded or slowed development seem to be related to either age or task difficulties. In age-related slowing, most children with a specific type of mental retardation slow in their development during a certain age span. For example, boys with fragile X syndrome have stable developmental rates until about age 9 or 10, when development slows. Similarly, both cross-sectional and small-scale longitudinal studies show that children with Down syndrome slow from ages 6 to 11;

throughout this age span, these children slow in their development of linguistic grammar, intellectual skills, and adaptive behavior. It remains unknown why such age-related slowings occur in both fragile X and Down syndromes, whether all children with the disorder show such slowings, or if slowings are seen across all domains.

A second type of slowing relates to pronounced difficulties mastering a specific developmental task. Unlike age-related slowings, these slowings occur at a variety of ages, whenever children with a particular type of retardation reach a specific developmental task. Consider young children with Down syndrome (who also show age-related slowings from 6 to 11 years). These children have difficulty with certain tasks of infant intelligence, even after one accounts for their already-slower rates of development, and toddlers are slower to develop expressive skills than receptive language skills. As a result of both age- and task-related slowings, children with Down syndrome generally exhibit their highest I.Q. scores during the first year of life.

An overview of development in children with mental retardation shows that these children develop along the usual sequences. At the same time, different subgroups show exceptional strengths or weaknesses in one or another area and have particularly slowed development in mastering different tasks or during differing age spans. Why different mental retardation groups show such developmental patterns remains generally unknown.

Contextual Aspects of Development

Mother-Child Interactions Following from research on interactions between typically developing children and their mothers, mother-child interaction studies in mental retardation began during the mid-1970s. Some similarities and some differences were found in mother-child interactions with children with mental retardation and those with other children of the same mental age (M.A.). The two groups of mothers behave similarly on what might be called the structural aspects of behavior. In language, for example, they both shorten their speech, simplify their vocabularies, raise their pitch, repeat key words, and generally provide typical “motherese.” Thus mothers of typically developing 2-year-olds and mothers of children with retardation who are at 2 years M.A. act almost identically.

At the same time, mothers of children with mental retardation show very different styles in their interactions. They are often more didactic and intrusive than mothers of typically developing, M.A.-matched children. They more often initiate the topic of interaction, take longer speaking turns, talk at the same time as their child, and in other ways control the interaction. As a result, the child has fewer opportunities to initiate and control the conversation.

Why such stylistic differences occur remains unclear. The prevailing view holds that mothers of children with mental retardation are worried about their child's development, and in their zeal to teach and instruct their children, they may go overboard. As one mother of a child with Down syndrome explained: “It's put him on your knee and talk to him, that's the main object. Play with him, speak to the child, teach him something.”

A more didactic interactive style may not, in fact, be most beneficial for the child's development. Although few studies have been performed, young children with retardation seem to develop faster when their mothers are less intrusive. One study examined mother-child interactions at 23 months and child outcomes at 36 months. Children whose mothers constantly redirected the child's attention had lower receptive language ages at 36 months than those whose mothers commented on the object at which the children was looking. These studies suggest that mothers might better respond to the child's interests and initiatives than be didactic or intrusive.

Family Reactions Over the past two decades, family studies in mental retardation have changed from a predominantly negative to a more balanced perspective. Before the early 1980s, these families were perceived to be families in crisis. Mothers were examined for their mourning reactions, couples for divorce, and mothers, fathers, and unaffected siblings for the presence of depression and other forms of psychopathology. The basic findings were that families of children with disabilities may suffer more divorces, parents and siblings are somewhat more prone to depression, and families and individual family members have more difficulty when there is only one parent, when the mother receives little support from the husband, or when the family is of low socioeconomic status.

In the early 1980s family researchers began to change their conception from the earlier focus on family pathology to families facing increased stress. Children with mental retardation might add stress to the family system, but this stress could result in negative or positive adaptation. This change implies a more normative view of these families: every family faces a variety of stressors (e.g., illness, loss of job), and having children with retardation can be thought of as a stressful situation.

The move from a negative to a stress-coping perspective has other implications. First, it permits change from a predominantly “between-group” research strategy. Previously, most studies compared families of children with disabilities to families of typical, nondisabled children of the same chronological age. Recently, the between-group focus has been complemented by within-group studies. Since families of children with mental retardation vary in their ability to cope, what causes better adjustment in one family and worse adjustment in another? What child, parent, or family characteristics foster better adaptation?

To date, most work has examined such child characteristics as age and degree of impairment. Findings have been inconsistent for both variables. Some studies find it more stressful to parent older children with retardation; others suggest that families experience more stress when the child begins puberty (11 to 15 years) and again when the child reaches early adulthood (20 to 21 years). Still other studies find no relation between increased family stress and the child's age. Similarly, some studies find that it is more difficult to parent children with more severe levels of retardation, and others do not.

Another, less-often examined characteristic involves the extent of the child's maladaptive behavior. So far, strong connections have been found between child maladaptive behavior and family stress in families of children with retardation of mixed etiology, with Prader-Willi syndrome, and with 5p (*cri du chat*) syndrome. Why such correlations occur is unclear. Although most researchers feel that child maladaptive behavior increases familial stress, increased familial stress may also elicit child behavior problems.

Another important variable concerns the coping style of the parents. Across several studies, parents who more actively, constructively attempt to deal with their child did better than parents who adopted a palliative coping style, one that either dwells on or ignores parental emotions. This difference in personality style may help buffer parents and families from the increased stresses of parenting a child with mental retardation.

COMORBIDITY

Attention-Deficit/Hyperactivity Disorder The rates of attention-deficit/hyperactivity disorder in mental retardation are estimated to be between 9 and 18 percent. Although considerable research has been done on the treatment of attention-deficit/hyperactivity disorder, virtually all of these studies have specifically excluded children with cognitive disability. Moreover, the diagnosis of attention-deficit/hyperactivity disorder is based upon developmental considerations, namely, significantly greater motoric hyperactivity, impulsivity, and inattention than is expected for a given developmental age; thus the threshold for diagnosis in persons with severe-to-profound mental retardation should be elevated.

For persons with mental retardation, the diagnosis of attention-deficit/hyperactivity disorder is qualified as being excessive for an individual's mental age. In the context of profound mental retardation, attention span, distractibility, or on-task behavior are predictably quite variable. Individuals given the diagnosis of attention-deficit/hyperactivity disorder in this context should exhibit shorter attention spans, greater psychomotor activity, and more remarkable impulsivity than their peers with similar levels of retardation. Often clinicians encounter situations in which an individual does not evidence remarkable psychomotor activity or attentional difficulties but may be unusually impulsive. In these situations one should entertain the diagnosis of an impulse control disorder not otherwise specified. Such a diagnosis, for example, might be appropriate for an individual who inexplicably strikes out at a peer in the absence of any identifiable environmental stressor.

Impulse-Control Disorders: Self-Injury and Aggression Every effort should be made to treat the underlying cause of self-injurious behavior or aggression, not merely suppress the behavior. However in some cases, for example, stereotyped movement disorder with self-injurious behavior, the symptom is essentially the diagnosis. Aggression and self-injurious behavior are common in mental retardation and increase as cognitive disability becomes more severe. Self-injurious behavior typically is a chronic, repetitive, and frequently stereotyped behavior causing trauma. It occurs in the context of specific genetic syndromes (e.g., Lesch-Nyhan syndrome and Smith-Magenis syndrome) but more commonly in persons with unknown or nonspecific causes for their mental retardation.

A review of psychiatric consultations in an institutional setting reported that self-injurious behavior was specifically cited as a reason for referral in 36 percent of the 251 cases examined. However, self-injurious behavior as a presenting symptom generally does not help to predict the ultimate psychiatric diagnosis. The single exception perhaps is the diagnosis of stereotyped movement disorder, in which the designation “with self-injurious behavior” was specifically created for persons who engage in this behavior in the absence of other diagnosable psychopathology.

Since self-injurious behavior and aggression are nonspecific symptoms, one must consider the presence or absence of a variety of factors to reach a presumptive diagnosis: the chronicity of the behavior, whether it may serve a communicative function, whether it is invariant in topography (e.g., hitting only the right ear, suggesting an ear infection), whether it is situational, whether it occurs in concert with regression from a previous level of function, and whether any associated neurovegetative signs correlate with its onset.

Oppositional Defiant Disorder and Conduct Disorder The DSM-IV diagnosis of oppositional defiant disorder or conduct disorder also requires comparisons with others of similar mental age. Further, both diagnoses assume some deliberateness on the part of patients (e.g., disobedience motivated by spite or resentment), which can be very difficult to discern in nonverbal subjects with profound cognitive deficits.

Anxiety Disorders Specific anxiety disorders (e.g., separation anxiety, overanxious disorder, obsessive-compulsive disorder, panic disorder, and generalized anxiety disorder) rely heavily on an individual's ability to describe the subjective symptoms of anxiety. According to DSM-IV, concurrent pervasive developmental disorder specifically precludes the diagnosis of most of these disorders. Yet, some individuals have constellations of signs and symptoms that are best captured in the anxiety disorder spectrum. Patients who are clearly avoidant, who exhibit autonomic arousal in the face of stimuli that most of their peers would not find aversive, and who evince other features of anxiety but cannot articulate their subjective states might be given a diagnosis of anxiety disorder not otherwise specified.

When individuals engage in behavior that appears compulsive or driven and seems ego-alien, the diagnosis of obsessive-compulsive disorder not otherwise specified might be considered. Often these patients engage in self-restraint (securing their extremities in their clothing) or cling to their parents or careproviders—seemingly to prevent self-injurious behaviors. Simple repetitive behaviors or an insistence on sameness that can accompany pervasive developmental disorder should not be given a separate obsessive-compulsive spectrum diagnosis. It may be useful to organize treatment with an additional diagnosis beyond “autism” if, for example, the focus of treatment is a sleep disturbance, impulsive aggression, or the like.

Although common, anxiety disorders appear to be underdiagnosed in persons with mental retardation. Variability in prevalence rates, from 1 to 25 percent, is attributed to difficulty in making a diagnosis. Moreover, an individual with mental retardation may not be able to identify subjective anxiety as an underlying cause of distress, and a patient's aggression or agitation may suggest a disorder of impulse control rather than reflecting underlying anxiety. Common symptoms of anxiety in persons with mental retardation include aggression, agitation, compulsive or repetitive behaviors, self-injury, and insomnia. Panic may be expressed as agitation, screaming, crying, or clinging, which might even pass for delusional or paranoid behavior. Phobias also occur in this population and may even be more common in persons with developmental disabilities. Ruth Ryan has noted that persons with developmental disabilities are at high risk for abuse, which puts them at a greater risk for posttraumatic stress disorder. With data suggesting that it may be seen in nearly 8 percent of the general population, posttraumatic stress disorder is an important diagnosis to consider in individuals with mental retardation.

Eating Disorders Because the diagnostic criteria rely upon subjective experiences, the diagnoses of anorexia nervosa and bulimia are effectively precluded for individuals with severe or profound mental retardation. For example, one would be hard pressed to identify such things as classic distortions in body image or guilt feelings associated with bingeing in nonverbal patients. Food refusal or self-induced vomiting would have to be considered atypical eating disorders if they occurred in the absence of other diagnosable disorders (e.g., depression or rumination). Pica is perhaps the most common eating disorder among persons with mental retardation.

Mental Disorders Due to a General Medical Condition One could argue that by definition everyone with mental retardation has some organic cerebral dysfunction, and thus any psychiatric illness should be regarded as organic or due to a general medical condition. In his study of psychiatric illness in a sample of institutionalized patients with Down syndrome, Frank Menolascino (1984) appropriately argued that psychiatric nosology did not have to be reinvented to accommodate individuals with a “tissue diagnosis.” Moreover, he reasoned that patients with so-called dual diagnoses of mental illness and Down syndrome need to be distinguished from those with Down syndrome alone. Thus, the application of the diagnoses of organic mental syndromes and disorders is best approached as if patients do not have mental retardation. The same principle should apply to Axis II personality disorders. The diagnosis of a personality disorder due to a general medical condition is best reserved for individuals whose preexisting personality was altered in a pathological way by some additional cerebral insult. In essence, this category was reserved for patients whose mental retardation is acquired, usually secondary to trauma experienced in childhood or early adolescence.

Psychosis Patients with developmental disorders are at increased risk for schizophrenia, bipolar disorder, and other mental illnesses that may include symptoms of thought disorder and hallucinations. The diagnosis of schizophrenia essentially requires that a patient relate the experience of delusions or hallucinations. As has been suggested by others, the diagnosis of classic schizophrenia is arguably impossible for individuals with profound mental retardation and limited communicative ability. Nonetheless, some individuals display presumptive evidence of response to hallucinations (e.g., striking or shouting at empty space, throwing imaginary peers from furniture) or adopt catatonic postures that can appear to be of psychotic origin. In these cases the diagnosis of psychotic disorder not otherwise specified should be considered if these signs exist in the absence of sufficient evidence to warrant the diagnosis of a supervening mood disorder.

Mood Disorders Even in profound mental retardation, the diagnosis of mood disorders is fairly straightforward. Generally, a change in mood from baseline is obvious (recent-onset lability, tearfulness, mood elevation, irritability). If it is coupled with changes in interests, activity level, sleep, appetite, or sexual behavior of sufficient duration and causing sufficient impairment in habilitative function, the diagnoses of mania or of depression can be made in nonverbal patients.

Mood disorders are not uncommon in persons with mental retardation. Learning problems, social skills deficits, and low self-esteem are often associated with developmental disabilities and represent risk factors for the development of mood disorders. No striking differences exist between the expression of mood disorders in persons functioning in the mild and moderate ranges of mental retardation and their normally developing peers. Differences may emerge among persons with severe-to-profound disability, but equivalents of mood disturbance are easily recognizable, including irritability, crying, problems in sleep or appetite regulation, agitation, mood lability, social withdrawal, and isolation. Aggression or self-injurious behavior may be seen as behavioral manifestations of dysphoria in persons regardless of developmental level.

Other Disorders The diagnosis of Tourette's disorder is difficult in persons with profound mental retardation. These individuals frequently also display stereotyped or other movements, and it is difficult to distinguish intentional from unintentional movements or sounds or vocal tics from spontaneous, stereotyped, or echolalic vocalizations in individuals frequently incapable of functional speech. The diagnosis of stereotyped movement disorder might be considered in such circumstances.

Since mental age of 4 years is required for elimination disorders, the diagnoses of functional encopresis or functional enuresis are seldom made in the context of severe intellectual disability. In some instances, individuals appear to lose previously acquired skills, (e.g., urinary continence), but such losses typically do not occur in isolation, suggesting alternate diagnoses (e.g., delirium or depression).

Somatoform disorders, depersonalization disorders, and sexual disorders are less frequently diagnosed in the context of mental retardation, though they are certainly not precluded. Sleep disorders ultimately require subjective input by the patient regarding the adequacy of rest, occurrence of nightmares, and so on. Given the frequent history of abuse reported for people with mental retardation as a group, one should not overlook the possibility of posttraumatic stress disorder when sleep disturbance is a presenting problem.

Provisional Diagnoses Individuals often do not clearly fall into a single diagnostic category. Comorbidity is common. Additionally, some individuals have psychiatric symptoms that significantly interfere with habilitative function but do not allow a clear distinction between certain diagnoses. It may be very difficult to distinguish between an impulse control disorder not otherwise specified (perhaps characterized by an individual who engages in impulsive aggressive acts) and an anxiety disorder not otherwise specified (perhaps suggested by an individual who strikes out in the context of a stressor that would go unnoticed by most people). The clinician should always make a best effort to generate working diagnosis and be prepared to modify it as indicated by data gathered through collateral sources and from increasing familiarity with a particular patient.

APPROACH TO MALADAPTIVE BEHAVIOR

As with child psychiatry in general, little specificity can be attached to a given symptom. Persons with mental retardation typically are referred for evaluation because of self-injurious, aggressive, impulsive, or hyperactive behavior. These symptoms lack diagnostic specificity and no diagnostic decision tree can be constructed. It may be more useful to ask a series of questions about the expression of a particular behavior. If the behavior is of recent onset, one is more likely to consider an acute medical or psychiatric cause. If the behavior is highly situational, occurring primarily in the context of the stress of task demands, the likelihood of a psychosis or mood disorder is probably reduced. If attempts are made to avoid the behavior by self-restraint, the inference of some ego-dystonic features may be tenable.

Assessing the sum of these and collateral data will lead the clinician to a presumptive diagnosis that will form the basis for a treatment plan.

PATHOLOGY AND LABORATORY EXAMINATION

Developmental disability is a significant risk factor for psychopathology in general, and this increased risk may derive from both biological vulnerabilities and the environment. Moreover, individuals with an I.Q. below 70 have a two- to five-fold higher rate of psychiatric disorders than normally developing persons.

A host of explanations, highlighted in Table 34-8, have been put forward to account for this added risk, including developmental experiences with which these individuals must contend such as perceived rejection from peers and frustration from parents. Repeated failure or difficulty achieving what appears to come naturally to normally developing peers, the recapitulation failure with each developmental stage, and less well developed or perhaps less-supportive peer groups must all take a toll on ego development. In addition to specific biological vulnerabilities, the common comorbidity of mental retardation with physical illness (e.g. epilepsy) may also increase the risk of mental disturbance.

Neuropathological process responsible for mental retardation may also cause or increase risk for mental illness
Increased likelihood of loss or separation, particularly in out-of-home placements
Communication deficits may predispose to emotional or behavioral disturbance
Vulnerability to exploitation or abuse by others
Inadequate coping skills
Family stress may be heightened by presence of child with developmental disability
Risk of limited network of social relationships and repertoire of social skills
Risk of reduced opportunities for development and exercise of recreational and occupational skills
Adverse effect on self-esteem of disability, possible dysmorphology

Table 34-8 Possible Contributions to Increased Vulnerability to Mental Disorders in Persons With Mental Retardation

The treatments for epilepsy and other medical conditions may carry some behavioral toxicity that can increase the likelihood of diagnosed mental illness. Phenobarbital has been widely reported to increase the risk of motoric hyperactivity and disinhibition in children and in individuals with developmental disorders, and phenytoin (Dilantin) may cause cognitive toxicity (as can essentially any of the medications used to manage epilepsy). Studies of the incidence of specific mental disorders reveal that individuals with developmental disorders may experience the same range of mental illnesses that occur in the population in general.

Medical Diagnostic Approach to the Patient With Mental Retardation

Clinical History The elements of a comprehensive clinical evaluation of a patient with mental retardation are summarized in Table 34-9. A good history is essential, and in many cases collateral informants are extremely useful. Family members may be able to fill in important aspects of the family pedigree by providing information about relatives ranging from learning problems to physical anomalies and developmental disabilities.

Clinical history
Prenatal and birth history
Family pedigree (three generations)
Relatives with learning problems, psychiatric disorders, mental retardation, neurological, or degenerative disorders
Family resemblance (reduced in aneuploidy)
Physical examination
Assessment of minor physical anomalies
Growth and physical development
Head circumference compared with norms
Growth trajectory (comparison with earlier measures)
Description of facial features (micrognathia, hypertelorism, thin upper lip); use of photographs or video, to document minor morphological variants, gait
Complete neurological examination
Documentation of behavioral phenotype
Wood's light, dermatoglyphic examinations as indicated
Adjunct diagnostics
Audiologic, ophthalmological, psychometric assessments
Diagnostic tests (for selective use as indicated)
Skeletal radiographs
Metabolic studies for lysosomal, peroxisomal, and mitochondrial disorders
Muscle biopsies
DNA molecular studies
Chromosome analysis, fluorescent in situ hybridization (FISH)
Fragile X testing
Organic and amino acid assays
Imaging studies (MRI, CT)

Table 34-9 Clinical Evaluation of the Patient With Mental Retardation

The clinical examination should give particular attention to minor anomalies and aberrant growth and physical development. Behavioral symptoms that may comport with a known behavioral phenotype and help delineate a diagnosis should be sought. In some disorders, the clinical course evolves over time, and ongoing attention to the unfolding behavioral phenotype may help establish a diagnosis. A representative list of such disorders appears in Table 34-10. Thus, a history of significant early feeding difficulties associated with hypotonia (and the tell-tale muscle biopsy scar) that later gives way to hyperphagia and weight gain is perhaps more useful for the diagnosis of Prader-Willi syndrome than the observation of hyperphagia alone.

Rett syndrome
Prader-Willi syndrome
Angelman syndrome
Kabuki syndrome
Velocardiofacial syndrome
Williams syndrome
Tuberous sclerosis
Hurler syndrome
Hunter syndrome
Neurofibromatosis I
Noonan syndrome
Smith-Magenis syndrome
Fragile X syndrome
Lesch-Nyhan syndrome
Hallervorden-Spatz syndrome
Metachromatic leukodystrophy
XL adrenoleukodystrophy

Am J Med Genet 72:468, 1997.

Table 34-10 Selected Syndromes and Conditions in Which a Recognizable Phenotype May Evolve Over Time

Chromosome Studies Since chromosome abnormalities are the single most common known cause of mental retardation found in series of unselected patients with mental retardation, a chromosome analysis is usually obtained. The presence of multiple physical anomalies and the severity of the mental retardation will influence whether chromosomal study is obtained. It is not uncommon to be presented with a history of birth complications, perinatal hypoxia, falls with suspected injury, and so on, and later discover an underlying genetic cause for mental retardation. Moreover, in some cases the genetic syndrome may set the stage for birth complications, with the latter being credited with the cause of disability until an appropriate diagnostic procedure is done. Thus, in some settings, the mere presence of developmental delay may prompt a chromosomal study.

Given advances in diagnostic techniques, there may be situations in which multiple physical anomalies in an individual suggest aneuploidy despite normal results

from a chromosome study. In these situations the clinical geneticist may suggest multiple skin biopsies, or special karyotyping, or molecular cytogenetic studies.

Neuroimaging At the turn of the century, William Thomson observed that “the brains of most idiots and of half-witted persons are usually smaller and weigh less than the average of normal brains, while many men distinguished for their mental powers have had large and heavy brains. But the exceptions are very numerous both ways.... No man's intellect can be judged by the size of his hat.” Thomson went on to argue that the material organization of the brain determines thought, feeling, and volition. Advances in brain-imaging technology now permit a much more refined look at the relation between neuroanatomy and mental retardation.

Table 34-11 summarizes the findings from computerized tomography (CT) and magnetic resonance imaging (MRI) in groups of patients with mental retardation. Since mental retardation should suggest obligate brain abnormality, it is surprising that the percentage of individuals in imaging studies who exhibit an abnormality ranges from only 9 to 96 percent. Clearly, the selection criteria and type of study significantly affect the resultant yield.

Study	Population	Number of Subjects	Type of Study	Findings
Hunt, Miller et al. (1981)	Moderate-to-severe mental retardation (included micro- and macrocephaly and significantly dysmorphic)	23	CT	1 case atrophy, 1 case prominent preposition cistern
Lingam et al. (1982)	Nonspecific mental retardation	76	CT	20% atrophy, 8% other findings
Sugimoto et al. (1983)	Microcephaly	15	CT	80% abnormal
Curry et al. (1991)	Microcephaly	31	CT/MR	68% abnormal
	Normocephaly	46	CT, 36; MR, 10	39% abnormal
Hajnamer and Shevell (1995)	Significant delay	60	85% CT; 19% MR	16.7% cerebral dysgenesis; 10% hypoxic ischemic encephalopathy
Schaefer (1995)	Mental retardation or developmental disorder disability	681	MR	62% variety of abnormalities
Curry et al. (1996)	CA cerebral palsy project	76/192	CT, 48; MR, 14; both, 14	96% abnormal
Root and Curry (1996)	Profound mental retardation	40	CT/MR	85% abnormal
	Genetic clinic patients	32	CT/MR	28% abnormal

Table 34-11 CT and MRI Findings in Persons with Mental Retardation

In general, MRI studies are considered superior to CT because the former provides better anatomical resolution. Myelination and more subtle anatomical abnormalities such as heterotopias are more easily visualized with MRI. On the other hand, CT may be more useful when the intent is to look for possible intracranial calcification (e.g., in tuberous sclerosis complex) or abnormalities of the skull itself (e.g., craniosynostosis syndromes).

When little doubt exists that structural brain abnormalities are present, an imaging study may serve as a baseline against which to measure progression. An individual with tuberous sclerosis may be followed with serial imaging studies to chronicle the emergence of new lesions, or an individual who engages in severe head banging behavior may warrant a baseline imaging study. Neuroimaging is also indicated for patients with seizures, microcephaly, or macrocephaly; the loss of previously acquired skills; or neurological signs such as spasticity, dystonia, or altered reflexes.

When none of these conditions are met, an imaging study may not be indicated. For example, for a normocephalic patient with no localizing neurological signs, the yield of an imaging study is remote, and its interpretation is confounded by a paucity of data concerning the incidence of minor anomalies in the population in general. Similarly, for patients with known genetic syndromes but without neurological signs (e.g., Down syndrome or Prader-Willi syndrome), there is little to be gained by subjecting the patient to an imaging study outside of research interest.

Diagnostic Instruments and Rating Scales A number of diagnostic and behavioral rating scales have been developed for the population with mental retardation. While neither diagnostic nor treatment decisions should be based entirely upon the results of a given instrument, systematic data collection with such a scale is a useful adjunct to clinical diagnostics or monitoring. Among the most common general behavior rating scales are the Aberrant Behavior Checklist and the Developmental Behaviour Checklist. The Behavior Problem Inventory is particularly useful for self-injurious, aggressive, and stereotyped behaviors. The Psychopathology Inventory for Mentally Retarded Adults, the Diagnostic Assessment of the Severely Handicapped, the Reiss Screen for Maladaptive Behavior, and more recently the Reiss Scale for Children's Dual Diagnosis are all instruments developed to screen for the presence of mental disorders.

TREATMENT

Prevention Treatment strategies largely focus on preventing intellectual disability and mitigating associated complications (e.g., treating associated mental disorders). The merits of primary prevention are obvious, and the successes enjoyed with PKU should continue to provide powerful incentive for the ongoing collaborations of basic scientists and clinicians. The impact of more-recent programs is less clear. For example, although folic acid supplementation appears to reduce the risk of neural tube defects significantly, compliance with recommendations to increase dietary folate appears disturbingly negligible. It also appears that the prevalence of trisomy 21 is likely to remain unchanged or increase despite the availability of prenatal diagnostic programs.

Influence of Etiological Factors on Treatment The approach to treatment begins with diagnosis. In some cases the underlying cause of mental retardation may be particularly important in considering treatments. For example, in mental retardation associated with phenylketonuria, a number of attempts have been made to minimize or to attenuate hyperactivity and impulsivity by dietary modification. More recently, as animal models of this disorder are developed and explored, it appears that dopaminergic abnormalities may play a particularly salient role in the expression of maladaptive behaviors and perhaps in the design of specific treatments. Thus, early intervention with dopamine agonists may ultimately play a unique role in the treatment of behavioral and cognitive disturbance associated with PKU.

Abnormalities in serotonergic function have been reported in the context of Down syndrome. This hyposerotonemia led to trials of serotonin replacement with mixed results, but serotonergic drugs may yet hold particular relevance for persons with Down syndrome. In Prader-Willi syndrome, both serotonergic abnormalities and responses to serotonergic agents have been reported. Identification of the underlying cause of mental retardation has become increasingly important in considering biological treatments. Likewise, the diagnosis of mental disorders or syndromes in persons with mental retardation will guide and influence treatment strategies.

Experience over the past decade clearly shows that mental retardation is a multidisciplinary problem and optimal treatment is multimodal. Typically, a treatment plan includes attention to psychoeducational, psychotherapeutic, and psychopharmacological interventions.

Psychotherapy One should never assume that persons with mental retardation cannot benefit from psychotherapeutic intervention simply because of their impaired intellectual functioning. For example, Anton Dosen has highlighted the use of psychoanalytic approaches that focus on developmental theories to improve emotional expression, enhance self-esteem, increase personal independence, and broaden social interactions. Christian Gaedt has similarly advanced the usefulness of ego psychology (in particular, object-relation theory) in the approach to individuals with mental retardation.

In addition to psychoanalytic or developmentally based approaches, cognitive therapy may benefit the treatment of depression, and brief relaxation therapy may help reduce anxiety even in the context of moderate-to-severe mental retardation.

However, all types of individual therapies in this population benefit from certain modifications in approach. For example, an active therapeutic stance should be used with concrete, supportive interventions and careful attention to the language abilities and developmental level of the patient. When these types of alterations are made, many patients with mental retardation clearly can benefit.

Behavioral therapies are also demonstrably effective in managing many difficulties in persons with mental retardation. Typically, a behavioral assessment begins with a functional analysis of behavior, that is, a detailed examination of the variables that reinforce or maintain particular behaviors. One considers the antecedent events and consequences of a behavior in question and typically tests hypotheses to confirm the results of the behavioral analysis. Some instruments (e.g., the Functional Analysis of Stereotyped Behavior [FAST]) may be useful in beginning to identify reinforcing variables, but a behavioral psychologist can best generate and implement a behavior program based upon a functional analysis of behavior.

Group therapy can be an important part of the treatment program for persons with mental retardation, particularly in the area of social skills building. Supportive groups for parents and siblings may also be of particular benefit. Family therapy can be particularly useful and provides a setting for education, support, and

consolidation of behavioral treatment and other interventions.

Pharmacotherapy Relatively few controlled clinical drug trials include persons with mental retardation, particularly those with the most severe cognitive impairment. Thus, clinicians must generally extrapolate from pharmacotherapy in the general population for persons with mental retardation. Fortunately, there is little reason to suspect that mechanisms of action of drugs change on the basis of retardation.

However, because of drug-drug interactions that may affect the availability or effectiveness of concurrent medications, individuals with mental retardation may require different dosing strategies. In institutionalized populations, for example, where 30 to 40 percent of persons have epilepsy and as many as 70 percent may have some other significant medical condition, drug interactions become an increasingly important consideration.

Antidepressants The use of antidepressant medications in persons with mental retardation appears to remain relatively low. Special considerations in the use of antidepressant medication include the common medical comorbidities. Use of tricyclic drugs in particular must acknowledge the risk of lowering seizure threshold. This risk in the general population is on the order of 1 in 1000, and in individuals with mental retardation it may increase to nearly 1 in 5. Cardiac anomalies are common in some mental retardation syndromes, and the anticholinergic adverse effects of some medications may be particularly significant in persons with Down syndrome. Individuals with mental retardation may require lower concentrations of antidepressant drug than their normally developing peers, and disinhibition has been described with typical antidepressant doses of selective serotonin reuptake inhibitors (SSRIs).

Some individuals (particularly a subgroup within the pervasive developmental disorder spectrum) appear to exhibit extraordinary sensitivity to drugs of this and other classes. This sensitivity is manifested by disinhibition and may present as an increase in target symptoms at doses of medication that otherwise appear quite standard. These individuals may be converted to responders with significant dosage reductions, for example, reducing the starting dosage of fluoxetine (Prozac) from 10 to 1 mg daily.

A subgroup of persons with self-injurious behavior also exhibit self-restraining behaviors; for example, binding their extremities in their clothing or seeking out helmets to wear for self-protection. Such behavior might indicate an ego-dystonic quality of self-injury and suggests the possibility of self-injurious behavior as a compulsion. Obsessive-compulsive disorder occurs more commonly in the Prader-Willi syndrome than in the general population, and treatment with an SSRI may improve compulsive skin picking along with other compulsive behaviors. Given these findings, trials of SSRIs are increasingly common among patients with self-injurious behavior. Favorable results have been reported for fluoxetine, paroxetine (Paxil), sertraline (Zoloft), trazodone (Desynel), and clomipramine (Anafranil). However, of these agents, only clomipramine has been shown effective in well-controlled studies. Because it lowers seizure threshold, clomipramine is generally not a first-line treatment for compulsive self-injurious behavior in individuals frequently comorbid for epilepsy.

Anticonvulsants Data on the use of anticonvulsant medications for indications other than epilepsy are limited. However, considerable experience suggests that as in the population in general, some anticonvulsant drugs may improve cyclical mood disorders and impulsive aggression.

Self-injurious behavior and aggression can also dramatically improve when phenobarbital administration is stopped. The potential behavioral toxicity of this or any drug should not be overlooked in designing treatment strategies for persons with mental retardation. Moreover, medical comorbidity is the rule in individuals with developmental disabilities, and the importance of identifying and treating underlying medical problems (or refining that treatment) cannot be overstated.

Anxiolytics Although benzodiazepines are commonly prescribed to treat anxiety in the general population, unique concerns arise in the context of developmental disorders, particularly regarding the possibility of increased confusion, cognitive impairment, unsteadiness, and paradoxical excitement. Jennifer Barron and Curt Sandman reviewed disinhibition associated with benzodiazepines, which occurred in 35 to 68 percent of an institutionalized mentally retarded population compared with controls. Nevertheless, alprazolam (Xanax), clonazepam (Klonopin), and lorazepam (Ativan) are widely used in the treatment of acute anxiety, particularly anxiety associated with medical or surgical procedures. Their use should be considered in the absence of evidence of previous abnormal responses to these agents.

Buspirone (BuSpar) is another serotonergic agent that has been reported to benefit some persons with developmental disorders. John Ratey and colleagues reported the use of buspirone in an open trial in persons with diagnosed anxiety disorders manifested by aggressive and self-injurious behaviors. Typical dosages at which patients responded were about 15 to 45 mg a day. In an open trial by Bryan King and Pablo Davanzo, nonresponders to buspirone remained so even when the medication dosage was increased to 60 mg daily. Willem Verhoeven and Siegfried Tuinier also studied buspirone in the treatment of anxiety in persons with mental retardation and suggested that this agent should be among those considered for treating this population. Its advantages include a relatively benign side-effect profile, specifically the absence of common motor or cognitive adverse effects at dosages used to treat anxiety.

Antipsychotics Antipsychotic medications have long been used, arguably indiscriminately, in persons with mental retardation. Antipsychotics continue to be the most widely prescribed class of psychotropic medication and are even more commonly prescribed than anticonvulsant drugs for persons with mental retardation. Given this ample experience with antipsychotics in persons with mental retardation, where in residential or institutional settings as many as 50 percent of individuals may be treated with this class of drug, the adverse effects are well-known.

Individuals with mental retardation appear to be at greater risk of developing tardive dyskinesia than the general population; recorded rates range from 18 to over 30 percent. On the other hand, spontaneous abnormal involuntary movements are not uncommon in this population, which may confound interpretation of rates of neuroleptic-induced tardive dyskinesia. The growing availability of serotonin-dopamine antagonists (atypical antipsychotics) and their use in persons with mental retardation suggest that these drugs may be very helpful considering their apparently reduced risk for tardive dyskinesia and extrapyramidal symptoms as well as cognitive toxicity. Studies reporting the effectiveness of clozapine (Clozaril), risperidone, and sulpiride through open trials now exist to support the use of these agents in individuals with mental retardation.

Evidence supports the use of dopamine antagonists in self-injurious behavior and aggression, both in theory and in practice. For thioridazine (Mellaril) in particular, ample experience indicates that both self-injurious behavior and aggression may improve. Typical dosages average less than 300 mg a day, with dosages as low as 15 mg a day reported for some children. Positive reports also exist for most other neuroleptics in this population. Although suggested by some, no convincing evidence suggests that these merely suppress behavior generally through a nonspecific sedating effect. Such an outcome is clearly undesirable in individuals with preexisting cognitive impairment, and many of the earliest reports specifically note the absence of sedation. Nonetheless, enthusiasm for neuroleptic use in self-injurious behavior should be dampened by significant adverse effect liability. Interest in atypical neuroleptics for self-injurious behavior and aggression has grown in recent years. Based upon preclinical data, drugs that selectively antagonize dopamine type 1 (D_1) receptor function may have a unique potential for attenuating repetitive self-injurious behavior.

Psychostimulants Despite reports of paradoxical responses to stimulant medications in persons with mental retardation, with higher than expected rates of emergent motor tics and emotional lability, a growing body of literature supports the use of stimulant drugs for the treatment of attention-deficit/hyperactivity disorder in the context of mental retardation. Additional study is needed concerning the likelihood of a response to stimulants in relation to the severity of cognitive disability. Data are mixed on whether I.Q. negatively or positively predicts treatment response.

Opioid Antagonists Some individuals who self-injure appear to have altered pain sensitivity, as Ireland suggested nearly a century ago. This observation, coupled with data indicating that opioid antagonists can attenuate stereotypies and self-injury in animal models and data indicating that opioids may modify the function of dopaminergic systems has fueled interest in the opioids. Naltrexone (ReVia) is the opioid antagonist most widely used for self-injurious behavior, but the literature is mixed. Typical dosages range from 0.5 to 2.0 mg/kg a day in children and up to 200 mg a day in adults. The relatively long half-life of naltrexone (72 hours in brain) must be kept in mind in designing titration strategies for this drug. On balance, naltrexone appears to be well tolerated in persons with developmental disorders; sedation is the side effect most likely to be observed.

Other Drugs b-Adrenergic receptor antagonists have also been reported to be of use in the population with developmental disorders, it is not clear whether the mechanism is central or peripheral, however Ratey and colleagues explored this class of drugs on the basis of their perception that many individuals with developmental disabilities appear to have a low frustration tolerance for ambient stimuli. At dosages of propranolol (Inderal) above 1000 mg a day, the precise mechanism of action of this drug arguably becomes nonspecific, but lower dosages of this and other b-adrenergic receptor antagonists are also reportedly beneficial.

A growing appreciation exists for the potential therapeutic utility of drugs acting at glutamate receptor subtypes. Glutamatergic and dopaminergic interactions in the neostriatum are the focus of research on the pathogenesis of a host of neuropsychiatric illnesses including schizophrenia, obsessive-compulsive disorder, self-injurious behavior, and aggression. Dextromethorphan (Dimetane, Sudafed) an antitussive agent which also binds to the NMDA receptor, was reported by Leisa

Welch and Robert Sovner to have markedly attenuated self-injurious behavior in a 25-year-old individual with congenital rubella syndrome. The patient was maintained on dextromethorphan for 16 months with sustained benefit. Surprisingly (and perhaps ominously) no follow-up studies have been reported with this drug in self-injurious behavior. Lamotrigine (Lamietal) is an anticonvulsant drug that also appears to antagonize glutamate by reducing its release. A recent case report suggests that lamotrigine may be useful in reducing self-injury in the context of a stereotyped movement disorder. A larger study in which lamotrigine was added to the anticonvulsant regimen of children with mental retardation suggested that those with autism experienced gains that could not be readily attributable to better seizure control alone. However, a recent double-blind, placebo-controlled trial of lamotrigine in autism had negative results.

Services and Supports In contrast to even 20 years ago, individuals with mental retardation now enjoy a wide variety of services that can be found throughout the United States and that last throughout the lifespan; Table 34-12 lists some of these services.

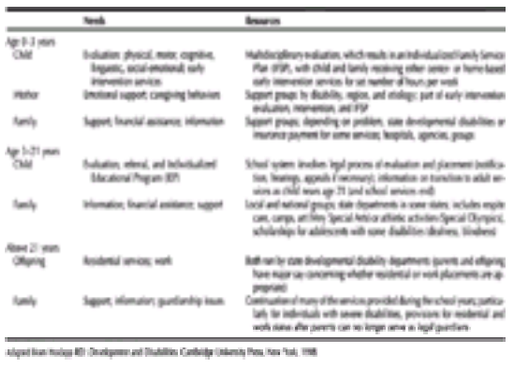

Table 34-12 Service Needs and Resources for Families of Children at Different Ages

Services

Early Intervention Early intervention serves individuals from birth until 3 years. Such services are provided by the state, with a different lead agency coordinating services in each state. These services begin with early intervention specialists visiting the child's home for a few hours a week; when the child is slightly older, center-based care is also often provided.

Since the passage of part H of PL 99-457—the Education of the Handicapped Amendments of 1986—early intervention services have increasingly emphasized the family. Agencies are required to develop an Individualized Family Service Plan (IFSP) for each family, focusing on family strengths and needs in caring for their young child with mental retardation.

School From ages 3 until 21, school takes over. These educational services became widespread following the passage of PL 94-142 (the Education for all Handicapped Children Act of 1975); this legislation has recently been extended and modified by the Individuals with Disabilities Act of 1990.

These laws require that public school systems serve all children with disabilities and institute what are essentially legal provisions to do so. This process provides notice that the child is being considered for special services; a formal, scheduled hearing at which the parents and school personnel discuss the most appropriate school placement and specialized services; the right to present a defense if parents disagree with school personnel; a written decision given to the parents notifying them of the school's decision; and the parents' right to appeal this decision, first to the school itself, then to district and state educational authorities, eventually to the courts. This entire process results in an Individualized Educational Program or Plan (IEP), which assesses the child's academic performance, provides annual goals, provides instructional objectives, describes services the child will receive, and includes starting dates of services and when and how the child's progress will be reevaluated. Although receiving services for one's child can be complicated, educational services have become a right—not a privilege—for parents of children with mental retardation.

A further element of education law involves the right to a public education “within the least restrictive environment.” This phrase has engendered many debates within the special education community about inclusion. Essentially, the debate centers on whether all children should be educated in classes composed primarily of typically developing children. Inclusion advocates consider education alongside typically developing children to be every child's right, while proponents of a continuum of care argue that the child's individual educational needs should be paramount.

Adult Services When an individual with mental retardation turns 21, service delivery comes under the auspices of the state department of developmental disabilities, but in contrast to educational services, adult services are not federally mandated. States thus vary widely in their services and how they offer them. Services are often spread out across various locations, and qualifying for and getting services can sometimes be difficult.

During the adult years, residential and vocational services predominate. Residential services run the gamut from institutional to community-based, and from constant to no supervision. More-restrictive placements involve large or small institutional residences, which mainly serve the lowest functioning, often multiply-impaired individuals. Group homes for from four to eight residents are probably the most common residential option; these homes typically exist within residential neighborhoods and provide round-the-clock staff to ensure safety and programming. Supervised living arrangements usually consist of apartments that are shared by a few persons with mental retardation; the residents are visited by program staff, who often instruct them in cooking, cleaning, and shopping. Unsupervised apartments, where individuals live by themselves or with a roommate under little supervision, mainly succeed with clients who have milder intellectual impairments and fewer behavior problems.

Vocational services also show a continuum from most to least restrictive. The most restrictive are sheltered workshops in which individuals with retardation assemble or test products next to others with disabilities. Supported employment provides a job coach or other specially trained individual to help the client find a job, learn how to take public transportation to get to work, and acquire the technical and social skills needed to handle the job. Competitive employment is the least restrictive job option for adults with mental retardation. Competitive employment involves a job that a nondisabled person might have, with the same pay levels and benefits and the same pressures and responsibilities for work performance. As in unsupervised apartment living, competitive employment operates best for the highest functioning and least behaviorally disordered individuals.

In considering working and living arrangements for any young adult with mental retardation, one should also consider transitional services. Schools offer these services to children with disabilities who have reached age 14. They teach vocational and adaptive skills that will be necessary later on. Parents need to work with schools to determine the most appropriate residential and vocational goals for each young adult.

Supports In addition to services provided by early intervention, school, and adult services, individuals with mental retardation and their families can also benefit from a variety of other supports. These range from short- or longer-term respite care (allowing families a break from full-time care), to summer camps, to sports activity programs such as Special Olympics (Fig. 34-1). In addition, several major universities have specialty clinics for behavioral and medical management of certain types of mental retardation.

FIGURE 34-1 Athletes competing in activities sponsored by Special Olympics, whose athletes take the oath: “Let me win. But if I cannot win, let me be brave in the attempt.” Special Olympics was founded in 1968 by Eunice Kennedy Shriver. The mission of the organization is to provide year-round sports training and athletic competition in a variety of Olympic-type sports for individuals with mental retardation by giving them continuing opportunities to develop physical fitness, demonstrate courage, experience joy, and participate in sharing gifts, skills, and friendship with their families, other Special Olympics athletes, and the community.

A wide variety of organized groups are also helpful to affected individuals and their families. Parent groups are available for parents of children with disabilities and for parents of children with specific types of retardation. Sibling groups and networks are also available, and the federal government fosters service and advocacy through University Affiliated Programs in almost every state. See Table 34-13 for some of the parent and professional groups that help persons with disabilities and their families.

Table 34-13 Prominent Organizations in Mental Retardation

LEGAL ISSUES IN MENTAL RETARDATION

The Americans with Disabilities Act of 1990 spells out four aims: (1) to provide a clear and comprehensive national mandate for the elimination of discrimination against individuals with disabilities; (2) to provide clear, strong, consistent enforceable standards addressing discrimination against individuals with disabilities; (3) to ensure that the federal government plays a central role in enforcing the standards established in the act on behalf of individuals with disabilities; and (4) to invoke the sweep of congressional authority, including the power to enforce the fourteenth amendment and to regulate commerce, to address the major areas of discrimination faced day-to-day by people with disabilities. This act represents a major turning point in ensuring the rights of persons with disabilities who, even 50 years ago, were frequently institutionalized and given compulsory sterilization in misguided efforts to protect society. While attitudes have shifted repeatedly over the centuries from asylum to punishment of persons with disabilities, the prevailing paradigms in developed countries today are community integration and support. Disabilities law over the past three decades reflects these values—section 504 of the Rehabilitation Act of 1973, the Individuals with Disabilities Education Act of 1990 (originally Public Law 94-142 of 1975), and the Americans with Disabilities Act Collectively, these laws ensure that all children with disabilities receive a free appropriate public education in the least restrictive environment and that reasonable accomodation is made for the employment of adults. Clinicians working with this population should be aware of their personal obligation to provide an accomodating environment but should also familiarize themselves with local guardianship, informed consent, and abuse-reporting laws to serve this population best.

SUGGESTED CROSS-REFERENCES

The neural sciences are discussed in Chapter 1, functional neuroanatomy in Section 1.2, principles of neuroimaging in Section 1.15 and Section 1.16, basic molecular neurobiology in Section 1.10. Neuropsychiatry and behavioral neurology are discussed in Chapter 2, including approach to diagnosis in Section 2.1, neuropsychiatric aspects of epilepsy in Section 2.4, brain trauma in Section 2.3, movement disorders in Section 2.6, and neuroimaging in clinical practice in Section 2.13. Contributions of the psychological sciences appear in Chapter 3, including perception and cognition in Section 3.1, Piaget's approach in Section 3.2, learning theory in Section 3.3, and biology of memory in Section 3.4. Neuropsychological and intellectual assessment is discussed in Section 9.5 and Section 9.6, medical assessment and laboratory testing in Section 9.7, and psychiatric rating scales in Section 9.8. Borderline intellectual functioning and academic problems are covered in Section 27.4. Abnormal and atypical patterns of behavior are also discussed in a Chapter 35, Chapter 36 and Chapter 37 on learning disorders, motor skills disorder, and communication disorders. Chapter 38 covers pervasive developmental disorders, and Section 44.2 provides an in-depth review of stereotypic movement disorder. Forensic psychiatry is covered in Section 49.12 and Section 54.1.

CHAPTER 35. LEARNING DISORDERS

35.1 READING DISORDERS

MICHAEL E. SPAGNA, FH.D., DENNIS P. CANTWELL, M.D. AND LORIAN BAKER, FH.D.

DEFINITION AND COMPARATIVE NOSOLOGY

Reading disorder is characterized by significant impairment in reading acquisition that does not have any demonstrable cause in visual, hearing, or physical disorders; mental retardation; emotional disturbance; or environmental, cultural, or economic disadvantage. Specific symptoms of reading disorder include difficulties in single-word decoding, slow oral reading, and poor comprehension of written text.

The study of children with reading disorders dates back to the late nineteenth century as recorded in case studies collected primarily by physicians. The terms “pure word blindness” and “congenital word blindness” were used to discriminate between adults and children, respectively, who were diagnosed as experiencing difficulty reading words in spite of normal visual acuity and adequate exposure to formal education. These reading disorders were recognized as heterogeneous; some individuals experienced difficulty labeling letters, some could only read letters and single syllables, some manifested word reversals in reading, and some had obtained an adequate sight-word vocabulary but could not read uncommon monosyllabic words. Als at this time several investigators postulated that genetic links might exist within families in which at least one member was diagnosed as having a reading disorder. Attempts were made in the early 1900s to refine the conceptualizations of word blindness, and one researcher proposed the *developmental alexia*, defined as a developmental difficulty in recognizing printed symbols. This term received wide acceptance in professional circles and was eventually shortened in the 1960s to *dyslexia*.

By the early 1900s, a significant knowledge base was established. Case study research suggested that reading disorders (1) were heterogeneous, affecting different areas of reading ability; (2) existed in children, youth, and adults with otherwise intact cognitive functioning; (3) occurred in more males than females; (4) appeared to have a familial component; and (5) were for the most part resistant to traditional educational intervention programs.

Despite over a century of research, however, the definition of a reading disorder remains controversial. A review of various definitions yields five common elements, each of which has generated considerable controversy in the field. The first common element is that the underlying cause for reading disorder is central nervous system dysfunction. Although, neurological conditions often cannot be determined in individuals via external tests and medical examinations, it is presumed that dysfunction can be inferred from observation of behaviors.

The second common element is an uneven pattern of cognitive functioning. In other words, although overall cognitive functioning is intact, specific areas (what one researcher calls informationally encapsulated “vertical modules”) are significantly degraded—in some instances to such an extent that the acquisition of basic decoding skills is extremely difficult. This uneven pattern of cognitive functioning has been referred to in the literature as the presence of a “psychological processing deficit” in spite of overall adequate cognitive functioning.

Most reading disorder definitions contain the third common element, difficulty in single-word decoding. All 50 states have adopted definitions of “specific learning disabilities” that identify decoding skills as an area of academic achievement affected by reading disorder.

The fourth element common to most definitions of reading disorder is a discrepancy between learning potential and actual reading achievement. This element has been the target of considerable recent debate. It assumes that individuals are underachievers in the area of reading achievement, failing to exhibit decoding or comprehension skills or both commensurate with their ability level.

The final common definitional element is the exclusion of other causes of reading difficulty. Similar to the first, second, and fourth elements, considerable disagreement exists about whether or not reading disorders can exist in combination with other disorders. However, 48 of the 50 states have adopted this element in their definitions of specific learning disabilities. Inclusion of this fifth element reflects the need in the mid-1970s to establish specific learning disabilities and thereby reading disorders as a discrete and separate entity for federal legislation.

Lacking an agreed-upon definition, the terms most commonly used in the educational and psychiatric fields today include “developmental reading disorder,” used in the third edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III) and the revised third edition of DSM (DSM-III-R), “reading disorder,” used in the fourth edition of DSM (DSM-IV), and “specific reading disorder,” used in the 10th revision of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-10). The conceptualization of reading disorder has changed little across DSM editions. However, the definition in ICD-10 differs somewhat in requiring a history of impairment in speech, language, sound categorization, motor coordination, visual processing, or control of attention or activity.

Recently domain-specific definitions of learning disorders have been developed. One professional organization has offered the following definition of dyslexia:

> Dyslexia is one of several distinct learning disabilities. It is a specific language-based disorder of constitutional origin characterized by difficulties in single word decoding, usually reflecting insufficient phonological processing. These difficulties in single word decoding are often unexpected in relation to age and other cognitive and academic abilities; they are not the result of generalized developmental disability or sensory impairment. Dyslexia is manifest by variable difficulty with different forms of language, often including, in addition to problems with reading, a conspicuous problem with acquiring proficiency in writing and spelling.

Although this definition contains several of the aforementioned common definitional elements, it poses two important advances. First, instead of defining reading disorders generically, it focuses on one type of reading disorder, dyslexia. Second, this definition of dyslexia, for the first time, localizes the difficulty associated with dyslexia at the single-word level and pinpoints the cause as insufficient phonological processing. Although this definition has not gained wide acceptance, it represents a significant first step in addressing some of the previous confusion and disagreement surrounding definitions of learning disabilities.

EPIDEMIOLOGY

Few studies have examined the incidence of reading disorder, and those that have used different definitions of the disorder. More incidence studies have focused on learning disorder without specifically differentiating the combinations of reading, spelling, mathematics, and other problems involved. Generally, reading disorder is estimated to affect 80 percent of children identified as having learning disabilities; this represents approximately 4 percent of the school-age population. Similar incidence estimates have been reported worldwide.

Clinical and school-based studies have typically reported that three to four males are affected with reading disorder for every female. However, these data may reflect a referral bias in which symptoms in females are overlooked. One recent epidemiological study found no significant differences between the sexes in rates of reading disorder among research-identified children. However, the same study found that school-referred children with reading disorder were predominantly male. Boys with reading disorder appear to be more noticeable in the educational setting than girls with reading disorder because of associated behavioral and activity symptoms and disorders.

ETIOLOGY

The etiology of reading disorder is not known. The traditional view is that the disorder has multiple causes, most likely involving some biologically based dysfunctions that result in a lag or impairment in the development of cognitive skills needed for learning to read. Numerous hypotheses exist regarding the types and sources of biological factors and cognitive impairments that may be involved.

Some of the conflicting results and part of the overall confusion exist because many studies failed to distinguish reading disorder from general learning disability or low academic achievement or to distinguish among different subtypes of reading disorder. The co-occurrence of reading disorder with language disorders, attention-deficit/hyperactivity disorder, and other learning disorders is also of concern. The often-associated disorders may reflect distinct subtypes of reading disorder, each with a different cause.

Theories of Brain Function Many of the theories of brain function in children with reading disorder are based on observations of associated symptoms. For example, because language and speech problems are often associated, abnormalities in the left hemisphere and in the frontal speech regions in both hemispheres have been postulated. Similarly, because motor problems with balance and equilibrium are often associated, abnormalities in cerebellar-vestibular function have been postulated. Thus, brain anomalies are inferred but not demonstrated. Unfortunately, the type of neuroanatomical studies needed to demonstrate brain anomalies (e.g., computed tomography, electrophysiological studies, or postmortem studies) are very limited and have produced contradictory results.

The notion that reading disorder results from a delay or abnormality in lateralization or cerebral dominance is popular. It was first proposed by Samuel Orton in the 1930s as a cause of two common symptoms of reading disorder—poorly established or unstable handedness and the tendency to reverse letters in reading and writing.

Lateralization Although controversial, some evidence suggests abnormal or reversed lateralization or cerebral asymmetry in some children with reading disorder. The data come from handedness reports, dichotic listening studies, an evoked-potential study, a cerebral axial tomography study, and one postmortem study. Much of the data, particularly that on handedness and dichotic listening, can be explained by alternative hypotheses; for example, task-dependent attentional dysfunction interferes with left hemispheric language processes by overengaging either hemisphere.

The postmortem data have led to an intriguing hypothesis about dominance that also considers clinical and familial data. In postmortem examinations of the brains of five males with a familial reading disorder, Albert Galaburda, Norman Geschwind, and their colleagues found a consistent lack of hemispheric asymmetry along with some developmental cortical abnormalities and some alterations in subcortical structures. The affected areas of the left hemisphere were those whose fetal development is regulated by testosterone. Consequently, it was hypothesized that abnormal testosterone levels in fetal blood during critical periods of development, possibly genetically controlled, could be responsible for producing the brain abnormalities and the reading disorder syndrome.

Neuroanatomical Data Some neuroanatomical data (from regional cerebral blood flow studies and positron emission tomography studies) indicate bihemispheric activation during reading. Those findings are relevant to the theories that suggest that different subtypes of disability are associated with different dysfunctional regions in both hemispheres of the brain. For example, it has been hypothesized that disorders involving basic phonological processing may originate in the left temporal lobes, disorders involving phoneme-grapheme matching may originate in the parietotemporal region of the left hemisphere, and disorders involving difficulties with outputs in all modalities may originate in the prefrontal regions of both hemispheres.

A study that used sophisticated computer graphics technologies to map brain electrical activity delineated specific areas of the brain that, in combination, could constitute a physiological signature of dyslexia. In addition to aberrant brain function in the left posterior language region, differences in medial frontal lobe function were also found.

Genetic Factors Perinatal and postnatal factors associated with reading disorder include prematurity, low birth weight, toxemia of pregnancy, hyperbilirubinemia, recurrent otitis, meningitis, encephalitis, and anemia. Some studies of groups of children with reading and learning problems have reported that as many as 80 percent had at least one perinatal factor. However, several longitudinal studies, including the Kauai study and the Collaborative Perinatal Project, found that environmental factors (e.g., family size and socioeconomic status) were stronger predictors of learning problems than biomedical factors.

In the 1950s a landmark study of adults with reading disorder found that almost half of their offspring also had reading disorder. Subsequent family studies have all found high rates of reading disorder in the families, and especially in the first-degree relatives of persons with reading disorder. However, family studies have been unable to establish a specific mode of genetic transmission.

Twin studies have consistently found higher concordance rates for dyslexia in monozygotic twin pairs than in dizygotic pairs. An elevated concordance rate in monozygotic twins is generally accepted as proof of a genetic component. However, one investigator has argued that, owing to more cognitive or emotional similarity, the monozygotic twins could have created more similar environments for themselves, which in turn could have affected their reading acquisition. Nonetheless, the various twin studies that have looked at the heritability of reading disorder have attributed 30 to 60 percent of the similarity between monozygotic twins to genetic factors and the balance to environmental factors. The observation that some monozygotic twin pairs are discordant for reading disorder proves that genetics is not the only cause.

Most studies that have used segregation analyses to examine family pedigrees have failed to find any single dominant or recessive gene model to explain the data. The heterogeneity of reading disorder may be responsible for these negative findings, and once valid subtypes are identified, genetic research may be more fruitful.

In fact, a recent review pointed out that when separate subtypes of reading disorder are considered, patterns of possible genetic influence do become apparent. Limited evidence of inheritance exists for reading disorder with associated visual-spatial deficits, and a fairly strong literature suggests a genetic influence for reading disorder with associated verbal or language deficiencies. One study that looked at that type of reading disorder isolated a gene on chromosome 15 that may be responsible for transmission of the disorder, which seemed to follow an autosomal dominant pattern.

Cognitive Factors Children with reading disorder perform poorly on so many tasks that there is almost no limit to the hypothesized underlying cognitive difficulties. Difficulties have been reported with tasks spanning visual, motor, and auditory modalities and including such abilities as discrimination, integration, attention, and memory. In general, cognitive theories of reading disorder tend to fall into three major groups: models of visual-spatial-motor deficits; models of verbal, auditory, or linguistic deficits; and models of cross-modality integration deficits. As with all the research on reading disorder, definitions and subclassifications are problematic. In addition, many proposed cognitive-psychological deficiencies have problems of construct validity. It is unclear, for example, whether some of the constructs represent real ability differences or are simply measurement artifacts. Similarly, some of the constructs may not actually underlie or even be related to reading ability.

Perceptual Factors The notion that visual-perceptual, visual-spatial, or visual-motor deficits underlie reading disorder dates back to Orton's work in the 1930s, which focused on two types of letter reversals, kinetic or sequencing reversals (e.g., reading *was* for *saw* or *on* for *no*) and static or letter-form orientation reversals (e.g., confusing *b* and *d*). Such reversals led to the hypotheses that children with reading disorder experienced spatial disorientation or left-right discrimination difficulties. Recent attention to the reversals made by children with reading disorder has shown that these errors constitute a small fraction of the reading errors made. Some children with reading disorder do have deficits in visual perception. However, they have not been shown to be major deficits for the children, and no direct correlations have been found between these deficits and reading levels. Further, much of the evidence for a visual perceptual deficit concerns aspects of visual processing that are peculiar to written language. For example, a group of poor readers had difficulties matching, recognizing, and recalling visual stimuli when the stimuli were printed nonsense words. However, they did not have difficulties when the visual stimuli were meaningless shapes. Similarly, poor readers demonstrated impaired visual recall for pictures of objects that could be named and for printed nonsense syllables but not for nonsense doodles or faces of strangers.

The ability to integrate different modalities, known variously in the literature as intersensory integration, cross-modal perception, or intermodal transfer, has been suggested as another underlying dysfunction in children with reading disorder. There is very little support for this hypothesis.

Language The most compelling evidence for deficits underlying reading disorder is evidence of deficits in auditory, verbal, or linguistic functioning. An extremely large literature, including both experimental and clinical studies, demonstrates that children with difficulties in reading also have pervasive and enduring language problems. A recent screening of more than 200 children in learning-disorders classes, using standardized testing data, found that 90 percent had a language deficit and 96 percent had a language, speech, or hearing problem. This is not entirely surprising because factor analyses of neuropsychological testing results in children

with reading disorder have shown that the largest subgroups have disturbances in language functioning.

Virtually all areas of language development are deficient in at least some groups of children with reading disorder. Studies using formal testing procedures have revealed deficits in phonology or sound system processing, grammar or syntax, vocabulary or semantics, and pragmatics or conversational strategies. Similarly, analyses of the spontaneous speech and interactions of children with reading disorder have found linguistic problems, including limited verbalizations, nonfluency of speech, limited vocabulary, word-finding difficulties, poor comprehension of word derivations, lack of grammatical rules for pronoun use, and inability to abstract meanings from interactions.

It has been suggested that some of the language deficiencies found in poor readers (e.g., lags in higher-level semantic and grammatic skills) may actually be a result of limited exposure to certain vocabulary and grammatical forms. However, language deficits occur in very young children with reading disorder, before the lack of reading exposure could exert a large impact. Moreover, most follow-up studies have found that children with early speech or language problems have reading or other learning disorders once they reach school age.

Furthermore, it is difficult to see how weak phonological skills could result from reading disorder rather than vice versa. In fact, several studies that looked at various aspects of language development in children with reading disorder find no deficits in syntax and semantics, although deficits in phonological development were found.

Phonological processing deficits are deficits in skills such as segmenting sound sequences and forming and accessing representations of the sound sequences in words—skills that assist in the storage and retrieval of linguistic information. Thus, an underlying phonological processing deficit could explain the difficulties that children with reading disorder have with perceiving speech through noise, with repeating sentences and sequences of words, with comprehending certain spoken sentences, and with remembering linguistic material. The fact that children with reading disorder seem able to manage print when they do not have to translate print to speech is further evidence that their word-recognition difficulties may be related to underlying phonological processing deficits.

DIAGNOSIS AND CLINICAL FEATURES

The essential feature of reading disorder is a significant impairment in the development of reading ability that is not due to low intelligence, a visual or hearing deficit, a neurological disorder, or lack of opportunity for instruction. Although the severity of impairment and the type of associated symptoms vary widely, all children with the disorder exhibit three key symptoms: inaccurate reading, slow reading, and poor reading comprehension. The DSM-IV diagnostic criteria for reading disorder are given in Table 35.1-1. The ICD-10 diagnostic criteria for specific developmental disorders of scholastic skills, including specific reading disorder, are listed in Table 35.1-2.

A. Reading achievement, as measured by individually administered standardized tests of reading accuracy or comprehension, is substantially below that expected given the person's chronological age, measured intelligence, and age-appropriate education.

B. The disturbance in criterion A significantly interferes with academic achievement or activities of daily living that require reading skills.

C. If a sensory deficit is present, the reading difficulties are in excess of those usually associated with it.

Coding note: if a general medical (e.g., neurological) condition or sensory deficit is present, code the condition on Axis III.

Table 35.1-1 DSM-IV Diagnostic Criteria for Reading Disorder

Table 35.1-2 ICD-10 Diagnostic Criteria for Specific Developmental Disorders of Scholastic Skills

Word recognition (ability to read single words aloud accurately) is poor. Children with reading disorder demonstrate word recognition problems (compared with normal readers of the same chronological age and with normal readers at the same reading level). Nevertheless, a recent study indicates that the general approaches to, and patterns of, word recognition are the same for normal readers and children with reading disorder. Thus, for example, both normal readers and those with reading disorder rely primarily on phonological information for word recognition, both use contextual information to assist in word recognition, and both find recognition of low-frequency words more difficult.

The misreadings of a child with reading disorder may be distortions, substitutions, or omissions of words or morphemes (meaningful parts of words). All types of words can be misread, both important content words (usually nouns or verbs) and the less important function words (e.g., prepositions or articles). Substitutions often, but not always, involve words belonging to the same grammatical category (e.g., nouns are usually substituted for nouns). Substitutions may involve phonetically or graphemically similar words (*read* for *red*), semantically similar words (*blue* for *violet*), or unrelated words. Errors occur just as often in reading single words as in reading paragraphs or stories.

Both oral and silent reading are characterized by slowness and comprehension difficulties. Reading is slower with unfamiliar words. Part of the slowness results from the child's need to go back and revise or recheck previous words that were guessed at or read inaccurately, and part is likely due to the word recognition deficit. An artifact of this rechecking of previously read words can be observed in “kinetic reversals”; for example, reading *was* as *saw*.

A recent study examined the reading comprehension performance of reading-disordered and normal-reading college students on timed and untimed tests. Poor readers did not differ significantly from normal readers in the untimed condition but differed significantly in the timed condition. The authors of the study interpreted this as suggesting that problems with attention span and concentration among the poor readers necessitated rereading passages.

The associated impairments and disorders found with reading disorder vary more than the specific symptoms of the disorder. The disorders most often associated with reading disorder are mathematics disorder, disorder of written expression, specific expressive language disorder, and mixed receptive-expressive language disorder. The vast majority of children with reading disorder, perhaps as many as 95 percent, have at least one of those disorders concurrently. In addition, various cognitive processing difficulties in perception, language, attention, and memory as well as motor coordination difficulties are frequently associated with reading disorder.

Another important associated symptom is problems with social skills. Many children with reading disorder experience impaired social skills. It is not clear whether

those impairments constitute a separate underlying deficit or are among the social consequences of having a learning difficulty.

The psychiatric diagnoses reported most frequently in children with reading disorder are attention-deficit/hyperactivity disorder, conduct disorder, oppositional defiant disorder, and depressive disorder. A large literature exists on the association between reading disorder and attention-deficit/hyperactivity disorder, conduct disorder, and juvenile delinquency. It is not clear if reading disorder predisposes to the development of those psychiatric disorders, if the psychiatric disorders lead to underachievement and thence to reading disorder, or if a common risk factor leads to the simultaneous development of both.

An important issue in the learning disabilities field is subtyping. Some of the different associated symptoms and disorders may be markers for distinct subtypes of reading disorder, each with a different cause and prognosis. A number of different subtypes of reading disorder have been postulated (e.g., subtypes with specific types of intelligence quotient [I.Q.] profiles on the Wechsler Intelligence Scale for Children, subtypes with particular patterns of reading or spelling performance, and subtypes with or without motor impairment, language disorder, or attentional deficits).

Most research has concentrated on defining and describing subtypes; attempts to validate the subtypes with follow-up data, treatment data, and laboratory measures are more limited. Factor analysis studies of children with reading disorder has identified two major subtypes of reading disorder: a verbal-linguistic subtype and a nonverbal subtype. Children with the two subtypes of reading disorder can be distinguished by their performances on batteries of neuropsychological and educational achievement tests. In addition, some evidence suggests that they may have different associated behavioral or emotional problems and different prognoses.

N. was a 13-year-old girl who was referred for evaluation because of poor academic performance noted by several of her middle school teachers. An initial conference conducted by the middle school's student study team revealed that although no complications were reported during the pregnancy, the mother indicated that N. had a history of frequent ear infections in childhood. Those infections eventually led to myringotomes performed in both ears at the ages of 3 and 4 years. N. attended a nonacademic preschool and kindergarten. Her teachers described her as quiet, with no behavioral problems in the classroom. She attended a regular public school for first through fourth grades and was initially referred for evaluation of a reading problem in fifth grade. Testing revealed a normal pattern of cognitive functioning, language development, and adaptive behaviors; academic achievement testing revealed age-level performance in mathematics computation and reasoning, and spelling; however, although her sight-word reading skills were adequate, word attack and reading comprehension performance was below average. It was recommended at the time that N. receive after-school tutoring with an educational therapist to work on word attack skills and reading comprehension strategies. In spite of this intervention, N.'s academic performance did not improve markedly, and a decision was made to reconsider her case for possible referral for special education and related services.

As a result of student study team deliberations, a multidisciplinary team conducted a comprehensive assessment with the following results: intellectual testing revealed a nonverbal I.Q. in the high normal range and a verbal I.Q. in the normal range. However, closer inspection revealed that N.'s performance on the Digit Span, Information, Arithmetic, and Coding subtests was significantly below average. Achievement testing revealed slightly below average performance in mathematics and written language but significantly below average performance on measures of phonics, sight-word, and reading comprehension skills. Findings obtained from outside testing conducted at a university hospital revealed that N. has an attention-deficit disorder. This information combined with previously reported findings led the school-based Individualized Education Program committee to classify N. as having a specific learning disability (dyslexia) occurring along with an attention-deficit disorder. In an individualized education program the committee recommended that the family establish contact with the university hospital for possible treatment of the attention-deficit disorder. The committee also recommended intensive remedial reading instruction for one period a day through a resource specialist program.

Over the next 6 months N.'s reading performance improved dramatically. When she was retested at the end of the year, she had made significant progress in acquiring decoding skills and a decision was made to continue medical treatment for attention-deficit disorder and discontinue placement in the resource specialist program. The committee recommended bimonthly monitoring N.'s progress in the eighth grade general education program.

DIFFERENTIAL DIAGNOSIS

The essential feature of reading disorder is a significant impairment in development of reading accuracy, speed, or comprehension that is not due to low intelligence, visual or hearing deficit, neurological disorder, or lack of opportunity for instruction. However, distinguishing children with reading disorder from normal children with poor reading requires defining a *significant impairment*. This issue has generated extensive debate in the learning disabilities field.

Various methods and formulas have been applied to the problem. The approaches include identifying discrepancies between mental age and reading age scores, between reading age scores and chronological age, between reading age scores and standard scores, and between reading age scores and expected reading scores.

Expected reading scores are calculated from a regression equation based on population achievement, age, and intelligence. The various approaches identify different children with reading disorder. Although the regression equation method appears to be the most consistent across the I.Q. range, it is the most difficult method for clinicians to use. DSM-IV permits clinicians to compare a child's reading test performance with age and I.Q. norms. Generally, a discrepancy of 2 standard deviations is required for the diagnosis, but some flexibility is permitted in the DSM system. School districts may set more rigorous standards.

DSM-IV also permits concurrent diagnoses of reading disorder and mental retardation. The diagnosis of reading disorder is made in exactly the same way for a child with mental retardation as for a child with normal intelligence. Mentally retarded children who read poorly, but no more so than would be expected from their other cognitive functioning, are not given the concurrent diagnosis of reading disorder.

Inadequate schooling and impaired vision or hearing are other possibilities to consider in differential diagnosis. Inadequate schooling can usually be determined from the history and interviews; frequent school changes, frequent absences, or classmates with similar impairments in reading are clues. Impaired vision or hearing can be ruled out through screening tests.

COURSE AND PROGNOSIS

Although symptoms of reading disorder may appear as early as age 5 years (e.g., inability to distinguish among common letters or to associate phonemes with letter symbols), referral and formal diagnosis may not occur until later. Many children are first diagnosed when they fail to respond to formal instruction in the second grade. Some, especially those with high intelligence, may not be diagnosed until the fourth or fifth grade.

Over time, reading disorder tends to improve, with or without treatment. However, even with optimal remediation, short-term improvement is slow, and long-term improvement may not be complete. Complications include conduct or oppositional defiant disorder, low self-esteem and demoralization, and school dropout.

Adults with a childhood diagnosis of reading disorder show a wide range in reading skills. Typically, some residual difficulties exist, but complete inability to read is rare. Despite residual reading problems, adult educational and occupational attainments are typically those of the general population. Predictors of better outcome include less-severe impairment, higher intelligence and socioeconomic level, good psychiatric status, and earlier age at diagnosis and treatment.

TREATMENT

Attempted therapies for reading disorder include educational remediation, medications, and psychosocial interventions. The most effective therapy appears to be an educational approach that combines “meaning-emphasis” and “code-emphasis” programs. In a review of research studying beginning reading instruction, one educator found that code-emphasis programs that emphasize systematic instruction in phonics are most effective in the early grades, especially for students with reading disorders. Once automaticity is achieved in decoding, meaning-emphasis programs that stress the use of common sight words are recommended to increase fluency and develop comprehension.

In certain cases, specific remedial reading programs and approaches have proved particularly effective in educating students otherwise resistant to such a combination approach. Examples of these remedial programs and approaches are as follows: Reading Mastery, an intensive, highly structured program designed to be implemented up through third grade; the Corrective Reading Program, an advanced reading program, also highly structured and designed for students in grades four through twelve; the Fernald Method, a multisensory approach that teaches words as whole units using language experience and tracing (kinesthetic) techniques

to teach vocabulary selected from student-dictated stories; and the Gillingham Method, another highly structured approach that emphasizes consonants and vowels with only one sound as initially presented on drill cards, followed by learning of consonant-vowel-consonant words through blending exercises, and spelling and writing skills as a means of practicing words. Approaches have also been designed to increase fluency (e.g., Neurological Impress method; Repeated Reading method) and assist older students with comprehension skills (e.g., High-Interest Low-Vocabulary method).

Other instructional approaches that have proved highly successful with children with reading problems are Reciprocal Teaching (an interactive approach that promotes comprehension by engaging teachers and students in an active dialogue about the text), Story-Mapping (an organizational map used by readers to keep track of story components such as setting, problem, goal, action, and outcome), and Multi-Pass (an approach that explicitly trains students to make several structured passes through content-area texts, picking out important textual cues such as italicized words and captions to improve comprehension).

Various types of cognitive-perceptual skills training (e.g., sensory integration training, perceptual-motor training, occupational therapy, auditory memory training, vestibular stimulation, hemispheric stimulation, optometric training) have been used with reading-disabled children. The effectiveness of these methods in improving reading disorder in most children has not been convincingly demonstrated.

Medical approaches to treating reading disorder include stimulant medications, antianxiety medications, motion sickness stimulants, and piracetam. Both methylphenidate (Ritalin) and piracetam have been studied in double-blind trials. Although methylphenidate does not appear to be specifically beneficial to reading skills, there is some indication that piracetam may facilitate reading performance.

Psychosocial approaches to reading disorders include supportive psychotherapy, parent guidance and training, social skills training, relaxation training, and behavioral modification approaches. The effectiveness of such approaches for reading disorder has not been proved, although they are likely to be helpful for associated behavioral and emotional problems. Similarly, the benefits of speech or language therapy for reading are not known, although it may prove helpful for associated speech and language deficits.

An overall treatment program should include attention to associated disorders such as language disorders or psychiatric disorders. In addition, individual characteristics of the child—motivation, learning style, attentional abilities, and responses to instructional strategies or to curriculum materials may be significant to treatment selection and outcome.

SUGGESTED CROSS-REFERENCES

Commonly associated developmental or learning disorders are discussed in Section 35.2 on mathematics disorder, Section 35.3 on disorder of written expression, Section 37.1 on expressive language disorder, Section 37.2 on mixed receptive-expressive language disorder, Chapter 38 on developmental coordination disorder, and Chapter 34 on mental retardation. Commonly associated psychiatric disorders are discussed in Chapter 39 on attention-deficit disorders, Chapter 40 on disruptive behavior disorders, and Chapter 45 on depressive disorders.

35.2 MATHEMATICS DISORDER

MICHAEL E. SPAGNA, FH.D., DENNIS P. CANTWELL, M.D. AND LORIAN BAKER, FH.D.

DEFINITION

Mathematics disorder is an impairment in the development of arithmetical or mathematical skills that is sufficiently serious to interfere with academic achievement or daily living. This impairment in mathematical skills cannot be explained by the person's measured intelligence; educational background; visual, hearing, or physical disorders; mental retardation; emotional disturbance; or environmental, cultural, or economic disadvantage.

HISTORY AND COMPARATIVE NOSOLOGY

Compared with reading disorder, the study of learning disorders in arithmetic have been largely ignored, with empirical investigations of mathematics disorder few and narrowly focused. Early study of mathematics disorder focused on acquired calculation disturbances (acalculia) in adults that resulted from cerebral trauma. From this work, three broad categorizations of acalculia were accepted in the professional community: (1) number alexia or graphia (also termed *aphasic acalculia*), difficulties related to reading and writing numbers correctly or handling numbers as words; (2) *visual-spatial acalculia*, difficulties associated with the inability to align problems or sustain place-holding values; and (3) *anarithmetia*, a primary inability to perform calculations with errors particularly noted in carrying out arithmetic operations. A developmental disorder specific for mathematical skills was first described in 1937. Various terms have been used to describe the disorder, including *dyscalculia, Gerstmann syndrome, developmental acalculia, developmental dyscalculia*, and *developmental arithmetic disorder*.

The disorder appeared in the third edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III), the revised third edition of DSM (DSM-III-R) (under the name “developmental arithmetic disorder”), and the fourth edition of DSM (DSM-IV), with only minor changes in the wording of the diagnostic criteria. Specific disorder of arithmetical skills is included in the 10th revision of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) with largely similar diagnostic criteria (see Table 35.1-2). A key difference between the DSM definition and the ICD definition is that the ICD definition specifically excludes reading and spelling difficulties and disorders.

EPIDEMIOLOGY

Although the prevalence of mathematics disorder has not been studied in detail, several studies agree that approximately 6 percent of the school-age population has serious arithmetic difficulties unexplained by cognitive or sensory functioning. The study of mathematics disorder has been neglected even though it appears to occur with the same frequency as learning disorders in other academic areas. Several researchers have asserted that this situation reflects cultural values that afford literacy skills (i.e., reading and writing) a higher status than mathematics skills.

The sex ratio of the disorder is also unclear, and data are limited. However, girls are thought to have a greater predisposition to the disorder than boys.

ETIOLOGY

The cause of developmental mathematics disorder is unknown. The earliest view of mathematics disorder was derived from neurological studies of adults with acquired brain lesions that were accompanied by loss of arithmetical-mathematical skills. That early work implicated abnormalities in the cerebral right hemisphere (occipital) processing of visual-spatial stimuli. Subsequent work indicated that such lesions could not account for all cases of acalculia, in either children or adults. However, when children with developmental language disorders are excluded from consideration, symptom clusters of adults with acquired acalculia and children with mathematics disorder are markedly similar.

Some persons may have a genetic predisposition to mathematics disorder. Anecdotal and case history reports describe families with consistently high or low mathematical abilities. Furthermore, in the general population monozygotic twins show a higher than chance correlation in mathematics test scores.

More-recent models suggest that difficulties with mathematics are produced by differences in cognitive development that result in deficient learning strategies for arithmetic. In one model, internal developmental-cognitive factors and external environmental factors interact to produce the deficient learning strategies. Internal developmental-cognitive factors include (1) a general intelligence factor, (2) a verbal ability factor, (3) a visual-spatial ability factor, and (4) a numeric factor (specific to numerical test performance). External environmental factors identified as contributing to poor performance in mathematics include (1) complexity of subject matter, (2) insufficient mastery of prerequisite skills, (3) motivational disposition, and (4) inadequate instruction. Although educators have asserted that the most significant factors responsible for poor mathematical performance are such nonpersonal factors as confusing textbooks and inadequate teaching, these factors are generally discounted in individuals identified as having mathematics disorder.

DIAGNOSIS AND CLINICAL FEATURES

Common signs of mathematics disorder are listed in Table 35.2-1. The age of onset is unclear. Diagnosis may be made as early as first grade, but it is usually made after several years of schooling. Some children with mathematics disorder can make normal progress by using rote memory for the first several years at school. Those children begin to exhibit problems only in the later grades, when the demands in mathematics increase and rote memory is insufficient for problem solving.

Difficulty learning number names
Difficulty establishing rote count sequences
Difficulty learning to print numerals
Difficulty with concepts of combining and separating
Difficulty learning the meaning of operational signs or accurately acting on those signs
Difficulty in committing basic facts to memory
Difficulty with concept of place value
Difficulty in aligning numerals when copying problems
Difficulty maintaining alignment during computation
Idiosyncratic error patterns
Inaccurate computations
Slow computation
Difficulty with word problems
Difficulty with graphic representation of information

Courtesy of J.E. Fleischner, K. Garnett, B. Silver.

Table 35.2-1 Common Signs of Mathematics Disorder

The specific symptoms of mathematics disorder vary across individuals, falling into four major groups: linguistic symptoms, perceptual symptoms, mathematical symptoms, and attentional symptoms. Linguistic symptoms include difficulties in understanding or naming mathematical terms, operations, or concepts; decoding written problems into mathematical symbols; and understanding concepts used in mathematical problems (e.g., more and less, first and last, and before and after). Perceptual symptoms include difficulties recognizing or reading numerical symbols or arithmetical signs, clustering objects into groups, aligning strings of numbers during calculations, and ordering strings of numbers.

Mathematical symptoms include difficulties performing basic arithmetical operations, memorizing numerical facts, following sequences of mathematical steps, counting objects, and multiplying. Learning the multiplication tables frequently poses great difficulty for many children with mathematics disorder. Such children frequently develop elaborate adaptive strategies to avoid multiplication. These strategies, however, often involve an increased number of processes (grouping, adding, and counting) and may produce higher rates of errors.

Attentional symptoms include inaccurate copying of numbers; omitting digits, decimals, or symbols when writing answers; forgetting to add in carried numbers during addition; and failing to note arithmetical signs (e.g., adding when subtraction is indicated). Such errors are common among children with learning disorders. Sometimes they represent inattention or carelessness, but at other times they represent a true lack of understanding of what is needed in mathematical operations. One study of such errors showed that they occurred most often in problems on which the students spent the most time.

Other developmental learning disorders and difficulties are often associated with mathematics disorder. Reading disorder, disorder of written expression, expressive language disorder, mixed receptive-expressive language disorder, and developmental coordination disorder have all been reported in association with mathematics disorder. Specific cognitive processing difficulties (e.g., auditory-verbal deficits, visual-spatial deficits, motor deficits, memory deficits, and attention deficits) may be associated features.

Social immaturity, school and peer problems, social skills deficits, anxiety, and depression have also been reported as associated problems. However, the psychiatric syndrome that is most often found is attention-deficit/hyperactivity disorder. The precise nature of the association is not clear; however, three recent studies shed some light. One study compared relative mathematical underachievers with relative reading underachievers and found that the mathematically impaired children had higher rates of inattention but not of hyperactivity or impulsivity. The second study examined children with attention-deficit disorder and found correlations between measures of vigilance and distractibility and arithmetic test performance. The third study found that older children with attention-deficit disorder were significantly more likely than younger children with the disorder to show a discrepancy between intelligence levels and mathematical achievement. The DSM-IV diagnostic criteria for mathematics disorder are listed in Table 35.2-2.

A. Mathematical ability, as measured by individually administered standardized tests, is substantially below that expected given the person's chronological age, measured intelligence, and age-appropriate education.

B. The disturbance in criterion A significantly interferes with academic achievement or activities of daily living that require mathematical ability.

C. If a sensory deficit is present, the difficulties in mathematical ability are in excess of those usually associated with it.

Coding note: if a general medical (e.g., neurological) condition or sensory deficit is present, code the condition on Axis III.

Table 35.2-2 DSM-IV Diagnostic Criteria for Mathematics Disorder

Differential Diagnosis The differential diagnosis requires individual standardized testing of both intellectual functioning and achievement in mathematics. Mathematics disorder is indicated by an achievement score significantly (e.g., two standard deviations) below the score expected on the basis of the child's chronological age and intelligence.

Poor development in mathematics may also be associated with mental retardation, poor vision or hearing, and inadequate education. In mental retardation achievement scores in mathematics are generally commensurate with scores for intellectual functioning. However, children with mild mental retardation may receive the concurrent diagnosis of mathematics disorder if mathematical skills are impaired beyond other levels of functioning. Impaired vision or hearing may be ruled out with audiometric or vision screening tests. Inadequate educational exposure can usually be determined by obtaining a detailed educational history from the parents and the school. The history should cover such information as number of schools attended; frequency of school absences; presence of personality conflicts among the child, parents, and teacher; and the curriculum and styles of teaching used.

Rosa's sixth-grade general education mathematics teacher referred Rosa to the school's Student Study Team for evaluation to determine whether she might have a specific learning disability after noting the following behaviors in class: Rosa constantly lost her place on text pages; she appeared unable to copy problems accurately, either from the board or from a page; her written mathematics work was carelessly completed according to the teacher, with numerous mistakes such as copying operation symbols incorrectly and incorporating the number of the problem into the problem itself; and she continually reversed the order of digits, especially in two- and three-digit problems (e.g., writing 52 for 25).

After a series of in-class accommodations (e.g., moving Rosa's seat closer to the front of the classroom) and modifications of materials (e.g., reducing the number of problems required in assignments), the Student Study Team recommended a full assessment of Rosa's difficulties in mathematics.

Testing consisted of administering the Woodcock Johnson Psycho-Educational Battery-Revised, parts 1 and 2; the Enright Diagnostic Test of Mathematics; the Brigance Test of Basic Skills; and various curriculum-based assessments. The testing revealed that Rosa had a specific learning disability in the area of mathematics and thus qualified for special education and related services. More specifically, the multidisciplinary team, assembled for an Individualized Education Program meeting with Rosa's family, reported that Rosa encountered difficulties in mathematics due to visual perceptual deficits, evidenced by figure-ground difficulties, discrimination problems, and reversals. They recommended specific interventions in the general education classroom by her present teacher, with support provided to this teacher by a resource specialist specifically trained to help students encountering these difficulties.

To address Rosa's figure-ground difficulties, a geometrically shaped template was used to box problems in the textbook, effectively isolating one problem at a time. Additionally, problem numbers were color-coded to differentiate the number of the problem from digits in the problem itself. These modifications were incorporated into assignments by the teacher so that Rosa would box out problems and color-code problem numbers for homework and actually solve the problems in the subsequent class meeting. These adaptations were reported to be quite effective by the general education classroom teacher.

To address Rosa's difficulties with copying operation symbols and reversing numbers, lined paper was used to align number columns, and color-coding was used to identify each operation symbol (e.g., addition was identified by a blue “+” symbol) as well as ones, tens, and hundreds place values (e.g., ones identified in green, tens in red, etc.).

At a 6-month follow-up meeting with Rosa's family, the general education mathematics teacher reported that Rosa was making significant progress and had appeared to be using the curricular modifications effectively; for example, fewer reversals occurred and her operational symbol confusion was no longer observed.

Roger, a 15-year-old student, was recently diagnosed as having a nonverbal learning disability known as dyscalculia; in other words, Roger's verbal skills, as measured on the Wechsler Intelligence Scale for Children–Third Edition, were in the average range, but performance skills were significantly below average. Teachers consistently reported that Roger exhibited good-to-excellent reading, spelling, and writing skills but encountered difficulty in mathematic tasks that required abstract reasoning, particularly mathematic word problems. Teachers described Roger's work as sloppy and lacking proper organization. His parents reported that Roger had always experienced these difficulties; additionally, they indicated that Roger had always had difficulty correctly perceiving certain social cues such as tone of voice and facial expression, and that these deficits impeded his ability to build and maintain friendships with peers.

Presently, Roger is receiving special education in a resource room setting. His resource specialist created a highly structured program for Roger that systematically addresses his difficulties with mathematical word problems. In particular, the resource specialist uses flip charts that take Roger through each step of a mathematical word problem sequentially; a separate step is diagramed on each page and illustrations present concepts visually. This technique has had moderate success with Roger.

Recently, the resource teacher taught Roger how to use a highlighter pen to identify essential and extraneous information contained in mathematical word problems: yellow ink indicates important information necessary to solve the problem and blue ink identifies information unnecessary for correct problem solution. This highlighting strategy was combined with a poster chart that identifies key words indicating certain operations in the word problems (e.g., the words “take away” are equivalent to subtraction)

.

At follow-up, participation in this program resulted in marked improvement in Roger's performance on mathematical word problems; through consultation with the general education teacher, the resource specialist recommended that Roger be mainstreamed into a general education ninth-grade mathematics class.

COURSE AND PROGNOSIS

Although difficulties with counting and number concepts may be apparent as early as kindergarten, diagnosis is generally not made until the second or third grade. The prognosis of mathematics disorder is unclear; case reports show a full spectrum of outcomes, from chronic disability through partial recovery to complete remission of mathematical difficulties. Currently it is not known whether those differing outcomes reflect different subtypes of underlying disorder, different severity levels or degrees of impairment, or treatment, environmental, or other factors. School and peer relationship problems are considered possible complications, but how they develop has not been studied.

TREATMENT

The only treatment of mathematics disorder proved effective is systematic instruction guided by eight principles—two general and six specific. The first general guiding principle is making sure to consider the strengths and weaknesses of the individual with mathematics disorder when planning and implementing a course of education. To investigate the student's abilities, one should determine whether the student (1) comprehends number structure and arithmetic operations, (2) exhibits evidence of adequate spatial-relation skills, (3) has language difficulties that might contribute to learning mathematics, (4) has reading difficulties that affect mathematics learning, and (5) encounters attentional or memory problems or both that might affect mathematics performance.

The second general guiding principle involves providing a balanced mathematics program. In other words, the instructional program should include concepts, skills, and problem solving in an appropriate combination. The teaching of concepts emphasizes such basic understanding as the ability to group and classify objects and skills instruction equips students to perform correct operations using number concepts. Concepts and skills are both used in the third element of a balanced mathematics program, problem solving. In problem solving activities, students are given opportunities to apply understanding of concepts and skills acquisition to new and different settings.

In addition to these general principles, six specific principles are used to guide mathematics instruction for those with mathematics disorder. The first involves checking previously acquired learning of numbers to ensure that these individuals have the necessary foundation (prenumber learnings such as matching, recognizing groups of objects, relationships of parts to whole operations, among others) for more-advanced and abstract concepts.

Second specific guiding principle is that teaching of mathematical concepts should progress through concrete, semiconcrete, and abstract instructional phases. For example, at the concrete stage, concepts are demonstrated by allowing students to manipulate real objects; in the semiconcrete stage, graphic representations are substituted for actual, real-world objects to allow further practice in concept learning; and in the abstract stage, numerals are finally represented by graphic symbols (i.e., 4 + 6 = 10).

The third specific instructional principle emphasizes the need for constant review, drill, and practice of concepts. The objective is enabling the student to use mathematical concepts with a high degree of automaticity. Worksheets, flashcards, and instructional and computer games can be incorporated into the educational program to achieve this objective.

The next principle involves purposeful design and implementation of activities that allow individuals to generalize learned concepts to new and novel situations. For example, measurement skills can be applied to such real-world situations as following a recipe.

A fifth specific principle requires the explicit teaching of mathematics vocabulary to individuals with mathematics disorder. Although many students with mathematics disorder understand the operations required to complete calculation problems successfully, at the same time, they lack the vocabulary (e.g., division requires understanding the terms *divisor* and *quotient*) necessary to unerstand operations fully.

The sixth specific guiding principle involves using calculators, not as a substitution for learning numerical concepts but in lessons emphasizing mathematical reasoning. In other words, calculators are used judiciously and primarily for advanced conceptual work, not when the objective is teaching calculation procedures.

In addition, several recent approaches have been developed to address the unique learning needs of individuals with mathematics disorder: Acronym Mnemonics, the Think Aloud strategy, and the Cognitive Assault strategy. Acronym Mnemonics teaches children with mathematics disorder in primary grades to use a systematic procedure to answer mathematic fact questions from memory. For example, students learn to use the acronym SOLVE whenever they cannot quickly remember a math fact. SOLVE stands for the following steps:

1. **S**ee the sign. (Cues students to determine which operation to use on the math fact.)
2. **O**bserve and answer (if unable to answer, keep going). (Cues students to look at the problem and provide an answer. If the answer is unknown, students continue with steps 3 through 5.)
3. **L**ook and draw. (Reminds students to figure out answers by looking at numbers and drawing tallies.)
4. **V**erify your answer. (Reminds students to check their answers to ensure accuracy)
5. **E**nter your answer. (Cues students to record answers in the space provided.)

This approach is reportedly highly effective with children who have difficulty remembering basic math facts.

The second approach was developed for use with middle school students with mathematics disorder. Based on previous observations that students with mathematics disorder make fewer cognitive and metacognitive verbalizations than normal peers when engaged in solving word problems, this approach teaches students with mathematics disorder to use Think Aloud procedures to solve one-, two-, and three-step word problems. In addition to training students to become more strategic in their problem solving, this approach also resulted in increased perseverance by individuals with mathematics disorder, even when faced with tasks of increasing difficulty.

The third approach, the Cognitive Assault Strategy, was developed for secondary students with mathematics disorder. In this approach, students are assigned instructors or mentors who are responsible for detecting and correcting errors and developing verbalization and writing skills to produce a written description of how

students solve problems. More specifically, students receive a mathematics problem and then verbalize and write out all steps associated with solving it; next, the students write down each step in the sequence, indexing each step with its location in the actual problem; finally, students laminate correct solutions and place them in a notebook for future reference when encountering similar problems in the future. Additional steps include providing a title just above the problem (e.g., basic algebra problem) and possibly color-coding similar types of problems (e.g., algebra problems coded green, calculus problems coded orange). Overall, high school students who have used this approach have gained increased understanding of concepts and procedures and encounter similar problems with more confidence.

CHAPTER 35. LEARNING DISORDERS

35.3 DISORDER OF WRITTEN EXPRESSION AND LEARNING DISORDER NOT OTHERWISE SPECIFIED

MICHAEL E. SPAGNA, FH.D., DENNIS P. CANTWELL, M.D. AND LORIAN BAKER, FH.D.

DISORDER OF WRITTEN EXPRESSION

Definition Disorder of written expression is a significant impairment in written communication that is not attributable to low intelligence; visual, hearing, or physical disorders; emotional disturbance; environmental, cultural, or economic disadvantage; or lack of adequate instruction. The written compositions of persons with the disorder are usually short, poorly organized, and lack sufficient ideation. These written products are also replete with errors in handwriting, spelling, punctuation, and capitalization. The disorder is frequently associated with other learning and language disorders.

History and Comparative Nosology The major focus of learning has traditionally been on reading and only recently has any attention been paid to writing. The first attention paid to writing difficulties focused on handwriting and spelling. The earliest view was that writing difficulties were always associated with reading difficulties.

In the late 1960s the first comprehensive work was carried out describing disorders of written language. These early case studies reported learning disorders that only occurred in written form, with other forms of verbal behavior remaining intact. Difficulties in written expression were grouped into three primary categories: (1) disorders in visual-motor integration (persons could speak and read but could not correctly execute the motor operations necessary to print symbols such as letters and numbers), (2) deficits in revisualization (individuals could recognize and read words but could not revisualize letters and words and thus could not write words from dictation or spontaneously), and (3) deficiencies in formulation and syntax (persons could copy printed symbols accurately, could revisualize words, but could not organize thoughts into meaningful written communication).

Since this first set of disorders involved visual-motor integration and in an effort to parallel the use of the term “dyslexia” for reading disorder, the term “dysgraphia” was the first term associated with disorders of written expression. Other terms used to refer to spelling disorder were *spelling dyslexia, specific spelling retardation, developmental spelling retardation*, and simply *spelling disorder*.

The revised third edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III-R) was the first edition of DSM to include a description of a disorder of written language, then called “developmental expressive writing disorder.” The disorder was defined as an impairment in the development of writing skills not explainable by mental retardation or inadequate schooling and not due to visual or hearing defects or to a neurological disorder. Writing skills according to that definition included spelling, grammar, punctuation, sentence construction, and paragraph organization. The disorder is included in the fourth edition of DSM (DSM-IV) as disorder of written expression, with only minor changes in the wording of the definition. The disorder is also included in the 10th revision of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) with essentially the same diagnostic criteria (see Table 35.1-2) as those in DSM-IV (i.e., including spelling, grammar, and compositional difficulties).

Epidemiology The prevalence of disorder of written expression has not been studied. It is thought that the prevalence and sex ratio of the disorder are roughly similar to those of reading disorder (i.e., prevalence of 4 percent in school-age children; sex ratio of three to four boys to each girl). However, that does not mean that reading disorder and disorder of written expression always co-occur.

Etiology The cause of disorder of written expression is unknown, and the factors that may be associated with the disorder have not been examined. The factors associated with spelling difficulties have been studied, but the studies did not necessarily consider other forms of writing difficulties or associated reading disorder.

Etiological factors are generally assumed to be similar to those for reading disorder or the specific developmental language disorders. Some professionals believe that underlying cognitive processing difficulties are present, but no specific types have been identified.

Difficulties with attention and concentration, visual memory, and eye-hand coordination can all produce writing problems (e.g., careless punctuation, misspellings, and poor letter formation). Similarly, language disorder can be manifest in written language (e.g., word-finding problems, limited knowledge of grammar and syntax, and inability to sequence ideas expressively). How frequently or to what extent linguistic or other deficits underlie disorder of written expression is unknown.

Diagnosis and Clinical Features The essential feature of disorder of written expression is significant impairment in the ability to compose written text. The impairment may be exhibited in a variety of ways, the most common of which are spelling errors, grammatical or syntactic errors, punctuation errors, poor paragraph organization, and excessively poor handwriting. Written compositions may also show poor thematic development.

Spelling errors are among the most common and most noticeable errors in the writings of children with disorder of written expression. Various types of misspellings may occur, but the most common type appears to be phonetic or phonographical errors. In these errors, misspellings reflect the way the word sounds (e.g., spelling “fotograf” for “photograph” or “caim” for “came”). These spelling errors are similar to those made by young children just learning to spell. The misspellings of children with disorder of written expression sometimes resemble a mispronunciation or slurring of the word (e.g., “ineverable” for “inevitable” or “offen” for “often”). Other less common types of spelling errors include morphological errors (e.g., “laughter” for “laughed”), segmentation errors (e.g., “away” for “away”), reversals (e.g., “god” for “dog”), and spelling-rule errors (e.g., “bitting” for “biting”).

Grammatical or syntactic errors include word omissions, incorrect word order, incorrect verb and pronoun usage, and incorrect word endings. Written sentences may be incomplete or run-on sentences. Syntactic analyses of written language (e.g., mean number of words, subordinate clauses, or morphemes per sentence) typically reveal unsophisticated syntax. Among older (i.e., college) students with disorder of written expression, the grammatical and syntactic errors may be seen only with higher-level linguistic structures, such as coordination or subordination.

Punctuation and capitalization errors, the so-called writing mechanics, are also considered a major part of disorder of written expression. These errors are particularly common in the writings of younger children but also occur in the works of older disabled writers. Some researchers feel that this aspect of writing poses greater difficulties than do the more creative areas, such as choice of vocabulary and thematic maturity.

Excessively poor handwriting is another indication of disorder of written expression. Disordered handwriting (as opposed to handwriting that is simply messy) includes letter forms that are not decodable, rotations or inversions of letters, a mixture of printing and cursive writing, and inappropriate mixtures of upper-case and lower-case letters.

Poor story composition and poor paragraph organization are other essential features of disorder of written expression. Two main aspects of poor story composition are poor or missing story components (e.g., settings, characters, themes, conflict, and conflict resolution) and poor cohesion (e.g., unclear referents, rough transitions, and abrupt endings). Thus, the written paragraphs and stories of children with this disorder usually convey a clear message but have an unplanned, simplistic quality.

Learning disorders thought to co-occur frequently include phonological disorder, expressive language disorder, mixed receptive-expressive language disorder, reading disorder, developmental coordination disorder, and mathematics disorder. Deficits in social skills and self-esteem and peer relationship problems may accompany disorder of written expression. Attention-deficit disorder is the psychiatric disorder most likely to co-occur.

The diagnostic criteria for disorder of written expression appear in Table 35.3-1.

A. Writing skills, as measured by individually administered standardized tests or functional assessments of writing skills), are substantially below those expected given the person's chronological age, measured intelligence, and age-appropriate education.
B. The disturbance in criterion A significantly interferes with academic achievement or activities of daily living that require the composition of written texts (e.g., writing grammatically correct sentences and organized paragraphs).
C. If a sensory deficit is present, the difficulties in writing skills are in excess of those usually associated with it.
Coding note: if a general medical (e.g., neurological) condition or sensory deficit is present, code the condition on Axis III.

Table 35.3-1 DSM-IV Diagnostic Criteria for Disorder of Written Expression

B.C. was a 12-year-old male student who presented for evaluation of problems in school. He attended an academic preschool and was presently enrolled in a regular sixth grade class at a public school.

Current evaluation revealed no history of neurological, visual, or hearing problems that could explain B.C.'s school difficulties. Intelligence testing revealed high-average scores in both the verbal and performance subtests of the Wechsler Intelligence Scale for Children-III (WISC-III). Reading and mathematical scores on standardized tests of academic performance were consistent with his intelligence and chronological age; however, spelling scores were significantly below the predicted level of performance. Multiple misspellings occurred. Although the examiner noted adequate handwriting, B.C. appeared unable to express thoughts in complete sentences. His sentences were short and failed to state intended points clearly. Careful study of B.C.'s written paragraphs revealed numerous grammatical and syntactic errors as well as errors in punctuation and capitalization.

The clinical picture of the inability to compose a written text, poor spelling, and grammatical errors in the absence of low intelligence, problems with reading or mathematics, and pervasive attentional problems led to a diagnosis of a disorder of written expression.

Differential Diagnosis The diagnosis of disorder of written expression requires a score on an individually administered standardized test of spelling, handwriting, or written expression that falls significantly below that expected for the child's chronological age and measured intelligence. Numerous educational tests provide reliable standardized assessments of spelling skills. However, few standardized tests assess writing skills. Available tests of written language include the Test of Written Language, first and second editions (TOWL), the Diagnostic Evaluation of Writing Skills (DEWS), and the Test of Early Written Language (TEWL). In addition, some tests of educational achievement and of language development have subtests dedicated to written language (e.g., California Achievement Tests, Sequential Tests of Educational Progress, Test of Adolescent Language, and Woodcock-Johnson Psychoeducational Battery–Revised).

Normative standards differ for the different tests, and clinicians are cautioned to check those standards before relying on a particular test. Also, some tests do not require writing samples but provide examples of poor writing to be identified. In effect, they test editing rather than writing.

Owing to the limited number of tests available, DSM-IV does not require standardized testing in its diagnostic criteria. Instead, samples of a child's written schoolwork may be analyzed and compared with those of peers of similar age and intelligence. The limited studies available suggest that analysis of a spontaneous sample of written composition is as effective in distinguishing children with syntactic difficulties as a formal test for written language.

Reliable judgments of disorder require experience with the levels of writing acquisition appropriate for different age levels. Telegraphic statements, verb-tense switching, and repetitious sentence forms, for example, are normal in the writing of a first-grade child but not of a third-grade child. Similarly, unrelated characters and actions and focus on the ending rather than on the details leading to the ending are normal in the writing of a second-grade child, but not in that of a fourth-grade child.

Mental retardation, impaired vision or hearing, impaired motor coordination, inadequate schooling, language disorders, learning disorder not otherwise specified, and attention-deficit disorder can all produce difficulties in aspects of written language. In a mentally retarded child (as in a child with normal intelligence) disorder of written expression may be diagnosed only if the child's writing skills are significantly below those expected of children with that general intellectual functioning. Impaired vision and hearing can both be ruled out through screening tests. Inadequate schooling can usually be ruled out by a careful history.

Impaired motor coordination, as a result of developmental coordination disorder or neuromotor damage, may produce illegible handwriting. If spelling and expression of thoughts in writing are not affected, the diagnosis of disorder of written expression is not made.

Attention-deficit disorders may be associated with disorder of written expression or may itself result in difficulties with producing written work. Children with attention deficits may not pay attention to the details of writing, so that their written work is marked by careless punctuation errors and messy handwriting. In such cases, careful attention to spelling and syntactic performance is needed to determine whether the diagnosis of disorder of written expression should be made. Language disorders frequently precede disorder of written expression. Concurrent diagnoses of oral language disorders and disorder of written expression are permissible. However, DSM-IV suggests that severe disorder of written expression along with severe disorders in reading and mathematics, should be diagnosed as a learning disorder not otherwise specified (Table 35.3-2) rather than as three separate diagnoses.

This category is for disorders in learning that do not meet criteria for any specific learning disorder. This category might include problems in all three areas (reading, mathematics, written expression) that together significantly interfere with academic achievement even though performance on tests measuring each individual skill is not substantially below that expected given the person's chronological age, measured intelligence, and age-appropriate education.

Table 35.3-2 DSM-IV Diagnostic Criteria for Learning Disorder Not Otherwise Specified

Course and Prognosis Symptoms of writing difficulties, such as letter reversals and the inability to copy printed materials, may appear quite early. However, diagnosis of disorder of written expression should generally not be made until the age of 8 years.

Diagnosis is difficult and often inappropriate at early ages for several reasons. First, sufficient motor development to coordinate hand, arm, and shoulder movements necessary for pencil control is frequently not acquired until the age of 6 years. Second, depending on educational opportunities and socioeconomic background, sufficient exposure to written language may not take place until after the age of 7 years. Third, letter reversals, miscopying, and difficulty in mastering graphemes are normal in the early stages of writing acquisition. Finally, in the first several grades of school only simple narrative writings are expected, which may not reveal milder difficulties. The most common age of diagnosis appears to be 10 years (fifth grade). At this time the writing curriculum shifts from narrative to expository text, a shift that most children with disorder of written expression cannot make.

The course of the disorder has not been systematically studied. It is assumed that it resembles reading disorder in that writing skills eventually will improve, but aspects of the disorder may remain throughout life.

The course and outcome of spelling problems have been somewhat studied. In the Isle of Wight studies, spelling problems were more persistent than reading problems, even with remedial interventions.

Although there are no longitudinal studies of children with disorder of written expression, four publications reported on the writing abilities of learning-disabled children at different age levels. All of these papers found the writings of older children superior to those of younger children.

Just as there have been no studies on the possible etiological factors underlying disorder of written expression, no studies have examined factors that may influence the outcome of the disorder. Both educational factors (e.g., opportunities to practice writing and teaching of mechanics of writing) and personal factors (e.g., lack of self-confidence and negative attitude) are believed relevant.

Treatment Educational intervention is thought to improve disorder of written expression, although specific studies of its effectiveness are lacking. A number of educational approaches to remediation of disorder of written expression exist and no convincing evidence favors any one of them. Both formal instruction in writing and practice with writing are believed to be beneficial. Recent attention has focused on the use of computers to teach writing skills, but there is no empirical evidence that computer use is superior to any other method.

LEARNING DISORDER NOT OTHERWISE SPECIFIED

Learning disorder not otherwise specified is a catch-all category for disorders in learning that do not meet the criteria for a specific learning disorder (Table 35.3-2). The category could be used, for example, for a specific spelling disorder.

ICD-10 includes the diagnosis of specific spelling disorder, defined as spelling problems in the absence of reading and arithmetic difficulties (see Table 35.1-2). A specific spelling disorder is not included in DSM-IV, reflecting the view that spelling difficulties are pervasive in the general population. Consequently, in most of the United States, children who have difficulties only with spelling are not eligible for learning disability programs.

SUGGESTED CROSS-REFERENCES

Reading disorder is discussed in Section 35.1, mathematics disorder in Section 35.2, and developmental coordination disorder in Section 36. Expressive language disorder is discussed in Section 37.1, mixed receptive-expressive language disorder in Section 37.2, and phonological disorder in Section 37.3. Mental retardation is the subject of Chapter 34 and attention-deficit disorders of Chapter 39.

CHAPTER 36. MOTOR SKILLS DISORDER: DEVELOPMENTAL COORDINATION DISORDER

MICHAEL E. SPAGNA, PH.D., DENNIS P. CANTWELL, M.D., AND LORIAN BAKER, PH.D.

HISTORY

Movement abnormalities were first classified by the medical profession during the fifteenth century. By the 1700s and 1800s, neurological correlates with motor abnormalities were probed and described in the professional literature. This early history is best described as a period when researchers were primarily concerned with investigating and explaining dramatic, involuntary motor behaviors observed in adults supposedly at rest. Not until the early twentieth century, however, were motor signs of clumsiness documented, first described in 1911 as “motor deficiency syndrome,” marked by awkward voluntary actions, excessive tendon reflexes, mild hypertonicity, and neurological overflow. A shift occurred here, with research efforts focusing on “hidden” motor coordination behaviors observed in children given reasonably complex tasks to perform.

By the early 1920s, assessment instruments were developed to evaluate motor awkwardness in children; the most influential device was created in 1922 at the Moscow Neurological Institute. The term “clumsy child syndrome” first appeared in the literature in the 1930s to describe a set of symptoms associated with awkward motor behaviors that did not result from overt neurological damage. During the 1940s, remedial programs were established in an attempt to correct and improve academic learning through treatment of coordination difficulties observed in children.

Not until the 1960s was clumsy child syndrome clinically set apart from other categories of learning disorders. From this period to the mid-1980s, significant investigations were conducted into possible perceptual-sensory causes for motor impairments as well as social and emotional problems associated with such impairments. Over the past decade, scholars have begun to investigate the presence of several subsyndromes suggesting that clumsiness might be a multidimensional condition warranting syndrome-specific intervention and remedial programs.

Currently, the *clumsy child syndrome* implies difficulties or delayed development in fine and gross motor coordination skills. The motor skills of clumsy children tend to be imprecise or mildly affected rather than grossly impaired. In addition, clumsy children tend to have problems in peer relationships and social adjustments and frequently suffer from language and other learning difficulties.

DEFINITION

Both the revised third edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III-R) and the fourth edition of DSM (DSM-IV) define developmental coordination disorder as significantly impaired development of motor coordination not directly attributable to either a neurological disorder or general mental retardation. Children with developmental coordination disorder perform motor coordination tasks at levels markedly below those of peers of the same chronological age and intellectual capacity. The motor performance deficits are sufficiently marked to interfere with academic achievement and activities of daily living. Specific manifestations of the disorder are described in Table 36-1. Many are age related, including delays in achieving motor milestones (walking, crawling, sitting), dropping things or clumsiness, poor performance in sports, and poor handwriting.

Gross motor manifestations
Preschool age
Delays in reaching motor milestones such as sitting, crawling, walking
Balance problems: falling, getting bruised frequently, poor toddling
Abnormal gait
Knocking over objects, bumping into things, destructiveness
Primary-school age
Difficulty with riding bikes, skipping, hopping, running, jumping, doing somersaults
Awkward or abnormal gait
Older
Poor at sports, throwing, catching, kicking, hitting a ball
Fine motor manifestations
Preschool age
Difficulty learning dressing skills (tying, fastening, zipping, buttoning)
Difficulty learning feeding skills (handling knife, fork, or spoon)
Primary-school age
Difficulty assembling jigsaw pieces, using scissors, building with blocks, drawing, or tracing
Older
Difficulty with grooming (putting on makeup, blow-drying hair, doing nails)
Messy or illegible writing
Difficulty using hand tools, sewing, playing piano

Table 36-1 Manifestations of Developmental Coordination Disorder

COMPARATIVE NOSOLOGY

Various terms have been used for developmental coordination disorder including *congenital maladroitness, choreiform syndrome, psychomotor syndrome, developmental apraxia, developmental dyspraxia, congenital clumsiness, developmental agnosia,* and *developmental dyspraxia-dysgnosia*. Although the most appropriate label for the disorder is controversial, the terms in widest current usage are *clumsiness, clumsy child syndrome, development coordination disorder,* and *specific developmental disorder of motor function*.

The disorder was not included in the third edition of DSM (DSM-III) as a separate syndrome, although motor coordination problems were noted as common associated features for most of the childhood developmental disorders. Developmental coordination disorder has been included as a separate diagnosis in DSM-III-R and appears in essentially the same form in DSM-IV. The 10th revision of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) also includes the disorder, but the slightly more formalized definition requires an intelligence quotient of at least 70 and performance at least two standard deviations below the mean on a standardized test of motor coordination.

Although DSM and ICD view the disorder as a unitary undifferentiated syndrome, several investigators have suggested that there may actually be several distinct subtypes. Supporting that view is the interindividual variation in symptomatology, only some of which is clearly age related. One recent attempt to subclassify developmental coordination disorder proposed subtypes such as ataxic syndrome (marked by unsteadiness and mild tremors), hypotonic syndrome (characterized by below-average resting muscle tone), tension syndrome (manifested by constant and excessively high levels of muscle tone), dyspraxic syndrome (identified by the inability to chain together a series of submovements necessary to execute smooth motor movements), manual-graphic syndromes (two separate manual syndromes, one marked by inadequate dexterity but adequate ability to reproduce written symbols, and the other characterized by adequate dexterity but inability to reproduce written symbols accurately using fine motor movements), visual-perceptual clumsiness (ranging from ocular-motor problems involving inefficient movement of eye muscles to severe retinal deterioration), and mixed syndromes (a combination of symptoms already presented under the aegis of the previous six classifications). DSM-IV classifies developmental coordination disorder as the only motor skills disorder.

EPIDEMIOLOGY

The prevalence of developmental coordination disorder has been estimated at approximately 5 percent of the school-age population. Developmental coordination disorder has been noted in Europe, Asia, Africa, Australia, and North America. Although it has been traditionally assumed that clumsiness is more prevalent among

males than females, two recent studies indicate that the prevalence figures are the same for male and female children. Discrepancies between these latest findings and earlier estimates of gender differences have been attributed to either of two factors: a tendency for schools to refer more males than females for testing and possible special education and related services, and societal pressures for males to excel at physical tasks at earlier ages than their female counterparts. Further research is required to resolve the present gender imbalance debate.

ETIOLOGY

The mechanisms and causes of developmental coordination disorder are unknown. Different conceptualizations of the disorder exist, but research supporting or differentiating those views is very limited.

Evidence indicates both biological-organic and cognitive-developmental correlates of developmental coordination disorder. The biological-organic factors associated with the disorder include various birth and perinatal problems, such as low birth weight, prematurity, hypoxia, and neonatal malnutrition. Some investigators have postulated a continuum of reproductive casualty. There are also suggestions of incomplete cerebral dominance or lateralization, neurochemical abnormalities in the brain, and structural lesions in the parietal lobes.

Cognitive-developmental problems sometimes associated with developmental coordination disorder include speech-language disorders and delays, hyperactivity, distractibility, impulsivity, and academic and learning difficulties. Apparently, the association between speech-language problems and coordination problems is quite strong. Studies of children with motor coordination delays have frequently reported delays in speech and language development; similarly, studies of children with specific language impairment have frequently reported motor delays and difficulties. One recent study of 82 school-age children with specific, severe speech and language disorders revealed that 90 percent were clumsy and 22 percent had walked late (after 18 months of age).

Whether the association between coordination difficulties and speech-language difficulties is global or is limited to specific aspects of coordination and communication is not known. However, the literature suggests that the associations may be rather specific. One longitudinal study of children with language impairments revealed a continuing correlation between peg-moving performance and language performance. Another study found that fine motor skills, response speed, and upper limb speed were associated with language disturbances whereas gross motor coordination and visual motor control were not. Furthermore, evidence indicates articulation problems are related to motor impairment, even though the motor impairment is not necessarily dyspraxia.

The evidence for any one of those postulated factors is inconclusive. Most likely, developmental coordination disorder has multiple causes. One recent study of motor coordination, speed, and inhibition in poor achievers suggested two underlying processes: specific motor deficits and developmental motor lags.

DIAGNOSIS AND CLINICAL FEATURES

The essential feature of developmental coordination disorder is poor motor coordination. The manifestations may include difficulties or delayed development in fine and gross motor coordination skills. However, motor skills tend to be imprecise or clumsy rather than globally impaired.

Coordination problems are diagnosed according to movement characteristics, generally observed while the person is engaged in several different types of tasks requiring the use of different muscle groups. They are clinically assigned to one or more of seven diagnostic categories: dyspraxia, synkinesia, hypotonus, hypertonus, tremors, impersistence, and asymmetries. *Dyspraxia* describes the inability of the child to produce correctly sequenced, coordinated motor movements when presented with a demonstration or an oral request. Movements identified as *synkinesia* are best described as unintentional muscle movements, also termed *muscle overflow*. Mirror-movements such as finger twitching on the opposite hand when the child is asked to perform a finger opposition task, or facial grimaces when the child is asked to make hand movements, are examples of synkinetic motor actions.

Two categories clinically describe tonus abnormalities, hypotonus and hypertonus. *Hypotonus* can be observed in all parts of the body and is characterized by a flaccid or sleepy quality in the child's facial expression and general muscle tone. These children appear lazy and unfit; the condition is often accompanied by poor posture and obesity. *Hypertonus* describes generally high levels of muscle tone in a child. For example, a child with hypertonus movement cannot finish drawing a line at a given point, instead overshooting the intended stopping point. Another example is a child who tends to throw a ball too hard and inaccurately at short distances.

The movement category of *tremors* is marked by irregular unsteadiness in motor movements observed in tasks requiring walking and/or drawing. For example, legibly formed letters might reveal on closer inspection, rapid tremors in the actual lines themselves. Unsteadiness might be exhibited in the child's gait as high-amplitude fluctuations in leg muscle movement.

The category of *impersistence* refers to the child's inability to sustain and maintain various body postures for reasonable periods of time. Asking a child to “stick out your tongue” is an example of a task used often to investigate impersistent motor movements. In this example, the clinician would keep track of how long the child could maintain this tongue position.

The final movement category, *asymmetries,* describes motor behaviors that affect only one side of the body. This category includes unusual flexions, muscle weakness, or both on one side of the body or general muscle weakness in the limbs on one side. These asymmetric muscle movements can be observed by requiring a child to move laterally in a rapid manner (“like a basketball player on defense, not crossing your feet”). If the child executes the movement more fluidly on one side than on the other, it might indicate an asymmetry.

Specific manifestations vary across individuals; thus there is no typical clumsy child. In some instances, manifestations may be quite specific; one case report describes a child who could sew and do jigsaw puzzles without difficulty but could not write neatly. In fact, total disability in any one area of motor performance is rare.

A common symptom is a history of delays in achieving motor milestones (e.g., sitting, standing, crawling, and walking). Gross motor coordination manifestations may be seen in difficulties with such activities as sitting, walking, running, balancing, throwing, and kicking. Fine motor coordination manifestations may be seen in difficulties in performing such tasks as tying laces, fastening fasteners, drawing, tracing, sewing, and printing or writing. During coordination tasks, children with developmental coordination disorder often (but not always) exhibit fine choreiform movements in unsupported limbs, mirror movements or persistent associated movements, slight abnormalities of reflex, rhythmic disturbances, and other neurological signs.

Some manifestations of developmental coordination disorder are age dependent. Young children show such symptoms as delayed development in early motor milestones and delayed acquisition of such self-help skills as self-dressing (i.e., tying ties, fastening snaps, zipping zippers, buttoning, and unbuttoning) or self-feeding (handling a knife, fork, or spoon). Preschool-age children may also have balance problems, awkward gait, and a history of frequently bumping into objects, falling down, and getting bruised. Problems with balance, hopping, jumping, catching and bouncing a ball, and tracing appear to be among the more common symptoms of school-age children with developmental coordination disorder. Another common sign among school-age children is the very strong motivation (often to the point of truancy) to avoid physical education classes.

In addition, children with developmental coordination disorder frequently suffer from other developmental-learning difficulties. Among the more common of these difficulties are expressive language disorder, mixed receptive-expressive language disorder, phonological disorder, reading disorder, disorder of written expression, and mathematics disorder.

Secondary complications primarily involving peer group problems are frequently reported in developmental coordination disorder. The repeated failures that the children experience in sports and games often engender peer rejections and subsequent relationship and social adjustment problems. The DSM-IV diagnostic criteria for developmental coordination disorder are listed in Table 36-2. The ICD-10 diagnostic criteria for specific developmental disorder of motor function are presented in Table 36-3.

A. Performance in daily activities that require motor coordination is substantially below that expected given the person's chronological age and measured intelligence. This may be manifested by marked delays in achieving motor milestones (e.g., walking, crawling, sitting), dropping things, clumsiness, poor performance in sports, or poor handwriting.
B. The disturbance in criterion A significantly interferes with academic achievement or activities of daily living.
C. The disturbance is not due to a general medical condition (e.g., cerebral palsy, hemiplegia, or muscular dystrophy) and does not meet criteria for a pervasive developmental disorder
D. If mental retardation is present, the motor difficulties are in excess of those usually associated with it.

Coding note: If a general medical (e.g., neurological) condition or sensory deficit is present, code the condition on Axis III.

Table 36-2 DSM-IV Diagnostic Criteria for Developmental Coordination Disorder

A. The score on a standardized test of fine or gross motor coordination is at least 2 standard deviations below the level expected for the child's chronological age.
B. The disturbance described in criterion A significantly interferes with academic achievement or with activities of daily living.
C. There is no diagnosable neurological disorder.
D. *Most commonly used exclusion clause.* I.Q. is below 70 on an individually administered standardized test.

Table 36-3 ICD-10 Diagnostic Criteria for Specific Developmental Disorder of Motor Function

Differential Diagnosis Informal screening for gross motor coordination (e.g., hopping, jumping, and standing on one foot), fine motor coordination (e.g., finger tapping, shoelace tying), and hand-eye coordination (e.g., catching a ball and copying letters) is helpful in identifying difficulties. However, the cutoff between the normally clumsy child and the child with developmental coordination disorder is not always clear. The general guideline is that coordination difficulties interfere with academic achievement or activities of daily living. Formal tests of motor coordination (e.g., the Bruininks-Oseretsky Test of Motor Development, the Frostig Movement Skills Test Battery, the Slosson Drawing Coordination Test, the Southern California Sensory Integration Test, and the Stott Test of Motor Impairment) provide a comparative measure of a child's abilities.

Differential diagnosis must rule out other disorders that may lead to coordination problems, such as specific neurological disorders (cerebral palsy or lesions), pervasive developmental disorders, and generalized mental retardation. Children with physical-neurological disorders tend to exhibit more-global coordination difficulties. Children with mental retardation and pervasive developmental disorders do not show a large discrepancy between coordination skills and other skills.

Clumsiness due to excessive motor activity (in attention-deficit/hyperactivity disorder) must also be ruled out. The tendency for children with developmental coordination disorder to fall down, hurt themselves, and break objects may evoke presenting complaints of behavioral problems such as destructiveness. In the school setting, a child's motor difficulty with manipulating a pencil may result in discouragement and refusal to continue trying, which are mislabeled as laziness. Children with developmental coordination disorder have reportedly presented medically under the guise of various psychosomatic aches and pains.

Kevin (benign hypotonia) was brought to a university clinic for evaluation for suspected muscular dystrophy by his parents when he turned 7 years of age. In an initial interview, parents reported that Kevin had difficulty sitting up without assistance through 23 months of age and, over the past year and a half, had begun to put on excessive weight and had no interest in physical activities.

A comprehensive assessment of fine and gross motor skills yielded the following results: Kevin attempted to complete a skipping task with only partial success; he could initiate a skipping motion but could only succeed with one foot at a time. Kevin could stand with both feet together but could not rise on the balls of his feet without excessive wobbling. Assessment of dynamic balance showed that Kevin could walk on a balance beam 4 inches wide but not one less than 2 inches wide. Kevin's measured throwing motion resembled that of a 5-year-old: he could not step forward simultaneously on the leg opposite his throwing arm. Although Kevin could catch a ball, he cradled a ball bounced to him at chest-high level with stiff arms; he could not catch a tennis ball bounced to him on the ground from a distance of 15 feet. Kevin's agility and coordination were measured with the Bruinink's Oseretsky battery, which revealed functioning levels commensurate with those of an average 5-year-old child.

Based on these assessment results, Kevin was given the diagnosis of benign hypotonia, a nonprogressive disorder believed to be connected to central nervous system deficits. A rigorous physical conditioning program was recommended that included work with physical and occupational therapists as well as a coordinated adapted physical education program to be implemented at Kevin's elementary school. This intervention program was based on several accepted principles of motor learning and acquisition. First, all practice of motor skills took place 3 days a week, with rest days in between for more rapid improvement. Second, it was suggested that parents provide extrinsic rewards to Kevin for his participation in the program; in this case, he would be rewarded with trips to the zoo, park, and so forth by members of his family. Third, all specific motor performance objectives were clearly explained to Kevin as he participated in weekly tasks; for example, skipping activities were demonstrated for Kevin, and his success was graphed and placed on a bulletin board at the physical therapist's office. Finally, Kevin's improved performance on specific tasks was generalized to new environments and activities; for example, catching skills developed through a training program with the physical therapist were later applied to playground activities in adapted physical education at Kevin's school.

As a direct result of 10 months of this comprehensive training program, Kevin mastered many of his motor training performance objectives, and his parents reported that Kevin's weight had stabilized. Additionally, his family reported that Kevin had indicated that he now enjoyed participating in physical education activities at school and wanted to play games with neighborhood friends. At follow-up, the family was told that Kevin should be encouraged to maintain a systematic exercise program to prevent further weight gain and loss of muscle tone.

Maureen (dysgraphia), a 14-year-old student, had been referred to her school's Student Study Team for evaluation to determine whether she had a specific learning disability. The referring teacher had noticed that Maureen's handwriting was barely legible, with poorly formed letters, lack of appropriate spacing between words, and generally poor line quality (i.e., words appearing below and above page lines). One of the team members observed Maureen in class and also noticed that Maureen exhibited a high degree of tension in her face while writing, grimacing periodically as she attempted to form letters and words in handwriting exercises.

A comprehensive battery of tests was administered, including the Test of Written Language, third edition (TOWL-3) and the Zaner-Bloser. Results showed that despite average intellectual functioning and exposure to formal education in handwriting, Maureen had a specific learning disability in the area of handwriting and was thus eligible for special education and related services. More specifically, Maureen was identified as having the specific learning disability known as dysgraphia. Further informal assessment showed that Maureen could print block letters containing right angles (e.g., F, E) but could not execute the smooth fine-motor movements necessary to produce letters formed from circles (e.g., O, Q).

Based on these assessment results, the team decided that Maureen would receive assistance from a resource specialist for one period during the school day. This assistance consisted of using multisensory drill techniques accompanied by fading exercises to overlearn circular letter formation. Additionally, gross-motor skill strengths were used to teach letter formation by using sky-writing tasks. Generalization of these handwriting skills was ensured by allowing Maureen to use letter-formation cards at her desk to reinforce her handwriting when completing independent seatwork.

Maureen made good progress with this program, mastered the formation of all manuscript letters, and progressed to working on cursive letters. Assistance by the resource specialist was discontinued and in a follow-up meeting with the team Maureen's parents reported that they were satisfied with Maureen's academic progress. The family was told that learning typewriting skills with computer word processing software might facilitate development of Maureen's written composition skills.

COURSE AND PROGNOSIS

Little is known about the outcome of developmental coordination disorder; however, impaired coordination appears to be relatively stable. A 2-year follow-up study of children of primary school age who had failed a motor test battery revealed motor performance that, although improved, was still inferior to that of controls. The children with motor impairments also showed poorer educational performance than controls.

A more recent study reported on a 10-year follow-up of clumsy children and their age-matched, sex-matched peers. When first identified, the clumsy children were approximately 6 years of age; at follow-up they ranged from 15 to 17 years of age. Follow-up testing indicated that the clumsy children were still significantly below the controls in most motor skills (e.g., dexterity, ball skills, balance, cutting with scissors, catching, walking backward) and in global ratings by physical education teachers. The clumsy adolescents showed higher rates of dysgraphesthesia, dysdiadokinesis, and motor slowness. In addition the educational achievements of the clumsy adolescents were significantly poorer, and they had significantly lower perceived social competence than their nonclumsy peers. That finding substantiates reports of continuing secondary problems, including peer problems, low self-esteem, and academic difficulties.

Different aspects of motor coordination may progress at different rates. One study of 50 kindergarten and first-grade children typically found some improvement but overall continued poor performance in motor skills. Improvement was greatest in motor speed and poorest for motor inhibition.

TREATMENT

Although motor training programs gained wide acceptance in remediating various types of learning disorders in the late 1960s, 1970s, and early 1980s, no research supports the notion that motor skills training in isolation results in gains in academic achievement. However, two particular programs are widely accepted by schools as effectively addressing the motor needs of individuals with developmental coordination disorder: adaptive physical education and sensory integration programs. Adaptive physical education programs are basically physical education programs modified to help students with developmental coordination disorder enjoy exercise, recreation, and leisure activities. Such programs usually emphasize inclusion of movement games into the physical education regimen (e.g., serving a volleyball or kicking a football). For this approach to be effective, it is recommended that adaptive physical education programs be available at least two to five times a week, in sessions lasting from 40 minutes to an hour.

Sensory integration programs are usually delivered as a related service to children with developmental coordination disorder under the direction of occupational therapists. These programs prescribe specific physical therapies that attempt to modify the motor and sensory functioning of these children. The entire set of therapies are based on the notion that sensory integration disorders interfere with both body movements and body awareness. Activities are designed to target the tactile, vestibular, and proprioceptive systems. Some children with developmental coordination disorder, for instance, experience “tactile defensiveness” (discomfort when touched by another person). In addressing a disorder affecting the tactile system, occupational therapists might use a sensory integration program that includes touching and rubbing skin surfaces, using creams, and brushing skin surfaces (if working with infants). A sensory integration program that addresses disorders affecting the proprioceptive system (bumping into walls, inability to button, skip, or write) might involve using scooter boards to improve balance and body awareness.

SUGGESTED CROSS-REFERENCES

Mental retardation is discussed in Chapter 34, pervasive developmental disorder in Chapter 38, and attention-deficit disorders in Chapter 39. Reading disorder is covered in Section 35.1, mathematics disorder in Section 35.2, disorder of written expression in Section 35.3, expressive language disorder in Section 37.1, mixed receptive-expressive language disorder in Section 37.2, and phonological disorder in Section 37.3.

CHAPTER 37. COMMUNICATION DISORDERS

37.1 EXPRESSIVE LANGUAGE DISORDER

CARLA J. JOHNSON PH.D., AND JOSEPH H. BEITCHMAN, M.D.

Spoken communication is fundamental to most human endeavours. A child who is not proficient in communication may be unable to participate fully and competently in many personal, social, academic, and recreational situations. In turn, limited participation in these key life events may jeopardize further growth in communication and related abilities. Effective communication requires mastery of both language, the conventional code used to express ideas about the world, and speech, the complex and rapid motor movements that translate ideas into spoken words. Communication disorders affect language, speech, or both of these key abilities. The fourth edition of *Diagnostic and Statistical Manual of Mental Health Disorders* (DSM-IV) includes two diagnostic categories for language disorders (expressive and mixed receptive-expressive language disorders), two for speech disorders (phonological disorder and stuttering), and one for communication disorders not otherwise specified.

DEFINITION, AND COMPARATIVE NOSOLOGY

Children with expressive language disorders have difficulty communicating their needs, thoughts, and intentions via spoken language. They frequently (1) have speaking vocabularies that are limited in size and variety; (2) use sentences that are short, incomplete, or ungrammatical; and (3) relate stories and events in a disorganized, confusing, or unsophisticated manner. These communication problems are evident despite performance within the normal range on measures of hearing acuity, nonverbal intelligence, and understanding (comprehension, reception) of spoken language. As with many other childhood mental disorders, the definitional and diagnostic issues concerning expressive language disorders are complex and often controversial.

DSM-IV makes a categorical distinction between expressive language disorder, which affects only production of spoken language, and mixed receptive-expressive disorder, which also affects comprehension of spoken language. The distinction accords with common practice and with evidence that the two disorders vary in prognosis and comorbid conditions.

Many experts, however, question whether separate categories are warranted. An alternative view is that expressive language disorder represents a less severe manifestation of the same underlying problems of mixed receptive-expressive disorder. In this view, differences in severity account for the differences in prognosis and comorbidity. The view also accords with evidence that children with expressive language disorder frequently exhibit mild concomitant deficits in language comprehension and typically exhibit expressive language features similar to those shown in receptive-expressive language mixed disorder.

DSM-IV does not include a diagnostic category for receptive disorders in the presence of intact expressive language. The exclusion can be defended on the basis that in normal development, language comprehension usually precedes production. In some cases of pervasive developmental disorder or spina bifida, however, language comprehension skills appear to be weak relative to productive abilities. Further study of these children with possible receptive deficits may help to refine the understanding and diagnosis of language disorders.

Within the category of expressive language disorders, DSM-IV recognizes two types, which are also generally acknowledged in the literature on communication disorders. The developmental type, by far the most common, has no known cause and manifests gradually in delayed onset and below normal rates of expressive language growth. The acquired type, which is quite rare, arises suddenly from a known neurological cause, such as disease or head trauma. For the practitioner, the inclusion of developmental and acquired types under the same DSM-IV diagnostic category may be misleading. Although the two types are similar in certain expressive language manifestations, they vary substantially in etiological factors, prevalence, course, prognosis, treatment, and comorbid conditions.

Another controversial aspect of the DSM-IV scheme is its use of cognitive referencing, the requirement that nonverbal cognitive performance must be substantially higher than language performance for diagnosis of a language disorder (expressive or mixed). For years, cognitive referencing was a widely accepted practice in defining language disorders because it presumably identified children whose language growth was not keeping pace with their nonverbal cognitive development. Recently, cognitive referencing has been challenged on various theoretical and psychometric grounds. A key theoretical concern is that nonverbal cognitive functioning does not necessarily limit a child's potential for language growth, as is implied by cognitive referencing. For instance, children with little or no discrepancy between nonverbal and verbal scores may benefit from language intervention as much or more than those with a large discrepancy between the two. A related psychometric concern is that a discrepancy in performance on language and cognitive tests may be spurious if the effects of measurement error are not adequately considered, as is often the case in diagnostic practice. Further theoretical and empirical efforts are needed to resolve these issues.

The DSM-IV classification scheme is similar, but not identical, to other well-known diagnostic schemes, such as that of its predecessor, the revised third edition of DSM (DSM-III-R) and the 10th revision of the *International Statistical Classification of Disease and Related Health Problems* (ICD-10). DSM-III-R included separate expressive and receptive categories, but the expressive category could be coded either alone or as an associated feature of the receptive disorder. In DSM-IV and ICD-10, the categories of expressive and mixed (receptive) disorders are mutually exclusive. DSM-III-R and ICD-10 consider only developmental language disorders. The mention of acquired types is unique to DSM-IV. A number of other schemes for classification or subtyping of childhood language disorders are also elaborated in the scientific literature. The result is a diverse set of terms that refer to types and subtypes of childhood language disorders (developmental dysphasia, auditory verbal agnosia, semantic-pragmatic disorder), many of which do not correspond in a straightforward manner to the DSM-IV categories.

EPIDEMIOLOGY

Developmental Type Prevalence estimates for developmental language disorders (combined expressive and mixed receptive-expressive) range from 3 to 13 percent of children, depending on the age of the children surveyed, the nature of the sample tested (community or clinic-referred), and the specific language measures and definitional criteria used. DSM-IV suggests that the expressive form of developmental language disorder has a prevalence rate of 3 to 5 percent in school age children, which is generally consistent with results from the few studies that have separately identified expressive disorders.

Boys are more likely than girls to have developmental language disorders, including expressive language disorder. In some studies, boys outnumbered girls by ratios as high as 5 to 1. In others, the sex imbalance was less pronounced, with ratios of 2 to 1 or even less observed. The discrepancies likely reflect differences in sampling practices, testing procedures, and definitional criteria.

Evidence is mounting in support of familial aggregation of developmental language disorders, but there are few relevant data specific to expressive language disorder. One research group found no evidence of familial aggregation in a sample of 2-year-olds with expressive delays (but not necessarily disorders). A study of older children yielded higher rates of familial aggregation for children with expressive disorders than for those with mixed receptive-expressive language disorder. Further work is needed to establish whether expressive language disorder aggregates in families and, if so, to identify specific genetic and environmental contributions to such familial effects.

Acquired Type Acquired language disorders are rare in children, with those specific to expressive language rarer still. Prevalence rates, sex ratios, and familial aggregation data are available for certain specific causes (e.g., stroke, head injury) but not for the heterogeneous category of acquired expressive language disorder.

ETIOLOGY

Developmental Type The causes of developmental language disorders are unknown and most probably heterogeneous. Theoretical and empirical etiological efforts typically have focused on developmental language disorders in general, not on expressive language disorder in particular. A variety of biological and environmental risk factors have been identified, but none have been confirmed as causal agents.

Acquired Type Acquired language disorders arise suddenly, at any age, as a result of known neurological conditions such as stroke, head injury, disease, poisoning, or seizure disorder. At their onset, many acquired disorders affect both receptive and expressive language. Following a period of spontaneous recovery, language problems may partially resolve to be primarily expressive in nature. Selective expressive deficits also result on occasion from a focal injury to the left hemisphere, for example, from a gun shot wound or stroke.

DIAGNOSIS AND CLINICAL FEATURES

Expressive language disorder is diagnosed when a selective deficit in expressive language development occurs in the presence of intact nonverbal intelligence and receptive language skills (Table 37.1-1). Children with expressive disorders do acquire language, albeit at a slower rate than their peers. Accordingly, the specific manifestations of expressive language disorder change with maturation. Affected children often show expressive language characteristics that resemble those of younger children who are developing language at a normal rate. Table 37.1-2 provides an overview of typical milestones in language and nonverbal development. Although milestones are listed only up to age 8, it is commonly recognized that substantial growth in vocabulary, grammar, and language use continues through adolescence.

A. The scores obtained from standardized individually administered measures of expressive language development are substantially below those obtained from standardized measures of both nonverbal intellectual capacity and receptive language development. The disturbance may be manifest clinically by symptoms that include having a markedly limited vocabulary, making errors in tense, or having difficulty recalling words or producing sentences with developmentally appropriate length or complexity.
B. The difficulties with expressive language interfere with academic or occupational achievement or with social communication.
C. Criteria are not met for mixed receptive-expressive language disorder or a pervasive developmental disorder.
D. If mental retardation, a speech-motor or sensory deficit, or environmental deprivation is present, the language difficulties are in excess of those usually associated with these problems.

Coding note: if a speech—motor or sensory deficit or a neurological condition is present, code the condition on Axis III.

Table 37.1-1 DSM-IV Diagnostic Criteria for Expressive Language Disorder

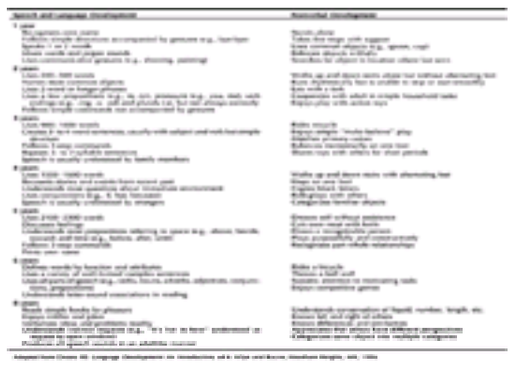

Table 37.1-2 Normal Development of Speech, Language, and Nonverbal Skills in Children

Developmental Type Expressive disorders may be observed to varying degrees in one or more aspects of the content, form, or use of language. Difficulties with content may be evident in a small vocabulary and limited ability to express complex or abstract ideas. Problems with the form of language may be manifest in short, incomplete, and ungrammatical sentences or in marked delays in learning the correct use of certain grammatical forms, such as pronouns (e.g., *he, she, they*), auxiliary or modal verbs (e.g., *is, were, could*), plurals (e.g., *cats, geese*), and verb tense endings (e.g., *-ing, -s, -ed*). Restrictions in the use of language may limit the expression of a range of communicative purposes (e.g., question, explain, comment) or the ability to maintain and extend conversational topics. Particular difficulties may arise in connected discourse, for instance, in telling stories, relating events, or giving explanations. The discourse may be uninformative, poorly organized, and difficult to follow.

Miguel was an alert, energetic 2-year-old with an expressive vocabulary that consisted of only five words (mama, daddy, bottle, up, bye-bye). He communicated by using these words one at a time or by pointing or using other simple gestures. He typically used his words and gestures to request desired objects or actions, but rarely used them for other communicative purposes (e.g., commenting, protesting). Except for his limited language skills, he appeared to be developing normally in other areas. He sat, stood, and walked at the expected times. He enjoyed the company of other children. His play skills and preferences were comparable to those of other 2-year-olds. He had a history of frequent ear infections, but a recent hearing test revealed normal hearing. Comprehension testing, carefully conducted to ensure his attention and motivation, indicated that he understood the names for most familiar objects and actions. He also had no difficulty following the types of simple verbal instructions that are understood by most children his age (e.g., Show me your eyes. Get your shoes. Say “bye-bye.”).

Although Miguel was clearly developing language more slowly than most children his age, it was not yet clear that he had an expressive language disorder. Recent prospective research on the development of children like Miguel, often termed *late talkers*, suggests that a significant percentage of them will spontaneously overcome their initial slow start in language development.

Jennifer was a sociable, active 5-year-old who was diagnosed with expressive language disorder. She often played with her best friend, Sarah. One day, in the course of pretend play, each girl told the story of Little Red Riding Hood to her doll. Sarah's story began: “Little Red Riding Hood was taking a basket of food to her grandmother who was sick. A bad wolf stopped Riding Hood in the forest. He tried to get the basket away from her but she wouldn't give it to him.”

By contrast, Jennifer's story illustrated her marked difficulties in verbal expression: “Riding Hood going to grandma house. Her taking food. Bad wolf in a bed. Riding Hood say, what big ears, grandma? Hear you, dear. What big eyes, grandma? See you, dear. What big mouth, grandma? Eat you all up!”

Many features of Jennifer's story were characteristic of children with expressive language disorder, including the short, incomplete sentences, the simple sentence structures, the omission of grammatical function words (e.g., *is, the*) and endings (e.g., possessive -'*s*, present tense verb -*s*), the problems in question formation, and the incorrect use of pronouns (e.g., “her” for *she*). Nonetheless, when tested by methods that did not require verbal responding, it was clear that Jennifer understood the details and plot of the Riding Hood tale as well as Sarah did. Jennifer also demonstrated adequate comprehension skills in her kindergarten classroom, where she readily followed the teacher's complex, multistep verbal instructions (e.g., “Before you get ready for recess, make sure that you draw a green circle around all the animals, put your library books under your chair, and line up at the back of the room.”).

Sean was a quiet, sullen 8-year-old whose expressive language problems were no longer obvious in casual, social conversations. He now rarely omitted words or made grammatical errors as he often did when he was younger. His expressive difficulties, however, were still apparent in tasks that require more elaborate or reflective use of language, including many that were part of his third-grade academic work. Take, for example, his explanation of the outcome of a simple science demonstration: “The teacher had stuff in some jars. He poured it and it got pink. The other thing made it white.” Although each sentence was grammatical by itself, the entire explanation was difficult to follow, as important ideas and details were omitted or poorly explained. Sean also showed problems in word finding, that is, in using specific words for the concepts and actions he was describing. Instead, he relied on vague and nonspecific terms such as *thing, stuff*, and *got*. Similar problems were evident in his written work. In earlier grades, Sean kept up with his classmates fairly well in reading and other activities, but the increased demands for written work in third grade negatively affected his overall academic standing. He also began to experience some teasing from classmates, to which he reacted quite aggressively, sometimes to the point of fighting. Nonetheless, he continued to show relatively good comprehension of spoken language, as evidenced by his ability to follow classroom lectures and to understand sentences that were grammatically and conceptually complex (e.g., “The boy the girl hit had a shirt with an abstract design; Had it been possible, they would have traveled in a van or in a bus.”).

It is relatively common for other disorders of speech, learning, development, and behavior to occur with expressive disorders. In preschoolers, the most common concomitant disorder is phonological disorder, which, if severe, may persist into the early school years. Problems in acquisition of written language may also be diagnosed at school age. Reading disorder is the most common of these, but disorder of written expression may also occur. Some children also show developmental coordination disorder.

Concomitant psychiatric disorders may also occur in as many as half of the children with persistent expressive language disorders. By far the most common associated psychiatric diagnoses are attention-deficit disorders, but externalizing or internalizing disorders may also be observed.

Most children with developmental expressive disorders have no overt neurological symptoms (e.g., electroencephalographic [EEG] abnormalities, seizures, dysarthria, or dyspraxia). The presence of neurological symptoms does not, however, preclude diagnosis of developmental expressive disorder, unless their onset is attributable to a known, acquired brain insult.

Acquired Type Acquired expressive language disorder may manifest somewhat differently than developmental disorders. The most common difference (after initial recovery stages) is that expressive grammar skills (language form) may be relatively preserved, resulting in sentences that resemble those of age-mates in length and grammatical complexity. Problems in word finding and discourse organization are common in acquired disorders but may be qualitatively different than the word-finding and discourse difficulties shown in developmental disorders. Qualitative differences in symptomatology may also be observed across different etiological factors for acquired language disorders.

Louise developed normally until age 10, when she had a stroke that caused focal left hemisphere damage. Immediately following the stroke, Louise could not speak and showed some comprehension difficulties. She also experienced hemiparesis, a partial paralysis on the right side of her body. In the weeks following the stroke, Louise quickly regained her language comprehension skills. Her expressive language skills recovered more slowly. When she began to speak again, she used short, telegraphic sentences with few grammatical function words or endings. Her speech, mildly dysarthric, was slow, labored, and slurred. Gradually the complexity of her sentences and the rate and precision of her speech returned to normal. Six months after her stroke, the hemiparesis had also resolved. Louise continued, however, to show subtle residual expressive problems, particularly in word finding during discourse. She often inadvertently replaced words that she intended to say with others that were closely related in meaning (e.g., “broccoli” for *cauliflower*) or sound (e.g., *symphony/sympathy*). Despite relatively complete recovery of her language skills, Louise experienced residual memory and attention problems that interfered with her academic performance in fifth grade. Louise was a competent student prior to her stroke but now became easily frustrated with her changed and inconsistent performance.

As in Louise's case, neurological insults may also affect cognitive, affective, gross motor, and speech motor skills, either temporarily or permanently. Many children with acquired disorders recover sufficiently to score within the normal range on structured intelligence tests but may not function adequately in less structured settings, such as school or home. Not surprisingly, overt neurological symptoms are more frequently associated with acquired disorders than with developmental ones. Concomitant conditions may include speech disorders, learning disorders, and (perhaps) behavioral and emotional difficulties severe enough to warrant psychiatric diagnosis.

DIFFERENTIAL DIAGNOSIS

Differential diagnosis of developmental expressive language disorder requires standardized evaluations of expressive language, receptive language, and nonverbal intellectual functioning (Table 37.1-1 and Table 37.1-2). Expressive language development must fall substantially below (1) the range of normal expressive performance expected for a child's age, (2) receptive language performance, and (3) nonverbal intellectual performance. Further, the expressive language difficulties must be severe enough to impair academic performance or social communication. To help determine whether this clinical severity criterion is met, standardized testing is often supplemented with observational techniques and analysis of spontaneous language use.

Substantial deficits in either receptive language or nonverbal intelligence preclude the diagnosis of expressive language disorder but may contribute to the diagnosis of other disorders that affect language growth. If both expressive and receptive deficits occur in the absence of nonverbal deficits, the diagnosis of mixed receptive-expressive language disorder is appropriate. If language and nonverbal functioning are both substantially below age level expectations, the diagnosis of mental retardation should be made.

A hearing test should also be a regular part of the diagnostic procedure when expressive language disorder is suspected. Many children with expressive problems experience regular ear infections or allergies, which may be accompanied by mild hearing loss of a transient or persistent nature. Medical treatment and monitoring of such conditions is warranted. A hearing test may also identify cases of language delay associated with more severe hearing impairments, in which hearing aids or other amplification devices may assist in language learning. If expressive language deficits exceed those expected for a given degree of hearing impairment or mental retardation, a concurrent diagnosis of expressive language disorder may be made.

Language delay is also associated with environmental deprivation, pervasive developmental disorders, and selective mutism. A careful history will help identify environmental deprivation. Observations of disturbed social interaction and communicative intent, as well as unusual repetitive behaviors, will suggest pervasive developmental disorder. Documentation of relatively normal expressive language use in some settings (e.g., home) but refusal to speak in others (e.g., school) indicates selective mutism.

Children from diverse linguistic and cultural backgrounds may pose a particular diagnostic challenge because it may be difficult to decide whether particular language characteristics are normal in the acquisition of a new language or reflect a disorder. Cultural and linguistic barriers may also make it difficult to communicate, not only with the child, but also with other family members for the purposes of collecting case history data and conveying assessment results. Nonetheless, it is usually possible to conduct at least a preliminary language assessment. If inconclusive results are obtained, the child can be monitored periodically to assess language progress.

The hallmark of the acquired type of expressive language disorder is a history of sudden onset of language symptoms associated with known neurological insult. Brain scans are often used to verify the existence and extent of brain lesions.

COURSE AND PROGNOSIS

Developmental Type Developmental expressive language disorder is characterized by considerable variability in severity, course, and outcome. Recently several research teams conducted prospective studies of late talkers (i.e., children with normal cognitive functioning who use fewer than 50 words and no word combinations at age 2). Experts disagree on whether late talkers actually meet criteria for the diagnosis of expressive language disorder. Nonetheless, their language delays often provoke parental concern and professional referral. The various studies of late talkers generally agree that 50 to 80 percent of these children achieve language skills within the normal range during the preschool years, with vocabulary skills perhaps recovering more fully than grammatical abilities. Most late talkers who recover during preschool appear to be at little risk for severe learning and behavioral problems, at least through the early school years. Nonverbal intelligence scores, receptive language levels, the extent of initial expressive delay, and the amount and variety of early communicative intentions have been suggested as possible

predictors of outcome in late talkers, but these suggestions require further empirical validation.

Prognosis is generally less favorable for children whose expressive language disorders persist into the late preschool or early school-age years. For these children, language growth proceeds but at a slower rate than for children who are developing typically. Children with persistent expressive disorders may also experience associated problems, particularly reading disorder and attention-deficit disorders. By adolescence, most children with expressive language disorder acquire sufficient language skill to function reasonably well in most daily communication activities. Subtle residual deficits may still be apparent in more demanding speaking tasks, such as those that require precise vocabulary and complex explanations. As a group, however, children with persistent expressive disorders show more favorable long-term outcomes than their counterparts with mixed receptive-expressive disorder.

Acquired Type Approximately two thirds of children with acquired language disorders recover to have language functioning that is broadly within the normal range, although subtle deficits may persist. Recovery may occur rapidly within days or weeks of the neurological insult or may be more protracted, occurring over months or even years. Persistent language and cognitive deficits of varying severity are seen in those who do not recover normal language functioning. Prognosis depends on a variety of factors, including the specific etiology for the disorder, the severity, extent, and location of brain damage, the age at injury, the extent of preinjury language development, and the existence of other preinjury disorders.

TREATMENT

Developmental Type Experts disagree on when intervention is warranted for expressive language disorder. Some suggest that a watch-and-see attitude is appropriate for young children with early expressive delays (late talkers) because most will acquire language functioning within the normal range during preschool. Intervention to improve expressive language would only be provided for children whose problems persist to age 4 or 5. Others argue that this policy would deny children early help that might serve to prevent or minimize later language, academic, and behavioral difficulties. Unfortunately, no relevant data are available on the efficacy of early versus late language intervention.

Research on the efficacy of language intervention is, in fact, rather sparse. Most available efficacy studies have targeted children with developmental language disorders, not just those with expressive disorders. Nonetheless, a variety of techniques have been shown experimentally to result in improved use of specific expressive language features (e.g., pronouns, question forms, verb tense markers, complex sentence forms, narrative coherence) during intervention. What is not yet clear is whether such intervention can close or narrow the gap in language growth on a long-term basis and so prevent or ameliorate the adverse academic and psychosocial consequences sometimes associated with persistent language disorders.

Another issue concerns whether intervention should be direct or mediated. In direct interventions, a professional (usually a speech-language pathologist) serves as the primary intervention agent and works directly with the child. In mediated interventions, the professional teaches others (e.g., parents, teachers, paraprofessionals) to be the primary intervention agents. Mediated interventions are thought to make efficient use of professional time and to allow mediators to incorporate language facilitation techniques into daily activities and routines, thereby providing regular, naturalistic opportunities for children to use newly learned language features. Several recent studies indicated that both direct and mediated (parent) interventions can be effective in promoting language growth in children with developmental language disorders (expressive and mixed), at least in the short term. Late talkers were the target population in another recent randomized control study that also demonstrated that parents could be taught to use specific techniques to effectively promote short-term language growth.

Additional systematic, well-controlled research on treatment efficacy is clearly needed. Although the limited literature to date supports the possible benefits of intervention, it provides little guidance on whether or how interventions should be tailored to address the specific language needs of individual children.

Acquired Type Little if any research has systematically evaluated the efficacy of language intervention for acquired expressive disorders in children. Recommendations are available in the literature, however, concerning how to facilitate the integration of children who have suffered brain insults back into their home and school environments. Many of these suggestions address cognitive, motor, and emotional sequelae of brain damage, but others deal with common expressive language symptoms, such as word-finding and discourse organization problems. Recommendations often incorporate techniques devised for adults with acquired language disorders, some of which have been shown to be effective with that population.

SUGGESTED CROSS-REFERENCES

Section 37.2 describes mixed receptive-expressive disorder, which is similar in many respects to expressive language disorder. Another closely related disorder is reading disorder, which is discussed in Section 35.1. Several other disorders are relevant to the differential diagnosis of expressive language disorder, including mental retardation (Chapter 34), pervasive developmental disorder (Chapter 38), selective mutism (Section 46.4). Other disorders may occur with expressive language disorder, including mathematics disorder (Section 35.2), disorder of written expression (Section 35.3), developmental coordination disorder (Chapter 36), phonological disorder (Section 37.3), stuttering (Section 37.4), and attention-deficit disorders (Chapter 39).

37.2 MIXED RECEPTIVE-EXPRESSIVE LANGUAGE DISORDER

CARLA J. JOHNSON PH.D., AND JOSEPH H. BEITCHMAN, M.D.

DEFINITION, AND COMPARATIVE NOSOLOGY

Children with mixed receptive-expressive language disorders, like their peers with expressive language disorders, characteristically have small speaking vocabularies, use unsophisticated sentences, and produce disorganized stories and descriptions. More importantly, however, they also have problems in understanding (reception, comprehension) of spoken language. Children with receptive problems may have difficulty learning new words, particularly those with uncommon or abstract meanings. They may misinterpret conversational questions or comments, leading them to make inappropriate or nonsensical remarks. They may fail to understand lengthy or grammatically complex directions and explanations. Such comprehension failures may not be recognized and may instead be attributed incorrectly to inattention, stubbornness, or other behavioral problems.

The fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) definition of mixed receptive-expressive language disorder is similar in many ways to that for expressive language disorder. Both mixed receptive-expressive and expressive disorders are defined by language difficulties in the presence of normal levels of nonverbal intelligence. Both mixed receptive-expressive and expressive language disorders have developmental or acquired subtypes. The developmental forms have no known causes and are more prevalent; the acquired forms result from known neurological conditions and are less common. Not surprisingly, many of the problematic definitional and diagnostic issues that arise with respect to expressive language disorder also apply to mixed receptive-expressive language disorder.

EPIDEMIOLOGY

Developmental Type The prevalence of mixed receptive-expressive disorder has not been established definitively. Study methodologies and definitions have varied greatly, resulting in a wide range (3 to 13 percent) of prevalence estimates for developmental language disorder (all types). Moreover, some studies have counted children with mental retardation, hearing impairment, and pervasive developmental disorder as language disordered; others have excluded such children. DSM-IV suggests that the mixed receptive-expressive form of developmental language disorder has a prevalence rate of 3 percent in school-age children and may be less common than expressive language disorder. These suggestions, however, await empirical verification, as no existing prevalence study has specifically used the DSM-IV criteria for expressive and mixed receptive-expressive language disorders.

Boys are more likely than girls to have developmental language disorders, including mixed receptive-expressive language disorders. Sex ratios as high as 4 to 1 and as low as 2 to 1 have been reported across various studies.

Familial aggregation is also characteristic of developmental language disorders, but there are few available data specific to mixed receptive-expressive language disorders. Work continues to identify relevant disorder subtypes and to discover the possible genetic and environmental factors that underlie familial aggregation.

Acquired Type Acquired language disorders are infrequent in children. Both receptive and expressive language are usually affected initially. Spontaneous recovery of function often occurs to varying degrees, but residual deficits in both receptive and expressive language may persist. Prevalence rates, sex ratios, and familial aggregation data are not available for the heterogenous category of acquired mixed receptive-expressive language disorders.

ETIOLOGY

Developmental Type The cause of mixed receptive-expressive disorder is unknown. Several correlates of developmental language disorder have been identified, but it is not yet clear whether these factors are causative and, if so, how they operate. A plausible working hypothesis, given current evidence, is that language disorders are multiply determined, with both biological and environmental factors playing a role. The heterogeneity of the population is also consistent with the possibility that certain factors or combinations of factors may be critical in some cases, while other factors or combinations may be important in others. Attempts to understand causation have focused on seven general possibilities: (1) brain abnormalities, (2) genetic factors, (3) environmental influences, (4) neurodevelopmental immaturity, (5) general cognitive factors, (6) specific linguistic factors, and (7) auditory processes. The possibilities are not mutually exclusive, and each enjoys some empirical support. None, however, currently accounts for all cases of language disorder.

Structural or functional brain abnormalities have long been considered possible causative factors because the symptoms of developmental language disorders resemble those of the acquired language disorders that result from known neurological insults in both children and adults. Children with developmental language disorders typically do not show hard neurological signs indicating brain damage (e.g., paralysis, seizures). As a group, however, they often show elevated rates of various soft neurological signs (e.g., mixed cerebral dominance, attention problems, subtle motor difficulties). Neuroimaging studies also indicate that some children with language and learning disorders have abnormal neuroanatomical characteristics, particularly in areas of the left hemisphere known to be crucial for language processing. Nonetheless, many questions remain. The brain abnormalities identified thus far do not occur in all children with developmental language disorders, nor has their functional significance been established.

Genetic factors are also implicated in some (but not all) cases of developmental language disorder. Familial aggregation of language disorders is commonly reported, but possible modes of genetic transmission have not yet been ascertained. The fact that boys are affected more often than girls may also reflect genetic factors, although other influences may contribute.

Environmental determinants may be critical in certain cases and of limited importance in others. Developmental language disorders are more common in children from families with low socioeconomic status, as indexed by family income, parental occupational status, or parental education level. In turn, low socioeconomic status is correlated with other known risks for developmental language disorders, such as single-parent family status, large family size, pregnancy and birth complications, and abuse and neglect. Children from low socioeconomic families are also at risk for malnutrition, health problems, increased exposure to known toxins (e.g., lead), and limited educational and social opportunities. It is not yet clear whether or how these various factors may interact with each other and perhaps with biological factors to cause developmental language disorders.

Another view is that neurodevelopmental immaturity underlies developmental language disorders. Proponents point to evidence that language development is delayed, not deviant, and generally follows a normal sequence and course but at a slowed rate. Slow myelinization of neural pathways or delayed maturation of other neural structures might also account for other characteristics often seen in children with language disorders, including subtle fine motor and oral motor problems, behavioral difficulties, and soft neurological signs. Boys may be more likely to evidence neurodevelopmental immaturities than girls. A related view holds that children with developmental language disorder are not disordered at all, but simply fall at the lower end of the normal distribution of language-related skills. Because language skills are so crucial for success in our literate society, however, these children are perceived as handicapped. Children who fall in the lower end of the normal distribution on other abilities, for example, musical talent, are not perceived as handicapped because musical proficiency is not expected of every member of society.

General cognitive factors have also been suggested as candidates for the core deficit in developmental language disorders. One such factor is speed of cognitive processing. Children with language disorders often perform more slowly than children without disorders on a variety of linguistic (e.g., naming) and nonlinguistic (e.g.,

fine motor) tasks. Problems in speed of processing may disrupt the language learning process. Slow processing could also reflect neurodevelopmental immaturity. Another cognitive factor implicated in language disorder is phonological working memory, the skill required for immediate processing and maintenance of verbal information. Deficits in phonological working memory have been linked to problems in learning new vocabulary items and in developing proficient reading skills, two areas of deficit for many children with language disorder. It is not clear, however, that phonological memory deficits can account for all characteristics of language disorder.

Specific linguistic factors have also been investigated in relation to developmental language disorders. Some theorists argue that children with language disorders cannot fully exploit the regularities in the language that they hear to induce its underlying grammatical rules. Accordingly, children may have difficulty in acquiring sets of grammatical features that are thought to share an underlying linguistic relationship (e.g., articles *a, an, the*; determiners *this, that, these, those*; possessives, both noun and pronoun forms). Certain parameters of grammar are thought to be especially problematic for children with language disorders to induce. Theories of this sort, however, are primarily descriptive rather than explanatory at this stage in their development.

Finally, auditory problems have been studied as possible causes of developmental language disorders. One type of auditory deficit is the temporary, mild hearing loss that accompanies inflammation of the middle ear (otitis media), which may result from ear infections or allergies. Many young children suffer repeatedly from otitis media and associated hearing loss during their early years when language skills are developing. Current research suggests that otitis media alone does not suffice to cause language disorder but that it may interact, in as yet unknown ways, with other risk factors. A second type of auditory problem involves perception of sounds. Children with language disorders often show deficits in perceiving small sound differences and rapid auditory transitions, aspects of the acoustic signal that are critical to understanding speech. As with other proposed causal factors, however, neither type of auditory difficulty appears to occur in all children with developmental language disorder.

Acquired Type Acquired mixed receptive-expressive language disorder may result from a variety of neurological insults, including (1) closed head injuries resulting from motor vehicle accidents, falls, or other blows to the head; (2) open head injuries such as those from gunshot wounds; (3) cerebral vascular accidents such as strokes; (4) infections such as encephalitis or meningitis; (5) severe respiratory problems that may lead to intraventricular hemorrhage or anoxia; (6) drownings or near-drownings; (7) toxins such as lead or household poisons; (8) damage from tumors or radiation treatment; or (9) seizure activity. Landau-Kleffner syndrome (acquired aphasia with epilepsy) is a rare condition characterized by a sudden, marked deterioration of language skills accompanied by the onset of seizures or abnormal electroencephalographic (EEG) activity.

DIAGNOSIS AND CLINICAL FEATURES

Mixed receptive-expressive language disorder is diagnosed when selective deficits in receptive and expressive language development occur in the presence of intact nonverbal intelligence (Table 37.2-1). Children with the disorder do acquire language, but they do so at a slower rate than their peers. Thus, the specific symptoms of mixed receptive-expressive language disorder change with age. Affected children often show receptive and expressive language characteristics that resemble those of younger children who are developing language at a normal rate. The 10th revision of *International Classifications of Diseases and Related Health Problems* (ICD-10) provides diagnostic criteria for receptive language disorder and acquired aphasia with epilepsy (see Table 37.5-2).

A. The scores obtained from a battery of standardized individually administered measures of both receptive and expressive language development are substantially below those obtained from standardized measures of nonverbal intellectual capacity. Symptoms include those for expressive language disorder as well as difficulty understanding words, sentences, or specific types of words, such as spatial terms.
B. The difficulties with receptive and expressive language significantly interfere with academic or occupational achievement or with social communication.
C. Criteria are not met for a pervasive developmental disorder.
D. If mental retardation, a speech-motor or sensory deficit, or environmental deprivation is present, the language difficulties are in excess of those usually associated with these problems.

Coding note: If a speech—motor or sensory deficit or a neurological condition is present, code the condition on Axis III.

Table 37.2-1 DSM-IV Diagnostic Criteria for Mixed Receptive-Expressive Language Disorder

Developmental Type Mixed receptive-expressive language disorder may be observed to varying degrees in one or more aspects of the content, form, or use of language. The expressive manifestations of the disorder are usually similar to those described for expressive language disorder. The receptive difficulties typically have adverse effects on social interaction and academic performance. Receptive problems may be evident in tasks that tap comprehension of single words, sentences, and larger units of discourse. Single words that refer to common observable objects, actions, or relations may be adequately understood (e.g., bowl, key, pull, sleep, on, under), but those that have less-common, less-observable meanings may not be well known (e.g., liquid, creation, theorize, obtain, among, if). Likewise, sentences with simple grammatical structures may be comprehended (e.g., The rabbit is hopping, The car stopped), while those with more complex syntax may be misinterpreted (e.g., The boy who chased the girl was no longer my friend; If I were to take this trip, I would need the approval of my manager). Lengthy and complex instructions, questions, and explanations may be misunderstood. Children with mixed disorders may make inappropriate comments or contributions to the ongoing conversation because they fail to correctly interpret the language of others. Partial or incomplete understanding of the language of others may also contribute to confusion or inaccuracy in telling stories, relating events, and giving explanations. Expressive language limitations may further exacerbate these problems. Children with mixed receptive-expressive language disorders are sometimes thought to be stubborn or uncooperative because their comprehension difficulties are not recognized.

Maria was a quiet, even-tempered 2-year-old, who had not yet begun to use any recognizable words. She communicated with vocalizations and simple gestures (e.g., pointing, showing) similar to those typically used by younger children. She pointed, on request, to a few familiar people and objects in the environment (e.g., mommy, daddy, dog, shoe, cup). Compared with other children her age, however, she understood few words and rarely responded correctly to simple verbal commands (e.g., Get your book, Throw the shirt). Nonetheless, she had normal hearing acuity, had reached early motor milestones at the expected ages, and enjoyed simple symbolic play activities commensurate with those expected for her age (e.g., pretending to fall asleep, pretending to feed her doll).

Trang was a shy, reserved 5-year-old who grew up in a bilingual home, where his parents and older siblings spoke both English and Vietnamese proficiently. Trang began to understand and speak both languages much later than his siblings had, and he developed slowly in both. When he entered kindergarten, assessment revealed difficulties in both comprehension and production of English. Compared with other children his age, Trang understood a limited number of words for objects, actions, and relations. He often failed to follow classroom instructions, particularly those that involved words for concepts of time (e.g., yesterday, after, week) and space (e.g., beneath, in front of, around). Trang also had difficulty identifying which of several pictures corresponded to a syntactically complex sentence he had heard (e.g., It was not the bus she was waiting for; Because he had already eaten his lunch, he was not kept in the cafeteria). His conversations with other children often broke down because he did not understand fully what they were saying, nor could he express his own ideas clearly. As a result he was not a favored playmate, and most of the children in his class ignored him. His limited interactions further reduced Trang's opportunities for improving and practicing his already weak language skills. Additional assessment, conducted with the assistance of a Vietnamese interpreter, revealed that Trang showed similar receptive and expressive language deficits in Vietnamese. His nonverbal skills, however, were generally appropriate for his age. He readily constructed intricate buildings and vehicles with small, plastic building blocks; he easily completed complex jigsaw puzzles; and he successfully solved numerical, conceptual, or analogical problems, as long as they were presented nonverbally.

As a preschooler, Jerry was diagnosed with mixed receptive-expressive language disorder. By age 8, he had also received the diagnoses of comorbid attention-deficit/hyperactivity disorder and reading disorder. Jerry's language, attention, and reading problems contributed to a negative spiral of academic failure. His receptive language difficulties and attention problems resulted in frequent failures to understand and learn important information from classroom instructions, discussions, and lectures. Because information critical to the understanding of future lessons was not learned, Jerry continued to fall further and further behind his classmates. Moreover, because he could read only a few single words, Jerry could not acquire other key information as his classmates did by reading textbooks, library books, newspapers, and other reading materials. His inability to read proficiently further limited his opportunities to acquire new words, learn complex sentence forms, and appreciate sophisticated ideas. However, Jerry continued to score within the low normal range on nonverbal intellectual tasks, albeit somewhat lower than he had scored as a preschooler.

Children with mixed receptive-expressive language disorder are also at considerable risk for other disorders of speech, learning, and development. Approximately 40 to 60 percent of preschoolers with mixed receptive-expressive language disorders also have difficulties in producing speech sounds, indicating phonological disorder. In a few cases, stuttering may accompany mixed receptive-expressive language disorder. Reading disorder occurs in as many as 50 percent of school-aged children with mixed receptive-expressive language disorder, a much higher rate than in children with expressive language disorders. Reading problems may be evident at the earliest stages of learning to read or may not become obvious until later stages when successful reading comprehension demands knowledge of sophisticated vocabulary and sentence structures. A few children with mixed receptive-expressive language disorder also experience disorder of written expression or developmental coordination disorder.

Children with persistent mixed receptive-expressive language disorder are also at greater risk for concomitant psychiatric disorders than children with expressive language disorder. As many as 70 percent of school-aged children with mixed receptive-expressive language disorder may also have comorbid psychiatric diagnoses. Attention-deficit disorders are the most common comorbid conditions, occurring in 30 to 60 percent of cases. Externalizing or internalizing disorders may also be observed, but they are less frequent than attention disorders.

Children with developmental mixed receptive-expressive language disorder usually do not show overt neurological symptoms (e.g., electroencephalographic abnormalities, seizures, dysarthria, or dyspraxia). However, neurological symptoms do not preclude diagnosis of mixed receptive-expressive language disorder, unless they arise from a known acquired brain insult.

Acquired Type The language symptoms of acquired mixed receptive-expressive language disorder vary considerably, depending on the nature and severity of the underlying injury or disease. Although acquired disorders may have certain language characteristics in common with developmental disorders, they also show distinctive patterns. One of the more common patterns of outcome follows closed head injury, which often occurs in motor vehicle accidents or falls. Basic skills in vocabulary and grammar are relatively spared (after initial recovery stages), but more-complex skills remain significantly impaired. Comprehension of extended or sophisticated discourse may be compromised. Likewise, expression in discourse may be characterized by inappropriate, illogical, disorganized, or tangential comments, despite relatively proficient use of basic vocabulary and sentence structure. ccompanying deficits in attention, memory, affect, behavior, and motor skills may further impair overall communication effectiveness. Landau-Kleffner syndrome also has a distinct profile.

Patrick, age 4, was a cheerful, talkative preschooler who had good language skills until he experienced a series of seizures for no apparent reason. His language skills then began to deteriorate noticeably. He no longer understood many words, commands, and sentences that he had readily understood before the seizures. His expressive skills also deteriorated. His sentences became shorter and less sophisticated. It became increasingly difficult to decipher what he intended to say, as important words were omitted or incorrectly used. He also experienced significant attention and memory problems, although he continued to show nonverbal intellectual skills that were grossly within the normal range. Eventually, Patrick's seizures were controlled with medication, but he continued to exhibit substantial difficulties in both comprehension and production of language that never fully resolved.

DIFFERENTIAL DIAGNOSIS

Differential diagnosis of mixed receptive-expressive language disorder requires standardized evaluations of expressive language, receptive language, and nonverbal intellectual functioning. Standardized testing of receptive language is particularly critical, as deficits in this area may be less obvious than those in expressive language. The diagnosis requires that both receptive and expressive language development fall substantially below (1) the range of normal language performance expected for a child's age and (2) nonverbal intellectual performance. Moreover, the receptive and expressive language difficulties must be severe enough to impair academic performance or social communication. To make this determination, speech-language pathologists often use observational techniques and analysis of spontaneous language in conjunction with standardized assessments.

The related diagnoses of expressive language disorder, selective mutism, and mental retardation are ruled out by the presence of a significant discrepancy between receptive language and nonverbal abilities. In expressive language disorder and selective mutism, receptive language and nonverbal abilities are generally commensurate and are notably better than expressive language skills. In mental retardation, performance is similar across receptive language, expressive language, and nonverbal abilities, but all three are depressed relative to age-level expectations.

Language comprehension may also be affected in children with hearing impairment, environmental deprivation, or a pervasive developmental disorder. A hearing test is an important diagnostic procedure whenever a language disorder is suspected. Environmental deprivation can usually be identified through careful history taking. Pervasive developmental disorder may be indicated by disturbed social interaction and communicative intent, as well as unusual repetitive behaviors. If receptive and expressive language deficits exceed those expected for a particular degree of hearing impairment or mental retardation, a concurrent diagnosis of mixed receptive-expressive language disorder may be made.

Other comorbidity issues require attention in differential diagnosis. Difficulties in speech sound production may accompany language disorders (either expressive or mixed) and may suffice to warrant a comorbid diagnosis of phonological disorder. Because of the high concurrence of language and reading disorder, school-aged children diagnosed with either disorder should be screened for possible problems in the other area. Likewise, a high proportion of children referred for psychiatric assessment may exhibit previously undetected comorbid language disorders. Thus, children with psychiatric diagnoses, particularly attention-deficit/hyperactivity disorder, should also be screened for language disorders.

Occasionally a child may show expressive language so difficult to follow and so disorganized that it may be considered thought disordered and symptomatic of schizophrenia.

The following is a brief discussion with a highly anxious 9-year-old youngster with mixed receptive-expressive disorder who earlier that day had visited the dentist.

What do you suppose you'd like to do today?

Taking a dentist appointment ...

[You're taking a dentist appointment]

Yeah, he has a little cavity ...

[He has a little cavity]

... and I'm going to take it from him cause it's stuck there he sure doesn't like it but he knows there is too far (mumbled)

... too far and so he was losing a lot of hair so he needs a new way... sounds like he's bald... so he has everything (mumbling) a guy whos not recep... teaching he will have to it's important like he will or he won't

Discussion The stream of language from this child raises concerns about the possibility of schizophrenia. However, language this disorganized can occur in children with a mixed receptive-expressive disorder, especially in situations of heightened anxiety. Reassessing the child when less anxious and careful attention to the presence or absence of comorbid symptoms usually help clarify the diagnosis.

Children from diverse linguistic and cultural backgrounds may also have developmental language disorders. The diagnostic challenge is to differentiate cases of disorder from cases in which children are making language errors that are a normal part of acquiring a new language. A key factor in a successful assessment is often the cooperation of a well-trained informant from the same cultural and linguistic background as the child in question. The informant assists in obtaining history information, evaluating the child's proficiency in the first language, and conveying assessment results to the family.

Mixed receptive-expressive language disorder of the acquired type is usually identifiable by its sudden onset and association with known neurological conditions. A difficulty in using standardized tests for diagnosis is that the structure of a one-to-one testing situation may help to optimize the performance of children with acquired disorders, who often have associated attention and behavioral problems. These children may experience greater difficulties in language comprehension and production when they must function in the more distracting and less structured environments of home, school, and community. For this reason, observational techniques may also be important in diagnosis. In cases where Landau-Kleffner syndrome is suspected, a sleep EEG is often used to document abnormal brain wave activity and to help differentiate the disorder from other conditions in which previously learned skills deteriorate (e.g., childhood disintegrative disorder).

COURSE AND PROGNOSIS

Developmental Type Wide variations in severity, course, and outcome are observed for the developmental type of mixed receptive-expressive disorder. Recent studies of late talkers (i.e., children with normal cognitive functioning who use fewer than 50 words and no word combinations at age 2) suggest that youngsters with early mixed receptive-expressive delays have less favorable long-term prognoses than those with early expressive-only delays. Some preliminary evidence suggests that higher levels of nonverbal intelligence, receptive language, and early communicative intentions may be associated with better prognoses. However, it is not possible to predict the outcome for an individual child with any degree of certainty.

Throughout the preschool and school-age years, children with persistent mixed receptive-expressive language disorder continue to have poorer prognoses than those with expressive language disorder. Both language comprehension and production skills typically continue to develop, but often quite slowly. Thus, these children may become increasingly disadvantaged relative to their peers who are acquiring language skills at a typical rate. Children with mixed receptive-expressive language disorder also have a high probability of developing other associated problems during the school years, particularly reading disorders. Comprehension deficits also appear to place a child at high risk for attention-deficit disorders. Language problems, particularly when coupled with reading or attention problems, may lead into a vicious cycle of poor academic performance, low self-esteem, reduced motivation, and social isolation. Some theorists also posit that language plays a central role in moral development. The possibility that language deficits may prevent children from attaining age-appropriate levels of moral development is an intriguing one because of its potential link to the development of comorbid psychiatric and behavioral difficulties. Eventually, some children with mixed receptive-expressive language disorder learn to communicate well enough to conduct their daily affairs as adults, but many continue to experience subtle (or not so subtle) language deficits that limit their ability to participate effectively in a full range of communication and life situations. Indeed, detectable language problems are evident in a substantial portion of adults who live in poverty, commit crimes, or suffer psychiatric disturbances.

Acquired Type Acquired mixed receptive-expressive language disorders may have their onset suddenly at any age. Children generally recover more completely than adults from acquired language disorders of similar severity. Spontaneous recovery of function may occur rapidly or may have an extended course over months or years. Approximately two thirds of children with acquired language disorders regain language functioning that is grossly within the normal range, but some subtle deficits, particularly in high-level receptive or expressive tasks, may persist. When language deficits persist, they may have an adverse impact on academic performance and social communication, particularly when they are also accompanied by associated deficits in other areas of functioning (e.g., attention, memory, emotion regulation, behavior, motor skills). The prognosis for recovery from mixed acquired language disorders depends in a complex fashion on a number of factors, including the severity, location, and extent of brain damage; the age of the child at injury; the specific cause of the acquired disorder; the extent of other associated deficits; and the child's level of functioning prior to the brain insult.

Landau-Kleffner syndrome has a less favorable prognosis than acquired disorders attributable to other etiologies. The typical age of onset for the syndrome is from 4 to 7 years, but it ranges from 1 and 13 years. The observed language degeneration is usually sudden and pronounced. The comprehension impairment may be so marked that the child appears to have suddenly gone deaf, although hearing remains normal. Language deterioration may precede, follow, or accompany the onset of seizures or abnormal brain wave activity. In a few cases, overt seizures do not occur, but abnormal EEG readings are observed. The seizure activity often responds well to medication, but language functioning may not recover. Fluctuations in language performance are characteristic. Language recovery, when it occurs, has a gradual, inconsistent course usually over a period of months or years. In general, the younger the age at onset, the poorer the prognosis for language recovery in this syndrome.

TREATMENT

Developmental Type Intervention is generally recommended for children with mixed receptive-expressive language disorder, because they are at substantial risk for persistent linguistic, academic, and behavioral difficulties. The goals of intervention for these children usually encompass both receptive and expressive language needs. A variety of intervention techniques, styles, and programs have been recommended in the literature, but many have not been subjected to rigorous scientific evaluation for efficacy. Reviewers of the available efficacy literature, however, generally conclude that language intervention can be effective in fostering short-term progress toward specific language goals, a conclusion that appears to hold across a variety of intervention techniques, styles, and programs. To date, however, the possible long-term benefits of language intervention have received limited study. Future research must determine whether and under what circumstances language intervention can limit or reverse the negative impact of language disorder on long-term linguistic, academic, and psychosocial outcomes.

Interventionists now appear to be recognizing the need for a focus on long-term, broad-based outcomes. Language interventions for preschoolers are being designed to focus not only on oral language outcomes, but also on promoting social communication and early literacy skills. Kindergarteners with language disorders are being specifically taught certain key prereading skills in an effort to prevent the early reading failure that is often associated with language disorder and that may lead to subsequent academic and psychosocial problems. Peers, parents, and teachers are being taught methods for fostering language growth, which can be used on a regular basis in natural communicative interactions with children who have language disorders. Preliminary results of these efforts appear to be positive, but many key questions remain concerning optimal goals, techniques, and programs for language intervention.

Other interventions that rely heavily on language as a medium (e.g., psychotherapy, cognitive behavioral modification) may need to be modified for children with language disorders. To compensate for comprehension problems, vocabulary, sentence structure, questions, and verbal instructions should be simplified, and (if

necessary) repeated. To minimize the impact of expressive difficulties, nonverbal response modes may be used to supplement verbal responses. Clarification of ambiguous or unclear responses should also be sought. Similar modifications may be required for assessment procedures that depend heavily on language (e.g., projective tests, diagnostic interviews).

Acquired Type Language intervention for acquired language disorders often has three distinct phases. In the first phase, intervention is intended to stimulate and complement the spontaneous recovery of function that typically follows the neurological insult. In the second phase, the goal is to reteach functional and adaptive language skills, usually in a one-to-one setting that is relatively free of distractions. In the final phase, the focus is on helping the child reintegrate into home, community, and school environments. At this stage, a child may be taught strategies intended to compensate for persistent deficits. Throughout, language goals are usually part of a larger program intended to foster improvement in other affected areas as well (e.g., cognitive, behavioral, motor). Intervention techniques frequently are a blend of those typically used for developmental language disorders and those used for acquired disorders in adults. Unfortunately, there has been little systematic evaluation of the efficacies of various interventional approaches for children with acquired language disorders.

SUGGESTED CROSS-REFERENCES

Two disorders closely related to mixed receptive-expressive disorder are expressive language disorder (Section 37.1) and reading disorder (Section 35.1). Disorders that are relevant to the differential diagnosis of mixed receptive-expressive language disorder include mental retardation (Chapter 34), pervasive developmental disorder (Chapter 38) and selective mutism (Section 46.4). Disorders that may occur with mixed receptive-expressive language disorder include reading disorder Section 37.2), mathematics disorder (Section 35.2), disorder of written expression (Section 35.3), developmental coordination disorder (Chapter 36), phonological disorder (Section 37.3), stuttering (Section 37.4), and attention-deficit disorders (Chapter 39).

37.3 PHONOLOGICAL DISORDER

CARLA J. JOHNSON PH.D., AND JOSEPH H. BEITCHMAN, M.D.

DEFINITION AND COMPARATIVE NOSOLOGY

Children with phonological disorders have difficulties in correctly producing the speech sounds appropriate for their age and dialect. They may omit sounds (e.g., saying “at” for *hat* or “bup” for *bump*), substitute sounds for other sounds (e.g., saying “tum” for *come* or “hewo” for *hello*), or distort sounds by producing them in an unusual manner (e.g., producing /sh/ while allowing too much air to flow noisily over the sides of the tongue or producing /*s*/ or /*z*/ while protruding the tongue). In many cases, the speech sound differences occur in systematic patterns. For example, consonants in the final position of words may be omitted (e.g., “fee” for *feet*, “no” for *nose*) or consonants that require a steady airflow may be produced with an interrupted airflow (e.g., “do” for *zoo*, “pan” for *fan*). Listeners may be unable to understand the speech of children with severe phonological disorders.

The fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) uses somewhat different terminology for speech sound production disorders than that commonly used in the clinical and scientific literature, which may cause a problem for diagnosticians. In DSM-IV the category of phonological disorder is an inclusive one, encompassing difficulties in speech sound production that have no known cause as well as those that arise from hearing impairment, structural abnormalities of the speech mechanism (e.g., cleft lip or palate), or neurological conditions (e.g., cerebral palsy, head injury). In the literature, the terms *articulation disorder* or *speech sound production disorder* are more often used to label such an inclusive category. The terms *dysarthria* and *dyspraxia* are typically used to refer to speech sound production difficulties that have a neurological origin. The term *phonological disorder* is usually reserved for speech sound problems that have no known cause and presumably reflect developmental difficulties in acquiring the regularities of phonology (the sound system of a language). In this section this more restrictive category is referred to as *developmental phonological disorder* to distinguish it from the larger DSM-IV category of phonological disorder.

The inclusive nature of the DSM-IV category of phonological disorder obscures some potentially important differences between speech sound difficulties of developmental (unknown) origin and those with known structural or neurological causes. In addition to etiology, there may be marked differences in characteristics, prevalence, course, prognosis, and treatment. Moreover, the inclusive category used in DSM-IV differs from the more restrictive category of developmental articulation disorder used in its predecessor, the revised third edition of DSM (DSM-III-R). The earlier category included only developmental speech disorders of unknown origin and excluded those with structural or neurological causes. Similarly, the category of specific speech articulation disorder in the 10th revision of *International Classification of Diseases and Related Health Problems* (ICD-10) encompasses only developmental speech difficulties. Structural or neurological conditions are excluded (see Table 37.5-2).

Developmental phonological disorders are far more common than speech production problems from structural or neurological causes. Phonology (the sound system) is an aspect of language that children must learn. Thus, it is not surprising that developmental phonological disorder shares many similarities with the developmental language disorders discussed in Section 37.1 and Section 37.2. All are relatively common disorders in young children. All have unknown etiologies. All are characterized by a delayed onset and slow rate of growth but a relatively normal sequence of development in the affected communication skills.

Speech sound development is thought to require both linguistic and motor learning, as well as integration and coordination of the two. Linguistic aspects of the phonological system that need to be acquired include information on the specific sounds that are used in a particular language and how those sounds can be contrasted and combined with each other. Permissible patterns of syllable and word stress and patterns of speech melody (intonation) also need to be internalized. Thus, speech sound development is often thought to involve the gradual implicit development of a complex system of linguistic rules that underlie the representation, perception, and production of speech. Whether these rules explain or merely describe phonological knowledge is a point of controversy.

Considerable motor learning is required for speech sound development. Speech is a complex fine-motor skill that requires rapid, precise, and coordinated action of the large number of muscles involved in breathing, voicing, and articulating speech sounds. The coordination of these numerous muscle actions must be accurate and rapid enough to permit rates of speech as high as 250 words a minute for adult speakers.

The normal course of speech sound development is systematic. Children's first words generally comprise consonant (C) and vowel (V) sequences that form simple syllables of the forms CV (e.g., “hi”), VC (e.g., “up”), or CVC (e.g., “pop”) and short repetitive sequences of the form CVCV (e.g., “mama”). Gradually, more-complex syllable and word shapes are mastered, including those with initial or final consonant cluster sequences, such as /*thr*-/, /*k*l-/, -/rst/, or /-nt/. The consonants typically used in early words are those designated the *early 8* (/*m*/, /*b*/, /*y*/, /*n*/, /*w*/, /*d*/, /*p*/, /*h*/). As development proceeds, consonants termed the *middle 8* (/t/, /*ng*/, /*k*/, /*g*/, /*l*/, /*v*/, /*ch*/, /*l*/) are gradually mastered; followed by those known as the *late 8* (/*sh*/, /*th*/ [two variants], /*s*/, /*z*/, /*l*/, /*r*/, /*zh*/). Mastery of the late-8 consonants may not be fully completed until the age of 7 to 8 years. In the course of normal development, children often produce speech sounds inconsistently and incorrectly. Their errors can be described as omissions (e.g., “dah” for *dog*), substitutions (e.g., “fink” for *think*), or distortions (e.g., a slurpy-sounding /*sh*/). Sound errors may also be described in terms of phonological processes or rules that seem to capture a pattern of errors. For example, many young children appear to be using a phonological process of final consonant deletion; that is, they consistently omit consonants that occur at the end of words. The process occurs normally in the speech of very young children but is typically overcome by the age of 3. Other common processes that are gradually overcome during development include reduplication (i.e., repeating a syllable to form a multisyllabic word—e.g., “bahbah” for *bottle*), unstressed syllable deletion (i.e., omitting a syllable that is not stressed—e.g., “tefon” for *telephone*), stopping (i.e., using an interrupted airflow to produce sounds that should have a continuous airflow—e.g., “tu” for *shoe*), *consonant harmony* (i.e., using a sound similar to one that occurs elsewhere in a word—e.g., “tat” for *cat*), and consonant cluster reduction (i.e., omitting or simplifying sounds in a consonant cluster—e.g., “moke” for *smoke*). All of these processes are common in the speech of young children, but all are usually eliminated by the age of 5 years.

EPIDEMIOLOGY

The prevalence of phonological disorder has not been definitively established, in part because definitions and test procedures have varied considerably across studies. One study of a large community sample found that 7 to 8 percent of 5-year-old children had speech sound production difficulties of developmental, structural, or neurological origins. Approximately 55 percent of them had problems only in speech sound production; the others experienced additional language difficulties. Another report suggested that 7.5 percent of children from 3 to 11 years of age have developmental phonological disorders: 2.5 percent with delayed speech (deletion and substitution errors persisting past 4 years of age) and 5 percent with residual articulation errors (distortions of a few sounds, often /*s*/, /*l*/, or /*r*/, persisting beyond age 8). Developmental phonological disorders are far more common than phonological disorders with known structural or neurological causes.

Boys are more likely to have speech sound production difficulties than girls. Sex ratios as high as 4 to 1 and as low as 2 to 1 have been reported in the literature. Familial aggregation of speech disorders is also common, with 30 to 60 percent of children with developmental phonological disorders having one or more immediate family members with a history of a similar disorder. Further work is required to determine the genetic and environmental factors that may underlie familial aggregation.

ETIOLOGY

The cause of developmental phonological disorder is not known. Many of the factors proposed as possible causes are the same as those considered for developmental language disorders, including (1) subtle brain abnormalities, (2) genetic factors, (3) environmental influences, (4) neurodevelopmental immaturity, (5)

linguistic factors, and (6) auditory processes. Speech mechanism and speech motor factors have also been considered as possible causes.

Each proposed cause has some support in the literature, but no single factor seems to account for all cases of developmental phonological disorder. The evidence suggesting brain abnormalities includes a higher-than-normal incidence of soft neurological signs as well as findings of abnormalities in children with related disorders, such as mixed receptive-expressive language disorder and reading disorder. Genetic factors are implicated by the observed patterns of familial aggregation and results from twin and adoption studies and linkage studies involving phonological awareness, a component skill in reading. Environmental influences may also contribute to familial aggregation, but no conclusive evidence links specific environmental factors to developmental phonological disorders. Neurodevelopmental immaturity may be reflected in the fact that children with developmental phonological disorder typically develop speech skills more slowly than (but in roughly the same sequence as) children without the disorder. Other characteristics such as soft neurological signs, subtle deficits in motor skills, and associated behavioral difficulties could also reflect neurodevelopmental immaturity. Linguistic deficits may limit the ability to extract the regularities of phonology (e.g., permissible sounds, combinations, and positions of occurrence) from the available linguistic input. Temporary hearing losses or more permanent problems in auditory perception or discrimination may also contribute to developmental phonological disorder in some cases. Subtle abnormalities in the structure and function of the speech mechanism also are relatively common in children with developmental phonological disorder, but it is not clear whether these abnormalities are causal factors or simply correlated deficits. Thus, no single causal hypothesis enjoys convincing support, which suggests that multiple factors may be responsible for developmental phonological disorder.

Abnormalities in the structure of the articulators (e.g., lips, tongue, jaw, soft palate) occasionally cause speech sound production problems. The most common of these structural abnormalities is cleft palate, a congenital condition in which a cleft (opening) in the palate (roof of the mouth) fails to close properly during fetal development. The condition is sometimes accompanied by cleft lip. Other structural abnormalities in the articulators may occur following tumor removal or injury to the mouth or face. Tongue tie and dental abnormalities are rarely responsible for speech sound production disorders.

Neurological conditions may also cause speech sound production problems. One type of speech difficulty attributable to neurological damage is dysarthria, which is characterized by paralysis, weakness, or incoordination of the speech musculature. Dysarthria may result from congenital neurological conditions such as cerebral palsy, from progressive degenerative conditions such as muscular dystrophy, or from acquired brain insults such as head injury, stroke, tumors, or infections. A second type of speech problem arising from neurological damage is dyspraxia or apraxia, which is characterized by difficulty in planning and executing speech movements in the absence of paralysis or weakness of the speech musculature. Apraxia may follow acquired brain insults. A developmental form of apraxia with no known cause has also been posited, but its status as an identifiable disorder is controversial.

DIAGNOSIS AND CLINICAL FEATURES

Phonological disorder is diagnosed when speech sound production is inappropriate for the age and dialect of the speaker (Table 37.3-1). The severity of the disorder may range from mild, in which speech intelligibility is barely affected, to severe, in which speech is totally unintelligible. Errors may occur with only one or two sounds or with virtually all sounds.

A. Failure to use developmentally expected speech sounds that are appropriate for age and dialect (e.g., errors in sound production, use representation or organization, such as, but not limited to, substitutions of one sound for another [use of /t/ for target /k/ sound] or omissions of sounds such as final consonants).

B. The difficulties in speech sound production interfere with academic or occupational achievement or with social communication.

C. If mental retardation, a speech—motor or sensory deficit, environmental deprivation is present, the speech difficult are in excess of those usually associated with these problems.

Coding note: If a speech—motor or sensory deficit or a neurological condition is present, code the condition on Axis III.

Table 37.3-1 DSM-IV Diagnostic Criteria for Phonological Disorder

Children with developmental phonological disorders typically have a delayed onset and slow rate of speech sound development, but the sequence of development is generally quite similar to that found in children who are developing normally. A repertoire of simple syllable and word shapes is slowly expanded to include more complex shapes. The early-eight consonant sounds are generally mastered first, followed by the middle eight and late eight, but acquisition may be very slow. Speech sound errors are usually similar to those that occur in normal development, but the relative distribution of omissions, substitutions, or distortions may be dissimilar. For example, one study of 3- to 6-year-olds found that omissions and substitutions accounted for 25 and 47 percent, respectively, of errors in the speech of children with developmental phonological disorders but only 5 and 14 percent of errors in the speech of children without disorders. Phonological processes common in normal development also characterize the speech of children with developmental phonological disorder, but these processes may persist well beyond the age when they are normally overcome. Occasionally, unusual or idiosyncratic phonological processes may be used by children with developmental phonological disorder.

Sasha was a talkative, likable 3-year-old whose speech was virtually unintelligible. Sasha had normal hearing and language comprehension skills. No firm conclusion about his level of expressive language development could be made because he was so difficult to understand. He did, however, seem to be producing multiword utterances. Sasha produced only a small number of early-developing consonants (/ *m*/, /*n*/, /*d*/, /*t*/, /*p*/, /*b*/, /*h*/, /*w*/), vowels (/*ee*/, /*ah*/, /*oo*/), and syllable shapes (V, CV, CVCV). As a result, many of his spoken words were indistinguishable from each other (e.g., he said “bahbah” for *baby, bottle*, and *bubble;* he used “nee” for *knee, need*, and *Anita* [his sister]). Moreover, he never produced consonant sounds at the end of words or used consonant cluster sequences (e.g., /*tr-*/, /*st-*/, /*-nt*/, /*-mp*/). On occasion, Sasha reacted with frustration and tantrums to his difficulties in making himself understood.

Don was a pleasant, cooperative 5-year-old diagnosed with a developmental phonological disorder. He had normal hearing and language comprehension skills. He showed some mild deficits in certain aspects of expressive language, particularly in using grammatical features (e.g., pronouns, auxiliary verbs, past tense word endings) and in formulating complex sentences. He produced all vowels and most early-developing consonants correctly, but his productions of later-developing consonants (e.g., /*r*/, /*l*/, /*s*/, /*z*/, /*sh*/, /*th*/, /*ch*/) were much less stable. Sometimes he used them correctly, sometimes he omitted them altogether, sometimes he distorted them or substituted other sounds for them (e.g., “w” for /*r*/, “f” for /*th*/). Don's phonological difficulties were most apparent in his productions of consonant cluster sequences and multisyllabic words. Clusters rarely contained the correct sounds or the required number of sounds (e.g., blue might be produced as “bue” or “bwue,” *hearts* might be said as “hots” or “hars”). Multisyllabic words also included incorrectly produced sounds and sometimes had syllables omitted (e.g., “efant” for *elephant*, “getti” for *spaghetti*) or sounds transposed (e.g., “aminal” for *animal*, “lemon” for *melon*). Strangers usually understood about 80 percent of what Don said. Fortunately, if asked to repeat something, he sometimes spoke more slowly and clearly than usual.

Barb was a shy, reserved 8-year-old whose speech development had been delayed as a child. Most of her earlier speech problems had resolved gradually during her preschool and early elementary school years. She continued, however, to have problems in producing a few late-developing sounds (/ *r*/, /*l*/, /*th*/). She often substituted /*w*/ for /*r*/ and /*l*/ and used /*t*/ or /*d*/ for /*th*/. Despite these minor errors, her speech was readily understandable. Nonetheless, her classmates teased her about her speech, which made her reluctant to speak in the presence of others.

Developmental phonological disorder may accompany other language, learning, and developmental disorders. Approximately 50 to 75 percent of children with developmental phonological disorders have mild-to-severe deficits in language expression (see Section 37.1 on expressive language disorder); 10 to 40 percent also show mild-to-severe deficits in language comprehension. Reading disorder is another common comorbid diagnosis, especially in children with associated language involvement, who are also at increased risk for other problems such as developmental coordination disorder, learning disorders, and attention-deficit disorders. Children with isolated developmental phonological disorders are at relatively little risk for behavioral or psychiatric disorders.

In contrast to children with developmental phonological disorders, children with structural or neurological disorders often exhibit patterns of speech sound errors that

are unlike those found in normal development. Children with structural and neurological deficits may also experience developmental phonological problems, which complicates diagnosis.

The speech of children with cleft palate may be characterized by excessive nasality and by inability to produce the many consonants that require the oral cavity to be closed off from the nasal passage by the palate. Children may develop unusual ways of articulating certain sounds in an attempt to compensate for structural deficiencies. Even after structural problems are corrected by surgical or prosthetic means, these unusual patterns may persist. Children with cleft palate are also at increased risk for upper respiratory infections and accompanying hearing losses, as well as developmental language and learning difficulties.

> Grace was a cheerful 6-year-old who was born with a severe cleft lip and palate. During infancy, she required surgery to effect initial repairs on her lip and palate. Several subsequent surgeries were needed to adjust those initial repairs to the growth of her face. Grace did not have sufficient palatal tissue for surgeons to achieve a completely adequate repair of the soft palate, so she was fitted with a prosthetic device for the roof of her mouth, which provided the separation of the oral and nasal passages required for speech. The prosthesis distorted her production of a few speech sounds that normally are produced with no separation between the oral and nasal passages (*m, n*, and *ng* sounded more like /*b*/, /*d*/, and /*g*/). These distortions, however, were minor relative to the severe speech difficulties Grace would have experienced without the prosthesis. Her speech likely would have been unintelligible because of excessive nasality and her inability to produce the oral consonants. Grace's upper lip was also a bit tight as a result of the corrective surgery. This limited her ability to round her lips but had no audible effects on her speech production. Grace experienced frequent upper respiratory and ear infections as a child. She also showed some mild expressive language delays, but her academic skills developed as expected.

Children with neurological conditions may have apraxia, a difficulty in planning and executing speech movements despite normal muscle strength and range of movement. Groping and hesitant articulation is characteristic of apraxia, which generally arises suddenly as a result of acquired neurological insults, such as head injury, stroke, or infections.

Neurological conditions may also result in dysarthria, a speech difficulty caused by weakness or paralysis in the speech musculature. There are several types of dysarthrias, each characterized by particular neuromuscular deficits and speech features. In one common type of dysarthria, speech is slow, labored, slurred, and imprecise, sounding much like the speech of someone who is drugged or intoxicated. The underlying muscular problems in dysarthria may affect not only production of speech sounds, but also breathing, voice quality, pitch, loudness, stress, and speech melody. Feeding, swallowing, and drooling problems may also result from impaired functioning of the oral musculature. Gross motor functioning of the limbs may also be affected by the underlying neurological disorder. Dysarthrias range from mild to severe. In severe cases intelligible speech may not be possible.

> Shane was an intelligent, likeable 12-year-old who was born with severe cerebral palsy. His quadriplegia made it necessary for him to use an electric wheelchair. Shane had a severe dysarthria and was able to produce only a few vocalizations consistently enough for them to be used for communication purposes. He was unable to use sign language as a method of communication because he could not execute the necessary hand movements. Nonetheless, he was able to communicate quite effectively, albeit somewhat slowly, by using a sophisticated computerized device as a communication aid. He operated this computerized system by selecting words or messages via an electronic switch that he activated with head movements, which he could control reasonably well. The message he composed could then be produced for his listener by a computerized voice output system. Using his computerized system, Shane also pursued many of his favorite leisure activities, such as playing chess and participating in chat groups on the Internet.

DIFFERENTIAL DIAGNOSIS

The key element in diagnosing phonological disorder is determining whether speech sound production is inappropriate for the age and dialect of the speaker. The decision may not be straightforward because the speech characteristics of children with developmental phonological disorder often resemble those of younger children who are developing normally. Speech errors indicating disorder in a 6-year-old may be perfectly normal in a 4-year-old. Thus, a particular pattern of speech sound errors must be carefully compared with the normal patterns of speech sound development in children.

Consideration must also be given to the dialect spoken by the child. Some sound differences that are normal in one dialect may indicate disorder in another. For example, the production of “hot” for *heart* is normal for speakers from Boston, but not for those from most other parts of North America. Children who are learning English as a second language may also present a difficult diagnostic challenge. Some difficulties in speech sound production are a normal part of acquiring a second language; others may suggest disorder. A careful history and an assessment of speech sound production skills, ideally in both English and the child's first language, may help to determine the correct diagnosis.

A hearing test and an oral examination are also important parts of the diagnostic assessment. The hearing test may identify temporary or permanent hearing problems that require medical or other interventions to improve the prognosis for development of intelligible speech. The examination of oral structures may reveal previously undiagnosed structural or functional problems that may be contributing to the speech difficulties. For example, children with neurologically based disorders may have difficulties in accurately and rapidly performing various speech and nonspeech movements (e.g., sequencing syllables, as in “putuku”; protruding the tongue; rounding the lips). Findings from the oral examination may, therefore, contribute to differentiating developmental and neurologically based disorders. Dysarthria involves muscle weakness and paralysis, signs of which may be observable during the oral examination. Drooling, feeding, or swallowing problems, either concurrently or in the history, may also suggest dysarthria.

Children diagnosed with developmental phonological disorders should also be screened for possible comorbid expressive or mixed receptive-expressive language disorders. When the history warrants, cognitive assessments may also help to rule out or confirm developmental delay or mental retardation. In these cases, a concurrent diagnosis of phonological disorder may be made when the speech difficulties exceed those expected for the degree of retardation or delay.

Referral to a speech-language pathologist for assessment of speech sound production skills is indicated when (1) a 2-year-old uses little or no speech, (2) a 3-year-old is poorly understood by family members familiar with his speech, (3) a 4-year-old is poorly understood by peers and strangers, (4) a child of any age appears to be withdrawing from social interactions because of teasing or frustration associated with speech difficulties, (5) a parent or teacher is concerned about a child's speech, or (6) a child (or adult) experiences a sudden deterioration in speech production skills. Deterioration in speech skills may be the first warning sign of a developing neurological condition and, therefore, warrants referral for neurological examination.

COURSE AND PROGNOSIS

Severe cases of developmental phonological disorder with comorbid language problems may be identified as early as 2 years of age, but diagnosis at about age 4 is typical. Variability in severity, course, and outcome is characteristic of developmental phonological disorders. In most children with the disorder, speech sound development proceeds gradually, at a slower than normal rate. Speech sound production skills often normalize eventually. One recent study investigated sound normalization over a 1-year period in a large group of children with developmental phonological disorders, whose average age was slightly more than 4 years at the start of the study. Approximately 20 percent of the children achieved normalized speech production skills during the year, but investigators were unable to find any significant speech, hearing, oral, cognitive, linguistic, or psychosocial variables that predicted normalization. A second study of long-term normalization suggested that speech sound development proceeds in spurts and plateaus until approximately 8 to 9 years. If speech has not fully normalized by then, residual articulation problems may persist into adulthood. Residual articulation errors are usually distortions of later-developing sounds, such as /*s*/, /*z*/, /*sh*/, /*ch*/, /*l*/, /*r*/, and /*th*/. Distortions that affect the sounds /*s*/, /*z*/, /*sh*/, and /*ch*/ are often called *lisps*. Residual errors are often mild, with little effect on speech intelligibility. Research suggests, however, that others may incorrectly consider a speaker with residual speech errors to be immature, lazy, or of low intelligence.

Children with mild-to-moderate isolated developmental phonological disorders are at relatively little risk for adverse long-term outcomes. Speech usually normalizes by 8 to 9 years of age, although subtle deficits in the speed and accuracy of articulation during complex speech tasks may remain detectable into adulthood. Adults with a history of mild-to-moderate developmental phonological disorder generally attain language, cognitive, academic, psychosocial, and psychiatric outcomes within the normal range.

Children with severe developmental phonological disorders that persist to school age are at greater risk for poor outcomes. They may fail to develop adequate phonological awareness (the ability to perceive, identify, and mentally manipulate speech sounds), which may contribute to marked difficulties in learning to read and spell. Thus, parents and teachers should carefully monitor the reading and spelling progress of school-age children with severe, persistent phonological disorders. Explicit training in phonological awareness may help to improve reading and spelling performance. There has been little systematic study of long-term psychosocial

and psychiatric outcomes for children with severe developmental phonological disorders.

The risk of adverse outcomes in language, reading, academic, psychosocial, or psychiatric functioning also increases for children who have comorbid mixed receptive-expressive language disorder. Those with significant receptive involvement are particularly at risk.

Children whose speech difficulties arise from structural abnormalities also have variable outcomes. In children with cleft palate, the adequacy of the speech outcomes is often determined by the success of surgical or prosthetic management. Children with cleft palate are, however, vulnerable to hearing and language difficulties, which may have a negative impact on overall prognosis for academic and social success. In addition, cleft palate is often part of a syndrome of abnormalities that may include mental retardation. Thus, prognosis for individual children will vary, depending on the extent of speech and associated involvements.

Children with speech difficulties of neurological origin also have varied prognoses. Those with mild difficulties may achieve intelligible speech, whereas those with more-severe problems may be unable to do so. Children with neurologically based speech problems also often have other involvements in the motor, language, and cognitive domains, which will influence overall outcome.

TREATMENT

Intervention is usually recommended for children of any age who are diagnosed with moderate-to-severe developmental phonological disorders. A speech-language pathologist may deliver the intervention directly or may teach parents, teachers, volunteers, or paraprofessionals to deliver the intervention under supervision. A variety of intervention techniques, styles, and programs have been recommended, but most can be grouped into two main approaches to treatment.

A *phonological approach* is usually implemented with children whose multiple speech sound errors can be described by the phonological processes (e.g., final consonant deletion, consonant cluster reduction). The goal in this approach is to help the child eliminate the use of these processes by emphasizing the communicative value of correctly using certain classes of sounds, such as final consonants or consonant clusters. Practice in producing a variety of final consonants and clusters then helps to consolidate these classes of sounds within the child's phonological system. Treatment generally continues until the child is using the new classes of sounds consistently in everyday communication situations.

A second approach, called the *traditional approach* because it was developed first, is more often used with children who have only a few error sounds, usually substitutions or distortions. The goal of this approach is to teach correct production of a sound by emphasizing its auditory and motor characteristics. Practice in producing the sound is provided, with cues about correct articulator placement or movement given by the clinician. Treatment generally continues until the child is using the new sound correctly in spontaneous speech.

One pattern of residual errors is often treated somewhat differently. Some children who lisp by protruding their tongue may also have an abnormal (for older children) swallowing pattern known as tongue thrust. These children may benefit from simultaneous treatment of the swallowing pattern and the lisp.

The research on treatment efficacy, while not extensive or comprehensive, does suggest that both phonological and traditional approaches can improve speech sound production skills. Long-term success appears to depend on the extent to which the new speech skills were established as automatic patterns of production. Not surprisingly, the extent to which children are motivated to change their speech patterns also appears to be a factor in the short- and long-term success of intervention.

Children with comorbid communication disorders may require language or fluency interventions in addition to speech sound intervention. There has been little systematic evaluation of the efficacy of such joint interventions. A few studies have examined whether speech production gains occur as an additional benefit of language or fluency interventions that do not focus specifically on speech sound production. The limited results to date have been mixed. Further systematic work is required on these and other questions concerning the efficacy of speech interventions.

For children with structural abnormalities, surgical or prosthetic management is often the first, and sometimes the only, step in intervention. Speech sound difficulties that remain after surgical or prosthetic management may require speech treatment, often with techniques similar to those used for developmental phonological disorders. On occasion, persisting structural deficits may not permit a sound or sounds to be produced in the usual way. Compensatory articulation strategies are then included in the intervention program.

Children with apraxia following acquired brain insults are often treated with techniques similar to those used in the traditional approaches. Production practice emphasizes rhythmic and efficient sequencing of difficult articulatory movements. Some children are also thought to have a developmental apraxia of speech (with no known cause), but the diagnostic category is controversial, and its characteristic features are poorly understood. Treatment approaches similar to those for acquired apraxia are generally recommended.

Interventions for children with dysarthria cannot eliminate the basic problems in muscle strength and control that underlie the disorder but can promote optimal use of available strength and control for speech purposes. Compensatory techniques for speech production are often a key part of this process. Prosthetic devices may also help to optimize speech intelligibility. Early intervention to limit abnormal muscular reflexes and promote optimal feeding and swallowing patterns may also be required. For children who are unable to achieve intelligible speech, a variety of augmentative and alternative communication systems may be recommended. Sign language may be used to supplement speech if hand movements can be well controlled. Other communication systems involve picture or symbol boards or sophisticated computerized devices, such as that described in the case example above. Research has shown that augmentative and alternative communication systems do not reduce a child's motivation to improve speech skills. Indeed, the opposite effect is often found.

Research that evaluates the efficacy of speech-sound interventions for children with structural and neurological problems is sparse, in part because such interventions are often tailored specifically to the particular needs of an individual child. Accordingly, the available studies often focus on outcomes for individual children.

SUGGESTED CROSS-REFERENCES

Other communication disorders that may accompany phonological disorder are discussed in Section 37.1 on expressive language disorder, Section 37.2 on mixed receptive-expressive language disorder, Section 37.4 on stuttering, and Section 37.5 on communication disorder not otherwise specified. Other possible concurrent disorders are described in Section 35.1 on reading disorder, Section 35.2 on mathematics disorder, Section 35.3 on disorder of written expression, and Chapter 36 on developmental coordination disorder. Disorders that may require attention in differential diagnosis are discussed in Chapter 34 on mental retardation and Chapter 38 on pervasive developmental disorders.

37.4 STUTTERING

ROBERT KROLL PH.D., AND JOSEPH H. BEITCHMAN, M.D.

DEFINITION

Stuttering is a condition in which the flow of speech or fluency is disrupted by involuntary speech motor events. Stuttering may include a variety of specific disfluency types such as sound and syllable repetitions, sound prolongations, dysthymic phonations, and complete blocking or unusual pauses, or both between sounds and syllables of words. More-severe forms of stuttering are frequently accompanied by a variety of struggle behaviors, commonly referred to as accessory, or secondary, features of the disorder. These struggle behaviors may be observed at the respiratory, phonatory, or articulatory levels of the speech mechanism and may manifest themselves in disordered breathing, glottal fry, lip pursing, and tongue clicking. Additional concomitant behaviors may be observed such as eye blinks, facial grimacing, head jerks, and abnormal body movements prior to or during instances of disrupted speech. Linguistic avoidance is a commonly observed feature of stuttering, which results in word substitution and circumlocution as the individual approaches the feared sound or word during the communicative attempt. Similarly, situational avoidance is often characteristic of chronic stuttering, and the type of communicative situation often influences the amount and severity of stuttering. Stuttering can vary in severity, ranging from mild, occasional disfluencies in speech to severe stuttering that renders communication all but impossible for the affected individual and often results in serious psychological difficulty and social withdrawal.

HISTORY AND COMPARATIVE NOSOLOGY

Psychiatric syndromes can be defined from the point of view of the observer or the patient. Depressed individuals may not look depressed, but if they report subjective symptoms sufficient to meet criteria, a diagnosis of a depressive disorder can be made. Likewise, stuttering can be defined from the point of view of the listener or the speaker. The speaker's sense of subjective distress or loss of control of the speech apparatus reflects an approach to nosology that focuses on the speaker's experience. The *Diagnostic and Statistical Manual of Mental Disorder* (DSM), on the other hand, focuses on the observer's point of view, that is, on the observable behaviors.

In both the third edition of DSM (DSM-III) and the revised third edition (DSM-III-R) stuttering was placed in the category of disorders usually first evident in infancy, childhood, or adolescence. In both these systems stuttering was coded on Axis I, along with clinical psychiatric syndromes. This remains controversial, as stuttering is not commonly viewed as a psychiatric disorder among speech-language professionals, and speech-language pathologists have argued that it should not be included in DSM at all.

In the fourth edition of DSM (DSM-IV), stuttering is categorized as a communication disorder. This is consistent with the speech-language pathology classification in which all speech and language disorders are kept within the same category. However, it remains to be shown that it belongs in this category; aside from the similarity of causing communicative difficulties, stuttering may differ fundamentally from the other communication disorders in this category. The 10th revision of *International Statistical Classification of Disease and Related Health Problems* (ICD-10) separates stuttering (stammering) from the speech and language disorders and places it in the category of other behavioral and emotional disorders with onset usually occurring in childhood and adolescence. The diagnostic criteria in ICD-10 are similar to the DSM-IV diagnostic criteria, but a few differences are notable.

DSM-IV requires that the disorder interfere with academic or occupational achievement or social communication, whereas the ICD-10 diagnosis (Table 37.4-1) applies only if it is severe enough to cause marked disturbances in fluency. ICD-10 requires a minimum duration of 3 months; DSM-IV has no duration criterion. DSM-IV further specifies that the disturbance must exceed what is appropriate for the individual's age, and if a speech-motor or sensory deficit is present, the speech difficulties must exceed those usually associated with these problems. ICD-10 has an additional category for cluttering, which is not accorded separate status DSM-IV (Table 37.4-2).

A. Stuttering (i.e., speech characterized by frequent repetition or prolongation of sounds or syllables or words, or by frequent hesitations or pauses) is persistent or recurrent and sufficiently severe to cause marked disruption of the fluency of speech.
B. Duration of the disorder is at least 3 months.

Table 37.4-2 ICD-10 Diagnostic Criteria for Cluttering

The differences between the ICD-10 and DSM-IV classifications of stuttering reflect the ongoing controversy about the true nature of stuttering, whether it should be regarded as part of the broader speech and language diathesis or as a separate entity. Similarly, whether stuttering should be considered a psychiatric disorder at all

remains controversial. Clinically it appears to differ qualitatively from more prototypical psychiatric syndromes (e.g., schizophrenia, autistic disorder, depressive disorders, and attention-deficit/hyperactivity disorder). However, those who suffer from stuttering show psychological distress that interferes with function and impairs enjoyment of life. The cause is unknown, but psychological factors may exacerbate or ameliorate the condition. Until the etiology is firmly rooted, the precise classification of this condition is likely to remain controversial.

EPIDEMIOLOGY

Surveys conducted chiefly in the United States and Europe indicate that the prevalence of stuttering in the general population is approximately 1 percent. Although data regarding incidence vary widely, most specialists would agree that the likelihood of an individual ever exhibiting some form of stuttering is between 3 and 4 percent. Of those who begin to stutter, a large portion stop by adulthood. The estimated percentages of spontaneous recovery in stuttering again vary widely because of differing definitions of stuttering and normal nonfluency, age groups studied, and data collection techniques. Several studies have estimated spontaneous recovery to be as high as 80 percent. Stuttering is more prevalent among males than females, with the sex ratio among American school children being approximately 3 to 4. A high familial incidence is indicated by the presence of stuttering among the relatives of about 50 percent of individuals who stutter. Additionally, a high degree of concordance of stuttering exist in identical twins. Individuals who stutter appear to have normal developmental histories except for speech and language. Numerous studies have demonstrated that young stuttering children are somewhat delayed in early language and articulation development; however, studies of older stuttering children appear to demonstrate that language skills are once again age appropriate. With regard to personality and social and emotional adjustment, children who stutter are often regarded by their parents or primary caregivers as nervous, and prone to specific fears. They are often described as overly sensitive to their environment. Adults who stutter tend to be somewhat more anxious and emotionally reactive than their nonstuttering peers. For the most part studies relating intellectual ability to stuttering are inconclusive; however, there is a significantly higher prevalence of stuttering in the developmentally delayed population.

ETIOLOGY

Researchers and clinicians working in the area of stuttering recognize that the causes of stuttering are complex. Understanding the etiology of stuttering can be facilitated by specifying the level of causation.

The first of these levels pertains to underlying causation. This refers to the genetic, neurophysiological, and psychological factors that may predispose a child to fluency disruption. Research in these areas has been rather cyclic since the 1940s, and various models implicating psychological, learning, and biological variables in stuttering have been postulated.

One early psychoanalytic theory of stuttering postulated that disrupted speech represents the individual's attempt to fulfill some type of unconscious neurotic need and usually results from disturbed early parent-child interaction. Empirical support for this psychoanalytic model is largely lacking, and studies investigating personality factors associated with stuttering have not revealed anything suggesting emotional disturbance or neurosis as a possible cause.

Later psychological models of stuttering have drawn upon the principles of classical and operant conditioning to explain stuttering. Several behaviorally oriented researchers offered a model of operant conditioning in which the early disfluencies of the child were subject to an intermittent schedule of reinforcement, resulting in incipient stuttering. The two-factor theory of stuttering posited that fluency failure resulting from negative emotion becomes associated with speech-related stimuli through a process of classical conditioning. The individual's response to the fluency failure, the repetitions, sound prolongations, and attempts to terminate the instance of disruption, are instrumentally conditioned. Perhaps the best known of modern psychological theories of stuttering is the diagnosogenic (semantogenic) model. This theory postulates that stuttering is caused by parents' diagnoses of the developing child's normal disfluencies as stuttering.

The large proportion of stuttering individuals who have relatives with a similar speech disorder and the high concordance for stuttering in identical twins have long suggested that biological inheritance plays some part in stuttering. Current models of genetic transmission that can account for familial patterns of stuttering provide strong evidence for the biological inheritance of stuttering. However, these genetic models point to a complex interaction between heredity and environment. Studies of identical twins reared apart generally show reduced concordance for stuttering, implicating the environment.

The theory of cerebral dominance, proposed in the late 1920s, was one of the earliest neurophysiological models used to explain the cause of stuttering. It arose from the observation that an unusually high number of individuals who stuttered were either left-handed, ambidextrous or had been shifted to right-handedness in childhood. It was further reported that the onset of stuttering occurred shortly after the shift of handedness. The theory of incomplete or atypical cerebral lateralization for speech has received varying amounts of support, but not until relatively recently did advances in electrophysiological techniques and brain imaging began to yield more definite data on cortical and subcortical processing of speech in stuttering. Several investigators have reported evidence of atypical cortical activation patterns in stutterers, including abnormal electroencephalogram measures and patterns of alpha wave suppression. Most recently, several brain-imaging techniques used to measure regional cerebral blood flow have been applied to the investigation of stuttering. Data from these initial studies using single photon emission computerized tomography and positron emission tomography point to differential activation patterns in stuttering during both oral and silent reading and even immediately following treatment for stuttering. Findings from these studies show increased right hemisphere activation during simple oral reading tasks conducted by stuttering adults. These subjects also show significant activation in the left anterior cingulate cortex during silent reading, a finding interpreted in the framework of anticipatory anxiety. A recent study investigating pretreatment and posttreatment brain activation patterns in stuttering suggests that increased fluency following intensive speech therapy results from greater sensorimotor control over articulatory movements, without eliminating a right hemisphere bias for language processing.

A second etiological level of stuttering involves the precipitating causes, that is, when, where, and under what conditions stuttering is most likely to occur. At this level concern is with the loci of stuttering and the specific speaking situations affecting fluency. Linguistic factors associated with stuttering have led some theorists to view it as a higher-level cognitive dysfunction. The vast majority of stuttering occurs mostly on the initial sounds of words or syllables. Fluency-facilitating conditions include choral reading, repeated reading of the same material, whispering, and speaking under conditions of altered auditory feedback or masking noise. Based upon these and other phenomenological features of stuttering, new theories have implicated higher-level linguistic processes as the fundamental causal elements for speech disruption in stuttering. These processes involve the planning or adjustments of linguistic plans via internal monitoring loops. One such theory, the covert-repair hypothesis, emphasizes the role of internal monitoring in detecting and correcting phonological errors in speech planning and production. The theory uses elaborate models of internal monitoring, self-repair, and priming in attempts to explain both the type of disfluency and the conditions that facilitate speaking.

A third level of causation and an area of active investigation concerns the motor speech and vocal tract dynamics characteristics of stuttering. The vocal tract events generating disrupted speech patterns have been the focal point of much of the physiological research in stuttering for over two decades. It is reasoned that increased knowledge of vocal tract events and the component behaviors of stuttering will ultimately have a direct impact on the assessment, measurement, and modification of these behaviors. Much information is available on the respiratory, laryngeal, and articulatory dynamics of stuttering. Physiological studies indicating differences between stutterers and nonstutterers are closely scrutinized because they may in fact be dealing only with peripheral events surrounding stuttering, not with underlying causation. The above argument notwithstanding, individuals who stutter, as a group, exhibit longer voice reaction times and phonatory onset times than do nonstutterers. This has led to a number of hypotheses implicating the larynx as the primary dysfunctional element in stuttering.

The final level of causation involves the environmental factors associated with the onset and development of stuttering. Much information has been collected on personality traits of young children who stutter and their parents, and psychodynamic, sociological and conditioning factors influencing stuttering and their interaction with linguistic development. Considerable inconsistency exists in data obtained from research on the personality of stutterers. There is little (if any) conclusive evidence that stutterers as a group exhibit a definable character structure or predictable set of personality traits. Moreover, there appears to be much overlap in overall adjustment profiles between stutterers and nonstutterers, with lower social adjustment and self-esteem scores characterizing individuals who stutter. These traits are most often explained by the impact of the stuttering itself on these individuals and their environment.

DIAGNOSIS AND CLINICAL FEATURES

Stuttering is typically characterized by involuntary disruptions in the fluency of verbal expression. These disruptions may be audible or silent and are usually characterized by repetitions or prolongations of sounds or syllables or by tense pauses or the complete cessation or blocking of speech sounds.

Instances of stuttering are frequently accompanied by accessory or secondary features. These secondary behaviors involve both the speech mechanism and related or unrelated body structures. Such behaviors may include eye blinks, facial grimacing, lip and tongue tremors, tics, vocal fry, head jerks, abnormal movements of the limbs, and breathing irregularities. Linguistic and situational avoidance behavior is often observable with confirmed stuttering. The affected speaker will often scan the intended utterance to predict stuttering and then attempt to avoid such disruption by substituting words, revising phrases, circumlocuting, or stopping the entire

communicative process. Situational avoidance is often reported, such as speaking in front of a group or on the telephone. Most adult stutterers report specific sounds, words, or situations that increase stuttering. Most of this information comes from studies carried out on chronic adult stutterers. Children who stutter have not been studied extensively, but it is generally accepted by clinicians that stuttering in its earlier forms is more often restricted to simpler types of disfluency such as repetitions and prolongations and less often involves the more severe struggle and avoidance behaviors. Definitions of stuttering vary widely and are usually based on listeners' observations of the disrupted speech pattern. However, some writers emphasize that the affected individual's sensations of the stuttering moment are crucial to any complete definition. Many forms of stuttering are so subtle that they are undetectable by the listener and are only perceived by the speaker.

While stuttering varies markedly in terms of frequency and severity both within and among individuals who stutter, some fairly predictable events or situations are commonly observed that either facilitate fluency or result in a deterioration of the stuttering (e.g., choral reading, singing, whispering, speaking in the presence of masking noise or under conditions of delayed auditory feedback, speaking when alone). Conditions commonly observed to increase stuttering include talking on the telephone, talking to groups, making introductions and saying one's own name, talking to authority figures, and attempting to communicate during stressful situations such as job interviews or formal presentations.

Although severe forms of stuttering are most often observed in adults, children and adolescents can be similarly affected. Stuttering can have a significant impact on the individual's quality of life, causing significant social, emotional, educational, and vocational problems. The preschool and young school-aged stutterer frequently develops social and school-related anxiety. The adolescent who stutters tends to withdraw from normal social interaction. The young adult stutterer often reports feelings of restricted academic and career choices and often foregoes the opportunity to develop specific talents and career paths.

The DSM-IV diagnostic criteria for stuttering are shown in Table 37.4-3.

A. Disturbance in the normal fluency and time patterning of speech (inappropriate for the individual's age), characterized by frequent occurrences of one or more of the following:
   (1) sound and syllable repetitions
   (2) sound prolongations
   (3) interjections
   (4) broken words (e.g., pauses within a word)
   (5) audible or silent blocking (filled or unfilled pauses in speech)
   (6) circumlocutions (word substitutions to avoid problematic words)
   (7) words produced with an excess of physical tension
   (8) monosyllabic whole-word repetitions (e.g., "I-I-I-I see him.")
B. The disturbance in fluency interferes with academic or occupational achievement or with social communication.
C. If a speech-motor or sensory deficit is present, the speech difficulties are in excess of those usually associated with these problems.

Coding note: If a speech-motor or sensory deficit or a neurological condition is present, code the condition on Axis III.

Table 37.4-3 DSM-IV Diagnostic Criteria for Stuttering

DIFFERENTIAL DIAGNOSIS

The ability to produce fluent speech is a skill that develops as the young child grows and it depends on such factors as motor coordination and timing and linguistic and cognitive development as well as emotional development and maturity. Preschool children quite commonly exhibit disfluency in speech during their communication efforts. The factors that distinguish normal nonfluency from incipient stuttering involve both the type and frequency of the observed disrupted speech patterns. Children who stutter exhibit predominantly part-word repetitions, voiced or unvoiced sound prolongations, and broken or fragmented words, whereas the normally nonfluent child is more likely to demonstrate whole word and phrase repetitions and revisions. Several researchers have emphasized the degree of speech fragmentation as the distinguishing factor between stuttering and normal nonfluency. The child who is developing normal speech patterns usually does not evidence more than 10 percent of any type of disfluency in speech, whereas the stuttering child often exhibits higher amounts of speech disruption. Another distinguishing factor is the presence or absence of struggle during speech attempts. The child who is stuttering often exhibits difficulty in initiating or maintaining breath flow or voicing during speech attempts. The normally developing child is more likely to evidence easy, effortless speech, even if it is intermittently marked by repetitions of whole words or phrases. Unlike the stuttering child, the normally developing child produces speech, voice, and airflow in a continuous, uninterrupted fashion.

Cluttering is another disorder of fluency characterized by rapid speech, reduced intelligibility, and frequent telescoping of words. Cluttering is often marked by grammatical and syntactic errors and is not typically associated with any specific sound or word fears or even limited awareness of the speech disorder. Cluttering has often been associated with a central language imbalance. Prognosis for improvement with treatment for cluttering is usually guarded, in large part because of the individual's general lack of awareness of the speech pattern.

COURSE AND PROGNOSIS

The onset of stuttering is usually between the ages of 2 and 7, peaking at about age 4. The stuttering fluctuates in severity initially, so that the course of development is not steady. Initially, days or weeks may go by with little or no speech difficulty only to be followed by a sharp increase in the amount and type of stuttering behavior. The stuttering pattern changes with time. Despite fluctuations in severity, young children beginning to demonstrate signs of true stuttering do not continue to be disfluent in the same manner in which they began. As children begin to demonstrate more struggle and fragmentation of words and syllables, the stuttering pattern becomes more complex. Moreover, while the stuttering is usually episodic in the beginning, it becomes more chronic as it progresses. In its most advanced form, speech disruptions are accompanied by secondary behaviors such as those described above. Complete recovery from stuttering is rare after the teenage years. Up to 80 percent of stuttering children experience spontaneous recovery, with girls more likely to become spontaneously fluent than boys. Investigations of prognosis in therapy for the older, confirmed stutterer have focused primarily on the influence of personality factors in treatment; subjects with less favorable speech attitudes were less likely to obtain long-term benefit from behaviorally oriented speech therapy for stuttering.

TREATMENT

The vast majority of treatment techniques for stuttering have been conducted on adults. Speech-language pathologists have traditionally practiced two distinct forms of therapy. The first deals directly with the psychological aspects of the problem, that is, the attitudes, feelings, and emotions displayed by the individual who stutters. Treatment procedures use various types of psychotherapy directed at self-acceptance, attitude change, and avoidance and anxiety reduction. The second major speech-therapy approach involves modification of the stuttering response to fluent-sounding speech by the application of systematic steps and rules of speech mechanics. In this framework, therapy procedures attempt to reconstruct the respiratory, phonatory, and articulatory gestures used in speech production, either by stuttering modification or fluency-shaping techniques. Therapy formats for adults who stutter have been intensified, and several major stuttering treatment programs now offer full-day treatment approaches administered in blocks of several weeks. Current research and clinical efforts are directed at maintenance of fluent speech in the posttreatment environment. A significant number of individuals have been reported to exhibit either partial regression or even total relapse of stuttering without continued practice of speech skills following treatment.

Measures of treatment efficacy have been largely hindered by varying definitions of stuttering and successful treatment. Current therapies report success rates ranging from 60 to over 90 percent when the sole dependent variable is perceived fluent-sounding speech immediately following treatment. However, thorough treatment outcome measures for stuttering should include three elements: (1) a significant positive change in speech output is produced (2) the change is generalized across speaking situations, and (3) the change is maintained over time.

Far fewer studies have been done on the effects of speech therapy for young stuttering children. Clinicians tend to be somewhat divided on the issue of direct therapeutic intervention for the preschooler who stutters. Many advocate an indirect approach, incorporating parent counseling and environmental manipulation to treat the disfluent child. This approach incorporates such techniques as parental modeling of relaxed, unhurried speech and reduction of communicative stressors in the home environment. The second approach introduces direct techniques of speech modification or fluency shaping, such as respiratory control and gentle phonatory onsets, as soon as the child's stuttering behavior has been identified.

SUGGESTED CROSS-REFERENCES

CHAPTER 37. COMMUNICATION DISORDERS

37.5 COMMUNICATION DISORDER NOT OTHERWISE SPECIFIED

REBECCA F. DETWEILER PH.D., AND JOSEPH H. BEITCHMAN, M.D.

DEFINITION AND COMPARATIVE NOSOLOGY

Any disorder of communication that does not meet criteria for inclusion as one of the defined communication disorders is coded as a communication disorder not otherwise specified. Examples of disorders subsumed under this inclusive heading are voice disorders and communication impairment secondary to structural anomaly (e.g., glossectomy, tracheostomy). The latter type of disorder is relatively self-evident; therefore, the balance of this section is focused on voice disorders in children and adolescents.

Voice production is a highly sophisticated physiological activity, involving minute muscular movement precisely coordinated with aerodynamic events, all subserved by multiple organ systems. It reflects physical and emotional state and plays a central role in human communication. A voice disorder, as described in the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV), is any “abnormality of vocal pitch, loudness, quality, tone or resonance.” Given the complexity and sensitivity of the process of voice production, it is not remarkable that these disorders may arise from a multiplicity of factors, including medical disease, emotional stress, psychological conflict, and environmental toxicity.

EPIDEMIOLOGY

Reliable data on the prevalence of voice disorders in the general population are lacking. Estimates of prevalence range from 5 to 25 percent in school-aged children and adolescents. Available data suggest that in younger children, voice disorders are more common among boys than girls; however, in adolescence, prevalence is roughly equal among males and females. In addition, the prevalence of voice disorder is higher in populations with mental retardation, hearing impairment, or disruptive behavior disorders.

Efforts to accumulate data on the incidence of voice disorders have been confounded by discrepancies in the definition of the disorder among studies. Cultural variation in the social acceptability of certain voice characteristics (i.e., low, hoarse voice in females; high-pitched voice in males; strident or hoarse voice in children; hypernasality) has made development of a precise, generally accepted definition problematic.

ETIOLOGY

Organic, behavioral, psychogenic, and environmental factors may all contribute, singly or in combination, to the development of a voice disorder. In patients referred for evaluation of voice symptoms, laryngeal pathology, or structural change to the laryngeal system was observed in 50 to 80 percent. The discrepancy in reported rates of organic pathology is due not only to differences in referral criteria among studies, but primarily to variation in the method of laryngeal visualization used to examine the patient. The application of stroboscopic laryngeal endoscopy in laryngological evaluation has significantly improved the identification of earlier and more subtle forms of organic disease. Stroboscopic illumination provides apparent slowing of the motion of the vocal folds, allowing more-detailed examination of their structure and oscillation patterns. In addition, stroboscopic endoscopy of the larynx is generally performed in the clinic with minimal topical anesthesia on an alert patient; thus the clinician has visual access that previously was obtainable only by direct laryngoscopic examination of patients under general anesthesia.

Voice disorders of organic cause among children and adolescents include laryngeal papilloma, vocal fold nodules, vocal hemorrhage, laryngomalacia, laryngeal webbing (congenital or traumatic), vocal polyps, vocal fold paralysis or paresis, endocrine dysfunction, and laryngeal cancer. Premature infants and children with a history of extended endotracheal intubation are at high risk for development of a number of laryngeal pathologies, including subglottic stenosis, arytenoid dislocation, vocal fold paralysis, and granuloma formation or loss of tissue of the vocal folds. Reflux esophagitis and irritation of the larynx are observed in anorexia nervosa and bulimia nervosa patients and are commonly accompanied by hoarseness and low-pitched voice. Because persistent hoarseness in a child or adolescent, as in an adult, may be a sign of malignancy or another serious medical condition, otolaryngological evaluation is warranted.

Behavioral factors are a major cause of voice disorders in children and adolescents. Habitual, maladaptive vocal behaviors such as throat clearing, use of excessive effort and tension in speaking, or screaming, are often the primary cause of vocal dysfunction in this population. Maladaptive behaviors may give rise to organic lesions of the larynx (e.g., vocal nodules, contact ulcers, chronic laryngitis) or may result in functional dysphonia. Cheerleaders, athletes, and young vocal performers are commonly associated with these types of voice disorders. Less obviously, children with histories of allergies or respiratory disease or who have suffered abuse or trauma, have a history of a learning disorder, disruptive behavior disorder, low academic performance, or substance abuse are also at risk. Research has yet to determine the precise relation of the latter factors to the development of voice disorders, but these children have a significantly higher incidence of voice pathology than the general population. Vocally abusive behaviors may be evidence of underlying psychological problems or may simply be detrimental habits developed spontaneously or imitated from another individual in their environment.

A significant number of voice disorders are primarily or secondarily psychogenic; conversion aphonia or dysphonia and persistent falsetto are classic examples. Conversion voice disorders include total (aphonic) or partial (dysphonic) loss of phonatory function in the absence of identified laryngeal pathology, associated with psychological factors that are judged to be etiologically involved (consistent with diagnostic criteria for conversion disorder as defined in DSM-IV). Persistent falsetto, also referred to as mutational falsetto or puberphonia, is the persistence of high-pitched voice production in adolescents following pubertal maturation of the larynx. In this disorder, the voice fails to change from the higher-pitched, harmonically thinner quality of childhood to the lower, harmonically richer quality of adolescence and adulthood. Though associated primarily with adolescent males, a similar disorder is observed in females. Psychosocial factors observed by clinicians to be associated with this disorder include predominant feminine emotional attachment and self-identification, self-consciousness about physical maturation, or resistance to or rejection of the roles and responsibilities of adulthood.

Functional or organic dysphonias associated with maladaptive vocal behaviors resulting from underlying emotional problems also fall in this category. Thus, a significant proportion of cases of muscle tension dysphonia, vocal nodules, and chronic laryngitis, polypoid degeneration may have a primary or contributory psychogenic cause. Studies indicate that approximately one third of patients evaluated for functional dysphonia received psychiatric diagnoses. Diagnoses in these cases included major depressive disorder and dysthymic disorder, generalized anxiety disorder, conversion disorder, phobias, adjustment disorders with depressed mood or anxiety, posttraumatic stress disorder, personality disorders, and (very rarely) schizophrenia.

In addition, reactive emotional stress is frequently concomitant to vocal dysfunction in cases arising from nonpsychogenic factors. The child or adolescent whose voice differs from those of peers is often subject to teasing; cheerleaders or young performers who lose their voice may suffer anxiety about continued success or popularity. Believing that one's voice is different can contribute to the development of selective mutism. Adults, similarly, have become anxious or depressed when a voice disorder jeopardized their established vocational or interpersonal patterns.

Environmental factors may be significant in the development or perpetuation of a voice disorder. Chronic laryngeal irritation and edema is observed among those exposed to chemical fumes and airborne particles. Second-hand smoke is a frequent cause of laryngeal and respiratory irritation among children, producing wheezing and a hoarse voice in those affected. Inhaled corticosteroid preparations used in the treatment of asthma are implicated in voice changes associated with laryngeal edema and mucosal thickening, as are the propellants used to deliver those medications. Another medication effect with implications for voice dysfunction is mucosal

dehydration produced by several classes of drugs, including antihistamines, diuretic agents, and opioids. Many psychoactive medications have this adverse effect, including several tricyclic and tetracyclic drugs, antipsychotic agents, anxiolytic agents, and particularly the older, high-dosage, low-potency antipsychotic drugs. Drugs with anticholinergic adverse effects (e.g., amitriptyline [Elavil, Endep], chlorpromazine [Thorazine], thioridazine [Mellaril]) and those with sympathomimetic actions (e.g., dextroamphetamine [Dexedrine], methylphenidate [Ritalin]) are known causes of mucosal dryness. Additionally, both intrinsic hormonal cyclic fluctuation (i.e., menstrual cycle) and ingested hormonal preparations may affect vocal function. Even drugs as seemingly innocuous as aspirin may have profound impact on laryngeal health, for example, a premenstrual adolescent who takes aspirin for discomfort and suffers acute vocal hemorrhage during her subsequent cheerleading activity.

The clinician should be alerted to the significance of the drying effect that many psychoactive drugs exert on the laryngeal and oropharyngeal mucosa. This mucosal dehydration reduces lubrication of the vibrating structures of the larynx, potentially compromising a critical protective mechanism against frictional damage to these structures. Use of these medications may exacerbate existing vocal symptoms or trigger the development of voice pathology in predisposed patients. In such cases, the patient should be counseled to maintain adequate oral hydration; consultation with a speech-language pathologist may be warranted if the patient is not currently being seen by one.

DIAGNOSIS AND CLINICAL FEATURES

The essential feature of voice disorder is that one or more parameters of voice production fall outside the normal range for the individual's sex, age, and developmental status. Parameters of voice production include fundamental frequency (pitch), intensity (loudness), voice quality, resonance, and prosody. The diagnosis is primarily perceptual; however, objective measures are increasingly valuable in differential diagnosis, determination of prognosis, and treatment planning.

Fundamental frequency is impaired when the individual's speaking pitch is inappropriately high or low for her or his sex, age, and physical maturation. *Disordered intensity* includes a voice that is inappropriately loud or soft or is inadequate in volume for functional communication in the individual's everyday speaking environment. *Voice quality disturbance* includes voices that are hoarse, breathy, harsh, strident, distracting, or effortful or painful to produce. *Resonance* refers to the quality of nasality in the voice; disorders of this parameter include hypernasality and hyponasality. Finally, *prosodic disturbances* include speech patterns that are monotonic in pitch or loudness, that is, lack the normal inflection of speech, exhibit an abnormally fast or slow rate of production, or include inappropriately spaced or distracting pauses for breath.

The DSM-IV diagnostic criteria for communication disorder not otherwise specified, which subsumes voice disorder, are presented in Table 37.5-1. The criteria for specific disorders of speech and language from the 10th revision of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) are listed in Table 37.5-2.

This category is for disorders in communication that do not meet criteria for any specific communication disorder; for example, a voice disorder (i.e., an abnormality of vocal pitch loudness, quality, tone, or resonance).

Table 37.5-1 DSM-IV Diagnostic Criteria for Communication Disorder Not Otherwise Specified

Table 37.5-2 ICD-10 Diagnostic Criteria for Specific Developmental Disorders of Speech and Language

DIFFERENTIAL DIAGNOSIS

A thorough voice evaluation is the foundation of accurate differential diagnosis of voice disorders. In addition to perceptual assessment, the voice evaluation includes investigation of the patient's history, instrumental measures of the respiratory function for speech, and objective analysis of acoustic output over the entire vocal dynamic range. Comprehensive examination of the patient's personal, medical, social, educational, and vocational history provides critical data relative to factors that may contribute to the development or maintenance of the disorder. Aerodynamic measures and acoustic analysis document deficits in the subsystems serving the perceptual parameters of voice production; identified deficits should be consistent with noted perceptual abnormalities.

Laryngological evaluation includes endoscopic visualization of the larynx, preferably performed under stroboscopic illumination to facilitate minute examination of vocal fold mobility and oscillation patterns. Small lesions and early tissue changes may be difficult to detect by standard indirect laryngoscopic technique. Accurate differentiation of organic and functional pathologies, which may require entirely different treatment approaches, depends upon the quality of laryngeal visualization. In addition, the otolaryngologist may refer the patient for complete medical examination to rule out underlying systemic disease.

Several other pathologies may disturb vocal function and must be differentiated by the clinician from primary disorder of voice. These include stuttering, verbal apraxia, and dysarthria.

Certain symptoms of voice disorder may resemble those of stuttering, including excess physical tension in speech production, laryngeal blocking, and evidence of struggle in production. These symptoms are among the most notable presenting features of spasmodic dysphonia. In general, the two pathologies may be differentiated by the clinician by the time of onset and clinical course of the disease.

Symptoms of spasmodic dysphonia (spastic dysphonia) first appear in early to midadulthood, generally between the ages of 25 and 40. Onset in adolescence or childhood is rare. Stuttering, by contrast, clearly manifests in childhood and is more common in boys than girls. In addition, stuttering shows a typical course of gradual recovery through adolescence, often resolving by age 16. Spasmodic dysphonia demonstrates a progression in which symptoms gradually or suddenly worsen until many patients are left with severe communication impairment. In many cases, symptoms have been unresponsive to voice therapy. Injection of botulinum toxin to paralyze the adductor musculature of the larynx appears to offer these patients the greatest promise of relief at the present time.

Verbal apraxia (also referred to as apraxia of speech) is a disturbance in the programing of speech movements. It is differentiated from voice disorder by its

association with a primary insult to the left cerebral hemisphere. Also, verbal output in apraxic patients is often easier or normal in automatic or overlearned speech output (e.g., automatic social greetings, the song “Happy Birthday”). In most voice disorders, again particularly spasmodic dysphonia, struggle and the strained-strangled quality of production is relatively constant across communication contexts.

When verbal apraxia is observed during childhood speech and language development, it is referred to as *developmental verbal apraxia* (or developmental apraxia of speech). Though the diagnosis is not universally accepted, with some arguing that these children exhibit severe phonological disorder, the literature suggests that this disorder may be differentiated from other developmental articulation disorders by several characteristics, including the coexistence of an oral apraxia or oral sensory deficit, imitative responses that are marked by articulatory groping and struggle, unusual substitutions or distortions, and much more difficulty producing multisyllabic words than monosyllabic ones. In addition, children diagnosed with developmental verbal apraxia often demonstrate associated problems, such as feeding and swallowing problems and difficulty with fine motor coordination or coordination of the extremities. In contrast to patients with acquired verbal apraxia, children with this diagnosis generally do not evince localized neurological insult in neuroimaging studies.

Finally, dysarthria typically affects the laryngeal and resonance musculature as well as that of the respiratory and articulatory systems, resulting in disturbed vocal function. It is differentiated from primary voice disorder by its association with specific neurological insult (e.g., stroke, cerebral palsy, traumatic brain injury) and by the multiplicity of systems involved.

COURSE AND PROGNOSIS

Clinical course and prognosis vary, depending on the nature of the voice disorder, the characteristics and motivation of the patient, and the number of factors functioning to reinforce and maintain the disorder. Straightforward medical disorders that are not complicated by behavioral factors tend to respond well to surgical management and a short course of subsequent voice therapy. Pathologies of this type include vocal polyp and submucous cyst, particularly if the latter is lateral to the vibrating margin of the fold. Other causes, particularly those with habitual maladaptive or abusive vocal behaviors, carry a poorer prognosis. Vocal nodules may be surgically excised but tend to recur unless the underlying vocally abusive behaviors are remediated by an adequate, occasionally extensive, course of voice therapy. Vocal nodules in children are typically not removed, because they may improve spontaneously with the structural change inherent in the physiological maturation of the vocal folds. However, unless the perpetuating behaviors are modified, the pathology tends to persist.

Psychogenic voice disorders tend to show prompt improvement once the underlying emotional problems are resolved. Interdisciplinary management by the speech-language pathologist and psychiatrist or psychologist appears to be most efficacious for these patients.

TREATMENT

Intervention in voice disorders is etiologically and symptomatically determined. Pathologies with an organic basis are typically managed medically or surgically, with adjunctive voice therapy to aid rehabilitation. Behavioral and psychogenic voice disorders are treated by the speech-language pathologist with a course of education, counseling, and behavior modification therapy aimed at reducing, modifying, or eliminating maladaptive vocal behavior. Psychological intervention to address underlying emotional problems is recommended when these issues are identified.

Referral to otolaryngology and speech-language pathology for voice evaluation should be made if any of the following are observed: (1) hoarseness in a child or adult that persists longer than 2 weeks, (2) pain in voice or speech production that persists longer than 2 weeks, (3) a voice quality or difference that either distresses the speaker or distracts the listener, or (4) any unexplained change in the voice. Thorough evaluation is requisite to effective treatment of voice disorders and to resolution of the complex of physiological and emotional factors often associated.

SUGGESTED CROSS-REFERENCES

Section 37.1 and Section 37.2 contain information relative to language disorders in childhood. Section 37.5 provides information on stuttering, which may have symptoms apparently similar to those of certain voice disorders. Information relative to hearing loss and mental retardation may be found in Chapter 34. Information on dysarthria and apraxia is contained in Chapter 35.

CHAPTER 38. PERVASIVE DEVELOPMENTAL DISORDERS

FRED R. VOLKMAR, M.D., AND AMI KLIN, PH.D.

DEFINITION

The pervasive developmental disorders are early-onset conditions characterized by delay and deviance in the development of social, communicative, and other skills. The individual lacks interest in the social environment, but unusual behavioral responses to the inanimate environment are typical, including various motor mannerisms (stereotypies), resistance to change, and idiosyncratic interests and preoccupations. In the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) this category includes autistic disorder, Rett's disorder, childhood disintegrative disorder, Asperger's disorder, and pervasive developmental disorder not otherwise specified.

AUTISTIC DISORDER

Definition Autistic disorder, also known as childhood autism, infantile autism, or early infantile autism, is by far the best known of the pervasive developmental disorders. In this condition there is marked and sustained impairment in social interaction, deviance in communication, and restricted or stereotyped patterns of behavior and interest. Abnormalities in functioning in each of these areas must be present by age 3 years. Approximately 70 percent of individuals with autistic disorder function at the mentally retarded level, and mental retardation is the most common comorbid diagnosis.

History In 1943 Leo Kanner first described 11 cases of what he termed “autistic disturbances of affective contact.” These 11 children had an “inability to relate” in usual ways to people, from the beginning of life. Kanner also noted unusual responses to the environment, which could include both stereotyped motor mannerisms and resistance to change (or insistence on sameness) as well as communication idiosyncrasies such as pronoun reversal and tendency to echo language (echolalia). Kanner's phenomenologically based description of this condition remains worthy of review. At the same time he was mistaken about some aspects of the condition, and his early misconceptions took some years to clarify. For example, Kanner believed that the condition was not associated with mental retardation because the children looked “intelligent” and did well on some parts of intelligence quotient (I.Q.) tests. As time went on it became clear that most of these children function in the mentally retarded range. However, consistent with Kanner's original impression, marked scatter in skills—with occasional splinter skills—is often observed. Kanner also mentioned that the condition was congenital but that in his original cases parents were unusually well educated, successful in their occupations, or both. This led to the notion that autistic disorder might somehow result from pathological patterns of care. Considerable evidence suggests that this is not the case. No particular bias in terms of social class distribution exists if factors that determine case ascertainment are controlled. Also, parents of autistic children do not exhibit specific deficits in parenting, do not exhibit unusual personality characteristics, and are not likely to suffer from other psychiatric disabilities at an increased rate (with the possible exception of depression). Finally, Kanner's use of the term “autism” was reminiscent of Leo Bleuler's earlier use of the term to describe the quality of self-centered thinking typically seen in schizophrenia. Although Kanner originally believed that autism and schizophrenia were unrelated, his use of this word suggested a relationship, which caused much confusion for many years. One part of this assumption rested on a presumption of continuity based on severity; that is, the presumption was that since autism was so severe, it must somehow be on a continuum with schizophrenia.

In his report Kanner carefully provided a developmental context for his observations. He emphasized both the centrality of deficits in social relatedness and unusual behaviors in the definition of the condition. During the 1960s, there was much confusion about the nature of autism and its etiology. In the early 1960s a growing body of evidence began to suggest that the condition resulted from a neuropathological process. Difficulties in consensual definitions and confusion about the similarities and differences of autism and childhood schizophrenia were complications. By the 1970s a considerable body of evidence began to suggest the neurobiological basis of the disorder. This included high rates of seizures in children followed over time, persistence of unusual primitive reflexes, and other neurological signs. Follow-up studies of large groups of psychotic children revealed a bimodal distribution of onset of this poorly defined condition. The early-onset group, noted by Israel Kolvin, M. Rutter, and others, appeared to have many of the characteristics described by Kanner. Children with later-onset psychosis (after age 5 or 6) seemed to resemble those with schizophrenia in having delusions and hallucinations. Family history also discriminated the groups; the family members of those with the late-onset-type had higher rates of schizophrenia.

A landmark in classification occurred in 1978 when Rutter proposed a definition of autism based on (1) social delay and deviance that were not just a function of mental retardation; (2) communication problems, again, not just a function of associated mental retardation; (3) unusual behaviors such as stereotyped movements and mannerisms; and (4) onset before age 30 months.

Rutter's definition and the growing body of work on autism were influential in the definition of the condition in the third edition of DSM (DSM-III), in which the condition was first recognized and placed in a new class of disorder—the pervasive developmental disorders.

Comparative Nosology The first and second editions of DSM (DSM-I and DSM-II) did not officially recognize autistic disorder; rather, it was viewed as being on some continuum with schizophrenia. Childhood schizophrenia, particularly very-early-onset childhood schizophrenia, is now known to be quite rare. However, in the 1950s and 1960s a broad view of schizophrenia predominated.

The definition of autism in DSM-III was based largely on Rutter's synthesis of Kanner's original description and subsequent research. The name of the disorder “infantile autism” emphasized its early onset but also reflected a certain lack of developmental orientation in the diagnosis and criteria for it. The criteria were monothetic and most appropriate to younger children with autism; a category “residual infantile autism” was available for children, adolescents, and adults who once had met criteria for the condition, but no longer did so. This concept was problematic in several respects and reflected the lack of a developmental orientation.

The revised third edition of DSM (DSM-III-R) addressed the concern about the lack of developmental emphasis. Age of onset could be specified before or after 36 months. The condition was diagnosed on the basis of a set of 16 very detailed criteria grouped in the traditional 3 categories of social disturbance, communicative disturbance, and restricted and repetitive behaviors. The greater developmental orientation of DSM-III-R also engendered a broader diagnostic concept, which was probably overinclusive. An additional change in DSM-III-R was the multiaxial placement of autism and other pervasive developmental disorders; the condition was moved to Axis II, and only the two diagnoses of autistic disorder and pervasive developmental disorder not otherwise specified were included.

The term “pervasive developmental disorder” has been controversial. Coined originally in 1980 as a new term for the class of disorders to which autism was assigned, the term was chosen to reflect the fact that multiple areas of functioning are affected in autism and related conditions. However, some investigators and clinicians have objected to the term since it seems to imply a greater severity than always occurs in individual cases. However, by the time of DSM-III-R the term had come into general usage, and in the 10th revision of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10), the term was used as a category as well.

In the ninth revision of *International Statistical Classification of Diseases* (ICD-9) the category of psychoses with onset in childhood included the subgroup of infantile autism among others. The use of the term “psychosis” in ICD-9 perpetuated the unfortunate impression that autism was related to adult schizophrenia. In ICD-10 the pervasive developmental disorder category includes childhood autism, atypical autism (in which there is a failure to meet the behavioral or onset criteria), Rett's syndrome, other childhood disintegrative disorder, overactive disorder with mental retardation and stereotyped movements, Asperger's syndrome, other pervasive developmental disorder, and pervasive developmental disorder unspecified (Table 38-1). In contrast to DSM-IV there is an even greater attempt to differentiate subgroups of pervasive developmental disorders. However, the validity of these conditions has been controversial, and definitive data are lacking. Despite the concerns about such distinctions, the working group responsible for DSM-IV decided, partly on the basis of a large international field trial, to try to achieve as much consistency with ICD-10 as possible. In the end they largely succeeded, although some differences in emphasis exist.

Table 38-1 ICD-10 Diagnostic Criteria for Pervasive Developmental Disorders

In DSM-IV, autistic disorder is defined on the basis of behavioral features and age of onset, which must be before 3 years. Behavioral difficulties must include some feature of social disturbance, communicative disturbance, and restricted interests or repetitive behaviors. The definitions of autism in both ICD-10 and DSM-IV are conceptually identical. There was an explicit attempt to avoid the overinclusiveness of DSM-III-R criteria for autistic disorder. In addition, the disorder was returned to Axis I. Criteria number and detail were also reduced.

The field trial for autistic disorder and related conditions in DSM-IV was an international, multisite study that included 977 subjects, 454 with autism and 283 with conditions other than pervasive developmental disorders. Characteristics of the field trial sample and results are summarized in Table 38-2 and Table 38-3. Interrater reliability was assessed for autism and related conditions and was generally good to excellent, particularly for experienced clinicians.

	Clinically Autistic (N = 454)	Other PDDs (N = 240)	Non-PDD (N = 283)
Sex ratio (M:F)	4.49:1	3.71:1	2.29:1
% Mute	54%	35%	33%

Epidemiology

Prevalence The first epidemiological study of autism was conducted by Victor Lotter in 1966, who reported a prevalence rate of 4.5 in 10,000 children among the entire 8- to 10-year-old population of Middlesex, a county northwest of London. Since then 23 epidemiological studies worldwide reported in the literature have surveyed over 4,000,000 children and identified 1545 individuals thought to have autism. Prevalence rates ranged from 0.7 per 10,000 to 21.1 per 10,000 (Table 38-4). The median prevalence estimate of 4 to 5 per 10,000 is consistent with Lotter's initial value. Variability among studies reflect methodological issues such as sample size, syndrome definition, and aspects of screening and ascertainment. Recent studies have reported higher prevalence rates. Possible reasons for the increased rates involve (1) broader definitions of autism; (2) smaller target populations, since in general, smaller studies have yielded the higher rates, and (3) better detection of cases in the extreme ranges (i.e., severely mentally retarded children and nonretarded individuals with autism). Some studies have also included estimates of the broader spectrum of autistic conditions. Although the reliability for diagnostic ascertainment of these autistic-like conditions remains questionable, compelling evidence indicates that perhaps 1 in every 1000 children may exhibit social disabilities consistent with the autistic spectrum of disorders.

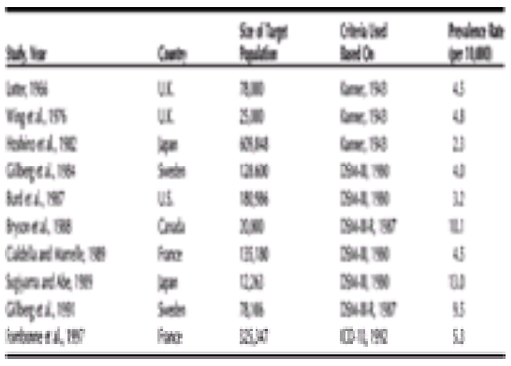

Table 38-4 Representative Epidemiological Studies of Autism

Sex Ratio Studies based on both clinical and epidemiological samples have suggested a higher incidence of autistic disorder in boys than in girls, with reported ratios averaging about 3.5 or 4.0 to 1. This ratio varies, however, as a function of intellectual functioning. Some studies have reported ratios of up to 6.0 or more to 1 in individuals with autism without mental retardation, whereas reported ratios within the moderately to severely mentally retarded range have been as low as 1.5 to 1.

Why females are underrepresented in the nonretarded range remains unclear. One possibility is that males have a lower threshold for brain dysfunction than females or, conversely, that more-severe brain damage is required to cause autism in a girl. According to this hypothesis, a girl with autism is more likely to be severely cognitively impaired.

Social Class Although a few early studies supported Kanner's impression of an association between autism and upper socioeconomic status, epidemiological studies by L. Wing, Eric Schopler, and others have failed to reveal such association. In addition to the bias for more-educated and successful parents to seek referral, families from disadvantaged backgrounds still seem to be underrepresented in clinically referred samples. Outreach initiatives are needed to give children from all socioeconomic backgrounds equal access to diagnostic and intervention services.

Etiology

Psychosocial Theories Kanner's original speculation that emotional factors might be involved in the pathogenesis of autism led others to conclude that the condition was always caused by a “refrigerator” mother who was not responsive to the child's emotional needs. This view was particularly expounded in this country by Bruno Bettelheim, who recommended intensive psychotherapy for mother and child or sometimes removal of the child from the family, in an attempt to remediate the basic deficit. Unfortunately, no evidence showed that such efforts were efficacious. A generation of parents was traumatized by the experience of being blamed for their child's condition.

Biological Theories Factors that suggested a biological basis for the condition included the high rate of mental retardation and seizure disorders and the recognition that various medical or genetic conditions are sometimes associated with the syndrome. The present consensus is that autistic disorder is a behavioral syndrome caused by one or more factors acting on the central nervous system (CNS). While the underlying biological abnormalities of autistic disorder are unknown, efforts are now under way to develop precisely testable neuropathological mechanisms.

Genetic Factors The early impression was that genetic factors had no role in the pathogenesis of autism. The condition is relatively rare and patients did not seem to reproduce. Studies of twins indicated high concordance, especially for monozygotic twin pairs, with reduced concordance for fraternal, or dizygotic, same-sex twin pairs. Evidence also suggested that the high rates of cognitive difficulties in the unaffected monozygotic twin were associated with perinatal complications in the autistic cotwin, suggesting a perinatal insult related to autism in the face of some inherited liability for the disorder. In general, family studies have shown a rate of recurrence in families of approximately 2 to 3 percent of autism among siblings. However, this is 50 to 100 times the rate of autism in the general population. Moreover, parents who are given the early diagnosis and presentation of autism might consciously or unconsciously decide against having additional children. If this phenomenon, “stoppage,” is taken into account, the risk to siblings is even higher. Even when not affected, siblings are at increased risk for various developmental difficulties, including problems in language and cognitive development. It remains unclear whether what is inherited is a specific predisposition to autistic disorder or a more general predisposition to developmental difficulties. Recent work on the family members of autistic persons finds higher rates of mood and anxiety problems and increased frequency of social difficulties. Although the role of genetic factors in autistic disorder is now well established, specific modes of inheritance remain unclear, and efforts are under way to identify potential genetic mechanisms. It is possible and indeed even likely that some genetic forms of autism will be identified over the next few years.

Other Medical Conditions and Autistic Disorder Autistic disorder has also been associated with other conditions with a strong genetic component, most notably fragile X syndrome and tuberous sclerosis. In fragile X syndrome, a marker X chromosome in cells grown in a special medium deficient in folic acid has a site that commonly fractures. The fragile X mutation includes a triplet repeat of cytosine-guanine-guanine (CGG) that may be amplified in succeeding generations. Physical signs of the condition include characteristic facies, enlarged testicles, associated mental retardation, and some autistic features. Behavioral difficulties include attention problems, impulsivity, and anxiety. Initially there was great enthusiasm for the notion that a fragile X chromosome might account for most cases of autism in males. In fact, only about 1 percent of individuals with autism are affected. This condition remains the second most important known chromosomal cause of mental retardation, after Down syndrome.

Tuberous sclerosis is characterized by abnormal tissue growth, or benign tumors (hamartomas), that affect various organ systems. This autosomal dominant disorder is associated with a range of phenotypes including mental retardation and seizure disorder. Studies find tuberous sclerosis in 0.4 to 2.8 percent of autistic individuals, a significantly higher rate than that in the general population. Rates of autistic disorder in individuals with this disorder are high.

Perinatal Factors Several studies have shown increased rates of prenatal, perinatal, and neonatal complications in autistic disorder children. Much of the difference relates to observations that something unusual is noted about the child at birth, which may reflect the operation of both genetic and perinatal factors. The genetic predisposition to autistic disorder may interact with perinatal factors in producing the syndrome.

Other Causes Various reports have associated autistic disorder with a host of other conditions. However, these reports usually describe single cases rather than controlled studies. Several associations have been of interest, for example, autism associated with phenylketonuria, neurofibromatosis, and congenital rubella. However, when children with congenital rubella who were initially thought to have autistic disorder were followed over time, their autistic-like features tended to diminish; also these children exhibit a range of sensory deficits and mental retardation, both of which complicate diagnosis.

Neuroanatomical Models Studies have focused on the cortical and subcortical systems related to language and cognitive processing, that is, on areas of the frontal and temporal lobes, as well as the neostriatum, sensory processing systems, and the cerebellum. A role for the mesial temporal lobe was suggested by dilatation of the temporal horn in the left lateral ventricle observed in early studies using pneumoencephalogram. Subsequent findings by computed tomography (CT) and magnetic resonance imaging (MRI) have been somewhat less consistent. Some autistic individuals have enlarged brains and heads, whereas others (particularly those more retarded) have smaller heads. Neuropathological studies have suggested cellular changes in the hippocampus and the amygdala; increased cell packing has been seen in the amygdala. The cerebellum was the focus of some interest after reduced cerebellar size in the neocerebellar vermal lobules VI and VII was reported; however, other investigators have failed to replicate this finding. Some neuropathological studies have suggested decreased numbers of Purkinje's cells in the cerebellar vermis and hemispheres.

Although animal models of autistic disorder have been attempted, young animals with marked social deficits would be much less likely to be cared for by their parents and thus are at greatly increased risk of mortality. Models of the condition have been attempted by administration of drugs (e.g., amphetamine) to induce motor stereotypy as well as by lesions of certain brain structures.

The severe deficits in language and communication that characterize autistic disorder have suggested the possibility of left cortical involvement to many investigators. Results of studies have, however, been equivocal. Since at least some functions affected in autistic disorder (prosody and language pragmatics) are more likely to be right-hemisphere related, a left hemisphere hypothesis cannot account for all deficits.

Neurochemistry Beginning in 1961 a number of studies have reported that approximately one third of children with autistic disorder have increased peripheral concentrations of the neurotransmitter serotonin. Despite much research the significance of this finding remains unclear since it is not specific to autism and the relation of peripheral concentrations to central concentrations of serotonin is unclear.

Other work has focused on other neurotransmitters, such as dopamine. Hyperdopaminergic functioning of the brain might explain the overactivity and stereotyped movements seen in autism. Administration of stimulants that increase dopamine concentration typically worsens behavioral functioning in autistic disorder. Studies of dopamine metabolites and catecholamine metabolites in cerebrospinal fluid (CSF) have yielded inconsistent results; however, agents that block dopamine receptors are effective in reducing the stereotyped and hyperactive behaviors of many autistic children.

The endogenous opioids were investigated given the possibility that these compounds, enkephalins and endorphins, might lead to social withdrawal and unusual sensitivities to the environment. This was the rationale for using opioid antagonists such as naltrexone (ReVia) to treat children with autistic disorder. Although these agents may have a modest effect on the high levels of activity and agitation, overall results have been disappointing.

Immune Theories Some work has suggested a possible role of immunological factors in autistic disorder. There has been a suggestion that maternal antibodies directed against the fetus may be produced in utero. There also have been reports of autism associated with viral infections.

Diagnosis and Clinical Features A diagnosis of autistic disorder requires at least six behavioral criteria, one from each of the three areas of disturbance in social interaction, communication, and restricted patterns of behavior and interest (Table 38-5). There is a marked range of syndrome expression in autistic disorder. The

lowest-functioning children typically are largely or entirely mute, are isolated from social interaction, and make few social overtures. At the next level children may accept social interaction passively but do not seek it out. At this level, some spontaneous language may be observed. The higher-functioning and somewhat older children have a different social style; they may be interested in social interaction but cannot sustain it in typical ways. The social style of such individuals has been termed “active but odd” in that they often have difficulty regulating social interaction once it has begun. Behavioral features of autistic disorder change over the course of development. Considerable potential for misdiagnosis exists, especially at the extremes of intellectual functioning. Evaluation of the autistic child should include a detailed history, comprehensive medical and developmental examination, and psychological testing.

Table 38-5 Diagnostic Criteria for Autistic Disorder

Age at Onset The onset of autism is almost always before age 3 years (Fig. 38-1); parents typically become concerned between the ages of 12 and 18 months as language fails to develop. Although they may be concerned that the child is deaf, the parents also note the child may respond quite dramatically to sounds in the inanimate environment; occasionally parents report in retrospect that the child was “too good,” made few demands, and had little interest in social interaction. This is in stark contrast to normally developing infants for whom the human face and social interaction are among the most interesting and salient features of the world. In 20 to 25 percent of cases parents report that children seemed to develop some language, and then their language either plateaued or was lost. Parents almost always report being worried by age 2 and inevitably by age 3 (onset of the condition after age 3 would result in a diagnosis of atypical autism). Occasionally parents of very high-functioning children with autistic disorder may be less concerned in the first year or two of life, but even these parents become concerned before age 3 as the severe deficits in social interaction become more apparent.

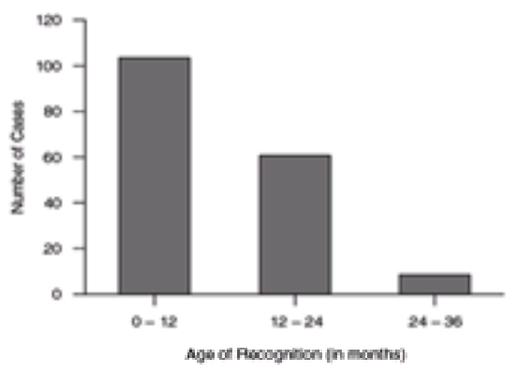

FIGURE 38-1 Age of recognition of autism in a series of 174 consecutive cases. (Reprinted with permission from Lewis M, Volkmar F: *Clinical Aspects of Child Development*, ed 4. Williams & Wilkins, Baltimore, 1996.

Qualitative Impairments in Social Interaction Normally developing infants have a marked interest in social interaction and the social environment from birth. This predisposition is an important foundation for development of other skills. In autistic infants and young children the human face holds little interest, and disturbances are seen in the development of joint attention, attachment, and other aspects of social interaction. For example, the child may not engage in the usual games of infancy, may have difficulties with imitation, and may lack usual play skills. These deficits are highly distinctive and do not just reflect associated developmental delay.

Social interest may increase over time. There is often a developmental progression with younger and more impaired individuals being avoidant or aloof from interaction while somewhat older or more advanced individuals are willing to accept interaction passively but do not seek it out. The most able persons with autistic disorder often display social interest but have difficulty managing the complexities of social interaction, which often leads to an unusual or apparently eccentric social style.

Qualitative Impairment in Verbal and Nonverbal Communication and Play As many as 50 percent of individuals with autistic disorder never speak. Delays in the acquisition of language are the most frequent presenting complaint of parents. Usual patterns of language acquisition (e.g., playing with sounds and babbling) may be absent or infrequent. Infants and young children with autistic disorder may take the parent's hand to obtain a desired object without making eye contact (i.e., as if the hand, rather than the person, is obtaining the item). In contrast to children with language disorder, these children have no apparent motivation to engage in communication or attempt to communicate via nonverbal means.

When individuals with autistic disorder do speak, their language is remarkable in various ways. They may echo what they have heard (echolalia). Speech tends to be less flexible so that for example, there is no appreciation that change in perspective or speaker requires pronoun change, which leads to pronoun reversal. Speech may be nonreciprocal (e.g., the child produces language that is not meant as communication). While the syntax and morphology of language are relatively spared, vocabulary and semantic skills may be slow to develop, and aspects of the social uses of language (pragmatics) are particularly difficult for individuals with autistic disorder. Thus humor and sarcasm may confuse a person with autistic disorder who fails to appreciate the speaker's communicative intent—resulting in an overly literal interpretation of the utterance. Often intonation is monotonic and robotlike.

Deficits in play may include a failure to develop usual patterns of symbolic-imaginative play. Children with autistic disorder may explore nonfunctional aspects of play materials (e.g., taste or smell) or use aspects of materials for self-stimulation (spinning the tires on a toy truck).

Markedly Restricted Repertoire of Activities and Interests Children with autistic disorder often have difficulty tolerating change and variation in routine. For example, an attempt to alter the sequence of some activity may be met with what appears to be catastrophic distress on the part of the child. Parents may report that the child insists that they engage in activities in very particular ways. Changes in routine or in the environment may elicit great opposition or upset. The child may develop an interest in a repetitive activity such as collecting strings and using them for self-stimulation, memorizing numbers, or repeating certain words or phrases. In younger children attachments to objects, when they occur, differ from usual transitional objects in that the objects chosen tend to be hard rather than soft, and often it is the class of object, rather than the particular object, which is important (e.g., the child may insist on carrying a certain kind of magazine around). Stereotyped movements may include toe walking, finger flicking, body rocking, and other mannerisms, which are engaged in as a source of pleasure, or self-soothing. The child may be preoccupied with spinning objects, for example, spending long periods of time watching a ceiling fan rotate.

Associated Features In contrast to Kanner's early belief that children with autism had good cognitive potential, approximately 75 to 80 percent are mentally retarded, with about 30 percent falling within the mild-to-moderate range and about 45 percent being severely to profoundly mentally retarded (Fig. 38-2). The mental retardation is not simply a consequence of negativism or lack of motivation. The typical profile on psychological testing is marked by significant deficits in abstract reasoning, verbal concept formation, and integration skills and in tasks requiring social understanding. Therefore, on the Intelligence Scale for Children, for example, weaknesses are usually obtained on the Similarities and Comprehension subtests. In contrast, relative strengths are usually observed in the areas of rote learning

and memory skills and visual-spatial problem solving, particularly if the task can be completed piecemeal, that is, without having to infer the context, or gestalt, of the task. Therefore, performance on the Block Design and Digit Recall subtests of the Wechsler scales usually correspond to peak performances. The typical preference for rote and sequential tasks rather than reasoning and integrative tasks usually carries the implication that individuals with autistic disorder fail to see “the trees from the leaves,” a difficulty that cuts across functioning modalities, from cognitive testing to communication and social interaction. Given the ubiquity of verbal deficits in autistic disorder, individuals usually have higher performance than verbal scores, particularly in the individuals scoring in the mentally retarded range. Interestingly, some studies have suggested the opposite pattern in individuals with Asperger's disorder.

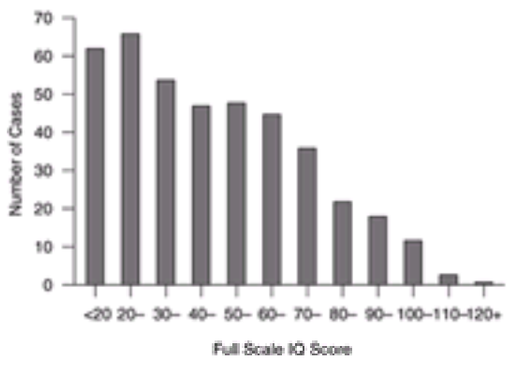

FIGURE 38-2 Full-scale I.Q. in a series of individuals with autism.

Several influential cognitive theories of the social dysfunction in autistic disorder have been proposed. One hypothesis posits a lack of a central drive for coherence, with the consequent focus on dissociated fragments rather than integrated wholes, leading to a fragmentary and overly concrete experience of the world. Another hypothesis posits deficits in executive functioning, that is, in the ability to abstract rules, inhibit irrelevant responses, shift attention and profit from feedback, and maintain a focus on multiple aspects of information in decision making. Since executive functions are thought to be mediated by frontal areas, this hypothesis highlights the similarities between autistic disorder and conditions resulting from frontal lobe lesions. However, this hypothesis lacks specificity for autistic disorder, since a range of developmental psychiatric conditions share such deficits. Another hypothesis, probably the most influential, posits that autistic disorder is caused by the child's inability to attribute mental states (e.g., beliefs and intentions) to others. Devoid of such a “theory of mind,” autistic individuals are presumed unable to infer the thoughts and motivations of others; and thus unable to predict their behavior and adjust accordingly, which results in a lack of reciprocity in communication and social contact. Although the topic of much research, this hypothesis does not account for the very early social abnormalities in autism, and it is not specific to autism.

One of the most fascinating cognitive phenomena in autistic disorder is the presence of so-called islets of special abilities, or splinter skills (i.e., preserved or very highly developed skills in specific areas, which contrast with the child's overall deficits in cognitive functioning). For example, autistic children frequently have great facility in decoding letters and numbers, at times precociously (hyperlexia), even though comprehension of what is read is much impaired. Perhaps 10 percent of individuals with autistic disorder exhibit a form of savant skills—high, sometimes prodigious, performance on a specific skill in the presence of mild or moderate mental retardation. This fascinating phenomenon usually relates to a narrow range of capacities, for example, memorizing lists or trivial information, calendar calculation, visual-spatial skills such as drawing, or musical skills involving perfect pitch or playing a piece of music after hearing it only once. Individuals with autistic disorder represent a disproportionate majority of all savants.

ABNORMALITIES OF MOTOR BEHAVIOR One of the prototypical aspects of autistic disorder is the display of motor stereotypies such as hand flapping, body rocking, and finger twiddling or waving in front of the eyes, as well as other repetitive and purposeless motor mannerisms such as tiptoe walking and assuming odd postures. Stereotypies are also seen in other conditions, particularly severe mental retardation and sensory impairments such as blindness and deafness, but they are clearly more common in autistic disorder, often emerging about ages 3 to 4. Often they are less frequent in adolescence and adulthood and in higher intellectually functioning individuals. Some children with autistic disorder may copy other people's motor movements without necessarily learning the purpose of that movement. This phenomenon, echopraxia, is to some extent the motor equivalent of echolalia in language. Normative motor skills are usually preserved relative to the child's intellectual level, although higher-functioning children can be clumsy and ill coordinated. Developmental course is an important consideration, since a large percentage of children with autistic disorder appear quite graceful and agile in preschool years but awkward and unnatural in adolescence and adulthood. Recent research on motor development has highlighted the ever-increasing control that higher cognitive and social functions exercise on motor skills and presentation, potentially accounting for this developmental course observed in autistic disorder. Overactivity is common in autistic disorder, particularly in preschool years. At the same time a lack of curiosity in the environment and passivity (i.e., hypoactivity) may also be observed in these children. The two may alternate in the same child in different settings or in relation to different activities. Task engagement and attention are important considerations in educational programing.

ABNORMAL RESPONSES TO SENSORY STIMULI Both hypersensitivity and hyposensitivity to sensory stimuli are typical of children with autistic disorder. Theoretical models have proposed that aberrant sensory modulation arises from impaired brainstem attentional mechanisms or from excessive amounts of striatal beta endorphin. Children with autistic disorder may be acutely sensitive to sounds (hyperacusis), for example, covering their ears when hearing a dog bark or the noise of a vacuum cleaner. Other children may appear oblivious to loud noise or people calling them but be fascinated by the faint ticking of a wristwatch or the sound of crumpling paper. Bright lights may be distressing, although some children are fascinated with light stimulation, for example, moving an object back and forth in front of their eyes. There may be extreme sensitivity to touch (tactile defensiveness), including major reactions to specific fabrics and social or affectional touch, but many children appear to be insensitive to pain and may not cry after a severe injury. Many children are fascinated by certain sensory stimuli, such as spinning objects or toy parts that can spin, while some enjoy vestibular sensations such as twirling and engage in this action apparently without becoming dizzy.

SLEEPING AND EATING DISTURBANCES Sleeping and eating disturbances can greatly disturb family life, particularly during childhood. Children with autistic disorder may display erratic sleep patterns with recurrent awakening at night for long periods. Eating disturbances may involve aversion to certain foods because of their texture, color, or smell or insistence on eating a limited choice of foods and refusal to try new foods. In the more severely cognitively impaired children, pica may pose a range of safety issues including the risk of lead poisoning.

MOOD AND AFFECT DISTURBANCES Poor affect modulation and the display of emotions inappropriate to a given social situation are common. Some individuals may show sudden mood changes, and laugh, cry, or giggle to themselves for no apparent reason. Higher-functioning individuals may display intense anxiety in social situations; they may also develop depression in adolescence, usually as a result of their negative social experiences over the years and their partial insight into their condition—knowing that they are different from others without fully understanding their own contribution to the rejecting or otherwise isolating reactions of their peers.

SELF-INJURIOUS BEHAVIOR AND AGGRESSION AGAINST OTHERS Lower-functioning children with autistic disorder may bite their hands or wrists, often causing bleeding and callus formation. Head banging, particularly by severely or profoundly mentally retarded children, may necessitate the use of helmets or other protective devices. Children may also pick their skin, pull their hair, bang their chests, or hit themselves. They have a decreased sense of danger that, along with impulsivity, may lead to injuries. Temper tantrums are common, particularly in reaction to demands (e.g., to comply with a task), changes in routine, or otherwise unexpected events. Lack of understanding or inability to communicate, or sheer frustration may occasionally prompt aggressive outbursts. Although some higher-functioning individuals (e.g., those with Asperger's disorder) have been described as particularly apt to exhibit antisocial behaviors, these individuals are in fact more likely to be victims of practical jokes or other forms of aggression; more commonly, these individuals tend to gravitate toward the periphery of social settings.

SEIZURE DISORDERS Epilepsy develops in approximately 10 to 35 percent of the autistic disorder population by young adulthood, based on the occurrence of readily identifiable major motor seizures (Fig. 38-3). Although there is evidence of seizure onset at all ages, early childhood and adolescence have been reported to be the peak periods. Lower-functioning individuals are at increased risk. The onset of seizures may be associated with deterioration.

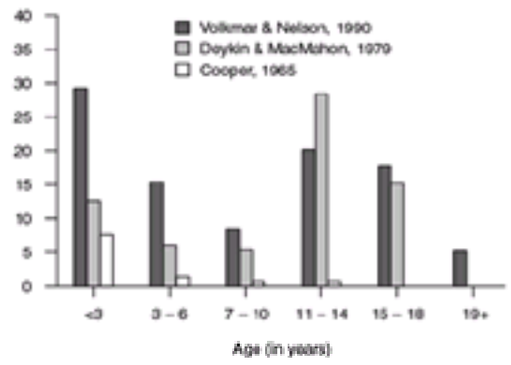

FIGURE 38-3 Rates of first seizure (incidence rate per 1000) in samples of individuals with autism. Data from patients with autism (Volkmar F, Nelson D: Seizure disorders in autism. J Am Acad Child Adolesc Psychiatry *29:*127, 1990) and patients with autism/PDD Deykin EY, MacMahon B: The incidence of seizures among children with autistic symptoms. Am J Psychiatry *126:*1310, 1979) compared with rates in a normative sample Cooper JE: Epilepsy in longitudinal survey of 5000 children. Br Med J *1:*1020, 1965).

PHYSICAL CHARACTERISTICS Children with autistic disorder exhibit a higher incidence of minor physical anomalies such as ear malformations. These anomalies may reflect the embryological period in which the factors responsible for autism act (e.g., ears are formed at about the same time as older regions of the brain). Young children with autistic disorder are often described as very attractive and fail to exhibit any forms of stigmata. Such descriptions are less common with adolescents and adults when the social dysfunction has a cumulative effect on physical appearance.

Pathology and Laboratory Examination

Electroencephalography A variety of electroencephalographic (EEG) abnormalities may be seen in autistic disorder, including diffuse and focal spikes, paroxysmal spike and wave patterns, multifocal spike activity, and a mixed discharge. The prevalance of EEG abnormalities in autistic disorder (in the absence of a clinical seizure disorder) ranges from 10 to 83 percent and depends on the number of recordings and the nature of the sample obtained. The prevelance of abnormal EEGs is significantly higher in individuals with mental retardation and autistic disorder. The high prevalance of EEG abnormalities and seizure disorders in autism were among the first compelling pieces of evidence supporting a biological basis for the condition.

Evoked Potential Recording Both early and more-recent studies of auditory brainstem evoked potentials in autistic disorder indicate that if children with underlying neurological conditions are excluded and age and gender are controlled, no evidence exists for abnormalities in the auditory brainstem pathways. However, abnormalities of cognitive potentials, particularly the auditory P300 (which represents the brain's processing of sensory stimuli) have been demonstrated in autistic disorder. This presumably reflects abnormalities in higher auditory processing and neural pathways.

Oculomotor and Postural Physiology Studies that focus on oculomotor and postural physiology of motor pathways have found bilaterally symmetric abnormalities in functions that depend on neocortical circuitry, with subtle or no abnormalities in parameters that depend on widely distributed pathways between posterior fossa and cortex and intact oculovestibular reflexes and posterior fossa circuitry.

Neuroimaging Studies

Computed Tomography Although some CT studies have shown enlargement of the lateral and third ventricles in approximately 15 to 45 percent of autistic individuals, several subsequent studies failed to corroborate this finding. Additionally, with the exception of the ventricular finding, the CT scans of subjects participating in these studies were otherwise normal, and since ventricular size was unrelated to all clinical indices examined in these studies, the implications of ventricular enlargement for the pathophysiology of autism are unknown.

Magnetic Resonance Imaging Two MRI studies of total brain area and volume found increased total brain volume above the lower boundary of the brainstem, reflecting increased tissue volume and lateral ventricular volume. A follow-up study reported that the enlargement of the cerebral hemisphere was regional, involving occipital, parietal, and temporal regions but not the frontal lobe. A series of MRI studies focusing on the cerebellar vermis revealed decrease in the midsagittal area of vermal lobules VI and VII, but these findings have not been independently replicated in studies controlling for age and I.Q. A small number of MRI studies of the brainstem revealed a reduction in area, although most studies found no differences from controls; similarly, volumetric studies of hippocampus revealed no abnormalities. While an early MRI study of corpus callosum found no abnormalities in the midsagittal area, a recent study reported decreases in the middle and posterior regions when measurements were adjusted for total brain volume. The latter study involved the same subjects in whom increased volumes of the parietal, temporal, and occipital lobes but not the frontal lobes were found. The dissociation between the sizes of the cerebral cortex and corpus callosum was interpreted as evidence of abnormal development of neural connectivity between the hemispheres.

Neuropathological Studies Autopsy studies of a small number of autistic individuals have failed to reveal gross brain abnormalities. However, microscopic analysis has revealed reduced neuronal size and increased cell packing density in the hippocampus, amygdala, mammillary body, anterior cingulate cortex, and septum. These areas are known to be related to each other by interconnecting circuits making up a major portion of the limbic system of the brain. There is evidence of decreased numbers of Purkinje's cells and granule cells in the neocerebellar cortex.

Differential Diagnosis Autistic disorder must be differentiated from other pervasive developmental disorders and other developmental disorders (e.g., mental retardation and communication disorders) as well as from sensory impairments, particularly deafness. Both history and current examination help in differentiating autistic disorder from other pervasive developmental disorders (Table 38-6). The onset of autistic disorder is usually well before the third birthday. The unusual patterns of onset noted in Rett's disorder and childhood disintegrative disorder are not observed. Some potential for confusion with Asperger's disorder exists, since a diagnosis of autistic disorder takes precedence over Asperger's disorder. The early preservation of language skills in Asperger's disorder and the later age of parental concern are helpful diagnostic features. Sometimes, extensive questioning elicits the observation that parents noted some minimal abnormality or oddity in the child with Asperger's disorder in the first 3 years of life; usually this should not be taken to mean that the child meets criteria for autistic disorder.

Feature	Autistic Disorder	Asperger's Disorder	Rett's Disorder	Childhood Disintegrative Disorder	Pervasive Developmental Disorder NOS
Age at recognition (months)	0–36	Usually >36	5–30	>24	Variable
Sex ratio	M>F	M>F	F	M>F	M>F
Loss of skills	Variable	Usually not	Marked	Marked	Usually not
Social skills	Very poor	Poor	Varies with age	Very poor	Variable
Communication skills	Usually poor	Fair	Very poor	Very poor	Fair to good
Circumscribed interests	Variable (mechanical)	Marked (facts)	NA	NA	Variable
Family history of similar problems	Sometimes	Frequent	Not usually	No	Unknown
Seizure disorder	Common	Uncommon	Frequent	Common	Uncommon
Head growth decelerates	No	No	Yes	No	No
I.Q. range	Severe MR to normal	Mild MR to normal	Severe MR	Severe MR	Severe MR to normal
Outcome	Poor to fair	Fair to good	Very poor	Very poor	Fair to good

Table 38-6 Differential Diagnostic Features of Autism and Nonautistic Pervasive Developmental Disorders

In mild-to-moderate mental retardation social skills are usually consistent with abilities in cognition and communication. In persons with severe and profound retardation the frequency of both autistic disorder and autistic-like behaviors increases. A common source of diagnostic error is the confusion of stereotypies in such

individuals. In higher-functioning individuals there is potential confusion with personality disorders that involve social isolation (e.g., schizoid personality disorder).

Videotapes or other aids to memory may facilitate in obtaining a history. It also may help to ask the parent to recall the child at particular dates (e.g., third birthday). In autistic disorder usually there is no history of normal development, although about 20 to 25 percent of cases there may be a question of an apparent period of normal development prior to either developmental stagnation or developmental regression. A history of clearly normal development raises the possibility of selective mutism, Rett's disorder, childhood disintegrative disorder, language disorder, schizophrenia, and degenerative CNS disorders. Typically children who have experienced severe neglect exhibit delayed or deviant social skills, but other features of autistic disorder are not present, and the social deficits remit with appropriate care. In schizophrenia of childhood onset there is usually a long period (many years) of normal or near normal development prior to the onset of characteristic delusions, hallucinations, and so forth. In some instances the diagnosis can be made with certainty only over time.

John was the second of two children born to middle-class parents after normal pregnancy, labor, and delivery. As an infant, John appeared undemanding and relatively placid; motor development proceeded appropriately, but language development was delayed. Although his parents indicated that they were first concerned about his development when he was 18 months of age and still not speaking, in retrospect they noted that in comparison to their previous child, he had seemed relatively uninterested in social interaction and the social games of infancy. Stranger anxiety had never really developed, and John did not exhibit differential attachment behaviors toward his parents. Their pediatrician initially reassured John's parents that he was a “late talker,” but they continued to be concerned. Although John seemed to respond to some unusual sounds, the pediatrician obtained a hearing test when John was 24 months old. His hearing appeared adequate for development of speech, and John was referred for developmental evaluation. At 24 months, motor skills were age appropriate, and John exhibited some nonverbal problem-solving skills close to age level. His language and social development, however, were severely delayed, and he was noted to be resistant to changes in routine and unusually sensitive to aspects of the inanimate environment. His play skills were quite limited, and he used play materials in unusual and idiosyncratic ways. His older sister had a history of some learning difficulties, but the family history was otherwise negative. A comprehensive medical evaluation revealed no EEG and CT abnormalities; results of genetic screening and chromosome analysis were normal as well.

John was enrolled in a special education program, where he gradually began to speak. His speech was characterized by echolalia, extreme literalness, a monotonic voice quality, and pronoun reversal. He rarely used language in interaction and remained quite isolated. By school age, John had developed some evidence of differential attachments to family members; he also had developed a number of self-stimulatory behaviors and engaged in occasional periods of head banging. Extreme sensitivity to change continued. Intelligence testing revealed marked scatter, with a full-scale I.Q. in the moderately retarded range. As an adolescent, John's behavioral functioning deteriorated, and he developed a seizure disorder. Now an adult, he lives in a group home and attends a sheltered workshop. He has a rather passive interactional style but exhibits occasional outbursts of aggression and self-abuse. (Reprinted with permission from Volkmar F: Autism and the pervasive developmental disorders. In *Child and Adolescent Psychiatry: A Comprehensive Approach*, ed 2, M Lewis, editor. Williams & Wilkins Baltimore, 1996.

Course and Prognosis Autistic disorder is a lifelong disability, and most individuals affected with this condition remain unable to live independently and require family or community support or institutionalization. However, most children with autistic disorder show improvement in social relatedness, communication, and self-help skills with increasing age. Several factors are thought to predict course and long-term outcome, particularly the presence of some communicative speech by the age of 5 or 6, nonverbal intellectual level, severity of the condition, and response to educational intervention. Younger children more typically display the “pervasive” unrelatedness typically included in earlier diagnostic systems. Although some evidence of differentiated responsiveness to parents may be observed as the child reaches elementary school, patterns of social interaction remain quite deviant. For example, enjoyable social interaction may be restricted to circumscribed activities, such as “rough-and-tumble” or “tickling” games, whereas left to their own devices, children with autistic disorder may be withdrawn or absorbed with trivial aspects of the environment (e.g., light switches) or isolating activities (e.g., puzzles). That notwithstanding, gains in social compliance and communication are often made during elementary school years, particularly if structured, individualized, intensive interventions are in place. During adolescence, some autistic disorder children may exhibit behavioral deterioration; in a minority of these, the decline in language and social skills may be associated with the onset of a seizure disorder. Various interactional styles can be observed, ranging from aloof to passive to eccentric (e.g., children attempt to initiate contact with others, but do so in a very awkward or rigid fashion); these styles are related to developmental level. Depressive and anxiety symptoms may appear in higher-functioning adolescents, who become painfully aware of their inability to form friendships despite a desire to do so, and who begin to suffer the cumulative effect of years of failed contact with others and teasing by peers.

Several long-term outcome studies suggest that approximately two thirds of autistic disorder children have a poor outcome (unable to live independently), with perhaps only one third able to achieve some personal independence and self-sufficiency as adults. Among the latter, most may have a fair outcome (social, educational, or vocational gains despite behavioral and other difficulties), and a minority (about a tenth of all individuals with autistic disorder) may have a good outcome (successful work placement and some social life). However, the autistic person is rarely capable of being self-supporting as an adult, having reciprocal friendships, and getting married. Nevertheless, several factors must be considered when evaluating outcome data. For example, much of the available outcome information is based on data collected at a time when institutionalization of autistic disorder patients was commonplace, schooling was not mandatory, early diagnostic services were not accessible, and early intervention services did not exist. There is some reason to hope that over the past decade, the increased interest in early screening techniques and early diagnostic services, more intensive and early interventions, and the current focus on realistic life skills such as self-sufficiency and vocational training have improved the long-term outcome for those with the disorder.

Treatment The goals of treatment for children with autistic disorder are to reduce disruptive behaviors and to promote learning, particularly language acquisition and communication and self-help skills. These goals are best achieved after a comprehensive assessment has determined a profile of strengths and needs and a highly structured and individualized intervention program is put in place that addresses the child's weaknesses and maximizes the child's assets. This program should usually take place in a special education setting and should be carried out by professionals experienced in working with children with autistic disorder. A recent review of several treatment studies highlighted the importance of intensive, early intervention to individual outcome. Treatment goals should be updated regularly, because different issues should be prioritized as a function of the child's rate and profile of progress and age (e.g., vocational training and independent living skills should be aggressively promoted in adolescence). Additionally, psychopharmacological treatments may be beneficial when specific symptoms are not amenable to other treatment modalities.

Educational Approaches Children with autistic disorder require intensive, highly structured special education, starting as early as the child can tolerate a school routine. Given the challenges involved in teaching autistic disorder children, usually a classroom setting with a low student to teacher ratio is essential. For the more impaired children, a typical hierarchy of priorities should include the ability (1) to tolerate individual adult guidance in performing tasks, (2) to follow a daily routine consistently, (3) to develop communication intent and communication means, and (4) to move from associative to conceptual learning. Learning should take place in an environment that minimizes such distractions as nearby windows or richly decorated walls; the more-challenged children may require individual work stations and forceful adult intrusion. Highly predictable, consistent routines are necessary to promote the child's own internal sense of order, scheduling, and organization of experiences and thus more-systematic learning. Children with autistic disorder often learn skills in a highly circumscribed fashion, exhibiting a capacity only in a very concrete and specific setting. Therefore, one must ensure that the child both begins to use the skill spontaneously (e.g., uses new words for requesting in an unpromoted fashion) and generalizes from the setting in which the skill was acquired to a different setting (e.g., uses the new words at home and in other settings where they would be appropriate). An improved ability to predict impending activities and to express one's wishes and protest usually help reduce frustration and associated disruptive behaviors.

Speech and language therapy focuses on the use of words for meaningful communication. Children with autistic disorder may acquire a considerable vocabulary that is dissociated from the act of communication. Therefore, language acquisition should go hand in hand with promotion of the child's intent to communicate with others. For this purpose, vocabulary expansion should focus on words that are relevant to the child's attempt to negotiate the demands of everyday life. Children who do not vocalize should be engaged in programs that use alternative forms of communication, including signs, communication boards, or other forms of augmentative communication. The use of nonvocal forms of communication should not preclude the simultaneous use of words by children whose vocalizations are just emerging and for whom vocal communication is a realistic goal. For older or higher-functioning children, the educational program should focus intensively on social and communication skills training. Positive actions in frequently troublesome situations may have to be rehearsed and scripted; concrete social and communication skills—eye gaze, voice modulation, gestural communication, posture, proximity, greeting behaviors, rules of conversation, and social expectations—may have to taught in a very explicit fashion. Social and communication skills therapy may have to alternate between small group instruction (where appropriate behaviors can be practiced and supportive feedback can be gained) and naturalistic settings (where the newly acquired skill can be practiced or where additional target problematic behaviors can be identified for practice in the small setting). Successful techniques include modeling of behaviors by an instructor, self-observation, role-playing, and the use of individualized social stories.

Behavior Therapy Behavior therapy, which is based on learning theory principles, uses behavior modification technique to establish desired behaviors and eliminate

problem behaviors. Most educational programs for children with austistic disorder use behavioral management technique, although they vary in how integrated these procedures are in the comprehensive educational program. Behavior therapy is particularly useful in managing disruptive behaviors, which range from difficulties in attention and compliance to tantruming and self-injurious behaviors. After a functional analysis of the target behavior is performed and patterns of reinforcement are identified, techniques such as shaping, prompting, and extinction are used to promote the desired alternative behavior, which is then reinforced by increasingly mature rewards. Behavior therapy is also used to facilitate learning, including the promotion of early cognitive skills such as categorization and elicitation of vocalization and speech. Given the autistic child's tendency to learn things in isolation, skills learned through behavior interventions must be relevant to the child's adaptation and must be increasingly used spontaneously and in different settings. Thus, an appropriate behavioral curriculum should place special emphasis on generalization and self-initiated skills. Although most agree that children with autistic disorder profit from behavior therapy, it is still unclear whether some claims of extraordinarily good outcome for autistic children receiving intensive behavior treatment are justified. One must also ensure that higher-level forms of teaching are not more appropriate to a given child (e.g., a more intellectually able child) before most of the educational resources are focused on behavior therapy.

Psychotherapy With the shift from a psychogenic to a biological understanding of autistic disorder, it became clear that psychodynamic psychotherapy and unstructured play therapies in general were not appropriate for the treatment of young children. Individual psychotherapy may be appropriate for higher-functioning individuals who may present with anxiety and depressive symptoms as they grow older and become more aware of their differences and difficulties relating to others. In these instances, psychotherapy should focus on rather explicit problem-solving skills rather than being insight oriented, with the goal of promoting better adjustment and self-satisfaction.

Psychopharmacology No pharmacological agent has proved curative, but certain medications may be of benefit for specific symptoms such as self-injury, aggression, stereotyped movements, and overactivity. Because autistic individuals are often enrolled in educational and behavioral programs, it may be possible to have staff participate, for example, by collecting behavioral data that can be used to monitor the effectiveness of the drug. As with all medications the potential benefits and adverse effects should be considered; for example, the major tranquilizers carry a potential for oversedation, which can be mistaken for a positive therapeutic response. Prior to beginning drug treatment, baseline laboratory studies (tests of liver and renal function, electrocardiogram [ECG], urinalysis, blood count, weight, blood pressure) should be conducted. An examination for abnormal movements is usually performed (typically with the Abnormal Involuntary Movements Scales [AIMS]).

ANTIPSYCHOTICS The dopamine receptor antagonists are the most extensively studied agents in autistic disorder. At relatively low dosages they may decrease stereotyped behaviors and agitation and may help the individual profit from remedial programming. Some data suggest that the combination of these agents with behavior therapy is more effective than either treatment alone. Adverse effects may limit the usefulness of these agents (e.g., sedation, withdrawal, and tardive dyskinesia). The higher-potency neuroleptics have often been used because of their lower likelihood of sedation, although these agents do carry increased risk for dystonias. Recent interest has centered on the serotonin-dopamine antagonists, which appear to offer considerable potential promise.

SELECTIVE SEROTONIN REUPTAKE INHIBITORS Several reports suggested the potential usefulness of the selective serotonin reuptake inhibitors (SSRIs) in autistic disorder and related conditions with the observation of higher peripheral serotonin concentrations in autistic persons. In several controlled studies these medications have proved superior to placebo in treating such symptoms as repetitive behaviors, impulsive aggression, or both. There is a suggestion that seizure disorders may be exacerbated in some cases.

CLONIDINE The use of clonidine (Catapres) was suggested because of the apparently high levels of arousal in autistic disorder. This agent, an a $_2$-adrenergic receptor agonist, reduced noradrenergic activity. It may exert a modest effect on activity levels, but sedation and hypotension can be serious adverse effects.

NALTREXONE Interest in the endogenous opioid system was spurred by early studies that reported high endogenous opioid concentrations. The opioid receptor antagonist naltrexone has been evaluated in several studies. The major effect of this agent appears to be a mild decrease in activity levels. Neither increased social engagement nor facilitation of learning has been observed.

OTHER AGENTS Various other agents have been reported to sometimes be effective in treating at least some of the symptoms of autistic disorder. Such evidence is usually based on single case reports, and controlled studies are often lacking. Lithium (Eskalith) is generally not clearly helpful unless a personal or family history of bipolar disorder exists. Although the available data are limited, in general, psychostimulants appear to exacerbate behavioral difficulties in autistic disorder, probably because of their effect on dopamine. b-Adrenergic receptor antagonists (beta-blockers) have been used in several open trials concerned with reducing aggressive, self-injurious, and impulsive behaviors. These agents may decrease arousal levels, and positive responses have been noted, although the potential for serious adverse effects limits their more general use.

Parents are often interested in so-called alternative treatments, including diet and vitamin therapy. Although they are the focus of much interest, substantive data are lacking. Various somatic treatments have not proven clinically useful. In general, unproved treatments should be avoided, particularly if they are pursued at the expense of educational and behavioral interventions that are known to be efficacious. Treatments that pose actual danger to the child are sometimes proposed and clearly should be avoided. Given the relatively poor prognosis associated with autistic disorder, parents are easily attracted to treatments that propose a rapid cure. Parents should be encouraged to pursue treatments with known efficacy.

RETT'S DISORDER

Definition Rett's disorder is a progressive condition that develops after some months of apparently normal development. Head circumference at birth is normal, and early developmental milestones are unremarkable. Between 5 months and 48 months (usually between 6 months and 1 year), head growth begins to decelerate. Purposeful hand movements are lost, and characteristic midline hand-wringing or hand-washing stereotypies develop. Expressive and receptive language skills become severely impaired and are associated with marked mental retardation. Gait apraxia and truncal apraxia and ataxia develop in the preschool years. A loss of social interactional skills is frequently observed during the preschool years, but social interest often increases later. To date the condition has been convincingly demonstrated only in girls.

History Cases of Rett's disorder were first reported in 1966 by Andreas Rett. His initial report noted the characteristic history and such clinical findings as gait and truncal ataxia and apraxia, breathing difficulties, EEG abnormalities, and occasional seizures. He also observed some features suggesting autism. Subsequently, Bengt Hagberg and colleagues reported similar findings in a new series of patients. The presence of some symptoms suggesting autism, particularly in the preschool years, is the major rationale for including this condition in the pervasive developmental disorder class of disorders in both DSM-IV and ICD-10.

Comparative Nosology Rett's original report provided guidelines for the diagnosis, which subsequently were revised at a 1984 conference on the condition. These Vienna criteria included features necessary for the diagnosis, those that supported it, and those that were exclusionary. Features that support the diagnosis but are not necessarily present include breath-holding spells, periodic hyperventilation, periodic apnea, growth retardation, EEG abnormalities and seizures, dystonia, spasticity, scoliosis, and peripheral vasomotor problems. Features that mitigate against the diagnosis include demonstrable prenatal growth retardation or postnatal CNS trauma. The definitions in DSM-IV and ICD-10 are essentially the same and focus on the features necessary for diagnosis.

Epidemiology Estimates of the prevalence of the condition range from 1 in 15,000 to 1 in 22,000 females. Several thousand cases are now registered with the International Rett's Syndrome Association. Although several males have been reported to have some features of the condition, to date no male has clearly met all criteria.

Etiology Although it is generally agreed that Rett's disorder has a neurobiological basis, the exact cause remains unknown. Rett originally speculated that the condition was associated with high peripheral ammonia concentrations, but this did not prove to be the case. There are no specific biological markers or laboratory tests for the condition. Genetic factors have been implicated by reports of the condition in monozygotic twins and in extended family members, but most cases appear to be sporadic.

Diagnosis and Clinical Features The DSM-IV diagnostic criteria for the condition are presented in Table 38-7. Early development of the child is normal. The onset of the condition may be insidious and follow a period of developmental stagnation; it may delay recognition slightly. Over time the developmental delay, decelerated head and body growth, and diminished interest in the environment become quite striking. Previously acquired abilities are lost, including purposeful hand movements. The lack of social interest and potential for misdiagnosis of autistic disorder are greatest in the preschool years, since usually by the time the child reaches school age the autistic-like features are less prominent and development plateaus for a time. At this point severe mental retardation, seizures, and motor problems are of major concern. During this plateau, or pseudostationary phase, breathing difficulties, bruxism, motor problems, and early scoliosis may be noted. Apneic episodes may

alternate with hyperventilation. Most children remain ambulatory until a final period of motor deterioration. The EEG is frequently abnormal, and seizures are common.

A. All of the following: (1) apparently normal prenatal and perinatal development (2) apparently normal psychomotor development through the first 5 months after birth (3) normal head circumference at birth
B. Onset of all of the following after the period of normal development: (1) deceleration of head growth between ages 5 and 48 months (2) loss of previously acquired purposeful hand skills between ages 5 and 30 months with the subsequent development of stereotyped hand movements (e.g., hand wringing or hand-washing) (3) loss of social engagement early in the course (although often social interaction develops later) (4) appearance of poorly coordinated gait or trunk movements (5) severely impaired expressive and receptive language development with severe psychomotor retardation

Table 38-7 DSM-IV Diagnostic Criteria for Rett's Disorder

Darla was born at term after an uncomplicated pregnancy. An amniocentesis obtained because of maternal age was normal. At birth, Darla was in good condition; weight, height, and head circumference were all near the 50th percentile. Her development during the first months of life was within normal limits. At about 8 months of age, her development seemed to stagnate, and her interest in the environment, including the social environment, waned. Her developmental milestones then became markedly delayed; she was just starting to walk at her second birthday and had no spoken language. Evaluation at that time revealed that head growth had decelerated. Some self-stimulatory behaviors were present. Marked cognitive and communicative delays were noted on formal testing. Darla began to lose purposeful hand movements and developed unusual hand-washing stereotyped behaviors. By age 6, her EEG was abnormal, and purposeful hand movements were markedly impaired. Subsequently, she developed truncal ataxia and breath-holding spells, and motor skills deteriorated further. (Reprinted with permission from Volkmar F: Autism and the pervasive developmental disorders. In *Child and Adolescent Psychiatry: A Comprehensive Approach*, ed 2, M Lewis, editor. Williams & Wilkins, Baltimore, 1996.)

Pathology and Laboratory Examination Various nonspecific abnormalities reported in Rett's disorder include elevated copper and ammonia concentrations in the blood, cortical atrophy on brain scan, and EEG abnormalities. Some neuropathological studies have noted decreased brain weight and loss of neurons, with changes in the substantia nigra and caudate nucleus. The results of neurochemical analyses (e.g., endorphins, cortisol, and dopamine) have been contradictory.

Differential Diagnosis Diagnosis of the condition is most straightforward in somewhat older individuals (i.e., school age), but it can be made reliably early in life. The condition differs from autism in its unusual pattern of developmental loss and characteristic clinical features. The potential for incorrect diagnosis of autistic disorder is greatest in the preschool years when many patients with Rett's disorder may exhibit some deterioration of social skills. The onset of childhood disintegrative disorder is typically later than that of Rett's disorder, and the period of normal development is usually much longer in that condition, which also usually affects males. In Asperger's disorder cognitive and language skills are preserved and there is not a marked loss of abilities.

Course and Prognosis Rett's disorder is a progressive neurodegenerative condition. Adult patients may be nonambulatory because of motor problems and scoliosis. There is increased risk of sudden death.

Treatment There is no specific treatment for Rett's disorder. Special education, behavior modification, and physical and respiratory therapies may be useful. No specific pharmacological treatment is available. Given the high rate of seizure disorder, caution is needed in the use of medications that lower the seizure threshold. As with other pervasive developmental disorders, consideration should also be given to support for the parents and siblings of affected individuals.

CHILDHOOD DISINTEGRATIVE DISORDER

Definition Childhood disintegrative disorder is a rare condition characterized by a marked regression in multiple areas of development after several years of normal development.

History Childhood disintegrative disorder was first described by an educator, Theodore Heller, in 1908. He reported a series of patients who displayed a marked and persisting developmental regression after 3 or 4 years of normal development. He originally termed the condition *dementia infantilis;* subsequently it has also been termed *disintegrative psychosis* or *Heller's syndrome*. Over 100 cases have been reported in the years following Heller's report. While the condition is certainly quite rare, it also is probably underrecognized.

Comparative Nosology ICD-9 included a category for disintegrative psychosis defined on the basis of “normal or near normal development in the first years of life, followed by a loss of social skills and of speech together with a severe disorder of emotion, behavior, and relationships.” The condition was not included in DSM-III or DSM-III-R on the presumption that the condition was almost invariably associated with some identifiable general medical condition or progressive neuropathological process; however, review of cases suggests that is not usually the case. Review of cases also suggested important potential differences from autistic disorder, for example in course and outcome.

The definitions of the disorder in DSM-IV and ICD-10 (Table 38-1) are very similar. The ICD-10 definition notes that a general loss of interest in the environment may be observed.

Epidemiology Although available data are limited the disorder appears to be quite rare. Prevalence estimates of 1 in 100,000 children have been suggested. More-recent case series suggest a preponderance of the condition in males. It is likely that some early cases reported in girls were actually cases of Rett's disorder.

Etiology Several lines of evidence suggest the importance of neurobiological factors in the pathogenesis of childhood disintegrative disorder. In about half of cases the EEG is reported to be abnormal, and seizures are sometimes observed. The condition has been associated with various general medical conditions (e.g., the neurolipidoses, metachromatic leukodystrophy, Addison-Schilder's disease, and subacute sclerosing panecephalitis). Although an intensive search for such conditions is always indicated, they are usually not found. Such conditions are more likely if the onset is later (after age 6). Data on other aspects of the neurobiology of the condition are very limited.

Diagnosis and Clinical Features The DSM-IV diagnostic criteria for childhood disintegrative disorder are presented in Table 38-8. Early development must be normal for at least 2 years; this should include normal communication and social skills. Before age 10 years there is a regression in at least two (usually many) different areas (e.g., loss of previous skills in communication, social interaction, toileting, or motor abilities) and the development of symptoms similar to those seen in autistic disorder.

A. Apparently normal development for at least the first two years after birth as manifested by the presence of age-appropriate verbal and nonverbal communication, social relationships, play, and adaptive behavior.
B. Clinically significant loss of previously acquired skills before age 10 years) in at least two of the following areas: (1) expressive or receptive language (2) social skills or adaptive behavior (3) bowel or bladder control (4) play (5) motor skills
C. Abnormalities of functioning in at least two of the following areas: (1) qualitative impairment in social interaction (e.g., impairment in nonverbal behaviors, failure to develop peer relationships, lack of social or emotional reciprocity) (2) qualitative impairments in communication (e.g., delay or lack of spoken language, inability to initiate or sustain a conversation, stereotyped and repetitive use of language, lack of varied make-believe play) (3) restricted, repetitive, and stereotyped patterns of behavior, interests, and activities, including motor stereotypies and mannerisms
D. The disturbance is not better accounted for by another specific pervasive developmental disorder or by schizophrenia.

Table 38-8 DSM-IV Diagnostic Criteria for Childhood Disintegrative Disorder

Onset is usually between the ages of 3 and 4 years and may be either abrupt or gradual. There may be nonspecific agitation or anxiety prior to developmental deterioration. Figure 38-4 provides a summary of clinical features. The loss of social and communicative skills is (understandably) of great concern to parents. Stereotyped behaviors, problems with transitions and change, and nonspecific overactivity often develop. Deterioration in self-help skills can be striking and is in contrast to autistic disorder, in which such skills are acquired somewhat later than usual but typically are not lost.

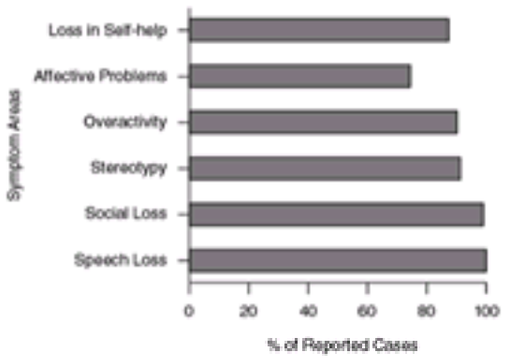

FIGURE 38-4 Clinical features in childhood disintegrative disorder. (Data from Volkmar F, Klin A, Marons W, Cohen DJ: Childhood disintegrative disorder. In *Handbook of Autism and Pervasive Developmental Disorders*, ed 2, DJ Cohen, FR Volkmar, editors. Wiley, New York, 1997.)

Bob's early history was within normal limits. By age 2, he was speaking in sentences, and his development appeared to be proceeding appropriately. At age 40 months he abruptly exhibited a period of marked behavioral regression shortly after the birth of a sibling. He lost previously acquired skills in communication and was no longer toilet trained. He became uninterested in social interaction, and various unusual self-stimulatory behaviors became evident. Comprehensive medical examination failed to reveal any conditions that might account for this developmental regression. Behaviorally, he exhibited features of autistic disorder. At follow-up at age 12 he spoke only an occasional single word and was severely retarded. (Reprinted with permission from Volkmar F: Autism and the pervasive developmental disorders. In *Child and Adolescent Psychiatry: A Comprehensive Approach*, ed 2, M Lewis, editor. Baltimore, Williams & Wilkins, 1996.)

Differential Diagnosis Children with autistic disorder typically exhibit difficulties before age 2 and almost always before age 3 years. Early development is usually not unequivocally normal in autistic disorder, although occasional children are reported to either stagnate in development or experience developmental regression. Baby books or early home movies or videos may help establish that early development was normal. In Rett's disorder there is characteristic head growth deceleration as well as clinical features such as unusual hand movements. In rare instances childhood disintegrative disorder may be confused with schizophrenia, but usually the characteristic findings of schizophrenia on clinical examination will clarify the diagnosis. In the syndrome of acquired aphasia with epilepsy (Landau-Kleffner syndrome) social interest is preserved, and nonverbal communicative skills may be extensive. Specific findings on examination or in the history may help guide diagnostic evaluation.

Course In about three fourths of cases the child's behavior and development deteriorate to a much lower functional level and then stabilize with no further deterioration but only minimal subsequent gains. Some children show more recovery of previous developmental skills; a few have made very good recovery. Deterioration is progressive in some children, particularly in cases associated with a progressive neuropathological process, and death may result. Otherwise life expectancy is normal. In general the outcome appears to be worse than that in autistic disorder.

Treatment As with autistic disorder, special education and behavioral treatments are indicated to help encourage reacquisition of skills. No specific pharmacological treatments exist.

ASPERGER'S DISORDER

Definition Asperger's disorder is characterized by impairments in social interaction and restricted interests and behaviors as seen in autism, but its early developmental course is marked by a lack of any clinically significant delay in spoken or receptive language, cognitive development, self-help skills, or curiosity about the environment. All-absorbing and intense circumscribed interests and motor clumsiness are typical of the condition but are not required for diagnosis.

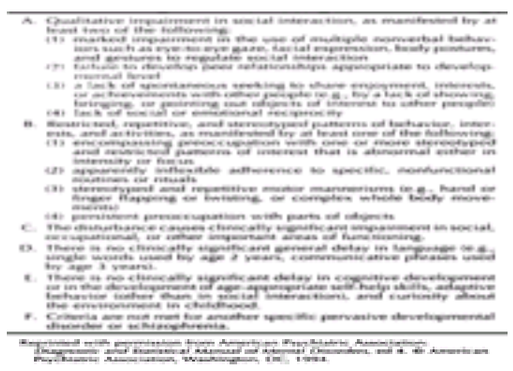
History In 1944 Hans Asperger, an Austrian pediatrician with interest in special education, described four children who had difficulty integrating socially into groups. Unaware of Kanner's description of early infantile autism published just the year before, Asperger called the condition he described “autistic psychopathy,” indicating a stable personality disorder marked by social isolation. Despite preserved intellectual skills, the children showed marked paucity of nonverbal communication involving both gestures and affective tone of voice; poor empathy and a tendency to intellectualize emotions; an inclination to engage in long-winded, one-sided, and sometimes incoherent speech; rather formalistic speech (Asperger called them “little professors”); all-absorbing interests involving unusual topics, which dominated their conversation; and motoric clumsiness. These children were not less withdrawn or aloof than Kanner's patients; they also developed (sometimes precociously) highly grammatical speech and could not in fact be diagnosed in the first years of life. Discarding the possibility of a psychogenetic origin, Asperger highlighted the familial nature of the condition and even hypothesized that the personality traits were primarily male transmitted. Asperger's work, originally published in German, became widely known in the English-speaking world in 1981, when Lorna Wing published a series of cases with similar symptoms. Her codification of the syndrome, however, blurred somewhat the differences between Kanner's and Asperger's descriptions, as she included a small number of girls and mildly mentally retarded children, as well as some children who had presented with some language delays in their first years of life. Since then, several studies have attempted to validate Asperger's disorder as distinct from autism without mental retardation, although comparing findings has been hindered by the lack of consensual diagnostic criteria for the condition. Although Asperger's syndrome was first granted official recognition in ICD-10 and appears as Asperger's disorder in DSM-IV, its nosological status is still uncertain.

Comparative Nosology Asperger's disorder was not accorded official recognition until publication of ICD-10 and DSM-IV, although it was first reported in the German literature in 1944. Asperger's work was known primarily in German-speaking countries, and only in the 1970s were the first comparisons with Kanner's work made, primarily by Dutch researchers such as D. A. Van Krevelen who were familiar with both the English and German literature. The initial attempts at comparing the two conditions were difficult because of major differences in the patients described—Kanner's patients were both younger and more cognitively impaired. Also, Asperger's conceptualization was influenced by accounts of schizophrenia and personality disorders, whereas Kanner had been influenced by the work of Arnold Gesell and his developmental approach. Several influential researchers in Europe and North America attempted to codify Asperger's prose into a categorical definition for the condition, but no consensual definition emerged until the advent of ICD-10. Given the reduced empirical validation of the ICD-10 and DSM-IV criteria, the definition of the condition is likely to change with new and more rigorous studies in the near future.

Epidemiology Given the lack of consensual definitions of the conditions until recently, it is not surprising that the prevalence of the condition is unknown, although a rate of 1 in 10,000 has been reported. The condition is more prevalent in males than females, with a reported ratio of 9 to 1. In the past few years, parent support organizations for Asperger's disorder have proliferated, and clinicians appear to be giving this diagnosis much more frequently than they did just a few years ago. There are also indications that Asperger's disorder is currently functioning as a residual diagnosis given to normal-intelligence children with social disabilities who do not fulfill criteria for autistic disorder, overlapping in this way with the DSM-IV diagnosis pervasive developmental disorder not otherwise specified. This pattern has diluted the concept and reduced its clinical utility. Empirical validation of specific diagnostic criteria is badly needed, although this must await reports of rigorous studies using standard diagnostic procedures, and validators truly independent of the diagnostic definition such as neuropsychological, neurobiological, and genetic data.

Etiology As with autistic disorder, the cause of Asperger's disorder is unknown. A few case studies reporting the presence of autism and Asperger's disorder in different family members and some recent studies suggesting that Asperger's disorder may be one of the conditions along the autistic spectrum suggest that autistic disorder and Asperger's disorder may be related genetically. However, some reports have described a stronger genetic contribution in Asperger's disorder than in autistic disorder, with more family members and sometimes the child's father either fulfilling criteria for the condition or having similar social difficulties. Asperger himself had alluded to some children who were much more severely involved than those he described and who suffered from varying degrees of mental retardation. His notion that these were children with “autistic psychopathy” who had also suffered brain damage has been taken up by some authors, although no neuroanatomical or neurofunctional data substantiate this view. In fact, there are a few reports of brain anomalies in individuals with Asperger's disorder with otherwise normal or superior I.Q.s.

Diagnosis and Clinical Features Diagnosis of Asperger's disorder (Table 38-9) requires the demonstration of qualitative impairments in social interaction and restricted patterns of interest, criteria identical to those for autistic disorder. In contrast to autistic disorder, there are no criteria in the cluster of language and communication symptoms, and onset criteria differ in that there should be no clinically significant delay in language acquisition, cognitive and self-help skills, symptoms that result in significant impairment in social and occupational functioning.



A. Qualitative impairment in social interaction, as manifested by at least two of the following:
(1) marked impairment in the use of multiple nonverbal behaviors such as eye-to-eye gaze, facial expression, body postures, and gestures to regulate social interaction
(2) failure to develop peer relationships appropriate to developmental level
(3) a lack of spontaneous seeking to share enjoyment, interests, or achievements with other people (e.g., by a lack of showing, bringing, or pointing out objects of interest to other people)
(4) lack of social or emotional reciprocity
B. Restricted, repetitive, and stereotyped patterns of behavior, interests, and activities, as manifested by at least one of the following:
(1) encompassing preoccupation with one or more stereotyped and restricted patterns of interest that is abnormal either in intensity or focus
(2) apparently inflexible adherence to specific, nonfunctional routines or rituals
(3) stereotyped and repetitive motor mannerisms (e.g., hand or finger flapping or twisting, or complex whole body movements)
(4) persistent preoccupation with parts of objects
C. The disturbance causes clinically significant impairment in social, occupational, or other important areas of functioning.
D. There is no clinically significant general delay in language (e.g., single words used by age 2 years, communicative phrases used by age 3 years).
E. There is no clinically significant delay in cognitive development or in the development of age-appropriate self-help skills, adaptive behavior (other than in social interaction), and curiosity about the environment in childhood.
F. Criteria are not met for another specific pervasive developmental disorder or schizophrenia.

Table 38-9 DSM-IV Diagnostic Criteria for Asperger's Disorder

In some contrast to the social presentation in autistic disorder, individuals with Asperger's disorder find themselves socially isolated but are not usually withdrawn in the presence of others; typically they approach others but in an inappropriate or eccentric fashion. For example, they may engage the interlocutor, usually an adult, in one-sided conversation characterized by long-winded, pedantic speech about a favorite and often unusual and narrow topic. They may express interest in friendships and in meeting people, but their wishes are invariably thwarted by their awkward approaches and insensitivity to the other person's feelings, intentions, and nonliteral implied communications (e.g., signs of boredom, haste to leave, and need for privacy). Chronically frustrated by their repeated failures to engage others and form friendships, some individuals with Asperger's disorder develop symptoms of a mood disorder that may require treatment, including medication. They also may react inappropriately to, or fail to interpret, the valence of the context of the affective interaction, often conveying a sense of insensitivity, formality, or disregard for the other person's emotional expressions. They may be able to describe correctly (in a cognitive and often formalistic fashion) other people's emotions, expected intentions, and social conventions; yet they cannot act upon this knowledge in an intuitive and spontaneous fashion and thus lose the tempo of the interaction. Their poor intuition and lack of spontaneous adaptation are accompanied by marked reliance on formalistic rules of behavior and rigid social conventions. This presentation is largely responsible for the impression of social naiveté and behavioral rigidity that these individuals so forcefully convey.

Although significant abnormalities of speech are not typical of individuals with Asperger's disorder, at least three aspects of their communication patterns are of clinical interest. First, speech may be marked by poor prosody, although inflection and intonation may not be as rigid and monotonic as in autistic disorder. They often exhibit a constricted range of intonation patterns used with little regard to the communicative functioning of the utterance (e.g., assertions of fact, humorous remarks). Rate of speech may be unusual (e.g., too fast) or may lack in fluency (e.g., jerky speech), and volume is often poorly modulated (e.g., voice is loud despite physical proximity to the conversational partner). The latter feature may be particularly noticeable as a lack of adjustment to a given social setting (e.g., a library or a noisy crowd). Second, speech is often tangential and circumstantial, conveying a sense of looseness of associations and incoherence. Even though in a very few patients this symptom may indicate a possible thought disorder, the lack of contingency in speech is a result of the one-sided, egocentric conversational style (e.g., unrelenting monologues about the names, codes, and attributes of innumerable TV stations in the country), failure to provide the background for comments and to clearly demarcate changes in topic, and failure to suppress the vocal output accompanying internal thoughts. Third, the communication style of individuals with Asperger's disorder is often markedly verbose. The child or adult may talk incessantly, usually about a favorite subject, often completely disregarding whether the listener is interested, engaged, or attempting to interject a comment or change the subject. Despite such long-winded monologues, the individual may never come to a point or conclusion. Attempts by the interlocutor to elaborate on issues of content or logic or shift the interchange to related topics are often unsuccessful.

Individuals with Asperger's disorder typically amass a large amount of factual information about a topic in a very intense fashion. The actual topic may change from time to time, but it often dominates the content of social interchange. Frequently the entire family may be immersed in the subject for long periods of time. This behavior is peculiar in the sense that often extraordinary amounts of factual information are learned about very circumscribed topics (e.g., snakes, names of stars, television guides, deep fat fryers, weather, personal information on members of Congress) without a genuine understanding of the broader phenomena involved. This symptom is not always easily recognized in childhood since strong interests in certain topics (e.g., dinosaurs or fashionable fictional characters) are so ubiquitous. However, in both younger and older children the special interests typically become more unusual and narrowly focused.

Individuals with Asperger's disorder may have a history of delayed acquisition of motor skills such as pedaling a bike, catching a ball, opening jars, and climbing outdoor play equipment. They are often visibly awkward and poorly coordinated and may exhibit stilted or bouncy gait patterns and odd posture. Neuropsychologically, there is often a pattern of relative strengths in auditory and verbal skills and rote learning and significant deficits in visual-motor and visual-perceptual skills and conceptual learning. Many children exhibit high levels of activity in early childhood, and the most commonly reported comorbid symptoms in adolescence and young adulthood are anxiety and (particularly) depression.

Tom was an only child. Birth, medical, and family histories were unremarkable. His motor development was somewhat delayed, but communicative milestones were within normal limits. His parents became concerned about him at age 4 when he was enrolled in a nursery school and displayed marked difficulties in peer interaction that were so pronounced that he could not continue in the program. In grade school, he was enrolled in special education classes and was noted to have some learning problems. His greatest difficulties arose in peer interaction; he was viewed as markedly eccentric and had no friends. His preferred activity, watching the weather channel on television, was pursued with great interest and intensity. On examination at age 13, he had markedly circumscribed interests and exhibited pedantic and odd patterns of communication with a monotonic voice quality. Psychological testing revealed an I.Q. within the normal range, with marked scatter evident. Formal communication examination revealed age-appropriate skills in receptive and expressive language but marked impairment in pragmatic language skills. (Reprinted with permission from Volkmar F: Autism and the pervasive developmental disorders. In *Child and Adolescent Psychiatry: A Comprehensive Approach*, ed 2, M Lewis, editor. Williams & Wilkins, Baltimore, 1996.)

Differential Diagnosis Unlike children with Asperger's disorder, the great majority of autistic children experience early delays and deviance in language acquisition and cognitive impairment. The differential diagnosis is more difficult when the comparison is made with children with autistic disorder without mental retardation. Asperger's disorder differs from the latter in that the onset is usually later and the outcome more positive. In addition, social and communication deficits are less severe and motor mannerisms are usually absent, whereas circumscribed interest is more conspicuous, motor clumsiness is more common, and a family history of similar problems is more frequent. In both ICD-10 and DSM-IV, if the child meets criteria for autistic disorder, this should take precedence over a diagnosis of Asperger's disorder. The distinction between Asperger's disorder and atypical autism (ICD-10) or pervasive developmental disorder not otherwise specified (DSM-IV) is more difficult, because the latter are basically subthreshold or residual categories without specific defining criteria. Reports attempting to distinguish between them have indicated that the social impairment is more severe and the communication deficits and deviance are less pronounced in Asperger's disorder than in atypical autism or pervasive developmental disorder not otherwise specified. Clinical reports have also emphasized the associated features of all-absorbing and interfering circumscribed interests, verbosity, and motor clumsiness in Asperger's disorder. Individuals with schizoid personality disorder show neither the level of severity of social impairment nor the early developmental patterns seen in Asperger's disorder. The combination of verbosity and severe pragmatic deficits (involving

long-winded, one-sided, and incoherent conversational patterns marked by failure to demarcate changes of topic, to provide background, or to adhere to a communicative message) may lead to the erroneous diagnosis of schizophrenia. However, in the vast majority of cases, these symptoms reflect a communication dysfunction rather than a thought disorder. Again, a detailed developmental history documenting early onset and continuity of symptoms may be important in the differential diagnosis.

Course and Prognosis There are no systematic long-term follow-up studies of children with Asperger's disorder as yet, partially because of nosologic issues. Many children can attend regular education classes with additional support services, although these children are especially vulnerable to being seen as eccentric and being teased or victimized; others require special education services, usually not because of academic deficits but because of their social and behavioral difficulties. Asperger's initial description predicted a positive outcome for many of his patients, who could often use their special talents to obtain employment and so lead self-supporting lives. His observation of similar traits in family members (i.e., fathers) may also have made him more optimistic about ultimate outcome. Although his account was tempered somewhat by the time he had seen 200 patients with the syndrome (25 years after his original paper), Asperger continued to believe that a more positive outcome was a central criterion differentiating individuals with his syndrome from those with Kanner's autism. Although some clinicians have informally concurred with this statement, particularly in regard to gainful employment, independence, and establishing a family, no studies specially addressing the long-term outcome of individuals with Asperger's disorder are currently available. The social impairment (particularly the eccentricities and social insensitivity) is thought to be lifelong.

Treatment As in autistic disorder, treatment of Asperger's disorder is essentially supportive and symptomatic and to a great extent overlaps with the treatment guidelines applicable to individuals with autistic disorder unaccompanied by mental retardation. One initial difficulty encountered by families is proving eligibility for special services. Since these children are often very verbal and many of them do well academically, educational authorities might judge that the deficits—primarily social and communicative—are not within the scope of educational intervention. In fact, these two aspects should be the core of any educational intervention and curriculum for individuals with this condition. Skills, concepts, appropriate procedures, cognitive strategies, and behavioral norms may be more effectively taught in an explicit and rote fashion using a parts-to-whole verbal instruction approach, in which the verbal steps are in the correct sequence for effective behavior. Additional guidelines should be derived from the individual's neuropsychological profile of assets and deficits. Acquisition of self-sufficiency skills in all areas of functioning should be a priority. The tendency of individuals with Asperger's disorder to rely on rigid rules and routines can be used to foster positive habits and enhance the person's quality of life and that of family members. Specific problem-solving strategies (usually following a verbal algorithm) may be taught for handling the requirements of frequently occurring, troublesome situations (e.g., involving novelty, intense social demands, or frustration). Training is usually necessary in recognizing troublesome situations and selecting the best available learned strategy to use in such situations. Social and communication skills are best taught by a communication specialist with an interest in pragmatics in speech, in the context of both individual and small group therapy. Communication therapy should include appropriate nonverbal behavior (e.g., the use of gaze for social interaction, monitoring and patterning of voice inflection), verbal decoding of nonverbal behaviors of others, social awareness, perspective-taking skills, and correct interpretation of ambiguous communications (e.g., nonliteral language). Often, adults with Asperger's disorder fail to meet entry requirements for jobs in their area of training (e.g., college degree) or fail to maintain a job because of their poor interviewing skills, social disabilities, eccentricities, or anxiety attacks. Thus they must be trained for and placed in jobs for which they are not neuropsychologically impaired and in which they will enjoy some support and shelter. Preferably the job should not involve intensive social demands, time pressure, or the need to improvise quickly or generate solutions to novel situations. The little experience available with self-support groups suggests that individuals with Asperger's disorder enjoy the opportunity to meet others with similar problems and may develop relationships around an activity or subject of shared interest. Special interests may be used to create social opportunities through hobby groups. Supportive psychotherapy as well as pharmacological interventions may be helpful in dealing with feelings of despondency, frustration, and anxiety, although a more direct, problem-solving focus is thought to be more beneficial than an insight-oriented approach.

PERVASIVE DEVELOPMENTAL DISORDER NOT OTHERWISE SPECIFIED

Atypical autism in ICD-10 and the equivalent pervasive developmental disorder not otherwise specified in DSM-IV (Table 38-10) essentially refer to a residual category with minimal defining criteria. The diagnosis is used to denote a subthreshold form of autism or an autistic manifestation that is atypical in terms of onset patterns or symptomatology. *Atypical autism* and *pervasive developmental disorder not otherwise specified* are used to describe a rather large and heterogeneous group of children who do not meet strict criteria for autistic disorder or another pervasive development disorder but do exhibit a pattern of developmental and behavioral dysfunction similar to that observed in autistic disorder. Such children typically exhibit unusual sensitivities and affective responses in the presence of more differentiated social relatedness and better cognitive and communicative skills than do most autistic children. It is likely that regularity patterns or new definable syndromes will be identified in this group in the future, thus reducing the number of children with social disabilities who are given what is essentially an undefined diagnosis. Some studies have attempted to delineate reliable and specific criteria for this group, whereas others have proposed new syndromes. For example, several studies have examined the validity of a condition named multiple complex developmental disorder, in which there are basic and early emerging deficits in affective modulation, capacity for relating, and stability of thinking, compounded by anxiety and learning difficulties. Validation studies of this and other proposed syndromes are needed before they can be incorporated in current nosology.

This category should be used when there is a severe and pervasive impairment in the development of reciprocal social interaction or verbal and nonverbal communication skills, or when stereotyped behavior, interests, and activities are present, but the criteria are not met for a specific pervasive developmental disorder, schizophrenia, schizotypal personality disorder, or avoidant personality disorder. For example, this category includes "atypical autism"—presentations that do not meet the criteria for autistic disorder because of late age at onset, atypical symptomatology, or subthreshold symptomatology, or all of these.

Table 38-10 DSM-IV Diagnostic Criteria for Pervasive Developmental Disorder Not Otherwise Specified

Leslie was the oldest of two children. She had been a difficult baby who was not easy to console but whose motor and communicative development seemed appropriate. She was socially related and sometimes enjoyed social interaction, but was easily overstimulated. She exhibited some unusual sensitivities to aspects of the environment and, at times of excitement, exhibited some hand flapping. Her parents sought evaluation when she was 4 years of age because of difficulties in nursery school. Leslie had problems with peer interaction. She was often preoccupied with possible adverse events. At evaluation she displayed both communicative and cognitive functions within the normal range. Although differential social relatedness was present, Leslie had difficulty using her parents as sources of support and comfort. She displayed behavioral rigidity and a tendency to impose routines on social interaction. Leslie was enrolled in a therapeutic nursery school where she made significant gains in social skills. Subsequently, she was placed in a transitional kindergarten and did well academically, although problems in peer interaction and unusual affective responses persisted. As an adolescent, she describes herself as a "loner" who has difficulties with social interaction and tends to enjoy solitary activities. CHAPTER 39. ATTENTION-DEFICIT DISORDERS

39.1 ATTENTION-DEFICIT DISORDERS

JAMES T. McCRACKEN, M.D.

ATTENTION-DEFICIT/HYPERACTIVITY DISORDER

Attention-deficit/hyperactivity disorder (ADHD) is the most common psychiatric disorder among school-age children and the best understood. Children with ADHD display the early onset of symptoms consisting of developmentally inappropriate overactivity, inattention, academic underachievement, and impulsive behavior. The need for treatment of ADHD is highlighted by the increased risk of ADHD children for delinquency, accidents, and substance abuse. Although the disruptive behaviors of ADHD are usually the reason for referral for treatment, ADHD in childhood and adolescence is often associated with other psychopathology. Considerable knowledge supports the premise that ADHD is a familial disorder associated with differences in central nervous system structure, metabolism, and processing. Treatment of patients with ADHD involves multiple interventions and should be guided by a complete assessment of current functioning in multiple domains of school, family, and peer relationships and comorbid symptoms.

Definition and Comparative Nosology The diagnostic criteria for ADHD have undergone frequent, and at times significant, changes. The definition in the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) is based upon extensive field testing that led to grouping symptoms into two primary categories: inattentive and hyperactive-impulsive symptoms. A minimum of six symptoms from at least one of the symptom categories is required for the diagnosis. Three different subtypes of ADHD may be diagnosed on the basis of the number and type of symptoms from each category, with subtypes referred to as either ADHD, inattentive type; ADHD, hyperactive-impulsive type; or ADHD, combined type. According to DSM-IV, symptoms of ADHD must be evident by age 7 years and have a minimum duration of 6 months. Although developmental shifts in symptom frequency and severity are well known to occur, the current criteria make no modification for age. While the diagnosis of ADHD has been frequently criticized as a form of inappropriate labeling of natural variants of child behavior, its validity is among the strongest of any psychiatric disorder.

In the 10th revision of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10), the category hyperkinetic conduct disorder overlaps considerably with ADHD. Besides generating overall lower prevalence rates for disorder in community samples, the ICD-10 criteria (Table 39.1-1) tend to identify children with higher rates of soft neurological signs, developmental delays, and learning problems. Recent data from family-genetic studies provide some support for the existence of a subtype of ADHD comorbid with conduct disorder, quite similar to the ICD-10 definition, which may possess additional and independent family-genetic and environmental risk factors. In general, hyperkinetic disorders are considered a subgroup within ADHD as currently defined.

Table 39.1-1 ICD-10 Diagnostic Criteria for Hyperkinetic Disorders

History The history of the recognition of ADHD as a child psychiatric disorder spans more than a century. Early conceptualizations included both neurological and moral notions of causation, which have evolved over time into models of the disorder that attempt to integrate knowledge of brain anatomy and function with behavior. Classic early case histories such as Fidgety Phil embody all of the core features of the disorder as currently defined. Later descriptions of hyperactivity in various neurological samples of children with coarse brain injury or disorder, including children with postencephalitic syndromes, mental retardation, and epilepsy, led to the suggestion of a possible syndrome of overactivity. Particularly notable were the common sequelae in children of overactivity and impulsive and disruptive behavior following the pandemic of encephalitis lethargica seen during, and for the 10 years following, World War I. The prominent increase in psychomotor activity in children was in stark contrast to the parkinsonism observed in many adults after recovery from the infection. Though the importance of brain dysfunction presumably resulting from injury or maldevelopment stimulated more interest in understanding the pathophysiology of ADHD, the uncritical application of the assumption of brain damage to the behavior of children with varying degrees of disruptive behavior (as seen in earlier diagnostic labels such as minimal brain damage or minimal brain dysfunction) led to wide differences in syndrome definition and therapeutic approaches between nations.

Over the past 25 years, much research has attempted to identify core deficits associated with the disorder, develop empirically tested diagnostic criteria, and further validate the diagnosis of ADHD by demonstrating the disorder's characteristic symptom profiles, natural history, family-genetic aspects, and response to treatment. Although emphasis has shifted somewhat from the importance of attention deficits to the current view of two primary dimensions of inattentive and hyperactive-impulsive behaviors, along the way ADHD has become one of the best-validated disorders in psychiatry. Furthermore, public acceptance of the need for treatment of the disorder indicated by the increased number of children receiving stimulant treatment.

Epidemiology In general, a variety of epidemiological data consistently find ADHD to be a common disorder in community samples of children and adolescents (on average identified in 3 to 5 percent) and one of the most common disorders among children referred to child mental health services. However, as with most mental disorders, changes in definitions also influence estimates of prevalence, and some variability in rates of ADHD in nonreferred samples have been noted. Available large-scale epidemiological surveys using contemporary diagnostic criteria are summarized in Table 39.1-2.

ADD, attention-deficit disorder; ADHD, attention-deficit/hyperactivity disorder; —, not reported.

Table 39.1-2 Prevalence Estimates for ADHD in Community Samples

These studies have found that prevalence rates of ADHD in nonreferred samples range between 2.0 and 9.5 percent. Prevalence rates of ADHD under DSM-IV definitions are 15 to 57 percent higher than those determined by use of revised third edition of DSM (DSM-III-R) criteria. Despite these differences, some interesting consistencies are seen across studies. A strong male predominance of approximately 2–3 to 1 has been seen for both clinic samples of children with ADHD and school-age children. Rate estimates for ADHD in girls have been generally consistent at approximately 3 percent, in spite of study differences. The field awaits a large-scale epidemiological study applying DSM-IV criteria to assess the full impact of this most recent criteria change on estimates of the prevalence of disorder, correlates, and comorbid difficulties.

Etiology Considerable progress has been made toward revealing the pathophysiological basis of ADHD. Studies of ADHD neurochemistry, neuroimaging, epidemiological risk factors, and genetics have supported the notion that ADHD is a familial disorder involving differences in monoamine regulation and frontal-striatal neural circuitry. Additional studies should soon add detail to early findings and improve early detection of risk and intervention.

Neurochemistry The incontrovertible benefit of psychostimulants on hyperactive and impulsive behaviors has resulted in research into neurochemical differences in children with ADHD, principally among the monoamines dopamine and norepinephrine. In general, earlier studies of peripheral and cerebrospinal fluid monoamine measures in ADHD were considered inconclusive; similarly, studies on the effects of medications on monoamine metabolism in children with ADHD initially yielded variable results. However, more-recent studies have yielded significant evidence supporting the involvement of both the dopaminergic and catecholaminergic systems in ADHD. For example, one study showed a significant correlation between the pretreatment cerebrospinal fluid concentrations of the major dopamine metabolite homovanillic acid (HVA) and response to psychostimulant administration. Alternatively, recent studies of changes in peripheral monoamine regulation reveal differences in catecholamines in children with ADHD and normal controls.

Although difficult to extrapolate to the human disorder, animal models incorporating neonatal lesions of dopamine tracts, rodent strains with alellelic variants at the dopamine transporter (DAT1) and SNAP-25 proteins, and inbred strains such as the spontaneously hypertensive rat (SHR) also support the prominent role of monoamines in the regulation of activity. Taken together, these clinical and basic studies support the importance in ADHD of differences in the dopaminergic ennervation of mesolimbic and cortical areas as modulators of persistence, distractibility, motivation, and motor control. Overactivity or poorly modulated responses of the noradrenergic locus coeruleus to novelty or challenge may elicit the poorly regulated behavioral responses seen in children with ADHD. Increasing dopamine availability and inhibition of locus coerulus activity via adrenergic agonism are hypothesized to be required for maximal therapeutic efficacy on ADHD symptoms, as is found with medications such as the rapidly acting stimulants.

Neuroimaging Both structural and functional neuroimaging studies have contributed to elucidating the etiology of ADHD. Early studies using xenon-133 regional cerebral blood flow pointed to brain areas that form the crux of current neuroanatomical models of pathology in ADHD. Although complicated by the co-occurrence of specific developmental problems in some samples, reduced perfusion in bilateral frontal areas, the caudate nuclei, and additional basal ganglia areas, partially increased by methylphenidate administration, have been reported. The apparent reductions in blood flow in frontal and basal ganglia regions were consistent with the emerging view that many of the self-regulation difficulties seen in children with ADHD resembled the behavior seen in classic frontal lobe damage syndromes. The first positron emission tomography (PET) study of adults with familial ADHD also found both global and specific patterns of reduced metabolism in the brains of patients compared with controls. Compared with normal control adults, those with ADHD showed global reduced metabolism bilaterally, as assessed by a [^{18}F] fluorodeoxyglucose (FDG) tracer. In addition, a survey of specific regions found significant metabolic reductions in superior prefrontal and premotor cortices. Attempts to replicate these findings in samples of adolescents with ADHD have found fewer differences; global metabolism did not differ, although metabolism in six specific regions (an equal number from right and left brain areas) was significantly lower than that in controls in one study. Gender apparently strongly influences regional cerebral blood flow, as only females with ADHD differed in group effects from controls in some studies. In general, the initial functional brain imaging studies indicate differences in brain activity associated with ADHD, which may vary with age. Reduced activity in brain areas associated with executive functions is consistent with the types of behavioral problems seen in the disorder.

Structural brain imaging studies complement the functional imaging studies cited above, and together they underscore the involvement of striatal and frontal brain areas in ADHD, although possible involvement of other brain regions has not been excluded and great variability in brain size is evident in both patient and controls. Initial small-scale magnetic resonance imaging (MRI) studies of ADHD reported lower right anterior frontal width in ADHD than in normal controls and loss of the normal right greater than left asymmetry of the caudate nucleus. The largest structural imaging study of ADHD identified a number of global and specific brain areas that differed between a sample of 57 boys with ADHD and 55 normal controls. Total cerebral volume was 4.7 percent smaller, and total cerebellar volumes were also significantly lower in the children with ADHD. In the striatum, the right globus pallidus was smaller in children with ADHD, and the normal right greater than left asymmetry of the caudate nucleus was lost. Elsewhere, a gross measure of the right anterior frontal lobe volume was also reduced in the ADHD sample. Other reports have generally confirmed these findings, although with some differences. In one report, subjects with ADHD did not differ in global or hemispheric volumes but displayed bilateral reduction in frontal lobe and parietal lobe measures. Other reports have commented on reductions in corpus callosal regions in ADHD.

The relation between these reported brain volume decreases associated with ADHD and their functional significance is largely unclear. One study examined the relation between regional volume and performance on cognitive measures of response inhibition. Significant correlations were observed between prefrontal cortex, caudate nucleus, and globus pallidus volume and task performance, greatest with right-sided structures. Such studies need replication. Additional experiments using noninvasive functional measures, such as functional MRI (fMRI), could significantly increase knowledge of areas and circuits that are involved in producing ADHD symptoms.

In summary, the available neuroimaging data strongly support the existence of differences in brain structure and, to a lesser extent, brain function in individuals with ADHD and normal controls. Rather than finding global brain involvement in ADHD, most studies identify relatively specific areas of difference associated with the disorder, mainly the richly interconnected areas of the frontal lobes and the striatum. However, additional research is needed before these findings can be fully integrated with other knowledge about the disorder.

Genetics Compelling evidence supports the view that ADHD is familial and in large part genetic. In spite of differences in diagnostic criteria, most published controlled family studies report a significantly higher relative risk of ADHD in first-degree and second-degree relatives of probands with ADHD than in normal controls. For example, the risk of ADHD for a sibling of a child proband with ADHD increases from 1.8 to 5 times, depending upon the study, the sample enrolled, and the gender of the probands. Comparisons of concordance rates for ADHD in monozygotic and dizygotic twins also strongly support genetic influence in ADHD and the core symptoms of hyperactivity and inattention. Concordance rates for ADHD have ranged from 51 to 80 percent for monozygotic twins versus 29 to 33 percent for dizygotic twins. Heritability estimates for individual symptom domains also strongly support a genetic influence in producting hyperactive and inattentive behavior. The heritability of hyperactivity has been calculated in twin studies to be between 64 and 77 percent, and that of inattention-related behaviors, between 76 and 98 percent. Therefore, from a dimensional perspective, these extremes along behavioral traits of activity and persistence also appear to be highly influenced by genes.

Analysis of patterns of illness within well-studied pedigrees of families with a member with ADHD may be consistent with the effect of a single major gene; other modes of mendelian transmission have been rejected. However, the cause of ADHD likely involves a complex interaction of multiple genetic factors (perhaps several genes) with effects of gender and environmental influences. This conclusion is supported by initial molecular genetic studies of ADHD, which have indicated a possible association of two specific genes with ADHD. Several studies have replicated an association between a specific allele for the dopamine 4 receptor subtype (the *DRD*4.7 allelle) with childhood ADHD. The association with ADHD follows other work suggesting an association between the *DRD*4.7 allele and novelty-seeking in adults from community samples. Therefore, this allele may relate to specific behavioral dimensions within ADHD, although this is speculative. Another allele (the 480 bp allele) of DAT1 was reported to be associated with transmission of ADHD, using data obtained from affected children and their parents (the haplotype relative risk method). However, some studies have been unable to replicate the association with the *DAT*1 allele. These findings underscore the likely genetic heterogeneity of ADHD (and its subgroups) and the need for additional research using these techniques within large samples.

Acquired Etiological Influences A variety of acquired influences have received support as etiologic factors for some children and adolescents with ADHD, including pregnancy and delivery complications, low birth weight, traumatic brain injury, and prenatal substance exposure. Although the strength and specificity of these influences appear to be more limited than familial factors within groups of subjects with ADHD, the risk factors below may be critical forces in the genesis of nonfamilial forms of ADHD for individual children and adolescents.

Several studies have reported associations between ADHD, pregnancy, and delivery complications. Some but not all reports have noted exposure to maternal toxemia in children later diagnosed with ADHD. Other studies suggest that problems during labor, fetal distress, and other birth complications are associated with later disruptive behavior problems. Such experiences may be particularly germane to the etiology of ADHD in children who lack a family history of the disorder. Similarly,

these adverse neonatal events may be associated with particular forms or subgroups of ADHD such as ADHD with comorbid conduct disorder.

Low birth weight has been identified as a risk factor for disruptive behavior disorders, including ADHD in particular, in several studies. The relation between low birth weight and risk for ADHD does not appear to be due to other perinatal risk factors commonly associated with prematurity. However, not all studies of pre- or perinatal adversity have found associations with ADHD per se: therefore, these events appear to function usually as nonspecific risk factors for psychopathology in children.

While traumatic brain injury has been thought to represent a risk factor for later hyperactivity, support for this association has been mixed. Nevertheless, more-recent studies of children and adolescents with carefully ascertained brain injury have uncovered a complex connection between severe brain injury and attentional and behavioral problems. The relation between brain injury and ADHD symptoms is defined by several aspects including severity of the injury, location of damage to brain tissue, and age at time of injury. The strongest relation has been found for more severe injuries and younger age at the time of injury. In one prospective sample of children with severe head injury, 19 percent had developed new-onset ADHD at follow-up. An association between mesial frontal lobe lesions and postinjury ADHD has also been described. These findings have been interpreted to suggest that earlier injuries may compromise ongoing brain development and disrupt executive functions and that individuals who have achieved greater cognitive development prior to injury may adapt better to loss of skills.

Substance exposure in utero has long been believed to lead to problems of behavioral control and emotional regulation. Prenatal exposure to alcohol and nicotine has been strongly associated with later assessment of ADHD symptomatology. While these effects may be moderated in part by socioeconomic variables and other environmental features, for many children, alcohol exposure represents a major etiologic factor associated with cognitive and behavioral problems. Similarly, prenatal nicotine exposure is also significantly associations with later development of disruptive behavior problems. Though the connection between prenatal nicotine exposure and ADHD has not always been consistent, there is general support for a relation between nicotine exposure and later disruptive behavior problems, including overactivity, in some individuals.

Diagnosis and Clinical Features The DSM-IV diagnostic criteria for ADHD are listed in Table 39.1-3. The symptom heterogeneity exhibited by children diagnosed with ADHD is considerable. The variability in behavioral profile within groups of children with ADHD is colored by many factors—age, symptom subtype, cognitive deficit, and comorbidity. Inconsistent behavior and poor academic performance are hallmarks of ADHD. Frequently, parents note that many child problems depend on context—with greater supervision, reduced stimulation, and support, their child's behavior and functioning can improve, at least momentarily. However, a careful history generally clearly shows an overall pattern of symptoms fitting the definition of ADHD. Besides a detailed clinical history of symptoms of ADHD, a general review of other possible psychopathology is indicated. Although children may report few indicators of their own ADHD symptoms, frequently their report can confirm impairment due to ADHD. Detailed descriptions of the individual's school history and performance is important. Additional direct observations of the child in the school setting and with peers can be revealing, particularly in less severe cases. A collection of observations and ratings on standardized behavioral rating forms from parents and teachers greatly aids diagnosis of ADHD. When available, the report of a spouse or parent is a key element in confirming the report of an adult being evaluated for ADHD. Additional self-report measures of ADHD symptoms are available for adults. At present, the specificity of computerized attentional tests for the diagnosis of ADHD is uncertain, and such results should be interpreted with caution.

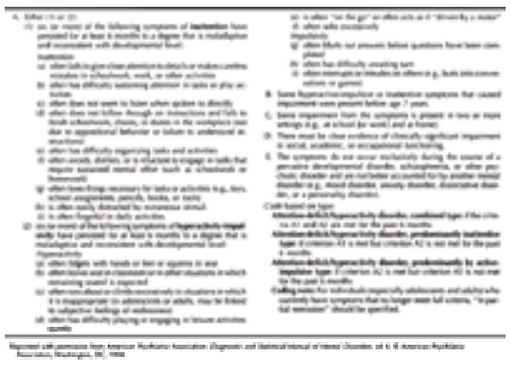

Table 39.1-3 DSM-IV Diagnostic Criteria for Attention-Deficit/Hyperactivity Disorder

Subtypes The DSM-IV subtypes of ADHD describe some of the symptom variability in ADHD: ADHD, inattentive type; ADHD, hyperactive-impulsive type; or ADHD, combined type. Estimates of the frequency of subtypes in clinic-referred children suggest that the combined type is most common, followed by the inattentive type, and finally by the hyperactive-impulsive type. The average age at diagnosis of ADHD is approximately 7 to 9 years. In the field testing of the DSM-IV ADHD categories, most children identified as having ADHD, hyperactive-impulsive type were 3 to 4 years younger than children diagnosed with other subtypes. ADHD children with the inattentive subtype tend to have a later age of recognition, perhaps because they exhibit fewer of the oppositional, defiant, and aggressive behaviors that often spark referrals for evaluation. Although symptoms often overlap across subtypes of ADHD and hyperactivity-impulsivity and inattentive behaviors are significantly correlated, some prominent differences can be observed in individual cases. For example, children with inattentive subtype are often described as sluggish, anxious, subject to daydreaming, and sleepy—if anything, hypoactive.

Nature of ADHD Cognitive Deficits Surprisingly, the nature of the attention deficits encompassed by the syndrome of ADHD has eluded precise identification. Initial conceptualizations of performance differences between ADHD children and normal controls on laboratory tests of cognition emphasized difficulties in sustained attention in ADHD. However, these differences were inconsistent across studies. The application of newer cognitive test paradigms has revealed more-specific patterns of weakness in samples of children with ADHD. Difficulties in inhibiting a behavioral response to a stop signal have been noted in samples of children with ADHD as well as children with other patterns of disruptive or aggressive behavior. However, the deficit in response inhibition is typically not seen in children with other types of psychopathology and thus may be an important correlate of externalizing behavior problems. Other cognitive paradigms applied to the study of ADHD have also observed asymmetries in response patterns in ADHD and normal control children. Tests of covert visual spatial orienting have revealed slower reaction times and unique types of hemispheric asymmetries involving poorer performance of both right and left hemispheres in children with ADHD, depending on cue type. An important area of current research focuses on whether types of cognitive deficits may be familial and serve as possible risk markers for the transmission of ADHD.

Comorbidity Studies of epidemiological and clinical samples of children with ADHD find a high frequency of other overlapping symptoms and diagnoseable disorders, including significant rates of both mood and anxiety disorders as well as other disruptive behavior disorders. Recognition of these associated conditions carries important implications for assessment, prognosis, treatment approaches, and research. For example, the association of ADHD and conduct disorder is reportedly related to later development of substance abuse. While continued debate exists over whether these apparent comorbidities are due to artifactual comorbidity produced by current criteria, other research finds cause for comorbidity in shared deficits and other possible mechanisms of association. In general, the high frequency of associated psychopathology has been argued to reflect the heterogeneity of ADHD itself.

The most common comorbid disorders found in both clinical and epidemiological samples of children with ADHD are oppositional defiant disorder and conduct disorder. These children display argumentativeness, temper outbursts, defiance of authority and rules, and aggressive, antisocial behavior in addition to symptoms of ADHD. Rates of oppositional defiant disorder in samples of children with ADHD reportedly average 35 percent; when oppositional defiant disorder and conduct disorder are combined, rates of comorbidity with ADHD rise to about 50 to 60 percent. A variety of influences may shape this association. For example, school-age children with oppositional defiant disorder or conduct disorder almost invariably meet criteria for ADHD. Conversely, adolescents with conduct disorder without ADHD are more common. Other influences include greater symptom severity, reading disorder, school impairment, and lower socioeconomic status in comorbid ADHD–conduct disorder children. Family and genetic studies support the premise that children with comorbid ADHD and conduct disorder may represent an etiologically distinct subtype. Children with ADHD associated with other disruptive behaviors are particularly challenging and require intensive intervention to prevent greater morbidity and impairment.

Significant comorbidity exists with ADHD and mood and anxiety disorders. Estimates of the co-occurrence of ADHD and mood disorders have ranged from 15 to 75 percent, with an average comorbidity of about 25 to 30 percent; association with anxiety disorders has been reported in up to 25 percent. Studies of comorbidity of ADHD with mood disorders have found common co-occurrence of ADHD with both dysthymic disorder and major depressive disorder. In general, comorbid depression and ADHD does not appear to affect the manifestations of either disorder. With the early onset of ADHD, most mood disorder diagnoses are made following the emergence of ADHD, which suggests that some instances of ADHD–mood disorder comorbidity are secondary to the experience of a chronic impairing disorder such as ADHD. However, most studies of the first-degree relatives of children with ADHD and mood disorder find an increased risk for mood disorders, suggesting that both

disorders breed true in families. Whether ADHD and mood disorders share vulnerability factors is under active investigation. In contrast, some differences in patterns of performance on cognitive tasks and reduced cognitive improvement with stimulants distinguish children with ADHD plus anxiety and those with ADHD without anxiety. These findings may suggest dysfunction in different or additional neural systems in children with ADHD plus anxiety.

A recent controversy involves a suggested association of ADHD with prepubertal bipolar disorder, with over 90 percent of those meeting criteria for bipolar disorder also meeting criteria for ADHD. In one clinical sample of children with ADHD, 16 percent reportedly met criteria for bipolar disorder. Children believed to display co-occurring ADHD and bipolar disorder have also been described as showing more severe ADHD and aggressive symptoms and higher internalizing symptom scores. However, the absence of patterns of classic cyclical mood and the lack of increased rates of bipolar disorder in all of the extant follow-up studies of ADHD suggest that ADHD plus bipolar disorder is infrequent.

Distinct from the academic underachievement and slightly lower (intelligence quotient) I.Q. test scores found in groups of ADHD children, learning disorders and reading disabilities also commonly occur in children with ADHD. Use of rigorous criteria has shown that learning disorders are more frequent in children with ADHD than in either psychiatric controls of normal children, but this comorbidity is modest (15 to 30 percent). Compared with conduct disorder, several studies find ADHD to be more strongly associated with reading disorders than with mathematics disorder. The co-occurrence of learning disability and ADHD has been suggested to result in poorer outcomes. This overlap may also relate to the association of ADHD with other disruptive behavior disorders, such as conduct disorder.

Other types of comorbidity can be found in individuals with ADHD. The overlap of ADHD and chronic tic disorders, including Tourette's disorder, is widely acknowledged, and rates of ADHD in children and adolescents with Tourette's disorder range from 30 to 50 percent. Individuals with mental retardation also often display attentional difficulties, hyperactivity, and impulsivity. For those who meet criteria for ADHD after developmental level is considered, treatment can be highly effective. In adults with ADHD, alcohol and substance abuse is a common comorbidity that poses a definite diagnostic and treatment challenge. Frequently, a period of abstinence is necessary before the adverse effects of substance use can be separated from a possible overlap with symptoms of ADHD. Anger outbursts, other patterns of mood lability, and relationship conflicts are frequent complaints of adults with possible ADHD.

Bill was an 8-year-old boy who lives with his adoptive parents and younger sister. After his school teacher raised concerns over his poor adjustment to his second grade classroom, his parents sought out a consultation. Bill was the product of an apparently normal pregnancy and delivery. He was adopted at age 3 months by his current adoptive parents. Early development was normal except for the description of Bill's temperament as hard to soothe and irregular sleep patterns in the first year of life. After he began preschool at 30 months, staff noted that he had difficulty sitting still for group activities and needed frequent reminders to resist hitting peers over disagreements during play. Later, a supportive first grade teacher described Bill as active but learning normally without concerns. However, soon after Bill entered second grade, his teacher called parents to express concerns that Bill showed problems listening in class and completing assignments without multiple reminders. He also frequently rose from his chair in class during quiet study activities. Overall, he was performing below expectations, and multiple reprimands had not led to sustained improvement.

Bill's parents noted that for about 9 months prior to evaluation, he had become more challenging to his parents at home; in particular, he was frequently argumentative and resistant to requests. Daily struggles over simple routines and limits ensued. Bill's mother had attempted to restrict his intake of sugar but without significant change in behavior. On examination, Bill appeared restless and shifted frequently from one item to another. He acknowledged difficulty listening to his teacher “sometimes.” Psychomotor activity was increased. Mood and affect were normal. Teacher ratings on behavior rating scales were above the 95th percentile, with no indication of a learning disorder. Parent ratings on the Child Behavior Checklist confirmed attention problems and aggresion. A physical examination performed 5 months earlier by Bill's pediatrician showed no abnormalities.

Results of the consultation were consistent with attention-deficit hyperactivity disorder and oppositional defiant disorder. Recommendations included a trial of methylphenidate (Ritalin) at 5, 10, and 15 mg given three times a day over 3 weeks and referral to a parent training program for behavioral management.

Pathology and Laboratory Examination ADHD remains a clinical diagnosis, based upon clinical history and examination. No specific diagnostic tests exist at present. Some data obtained in psychoeducation testing may be confirmatory, including behavioral observations of inattention or poor task persistence during test situations, and relative test performance scores across domains, including overall intelligence, presence or absence of specific learning disorders, and items such as the Freedom from Distractibility factor of the Wechsler intelligence test. Brain imaging, electroencephalography (EEG), and specific neuropsychological testing may be indicated under specific clinical situations to rule out other diagnostic possibilities such as mental retardation, epilepsy, or structural lesions or to evaluate for suspected uncommon comorbidities but should not be considered on a routine basis.

Differential Diagnosis The differential diagnosis of ADHD versus other types of disruptive behavior disorders is generally straightforward by clinical history and examination of specific symptoms and behavior patterns. Descriptions of inattention, overactivity, and impulsivity should be evident across situations and to multiple observers. Other sources of inattention and frustration in school settings, such as learning disorders, can be discerned by differences in behavior across settings, school grades, and results of psychoeducational evaluations. At times, these problems may co-occur, making accurate diagnosis more complex.

Another diagnostic challenge lies in separating interference from other psychopathology such as mood or anxiety disorders on concentration, school adjustment, and performance. In general, ADHD is distinguished by its chronicity and early onset rather than an episodic pattern, although school impairment from ADHD may be progressive, with increasing academic demands over many years. The temporal relationship between the appearance of internalizing symptoms with greater school difficulty usually is evident in instances of mood or anxiety disorders uncomplicated by ADHD.

A variety of other psychiatric and developmental disorders are commonly associated with attention deficits, including autistic disorder and other pervasive developmental disorders, schizophrenia, and mental retardation. In most instances, these disorders, if diagnosed, are considered primary, and a separate diagnosis of ADHD is not made, although interventions to enhance concentration, reduce interfering symptoms, and improve academic performance may be an important part of treatment efforts.

Course and Prognosis Although complicated by differing diagnostic criteria, sample characteristics, and methodology, studies have yielded much about the course of ADHD. These findings include reports from a variety of well-controlled prospective follow-up studies with follow-up as long as 15 to 17 years after initial assessment. In general, both longitudinal studies and descriptions of older samples of individuals with ADHD consistently reveal changes in the core symptoms of ADHD with the development and the appearance of new problem behaviors. The most striking observation is the strong persistence of the diagnosis over time, supporting the prognostic validity of the diagnosis. Recognition of the variety of adverse outcomes of individuals with ADHD shows the need for aggressive, multimodal intervention approaches.

P>Studies following school-age children with ADHD into adolescence find strong persistence of the syndrome over time, usually in spite of treatment. These longitudinal studies find that the symptoms of inattention are more persistent than those of hyperactivity-impulsivity, which tend to decline as a group over time. Besides continuation of most core ADHD symptoms, early studies found worse outcomes for ADHD adolescents: high rates of deliquent behaviors in 25 to 50 percent, poorer self-esteem, lower academic achievement, new diagnoses of conduct disorder, and greater substance abuse. However, subsequent research revealed that early conduct problems, particularly aggression and defiance, rather than severity of ADHD symptoms per se, tend to be more strongly predictive of poor outcomes at later ages. Other predictors, such as I.Q. and parental psychopathology have been identified in some, but not all, follow-up studies. However, given the high comorbidity of ADHD with oppositional defiant disorder and conduct disorder and the relatively modest strength of individual variables as predictors, children with ADHD should be considered at increased risk for adverse outcomes. On average, about 60 to 80 percent of children with ADHD continue to manifest the full syndrome well into adolescence.

In many respects, a slightly more optimistic picture is seen in the young-adult follow-up studies of individuals with ADHD. ADHD persists in 10 to 50 percent of young adults at follow-up, although many more individuals report some interference because of at least one remaining core symptom. Controlled follow-up studies consistently document increased incidence of the development of antisocial personality disorder and substance abuse problems at follow-up. Other characteristics seem to distinguish ADHD groups at follow-up, including high numbers of subjects with histories of incarceration, low educational achievement, and poor self-esteem. The worst outcomes of antisocial personality disorder and substance abuse occurred almost exclusively in subjects who had experienced persistent ADHD over follow-up. Interpretation of these follow-up studies is complicated and controversial. Nevertheless, they highlight the importance of intervention in an effort to prevent these adverse outcomes.

Treatment Practice parameter guidelines for the assessment and treatment of ADHD have been published by the American Academy of Child and Adolescent Psychiatry. While a wide variety of treatments have short-term efficacy for some symptoms of ADHD, few demonstrations of long-term efficacy of comprehensive and

clinically relevant treatment programs exist. Treatments with strong empirical validation of efficacy include medications (particularly the psychostimulants) and certain psychosocial therapies.

The short-term benefits of medication treatment of ADHD has been confirmed in well over 100 studies that included thousands of children with ADHD. The short-acting psychostimulants remain the first-line choice for the pharmacotherapy of ADHD, principally because of their ability to improve both behavioral and cognitive aspects of the disorder in 70 to 80 percent of children. The safety profile for the stimulants is also excellent. However, interest continues in identifying alternatives to stimulants, for such reasons as the significant comorbidity of ADHD with other disorders, occasional intolerance of stimulant adverse effects, the inconvenience of multiple dosing, and infrequent lack of efficacy.

The behavioral and cognitive effects of stimulants on ADHD are robust and extensive. These positive effects include a reduction in psychomotor activity in ADHD patients and normal subjects (not a paradoxical response) and decreased disruptive behavior, aggression and deviance from classmates as measured by peer ratings. The beneficial cognitive effects of stimulants in ADHD children and adolescents are also well documented, including enhanced attention, short-term increases in academic acquisition, and facilitated working memory. However, behavioral improvement clearly falls short of normalization, and significant residual ADHD symptoms, peer problems, and academic challenges remain in most children.

Four rapid-acting stimulants are currently available: methylphenidate, dextroamphetamine (Dexedrine), magnesium pemoline (Cylert), and a mixed preparation of amphetamine salts (Adderall). Table 39.1-4 describes commonly prescribed medications for ADHD and their approximate effective dosage ranges. While methylphenidate is the most commonly prescribed stimulant, there is no indication of differential efficacy among the currently available psychostimulants. In the few studies that have directly compared the responses of individual ADHD children to more than one stimulant, occasional preferential improvement with one agent has been observed.

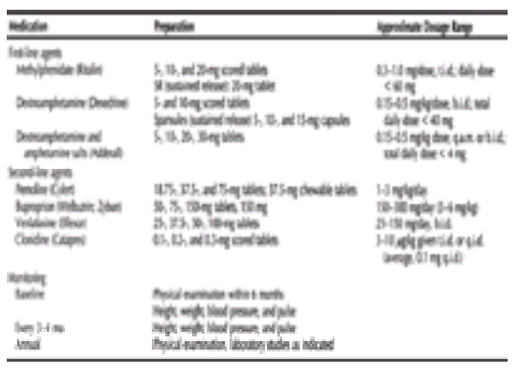

Table 39.1-4 Medications for the Treatment of ADHD and Suggested Monitoring

The psychostimulants have an excellent track record of safety. Adverse effects of the stimulants are fortunately minor or uncommon, although they can pose dilemmas in management. In general stimulant treatment–emergent effects are minor, dose related, and transient. The most common adverse effects are initial insomnia and appetite reduction, followed by headache, irritability, and dysphoria. Less commonly, reduced weight gain is problematic. In some patients, a rebound in ADHD symptoms can be difficult to manage late in the day. Although the convention of not prescribing stimulants to patients with comorbid tic disorders has been largely discounted, some individuals cannot tolerate the increase in tic symptoms produced by stimulants. Pemoline has been associated with a rare hepatotoxic reaction that has not been observed with the other stimulants. Although typical stimulant adverse effects can usually be managed by dosage reduction, or occasional change in agent, the continued presence of even minor adverse effects may strongly influence compliance. Causes for consideration of other medications than the stimulants include impairing comorbid psychopathology, the presence of a chronic tic disorder, comorbid substance abuse, and marked anorexia.

A number of nonstimulant alternatives have been proposed for the pharmacological management of ADHD (Table 39.1-4), however, their empirical support varies considerably, and they should be reserved for stimulant refractory or intolerant patients. These include bupropion (Wellbutrin, Zyban) tricyclic drugs, a-adrenergic receptor agonists such as clonidine (Catapres) and guanfacine (Tenex), and other atypical antidepressants. In general, these alternatives fall short of equaling the improvements on cognition produced by the stimulants, although modest positive effects of bupropion on cognition have been suggested. Safety concerns also limit the indications for wider use of these medications for ADHD.

In general, the approach to pharmacotherapy involves initial titration of a stimulant, usually methylphenidate or dextroamphetamine given in multiple daily doses. Intolerance or lack of efficacy should prompt a trial of a second stimulant. Thereafter, additional medication trials should be guided by comorbidity, acknowledging the substantial empirical support for bupropion and tricyclic drugs as effective second-line agents.

Despite the broad base of empirical support for medication treatment for ADHD, a number of gaps still exist in the literature. Most studies have primarily included male school-age children, and used short-term treatment periods. Emerging data does support the continued efficacy of treatment periods as long as 12 to 24 months, but additional data are needed.

Behavior therapy has clear support as a component of treatment for ADHD. In particular, behavioral parent training and classroom behavioral modification approaches are well documented to be probably effective interventions for ADHD, although the magnitude of behavior change typically falls short of that produced by stimulant treatment. Effective ingredients of these approaches include providing consistent contigencies for adaptive and maladaptive behavior, consistent praise, use of time out, and verbal reprimands. Additional elements that appear to be effective are daily report cards for behavior and point systems for positive and negative behaviors. Other, more-intensive behavior modification interventions may be helpful.

A variety of other traditional and nontraditional therapies have been touted as useful complementary treatments for ADHD but lack supporting studies. Attempts to show the benefits of cognitive therapy and other psychological therapies for ADHD have not proved fruitful. Dietary manipulations and restrictions, herbal preparations, biofeedback, and perceptual training cannot be endorsed for ADHD because of lack of supporting evidence. Because of the well-known academic underachievement problems of ADHD children and the significant comorbidity of ADHD with learning disabilities, educational tutoring and remediation are widely indicated.

Combined Approaches Few studies have provided true tests of the widely held belief that a combination of treatments may be most efficacious for children with ADHD. Initial findings from the recent Multisite Treatment Study of ADHD (MTA study) suggest that although psychostimulants exhibit the most robust short and longer-term benefits for ADHD symptoms, some additive benefits in peer relationships and parent satisfaction occurred in children receiving medication treatment combined with home and school behavioral interventions. Future research should help clarify better indicators for the use of combined treatments and the benefits of multimodal treatment approaches in other populations of youngsters with ADHD.

ATTENTION-DEFICIT DISORDER NOT OTHERWISE SPECIFIED

DSM-IV includes attention-deficit disorder not otherwise specified as a residual category for disturbances with prominent symptoms of inattention or hyperactivity that do not meet the criteria for ADHD (Table 39.1-5).

Category is for disorders with prominent symptoms of inattention or hyperactivity-impulsivity that do not meet criteria for attention-deficit/hyperactivity disorder.

Table 39.1-5 DSM-IV Diagnostic Criteria for Attention-Deficit Disorder Not Otherwise Specified

The incidence of adult manifestations of ADHD is unknown, but there are many more cases than were previously thought or diagnosed. This category of illness is being more frequently diagnosed and requires much greater attention and study. In adults, residual signs of the disorder include impulsivity and attention deficit (e.g., difficulty in organizing and completing work, inability to concentrate, increased distractibility, and sudden decision making without a thought of the consequences).

SUGGESTED CROSS-REFERENCES

Adult manifestations of attention-deficit disorders are discussed in Section 39.2. Conduct disorder and oppositional defiant disorder are discussed in Chapter 39, and Tourette's disorder is discussed in Chapter 41. Pharmacotherapy for children is discussed in Section 46.3, individual psychotherapy for children in Section 46.1, and family therapy in Section 31.5 and Section 48.5.

CHAPTER 39. ATTENTION-DEFICIT DISORDERS

39.2 ADULT MANIFESTATIONS OF ATTENTION-DEFICIT/HYPERACTIVITY DISORDER

PAUL H. WENDER, M.D.

Attention-deficit/hyperactivity disorder (ADHD) is a common psychiatric disorder in adults that was seldom diagnosed until recently, despite the publication of systematic studies since the mid-1970s. It was denoted in the third edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III) as attention-deficit disorder, residual type. The revised third edition of DSM (DSM-III-R) stated that approximately one third of children with ADHD showed continuing signs in adulthood but did not code this as a separate category. The fourth edition of DSM (DSM-IV) states that "symptoms attenuate during late adolescence and adulthood, although a minority experience the full complement of systems of ADHD into mid-adulthood," and thus continues to use the attention-deficit/hyperactivity disorder diagnosis with adults.

HISTORY

The systematic exploration of adults with ADHD, using operational definitions of the syndrome and evaluating treatment in a placebo-controlled fashion, was started in 1976 by the Utah group of the author, David Wood, and Paul Reimherr, and they continued it through the early 90s. During the past few years awareness of the syndrome has spread widely and will undoubtedly increase further.

EPIDEMIOLOGY

No data exist concerning the prevalence of ADHD in the adult population. However, an estimate can be made on the bases of its prevalence in childhood and longitudinal studies that have determined the persistence of the disorder into adulthood. Studies have variously estimated the prevalence at 3 to 10 percent of children. The variability in rates reflects the lack of validating gold-standard methods for ascertaining psychiatric diagnosis, hence diagnosis is based on a quantitative measure—an arbitrary cutoff in the number of symptoms present or an equally arbitrary cutoff in rating scale scores. Two large longitudinal studies have addressed the prevalence and persistence issues. Salvatore Mannuzza and Rachel Klein followed up a population of 103 boys, ages 6 to 12 years, with "hyperactive reaction of childhood" and 100 controls. They found persistence in 40 percent of patients at a mean age of 18 (versus 3 percent of the controls). At a mean age of 26, only 11 percent of the subjects manifested ADHD symptoms, while 18 percent had antisocial personality disorder and 16 percent had nonalcohol substance abuse disorder (versus 2 to 4 percent in matched controls). Gabrielle Weiss and Lily Hechtman followed up 6- to 12-year-old hyperactive patients to the age of 25 and could evaluate only 60 percent of the now-adult subjects. Two thirds of them exhibited at least one symptom of ADHD such as restlessness, distractibility, or impulsivity compared with 7 percent of the controls. Approximately one half continued to have moderate-to-severe problems, and one fourth manifested symptoms of antisocial personality disorder. The difference in outcome cannot be readily explained, but one factor may have been the absence of a reporting adult in the Mannuzza-Klein studies. Evaluation of initial psychopathology and changes produced by treatment are extremely difficult to evaluate without the help of an adult reporter. Based on these studies the estimate of the prevalence of ADHD in adults varies from 0.3 to 6 percent. Other studies have found an increased frequency of a history of ADHD in young male alcoholics and in populations of substance abusers.

An additional difficulty in determining the prevalence of ADHD in adults is the frequency with which it is mistaken for one of several, often common, disorders in adulthood or is hidden from view altogether. For example, not only is it found with increased prevalence in young alcohol abusers and in college students with poor study habits (generally due to an inability to concentrate), but it often mimics minor depressions. Typically it presents as a mild, periodic depression of short duration and marked lability that responds rapidly to improved environmental conditions. Other substantial groups of ADHD individuals go completely unrecognized because they belong to populations that generate little diagnostic attention such as the lowest classes in society and those embedded in the criminal and penal systems, which both appear to contain a high prevalence of individuals with this disorder.

ETIOLOGY

The etiology of the disorder in adulthood is obviously the same as that in childhood. The author hypothesized in 1971 that the disorder was a genetically transmitted disorder of catecholaminergic functioning. A number of studies have documented the genetic basis of ADHD. The author's inferences on genetic transmission were based on two crucial findings: the higher instance of ADHD in siblings of children and the increased incidence of other psychiatric conditions, particularly alcohol abuse and antisocial personality disorder in their parents. The latter relationship may have been mediated by the well-known comorbidity of ADHD and conduct disorder in child probands. Since one half of conduct-disordered children go on to develop antisocial personality disorder in adulthood, an increased frequency of alcoholism and antisocial personality disorder would be predicted in adults who had ADHD in childhood. Moreover, the clustering of alcohol abuse, antisocial personality disorder, somatization disorder agrees with results of the family studies of Samuel Guze at Washington University. Familial clustering can obviously result from genetic or psychosocial transmission. Studies of the concordance of ADHD in monozygotic and dizygotic twins found greater concordance in the former and no evidence for psychosocial transmission. Finally, adoption studies support the genetic hypothesis. Daniel Safer found that separately placed full siblings of ADHD children were twice as likely to have ADHD as their half-siblings, while Helene Deutsch found a higher frequency of ADHD symptoms in the biological relatives of ADHD children than in the adopting parents of these children.

The catecholaminergic hypothesis also drew early support from the development of ADHD-like symptoms in children who recovered from von Economo's disease. Pathological studies by Constance von Economo of children who died during the course of the encephalitis showed that they had damage to a variety of structures including the substantia nigra, the major site of origin of dopaminergic cells. The biochemical and genetic basis for ADHD is also supported by the fact that such children and adults often show dramatic improvement when treated with two indirect dopamine agonists, the amphetamines and methylphenidate (Ritalin). The availability of adults with ADHD allowed studies ethically precluded in children. The only study of cerebrospinal fluid (CSF) in adults with ADHD demonstrated a lower concentration of homovanillic acid (the principal metabolite of dopamine) in patients than in controls. Further, administration of amino acid precursors of dopamine revealed that tyrosine, the immediate precursor of dopamine, decreased ADHD behavior in adult patients. Finally, drugs with a specific effect on dopamine metabolism were used. Dopamine is metabolized by monoamine oxidase (MAO) type B (MAO_B). Administration of two inhibitors of this enzyme, pargyline and selegiline (Eldepryl), improved the behavior of ADHD subjects, these studies were not placebo controlled and must be replicated. Finally, there are an increasing number of imaging studies of children with ADHD and presumably such studies will soon be conducted in adults.

DIAGNOSIS AND CLINICAL FEATURES

DSM-IV defines subsyndromes of ADHD in children as predominantly inattentive type, predominantly hyperactive-impulsive type, and combined type. No definition is provided for the syndrome in adulthood. As might be expected, many items are age limited; for example, features such as "often runs about or climbs excessively" or "has difficulty playing or engaging in leisure activities quietly" clearly are designed for children. To study the syndrome in adults, the Utah group constructed operational diagnostic criteria. The first prerequisite specified in DSM-IV is that the specific symptoms have been present since before the age of 7. Since no evidence indicates that adults can accurately remember the presence or absence of such symptoms in that age span and parents or former caretakers were infrequently available, alternate diagnostic techniques were needed. To address the childhood requirements, the Utah adult ADHD research group demanded that either the narrow or the broad criterion below be met.

I. Childhood characteristics
   A. Narrow criterion: the individual met DSM-IV criteria for ADHD in childhood, determined from a parent interview.

B. Broad criterion: both characteristics 1 and 2 below are met, as judged by the patient.
   1. *Hyperactivity:* more active than other children, unable to sit still, fidgetiness, restlessness, always on the go, talking excessively
   2. *Attention deficits:* sometimes described as having a “short attention span,” distractibility, unable to finish school work

Even with best efforts, it was sometimes difficult to obtain this early history with certainty. However, the careful schedule of symptoms reported by patients about their current, adult functioning had greater reliability and importance. This information was gathered primarily from the patient but also, when possible, from a significant other as well. Thus, a second diagnostic criterion was (typically) the presence of motor hyperactivity in adulthood as well as at least three of the following descriptive groups of symptoms. As further measures of childhood symptoms, two rating scales were employed. The first, the Parents' Rating Scale is a 10-item scale on which the subject's mother rates him as he was between the ages of 6 and 10. The second, the Wender Utah Rating Scale (WURS) is a 61-item questionnaire on which the subject rates his behavior. Both have been standardized and permit the determination of the percentile of childhood ADHD into which the subject fell.

II. Adult characteristics
   A. *Motor hyperactivity:* restlessness; inability to relax; “nervousness” (meaning inability to settle down, not anticipatory anxiety); inability to persist in sedentary activities (e.g., watching movies or TV, reading the newspaper); always on the go, dysphoric when inactive
   B. *Attention deficits:* an inability to keep mind on conversations; distractibility (incapacity to filter out extraneous stimuli); difficulty keeping mind on reading materials or tasks (“mind frequently somewhere else”); frequent “forgetfulness”; often losing or misplacing things; forgetting appointments, plans, car keys, purse, and so on
   C. *Affective lability:* usually described as antedating adolescence and in some instances as far back as the patient can remember; manifested by definite shifts from a normal mood to depression or mild euphoria or (more often) excitement; depression described as being “down,” “bored,” or “discontented”; anhedonia not present; mood shifts usually last hours to at most a few days and are present without significant physiological concomitants; mood shifts may occur spontaneously or be reactive
   D. *Hot temper, explosive, short-lived outbursts:* outbursts of hot temper, “short fuse,” or “low boiling point” usually followed by quick calming down. Subjects may report having transient loss of control and being frightened by their own behavior; easily provoked or constant irritability; temper problems interfere with personal relationships
   E. *Emotional overreactivity:* cannot take ordinary stress in stride and reacts excessively or inappropriately with depression, confusion, uncertainty, anxiety, or anger; emotional responses interfere with appropriate problem solving; experience repeated crises in dealing with routine life stresses; describe themselves as easily “hassled” or “stressed out”
   F. *Disorganization, inability to complete tasks:* a lack of organization in performing on the job, running a household, or performing schoolwork; tasks are frequently not completed; the subject switches from one task to another in haphazard fashion; disorganization in activities, problem solving, organizing time; lack of “stick-to-it-tiveness”
   G. *Impulsivity:* minor manifestations include talking before thinking things through; interrupting others' conversations; impatience (e.g., while driving); impulse buying. Major manifestations may be similar to those seen in mania and antisocial personality disorder and include poor occupational performance; abrupt initiation or termination of relationships (multiple marriages, separations, divorces); excessive involvement in pleasurable activities without recognizing risks of painful consequences (buying sprees, foolish business investments, reckless driving). Subjects make quick and easy decisions without reflection, often based on insufficient information and to their disadvantage; inability to delay acting out without experiencing discomfort
   H. *Associated features:* marital instability; academic and vocational success below that expected on the basis of intelligence and education; alcohol or drug abuse; atypical responses to psychotropics; family histories of ADHD in childhood as well as antisocial personality disorder in male relatives and Briquet's syndrome in female relatives

These required characteristics are of a combined type and are based on disjunctive categories; hyperactivity is prerequisite both in childhood and adulthood, and a sufficient number of other related symptoms are required as well. However, it was possible to study (as the Utah group did) individuals who possessed a sufficient number of symptom groups but not hyperactivity.

These adult criteria are preliminary but have proved their usefulness. They are based on symptoms about which an adult can inform the examiner; the childhood psychiatric diagnosis is based on children's behavior or signs. Further delineation of the adults' symptoms benefit from direct subjective impressions of the adults rather than their presumably unreliable extrapolation of childhood behavior.

DIFFERENTIAL DIAGNOSIS

ADHD patients are often identified by prominent affective lability, irritability, and impulsivity. Thus, ADHD may be confused with chronic mood disorders such as dysthymic and cyclothymic disorders. Unlike these classic mood disorders, the mood symptoms in adults with ADHD are relatively brief, are not characterized by anhedonia, and have no physiological concomitants. The emotion most frequently described by these patients is “boredom.” ADHD “cyclothymic symptoms” differ from symptoms of cyclothymic disorder in that the up periods rarely last more than hours, are characterized by excitement rather than euphoria, and are usually reactive. Some symptoms of ADHD overlap those of borderline personality disorder such as impulsivity, affective inability, angry outbursts, and feelings of boredom. However, patients in the two groups show quantitative and qualitative differences in these symptoms. Impulsivity in ADHD is typically abrupt and thoughtless rather than driven, and the anger displayed is usually quick and short, unlike the brooding seen in patients with borderline personality disorder. Other associated conditions are antisocial personality disorder and substance abuse. The former is to be predicted because many conduct disordered children are comorbid for ADHD and half of them develop antisocial personality disorder in adulthood. Both the Mannuzza and Klein findings and those of David Wood predict an increased frequency of ADHD among alcohol and other substance abusers. The therapeutic consequences of this observation remain to be explored.

COURSE AND PROGNOSIS

In spite of the increasing recognition of ADHD among adults, there are no longitudinal studies of its course in adults. The Utah group has treated individuals in their 30s through their 50s and has found that they can be maintained for extended periods on the same dose of stimulants. In addition, clinical observation of parents of ADHD adults suggests that many symptoms continue well into the 60s (the seventh decade). No controlled studies of these issues exist.

TREATMENT

Sophisticated medication trials in ADHD adults are limited. The Utah group has conducted placebo-controlled trials and open-label studies in over 300 patients. These include four double-blind, placebo-controlled trials with 240 patients taking stimulants: three trials of methylphenidate (one of which is in progress) and one with pemoline (Cylert). In addition, 79 patients were included in trials of various medications including pargyline, selegiline, bupropion (Wellbutrin), levodopa (Larodopa), *dl*-phenylalanine, and L-tyrosine. Two additional placebo-controlled trials of methylphenidate have been conducted by Jeffrey Mattes and coworkers (who failed to replicate treatment effects, probably due to major differences in design) and Thomas Spencer and co-workers (who replicated the methylphenidate findings). The Utah group found that about 60 percent of patients receiving stimulant medication experience moderate-to-marked improvement, compared with 10 percent of controls. This is reflected by changes in Global Assessment of Functioning scores from pretreatment levels of 55 (moderate symptoms) to posttreatment scores of about 75 (slight symptoms present only in response to stress).

In general, current conclusions are that the drugs useful for ADHD children are useful in the management of adults with the disorder, with similar qualitative and quantitative effects in drug-responsive individuals. In fully responsive patients, concentration span is increased and distractibility decreased. Organizational ability improves, and patients think ahead and plan their tasks. Motor hyperactivity and feelings of restlessness disappear without the appearance of sedation; affective lability decreases, both highs and lows are eliminated, and patients experience calm without feelings of euphoria; hot temper and loss of control diminish; and many frustrations become tolerable. Impulsivity diminishes, at least in the short term; longer-term evaluation is necessary to observe important changes in vocational adjustment and interpersonal relationships. Stress intolerance abates. Patients report that they become “thicker skinned”; they can “roll with the punches,” and reverses may get them down slightly, but they bounce back.

The medications most widely used are the stimulant drugs. Methylphenidate, dextroamphetamine (Dexedrine), and methamphetamine (Desoxyn) appear to be equally efficacious; pemoline seems least effective overall. However, no predictors exist, and any one patient may do best on any one of these three agents. Dextroamphetamine and methamphetamine are equally potent; methylphenidate is approximately one half and pemoline approximately one quarter as potent as the amphetamines. The pharmacokinetics of the stimulants differ. Methylphenidate lasts 1½ to 3 hours, and many patients require four to six daily doses; amphetamines last 3 to 5 hours, and most patients need two or three doses. Pemoline has the longest duration of all, and one morning dose may suffice. Approximate dosage ranges

are methylphenidate, 30 to 90 mg a day; amphetamines, 15 to 45 mg a day; and pemoline, 37.5 to 150 mg a day.

Although long-acting forms of methylphenidate and amphetamines are marketed, the clinical consensus is that they do not always increase the duration of action; clinical experimentation may be necessary. Laboratory tests are unnecessary except for pemoline, which produces liver abnormalities in 2 to 3 percent of patients. The adverse effects of the stimulant drugs are anorexia (usually temporary) and insomnia (if the drug is given too late in the day); the latter can often be controlled with a small bedtime dose of a sedative phenothiazine such as thioridazine (Mellaril), 10 to 50 mg. The development of paranoid behavior usually indicates an undiagnosed schizophrenia spectrum condition.

The MAO inhibitors (MAOIs) appear to be effective in some patients with ADHD. The only systematic trials have been open ones with pargyline and selegiline. The advantages of MAOIs are their lack of abuse potential and their long duration of action; the latter averts fluctuations during the day and hence destructive temper outbursts before stimulant medication is taken in the morning or after it wears off in the evening. Compared with other MAOIs, selegiline in low (possibly subtherapeutic) dosages has no hypertensive “cheese effect.” Unfortunately it has not been evaluated in a placebo-controlled trial, and the higher dosages likely to be used run the risk of nonselective MAO inhibition and the cheese effect. Bupropion also appears to benefit approximately one half of stimulant-drug responders at a dosage of 300 to 400 mg a day. Bupropion is considerably less effective in stimulant nonresponders. It appears to control affective lability, dysthymia, and temper more effectively than concentration problems. A small, recent, open study suggests that venlafaxine (Effexor) may benefit some patients. Some clinicians have reported that tricyclic drugs are beneficial, but the author has found them of only moderate effectiveness. A therapeutic response occurs in days, but tolerance generally develops in weeks and does not respond to increased dosage. Symptom response appears more limited than with the stimulants, and ADHD patients seem less tolerant of the adverse effects than depressed patients; they are more troubled by the anticholinergic effects, weight gain, and impaired sexual functioning. Selective serotonin reuptake inhibitors (SSRIs), lithium (Eskalith), and antipsychotics are generally ineffective in patients without major mood disorders, although limited clinical experience suggests that the combination of SSRIs and stimulants may be of considerable benefit in individuals with ADHD and major depressive disorder.

Good clinical management requires having another person help evaluate treatment responsiveness. Previously untreated ADHD adults are often as unobservant about their behavior, its effect on others, and its changes with treatment as children with the disorder. A part of effective drug treatment requires teaching patients to observe and monitor their own behavior; therefore, another person is necessary. Failure to have an external judge results in false-negative treatment outcomes—substantial changes that are unobserved by the patient.

Appropriate management also requires assessing target symptoms. Of accurately diagnosed patients whose treatment progress is evaluated with the help of another person, 60 to 70 percent experience moderate-to-marked therapeutic benefit (an increase of 15 to 20 points on the Global Assessment of Functioning Scale), which often improves with time; indeed, the most dramatic benefits are seen over years.

The most effective psychological intervention begins with education. Patients are taught that some of the problems have a biological origin and can be suppressed by the use of medication. Patients learn how to monitor the severity of these symptoms and gradually come to understand that these biological problems have engendered psychological, vocational, and interpersonal problems that are, so to speak, self-sustaining. Psychological intervention is then directed at recognizing and altering these maladaptive patterns. Only individual and couple therapies have been used to date. Group approaches using these principles would likely be even more effective.

A 55-year-old high school teacher entered a long-term study of methylphenidate as a symptomatic volunteer. His Parents' Rating Scale score placed him in the 99th percentile of “hyperactivity” while his WURS placed him in the most severe category. His presenting problem was that his temper and verbal abuse of students had led to his being given the choice of quitting or being fired from his teacher's job. He perceived himself as the “most unlucky and misunderstood” person in the world. He manifested all seven symptoms of ADHD, was close to abusive at home, and had had a serious drinking problem (like most members of this family) which he controlled with the help of Alcoholics Anonymous. At the time he chose to quit his job, his family life (four biological and four adopted children) was chaotic, and several of the children were having emotional problems. His wife was ready to leave but could see no way to support the children financially or psychologically.

He was given a placebo-controlled trial of methylphenidate (15 mg every 2½ hours, 6 times daily). After this his wife described marked changes: he could concentrate throughout an entire telephone conversation (something he had been unable to do before), could communicate with his children and follow through with reasonable discipline, and manifested none of his early disabling temper outbursts. While his wife worked, he decided to return to school and study computers. On the basis of these skills, he obtained a government job that required great attention to detail and more concentration than “I ever could have had produced before this study.” At the job he helped integrate computers throughout his department, and several of his ideas were incorporated as policy. Over a period of 5 years he was advanced several times and became the supervisor of seven employees. At the same time, he returned to school and obtained a 4.0 average in mathematics and a 3.7 average overall. Family life stabilized, his wife reported that the marriage was better than it ever had been, and the children's psychological problems were greatly improved.

SUGGESTED CROSS-REFERENCES

ADHD in children covered in Section 39.1. Sympathommetics (psychostimulants) are covered in Section 31.27, MAOIs, in Section 31.20, and tricyclic drugs in Section 31.30.

CHAPTER 40. DISRUPTIVE BEHAVIOR DISORDERS

HANS STEINER, M.D.

The introduction of a psychopathological grouping containing disorders manifesting themselves mainly in antisocial conduct is a recent advance but not one without controversy. Prior to the introduction of these diagnostic categories that imply discontinuity from normal development, there existed voluminous research on aggression, delinquency, and criminality from a dimensional and sociological perspective. The ultimate validity of these categorical diagnoses remains to be established. In addition, there is some concern that by transferring the focus of study from criminogenic environments to psychopathology, the essence of these disorders will be misrepresented. Disruptive behavior disorders contain two subgroups: oppositional defiant disorder and conduct disorder. Both diagnoses have been remarkably robust in several field trials. Both categories are to be distinguished from antisocial behavior, where the kind of temporal, qualitative, and quantitative syndromal clustering is lacking. All three entities are independent of the legal status of the child or adolescent, offering opportunities for study and intervention regardless of legal proceedings. Such an independence is increasingly warranted as evidence accumulates that certain biological and psychological factors (in addition to social ones) define these disorders. These additional factors can be genetic, constitutional, or environmental in origin. They offer new ways of conceptualizing necessary prevention, diagnosis, and treatment independent of criminological management. Such emerging data help in the active debate as to whether it is most accurate and advantageous to address different forms of antisocial behavior as ecological adaptations to psychosocially toxic environments or as psychopathology that is inherently located within an individual. The predominant opinion at the present time is that only a subset of delinquency will ultimately be ascribed to psychopathological conditions, but this subcategory will be a significant one because these cases will have the highest chances of persisting in their criminal activities regardless of environment and developmental phase. Finding accurate positive predictors of disruptive behavior in early development is an important issue. Finally, debate is ongoing as to the best way to conceptualize any antisocial behavior (dimensional versus categorical or a combination of the two). There is some support from retrospective data in the Epidemiological Catchment Area Study that later substance abuse was best predicted in a linear fashion. Other aspects of antisocial behavior have not been comparatively tested. Current criteria of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) for oppositional defiant disorder and conduct disorder suggest discontinuities after a certain number of criteria are met, but data do not necessarily support this concept. On the other hand, the criteria as they currently stand are purely descriptive and allow only for some contextual interpretation, thus leading to considerable within-category heterogeneity. Different subtypes will be found and there is an active debate on the best way of subdividing these large categories.

OPPOSITIONAL DEFIANT DISORDER

Definition This disorder consists of negativistic, hostile, or defiant behavior, creating disturbances in one of three domains of functioning (academic, occupational, or social), lasting at least six months. The diagnosis also refers to angry and vindictive behavior and problems with control of temper. Most of the behaviors are directed at someone, that is, an authority figure. However, there are no major antisocial violations. The behavior is also not part of a developmental stage (i.e., coercive behavior around ages 2 to 3 years and in early adolescence). The diagnosis is not limited to a particular age group, but most commonly emerges in late-preschool or early–school-age children. Exclusion criteria for other diagnoses (conduct disorder, antisocial personality disorder, psychotic or mood disorder) are added. The diagnosis implies more circumscribed disturbances of lesser severity than in conduct disorder, but represents more troublesome behavior than normative oppositionality. Behaviors of the oppositional defiant disorder type on the average appear 2 to 3 years earlier than those of conduct disorder. The latest factor analysis also suggests that there is significant coherence of the oppositional defiant disorder behaviors as outlined in the diagnostic criteria. However, support for the diagnosis has not been uniform; some authors question its status as a separate diagnosis or even as any kind of taxon at all and there have been some negative public reactions that categorizing oppositional defiant disorder as a disorder is an attempt to characterize normative behavior as pathological.

History The Group for the Advancement of Psychiatry suggested this diagnosis first in 1966 and thus it represents a relatively new addition to the taxonomy.

COMPARATIVE NOSOLOGY

DSM In 1980 the third edition of DSM (DSM-III) included this diagnosis as *oppositional disorder* for the first time. There were five criteria, of which at least two needed to be met. In 1987 the revised third edition of DSM (DSM-III-R) expanded the diagnostic label to include the word “defiant.” The list of criteria was expanded to nine, and at least five had to be met for a diagnosis. In 1994 the fourth edition of DSM (DSM-IV) reduced the criteria to eight and required that at least four be met. The current set of criteria has good reliability when parents are the informants, has high internal consistency, and negative and positive predictive value.

ICD The 10th revision of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) includes this diagnosis for the first time under the category of conduct disorders. The label is distinct from Diagnostic and Statistical Manual of Mental Disorders in two major ways: there is an assumption, partially supported by data, that it is a milder form of conduct disorder, that is, that there are significant continuities between the two diagnoses; and (2) it specifies an age of occurrence, discouraging use in older children. The general criterion for conduct disorder and four of the specific symptoms listed must be met, but no more than two acts from the more severe antisocial acts of twenty-three items (as opposed to six for a conduct disorder diagnosis). There is no additional listing of behaviors specific to oppositional defiant disorder. Comparative studies assessing ICD and DSM diagnoses are not available.

Epidemiology The epidemiological data for oppositional defiant disorder need to be regarded with some caution because of the recent modifications of the diagnostic criteria. The point prevalence of the disorder has been reported to vary between 1.7 to 9.9, with a weighted average of 5.7 percent. The average age of onset is about six years. Boys outnumber girls in the prepubertal age range, after which the two genders are more equal. The disorder occurs mostly in cohorts of lower socioeconomic status.

Etiology The etiological studies of this diagnosis are usually contained in the body of research on conduct disorder. So far there are no separate systematic investigations into the origin of oppositional defiant disorder. The disorder is believed to be multifactorial and developmental in origin and a cumulative risk factor model might help explain its genesis. Such a model leaves open the questions of discontinuity (i.e., it allows for the possibility that qualitative changes may result in a categorical diagnosis). It is also consistent with a dimensional conceptualization where linear accumulation of risks leads to more disorder and impairment.

Biological Factors Most authorities believe that genes, temperament, and other constitutional factors may be responsible in interaction with adverse social factors in the production of oppositional defiant disorder. There is familial clustering of certain disorders that are at least in part related to oppositional defiant disorder: other disruptive behavior disorders, attention-deficit/hyperactivity disorders, substance-use disorders, and mood disorders are common in family members.

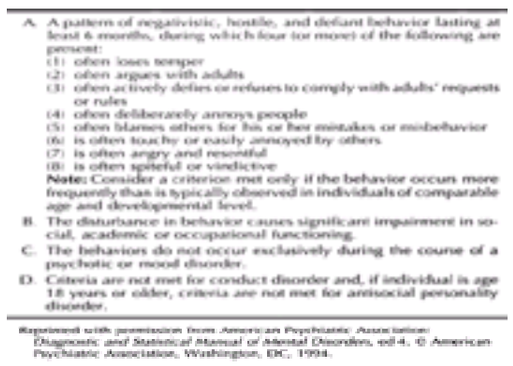
Psychological Factors Very little is known regarding the role of psychological factors in this disorder. Attachment theorists have noted the similarities between the behavioral manifestations of insecure attachment and disruptive behavior disorders. Antisocial behavior is seen as a special signal to an unresponsive parent. Findings linking infant attachment status with problematic behavior in preschool have been inconsistent, but interesting. Oppositional defiant disorder has been linked to the presence of anxious-avoidant attachment in particular. Insecure attachment also predicts aggression in elementary school in boys and multiple behavior problems in the classroom. Given the inconsistency in the data, most experts believe that multivariate transactional pathways will be found in this area of research. Another important area of research in a related area is the work of Kenneth Dodge who focused on aggressive children's deficient information processing in regard to social stimuli. Aggressive children have shown deficits at every phase of this multistage process: they underutilize pertinent social clues, misattribute hostile intent to peers, generate fewer solutions to problems, and expect to be rewarded for aggressive responses.

Social Factors Ecological factors such as poverty, crowding, and high-crime neighborhoods are believed to contribute to this disorder, but are mostly mediated by poor familial functioning and deficient parenting.

Developmental Trajectories One of the main explanatory problems in developmental psychopathology is the simultaneous existence of stability in behavior paired with its protean ability for appearance. Nowhere is this as apparent as in the area of antisocial behavior and its syndromal disturbances. Models need to be developed

that do justice to this heterotypic continuity. Underlying process may remain stable, but manifest disturbances can change depending on the context of the situation and the developmental phase of the individual in question. One of the crucial issues for the diagnostic category of oppositional defiant disorder is the demonstration of its continuity to conduct disorder and antisocial personality disorder. One longitudinal study establishes such a link: researchers have demonstrated that about one third of boys with oppositional defiant disorder progress to suffer conduct disorders. Conversely, 90 percent of boys with conduct disorder previously fulfilled criteria for oppositional defiant disorder. Thus, the syndrome has considerable sensitivity for the prediction conduct disorder from oppositional defiant disorder, but the positive predictive power is much less. One half of the sample retained oppositional defiant disorder diagnoses while one quarter desisted from oppositional defiant disorder at 3-year follow-up. It is an open issue whether children with oppositional defiant disorder who do not go on develop conduct disorder develop other psychiatric diagnoses.

Diagnosis and Clinical Features Typically, the patient is brought in by parents for problems in the home where difficulties are usually contained. Only with increasing severity does the child's behavior become out of control outside of the home. The DSM-IV diagnostic criteria for conduct disorder are listed in Table 40-1; Table 40-2 presents the ICD-10 criteria for conduct disorders.



A. A pattern of negativistic, hostile, and defiant behavior lasting at least 6 months, during which four (or more) of the following are present:
   (1) often loses temper
   (2) often argues with adults
   (3) often actively defies or refuses to comply with adults' requests or rules
   (4) often deliberately annoys people
   (5) often blames others for his or her mistakes or misbehavior
   (6) is often touchy or easily annoyed by others
   (7) is often angry and resentful
   (8) is often spiteful or vindictive
   Note: Consider a criterion met only if the behavior occurs more frequently than is typically observed in individuals of comparable age and developmental level.
B. The disturbance in behavior causes significant impairment in social, academic or occupational functioning.
C. The behaviors do not occur exclusively during the course of a psychotic or mood disorder.
D. Criteria are not met for conduct disorder and, if individual is age 18 years or older, criteria are not met for antisocial personality disorder.

Table 40-1 DSM-IV Diagnostic Criteria for Oppositional Defiant Disorder

Table 40-2 ICD-10 Diagnostic Criteria for Conduct Disorders

Robert, age 7, presented to the consultation-liaison team. He suffered from leukemia and was extremely difficult to manage. He would refuse all necessary blood work and repeatedly ran away from the clinic when asked to cooperate with requests for X-rays, blood tests, etc. He was sullen, argumentative, and irritable. The behavior was unchanged when mother was used as a “filter” for the demands. He was a chronically cranky child, although his illness was in remission and he was mostly medication free at the time of consultation. His care was severely compromised. At home his behavior was very similar and had been so for several months. He continuously argued with his single mother about any kind of request, such as cleaning up his room. Prior to his difficulties at the hospital, he began to exhibit similar problems at school. He was suspended for one week for being verbally abusive and out of control with his teacher. His mother had been diagnosed with acquired immune deficiency syndrome (AIDS) 2 years ago, having become infected by her drug-abusing husband who had died about 3 years ago from the effects of AIDS. She seemed dysphoric, passive, and extremely permissive with the child. She had no additional help because her own mother was also gravely ill and she had no current social support network. The patient would often scream at his mother at the top of his voice without her evidencing any kind of reaction or making any attempt to contain him. Testing showed him to be of normal intelligence, without the symptoms of attention-deficit/hyperaction disorder or learning disabilities. He knew of his father's death and his mother's illness. His mood remained dysphoric for many weeks when discussing this. He had never exhibited other reactions to being told about the illnesses of his parents. His mother described his early development as unremarkable except for his tendencies to have irregular sleep and eating patterns and his propensity to be cranky. His mother had intermittently taken drugs while pregnant with him, her only child.

This case illustrates a severe form of oppositional defiant disorder. In part, the severity was iatrogenic because the pediatric team and the school had attempted to manage this child without psychiatric input in order not to add insult to injury. The mother had been dysfunctional for many years. Her inability to regulate the child's behavior was not the effect of AIDS impairment; her illness compounded longstanding problems with mood regulation and self-efficacy. As is usually true with externalizing disorders, there was substantial discrepancy between the medical team, the school team, the parent, and the child as to precisely which behaviors presented problems and when, highlighting the necessity for multiple informants in the assessment of such cases.

Pathology and Laboratory Examination There are no pathognomonic tests and findings. A general chemistry panel may be helpful to identify chronic illness that might contribute to the problem. Often oppositional defiant disorder may be the first manifestation of more subtle specific developmental disabilities, and thus assessment of intelligence and learning might be helpful. Temperamental rating scales such as the Dimensions of Temperament–Revised, normed from preschool to adulthood and available in self and observer rating format can contribute to assessment.

Differential Diagnosis and Comorbidity Delineation of oppositional defiant disorder from normative oppositional behavior, transient antisocial acts, and conduct disorder is of paramount importance. Oppositional defiant disorder is not transient, leads to significant impairment, but does not involve major violations of the law and the rights of others. Attention-deficit/hyperactivity disorder is the most common comorbidity: between 25 to 60 percent of children with oppositional defiant disorder also fulfill criteria for attention-deficit/hyperactivity disorder by parental report, and half of attention-deficit/hyperactivity disorder children have oppositional defiant disorder. As with conduct disorder, the association of oppositional defiant disorder and attention-deficit/hyperactivity disorder confers poor prognosis. Youngsters tend to be more aggressive, show a greater range and persistence of problem behaviors, are rejected at higher rates by peers, and underachieve more severely in the academic domain. Furthermore, attention-deficit/hyperactivity disorder facilitates the early appearance of oppositional defiant disorder and conduct disorder. Antagonistic behavior is commonly found in internalizing disorders in this age group: dysthymic disorder, major depressive disorder, and early-onset bipolar I disorder should be considered. Anxiety disorders, especially separation anxiety disorder, can present with predominant temper control problems. Pervasive developmental disorders also can demonstrate oppositionality, but the underlying bizarre problems with relating to others are usually absent in oppositional defiant disorder children.

Course and Prognosis With the exception of one 3-year prospective study there is no information about the naturalistic progression or response to treatment in these children. Most of these children will not develop conduct disorders or antisocial personality disorder. One half will show stable signs of oppositional defiant disorder after 3 years; 25 percent will have no further diagnosis. Extrapolating from studies on conduct disorder and oppositional defiant disorder about one quarter of the initial total will go onto develop conduct disorders and about 10 percent will progress into antisocial personality disorder.

Treatment Adequately designed studies of controlled treatments are not available. The clinician needs to develop an individualized treatment plan based on the specific situation. First, the setting for the intervention needs to be determined. Issues of the safety of patients and those around them need to be considered. Intensive settings are needed for crisis management only. Long-term solutions are typically necessary to achieve positive outcome. Family therapy, parent management training, and conjoint treatment of parent and child along psychodynamic lines have some empirical support; day treatment may also be effective. In all

cases, there should be close collaboration with schools. Psychopharmacological treatments are mostly indicated to address issues of comorbidity, as there are no data on the pharmacological treatment of oppositionality without comorbidity. Generally, it is believed that early application of treatment is more effective than later.

CONDUCT DISORDER

Definition *Conduct disorder* is a clinical term referring to the clustering of persistent antisocial acts of children and adolescents. The condition is thought to be due to underlying psychopathology leading to significant impairment in one or more domains of functioning. The symptoms are clustered in four areas: aggression to people and animals, destruction of property, deceitfulness and theft, and serious violations of rules. Subtyping is allowed based on the age of onset of symptoms. Severity can be specified as mild, moderate, or severe. The category is currently conceived of as a polythetic diagnosis in that no one specific criterion is necessary for and any combination of criteria will suffice to establish the diagnosis. There is no formal provision for evaluating the context in which these antisocial clusters occur. Both these features contribute to the fact that the category is inherently heterogenous. The current criteria require that at least three of a list of fifteen antisocial behaviors be present over a period of 12 months; one of them has to be present in the past 6 months. Exclusion criteria for antisocial personality disorder are added. In epidemiological studies, this category has been robust, especially in its most recent more stringent versions. Its inherent heterogeneity has made conduct disorder less useful for causal and treatment studies. National practice guidelines have been developed for this disorder by this author.

History Clinical interest in antisocial behavior began with the specialty of forensic pathology. Early investigations focused on the detection of criminal stigmata in physiognomy and anatomy. Subsequently, Richard von Krafft-Ebing's detailed descriptions of deviant sexual behavior began to move the field into the realm of behavior observations. Following the writings of Sigmund Freud, whose speculations regarding aggression as an instinct were of direct relevance, psychiatric clinicians began the exploration of antisocial acts as psychopathology. Soon afterwards, ethologists began their naturalistic observations of animal aggression and explored its relationship to human behavior, providing ontogenetic and phylogenetic anchors. Konrad Lorenz was especially interested in aggression as an instinct. Following the results from several longitudinal studies that demonstrated the stability of antisocial acts within the same individuals over time and in diverse environments, their poor response to criminological management and supportive counseling, interest intensified in the clinical definition of antisocial behavior. Psychometric work in the middle of the twentieth century established the coherence of antisocial and aggressive patterns of behavior. At the same time, John Bowlby was studying subtypes of delinquents. The description of “affectionless characters,” with their histories of prolonged disruptions of early relationships, became one of the sources of inspiration for the study of attachment and also provided a bridge from analytic concepts and ethology to the clinical study of antisocial acts. Most recently, interest in biological substrates has reemerged. Stella Chess and Alexander Thomas introduced the notion of the “difficult temperament” which served as an early childhood antecedent of behavior problems in some boys; Robert Cloninger further specified the risks. High novelty seeking with low harm avoidance, both heritable traits, were instrumental in generating risk of conduct disorder. Recent studies of genetic transmission indicate certain heritability for antisocial behavior.

COMPARATIVE NOSOLOGY

DSM The first edition of DSM (DSM-I) did not delineate children's antisocial acts; the second edition (DSM-II) listed three reactions, suggesting a strong environmental bias; and DSM-III for the first time introduced conduct disorder as a syndrome. One action, displayed over long time periods, was necessary for diagnosis. There were four subtypes of conduct disorder, based on a 2 × 2 matrix on the axes of socialization and aggressivity. The resulting categories, informed by the initial psychometric work and supported in factor analytic studies by Herbert Quay, showed poor reliability and subsequently were dropped in 1987 in the DSM-III-R. DSM-III-R made the diagnostic criteria more stringent by expanding them to 13 and requiring that at least three were present for at least 6 months. This reflected the empirical finding that diversity of antisocial behaviors rather than specificity of a behavior best predicted chronic antisocial problems and recidivism. Subtyping was changed: group or socialized; solitary or aggressive; and undifferentiated subtypes were permitted. This subtyping was dropped in DSM-IV, reflecting its poor reliability. Instead, a subtyping by age of onset is permitted. Once again, criteria were made more stringent: in addition to three of 15 behaviors being present for at least 12 months, one of those three has to have been present in the past 6 months. There is still no differential weighing of the various antisocial behaviors listed, contributing to the poor negative predictive value. Some of the behaviors listed are endorsed by a majority of adolescents (e.g., truancy from school, staying out all night despite parental prohibitions) whereas others occur only exceedingly rarely (carrying out robberies).

ICD There are substantial differences between the two classifications in the definition of this disorder. For one, ICD-10 lists this grouping as a plural to indicate the heterogeneity of the category. ICD-10 only requires one major behavior to have been present in a repetitive and persistent pattern in the past 6 months; isolated dyssocial acts are excluded. A list of 23 behaviors is given and there is some weighing of criteria, as seven behaviors of greater severity (i.e., forcing sexual activity; using weapons; being physically cruel to others) need to have been present only once in order for the criterion to be fulfilled. The instructions exclude behaviors due to other illness and the clinician is encouraged to use other diagnoses as primary if present. Hyperkinetic disorder, mood disorders, pervasive developmental disorder, and schizophrenia are excluded. Subtyping by age of onset is recommended. In addition, describing cases in terms of the following characteristics: hyperkinesis, emotional disturbance and severity (mild, moderate and severe), is also recommended. Other subtypes are: conduct disorder confined to family context; unsocialized conduct disorder; socialized conduct disorder; oppositional defiant disorder; other conduct disorder; conduct disorder unspecified. In addition, there is a separate category provided for mixed disturbances of conduct and emotions, where both criteria for emotional disturbance (anxiety, depression, other emotion), an adult-type neurotic diagnosis, or a mood disorder are met. Subtypes here include depressive conduct disorder and other mixed disorder. ICD thus uses finer stratification of conduct disorder and avoids comorbidity diagnoses. The proposed subtypes await definitive empirical validation.

Epidemiology Conduct disorders are among the most frequently referred, diagnosed, and treated psychiatric problems. A number of large and well-designed epidemiological studies employing a range of assessment methods provide information. However, the diagnostic criteria have been changed substantially since the early 1980s, so results of older studies (i.e., prior to DSM-III-R) may not be fully comparable to current ones. The general population prevalence is estimated somewhere between 1.5 and 3.4 percent of children and adolescents when clinical interviewing is used as a method of detection, but reported prevalences vary widely (between 1 and 16 percent) depending on the samples used, the definitions given to the disorder, and the instruments applied. The male-to-female ratio has been found to range between 5:1 and 3:1, depending on the age range studied, but at all ages boys predominate over girls. It is only in adolescence that the gap between the sexes begins to close because of the increase of the disorder in girls. There is debate as to whether diagnostic criteria should be modified for girls to reflect their greater propensity for covert antisocial acts. Peak age of onset is in late childhood and early adolescence, but onset can range from preschool to late adolescence. The occurrence of conduct disorder appears to have increased in the 1990s, which may be a reflection of the increase in the adolescent cohort or improved case identification and diagnostic methods. At any given time it is estimated that about 1.3 to 4 million children and adolescents are afflicted with conduct disorders.

Etiology Most authorities agree that conduct disorder is a heterogenous disorder. It can best be described as a final common pathway for several initially divergent developmental trajectories. Although there is currently no agreement about a uniform model applying to all forms of conduct disorder, one possible model for the combination of causal factors is that of genetic liability triggered by an environmental adversity, mediated by other factors such as poor coping. Although there is some debate on the relative importance of the factors that have been implicated, there is general support for the developmental nature of the disorder. The following model describes one possible integration of such risk and resiliencies in the genesis of this disorder.

Risk-Resilience Model for Conduct Disorders This model posits that it is the gradual accumulation of risk as well as the absence or weak presence of protective factors and their interactions that ultimately lead to the conduct disorder rather than single risk factors operating in isolation. Rolf Loeber has illustrated the gradual stacking of factors in the genesis of conduct disorder. An expanded model would include a parallel pyramid of resilience or protective factors, balancing the gradual aggregation of risk as it accumulates over time. Figure 40-1 portrays the predominance of risks in ecological (e.g., poverty), constitutional (e.g., difficult temperament), and parenting (e.g., poor response to coercive behaviors, abuse) factors. This results in poor internal self-regulation, which becomes manifest especially during school age. School performance is also affected because these children lack the skills to deal with authority and cannot fulfill their academic potential. Peer relationships also suffer as the child tends to find acceptance only from similarly socially inept peer groups. As there is an increasing aggregation of risk it takes more and stronger protection to offset the risk and more domains may be adversely affected. Empirical data also support the fact that as risks accumulate in number, the greater is the chance that conduct disorder will develop via multiple interactive loops between risks.

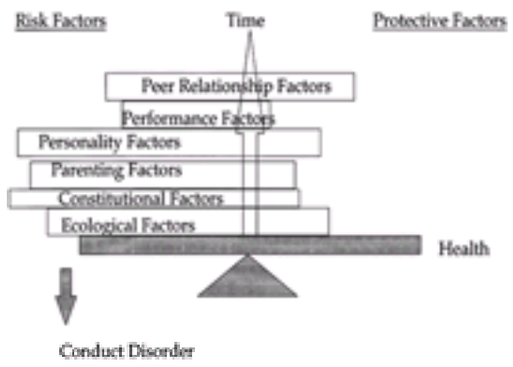

FIGURE 40-1 Developmental pathways to disruptive behavior disorders.

Biological Factors The familial aggregation of the disorder has suggested that there may be a genetic risk for conduct disorder. Data from the comparison of monozygotic and dizygotic twins in terms of concordance rates for criminality and the results of fast adopt studies support such a link, but a cautionary note is in order: these heritability estimates were mostly based on adult criminal populations, which represent the most severely ill individuals. The results also apply mostly to nonviolent offending, which appears paradoxical. The results in juvenile delinquency are much less impressive, most likely because of the high prevalence rates and the heterogeneity of conduct disorder. However, the results are interesting, suggestive, and merit attention. Most authorities feel that it is unlikely that any one gene or even any combination of genes would account for the occurrence of such highly complex behaviors as are expressed in conduct disorder, but that there may be genetic causes for certain risk factors, such as hyperactivity. Recent reviews present new and promising leads. Complex interactions of constitutional risk and environmental adversity will better explain etiological variance than any single factor model. Certain psychophysiological abnormalities have repeatedly been reported as constituting risk for the development of conduct disorder, supporting the claim that biological abnormalities that are under partial genetic control are involved in the problem. The best researched area is the autonomic nervous system, which shows low baseline activity and reactivity on a variety of parameters in the early-onset group, paralleling findings in the adult psychopathy studies. These abnormalities are presumed to relate to diminished avoidance conditioning in response to socialization. Another abnormality is the high base activity and reactivity in this system in the late-onset group, which has been shown to relate to increased desistance from crime on follow-up. Neurotransmitter abnormalities are found with some regularity, although the findings are less consistent when compared to the psychophysiological literature. Of particular interest are the compounds reflecting the activity of sympathetic arousal, which have direct connections to anxiety and sensation-seeking behavior. The latter is inversely related to 3-methoxy-4-hydroxyphenylglycol (MHPG) concentrations in older youth, but not in younger boys with delinquent behavior. Abnormalities in the systems reflecting noradrenergic and dopaminergic activity have been described, although these findings do not hold uniformly across other small samples. More recently, serotonin has been added to the list of neurotransmitters implicated in aggressive youth, but the literature is not methodologically strong. Neurotransmitter findings have been linked with an imbalance favoring the behavioral reward over the behavioral inhibition system. Many of these findings raise issues about the causal relationship between environmental stress and biological factors, because environmental adversity can result in such alterations. Multiple promising leads in terms of the biological implications of child maltreatment are currently identified, including associations between abuse and reduced hippocampal size, and lack of autonomic reactivity in victims of extended and severe abuse.

Sex is a clear risk factor in multiple studies. Much less is known about females in this population, although some recent studies have begun to document details. The findings implicating gender-specific hormones in the genesis of the disorder are very inconsistent and the current understanding is that responses to androgens depend on the biochemical, environmental, and historical context of the individual involved. The clear and consistent findings in animals regarding the role of androgens in aggression, brain development, and social dominance are not paralleled in the human literature. Difficult temperament has been repeatedly implicated in the genesis of the disorder. It could work in at least two ways: it may make children more likely to be the target of parental anger and thus of poor parenting or it may be directly linked to behavior problems later on. Inappropriate aggression at an early age, especially in combination with shyness, predicts later conduct disorder. Chronic illness and disability also have been known to increase the prevalence of conduct disorder, especially if the primary illness affects the central nervous system (CNS). Chronically ill children have three times the incidence of conduct problems than healthy peers; if chronic illness affects the CNS, the risk is about five times as high.

Psychological Factors Conduct disorder is more likely to be paired with diverse and complex disturbances in psychological domains. The origin of these disturbances is not clear, but their presence implies that many risks for conduct disorder are retained and internalized and independent of specific environments. Academic underachievement, learning disabilities, and problems with attention span and hyperactivity are all associated with conduct disorder. Hyperactivity, especially in the presence of poor parental functioning, is a risk; it seems to facilitate rapid development of conduct disorder. Neuropsychological deficits have been documented implicating frontal and temporal lobe dysfunctions. Laterality and language performance are disturbed. Higher personality functions are also affected: in complex social situations, children with conduct disorder have been shown to perceive fewer appropriate responses, lack the skills to negotiate conflict, and lose their ability to restrain themselves when emotionally stressed.

Social Factors Poor family functioning, familial aggregation of drug and alcohol abuse, psychiatric problems, marital discord, and especially poor parenting are all associated with conduct disorder. Abusive, neglectful parenting and child maltreatment is a highly specific risk factor for the development of conduct disorder. The specific parenting patterns that contribute to the development of conduct disorder have been described as training in noncompliance by inconsistent responses to coercive behavior of the child and by capitulating to demands in response to the child's coercion. There is fairly substantial evidence that viewing televised or other media violence and violence in the child's community contributes to the development of conduct disorder problems, especially in children who are at high risk for other reasons. Socioeconomic disadvantage as manifested in poor housing, crowding, and poverty all exert consistently negative influences.

Protective Factors Protection implies that certain factors affect core aspects of functioning positively and pervasively in the presence of considerable risk. Much less is known about these factors at the present time than is known about risk. An easy temperament and high base rates of autonomic nervous system activity offer protection. Ability to relate to others, good work habits at school, areas of competence outside school, and high intelligence are important. Social factors include a good relationship with at least one parent or another important adult, prosocial peers, a good school that fosters success, responsibility and self-discipline, and the selection of a good mate (as demonstrated by a stable interpersonal relationship, a good work history, and capacity for good parenting). Currently, there are no studies available that look at the experimental manipulation of these protective variables.

Diagnosis and Clinical Features The clinical manifestations of conduct disorder can be very diverse and difficult to assess. Research has repeatedly supported a fundamental division among externalizing behaviors: aggressive-antisocial on one hand and impulse-reactive on the other, but this distinction is not always easily made. In addition, the context in which these diverse symptoms occur is quite variable. Although DSM-IV does not provide a contextual subtyping and qualification of the symptoms (Table 40-3), there is a stipulation that symptoms only be considered as indicative of conduct disorder if the behavior in question is indicative of an underlying dysfunction in the individual and not a reactive adaptation to an immediate social context. In reality, it may be quite difficult to separate these two causes. Furthermore, patients and other informants differ widely in their appreciation of some of the problems and their evaluation, and thus it is of great importance to use a range of methods for assessment across different settings, addressing multiple domains, and using multiple informants. In general, there is a tendency for lower-grade delinquent behaviors to appear first, and gradually for more severe ones to appear later in the course of conduct disorder. In taking the patient's history particular attention should be paid to data that allow for further subtyping. Childhood-onset conduct disorder is characterized by more aggression, higher likelihood of neuropsychiatric impairment, and poorer prognosis. Other subtypes are still relevant: the literature supports a differentiation of predatory (i.e., planned and coldly executed) from reactive (i.e., occurring in response to frustrating circumstances) aggression. Rolf Loeber's differentiation of separate pathways for antisocial behavior manifesting itself in conflict with authority, overtly or covertly in high-risk youth can be useful. These pathways occur in the context of different comorbidities and family backgrounds and follow different trajectories, although there is a tendency for them to blend together in most severely disturbed youths. Although the distinction between socialized and unsocialized delinquents has been dropped in the DSM system, it is still retained in ICD (Table 40-2) and some authorities believe that it continues to have considerable support and usefulness. An assessment of the interpersonal context of the patient's symptoms would also give additional help in deciding management and prognosis: A pervasive lack of relationships and the isolated predatory nature of certain acts imply a worse prognosis than the crimes committed in consort or under the influence of dyssocial peers. Finally, there have been recent descriptions of conduct disorder that presents with personality profiles of paradoxical overrestraint. These antisocial acts tend to follow a different path than their more common and typical underrestrained conduct disorder cohort: they exhibit an intermittent loss of impulse control, precipitated by specific personal triggers. These crimes tend to be fewer in number, but more severe in degree. These patients do not present with all the typical risks of most delinquent youths, but follow the trajectories of what has been described as the “neurotic delinquent.” Remarkable is the capacity of these patients to selectively ignore negative information, especially about themselves and those whom they love. Such difficulty seems to relate to a repressor profile that has been amply studied in the adult literature. Recent investigations have also shown the validity of this concept in the juvenile age

range.

Table 40-3 DSM-IV Diagnostic Criteria for Conduct Disorder

In addition, ICD-10 contains a separate diagnostic category for patients that meet the criteria for conduct disorders and another emotional disorder. The ICD-10 criteria for mixed disorders of conduct and emotions are listed in Table 40-4.

Depressive conduct disorder

A. The general criteria for conduct disorders must be met.

B. Criteria for one of the mood (affective) disorders must be met.

Other mixed disorders of conduct and emotions

A. The general criteria for conduct disorders must be met.

B. Criteria for one of the neurotic, stress-related, and somatoform disorders or childhood emotional disorders must be met.

Mixed disorder of conduct and emotions, unspecified

Table 40-4 ICD-10 Diagnostic Criteria for Mixed Disorders of Conduct and Emotions

It is quite likely that many subtypes will be found to overlap. The late-onset one–channel-disturbed-repressor-socialized profile can be contrasted to the early-onset two–or three–channel-disturbed reactive-undersocialized conduct disorder, with perhaps a distinct core group of more predatory-psychopathic conduct disorder.

J.O. was raised in an impoverished minority neighborhood adjacent to a major urban center on the west coast. The area was infested by crime and gang activity and relatively devoid of community structure and resources. His mother was a teenage single woman with a history of drug abuse dating back to age 14. From age 16 on she lived outside the parental home having been asked to leave by her mother because she was found in bed with her father. J.O.'s mother took up prostitution as a way to support herself. At age 18 she married the father of J.O. because she was pregnant by him. J.O., the child from this relationship, was born with signs of drug addiction. The child was tracked by Child Protective Services because of the circumstances of his birth. He was repeatedly placed outside of the home because he was found in need of food and adequate care. The couple lived on Aid for Families with Dependent Children funds and the mother continued her prostitution, bringing home customers and exposing her infant to the details of her business. In addition, J.O.'s father started a pattern of bringing home men for either his own pleasure or for the business of prostitution. This led to a permanent breakup when the child was about 3 years old. J.O. was removed and placed in his sixth foster home since birth. His foster parents noted a high degree of activity in the child and very difficult temperamental characteristics, which led to frequent harsh parenting on their part. After 6 months the child was placed in another foster home because the current foster parents declared themselves unable to deal with him. A new placement was sought and a psychiatric assessment led to a diagnosis of oppositional defiant disorder and attention-deficit/hyperactivity disorder. A stimulant was started that had some effect. However, with entry into school J.O.'s status deteriorated and he rapidly developed difficulties with teachers, peers, and school work. He was placed in a special classroom and treatment of attention-deficit/hyperactivity disorder and conduct disorder were coordinated between foster home and teachers. An unremitting pattern of lying, stealing, and deceptiveness began to manifest itself in the home and school. Two years into this regimen his mother reappeared and wanted to be reunited with him. After 1 month of trial in the home J.O. once again had to be removed because he was uncontrollably angry and menacing towards others, was found to be cruel to animals in the neighborhood, and had set fire to a local elementary school. He was placed into a different foster home where after 1 year he was found to have been molested by one of the other children in the home and in turn had begun to victimize younger children sexually. He was placed in a locked unit and released into a residential treatment setting, which in turn sent him to another group home after 2 years. He was now about 13 years old, and shortly before his next birthday, he ran away from his placement, surviving by robbing and stealing while beginning to indulge in drug and alcohol abuse. At 15 he was apprehended while driving a stolen vehicle and put on probation. He ran away again and robbed a store at gun point. This lead to his arrest, conviction, and commitment for 5 years to the Youth Authority. His case shows the gradually escalating course of antisocial activities in a child with extreme environmental and severe temperamental risks, leading to a chronic and unremitting pattern of closely clustered antisocial behavior that becomes increasingly independent of the social context in which the child finds himself.

Evaluation From the outset it must be made clear to all concerned that the clinician is predominantly assessing the situation from the viewpoint of the patient. Issues of compliance in the child and the parents will be a prominent part of the process of evaluation. Even with such clarity, it is highly likely that there will be multiple inconsistencies and contradictions that directly bear on the situation. The clinician is well advised to expect these and not attempt to clear them up in one session, lest this lead to alienating and premature confrontations. The best way to approach them is from a longitudinal perspective: as the evaluation unfolds, it will become increasingly clear what transpired. Interviews with parent and child are necessary, as are auxiliary ones. The child should be interviewed alone for significant parts of the evaluation. Probation and legal information should be presented in a dispassionate and unobtrusive manner, as a point of departure for discussion and not as a standard against which the patient's reports are going to be assessed. The evaluation must include a detailed physical examination and an assessment of neuropsychiatric and neuropsychological functioning. Particular attention must be given during the mental status exam to disturbances of mood and affect, suicidality, impulsivity, and associated comorbidities.

Pathology and Laboratory Examination At the present time there are no pathognomonic test findings for this diagnosis, but as the disorder presents with disturbances in multiple domains, several auxiliary assessments can be of value. As part of the routine assessment of conduct disorder, a careful assessment of the physical health domain needs to be performed to rule out chronic illness that contributes to the onset of disorder or to detect the ill-effects of comorbidities and the effects of abuse and general trauma. Head traumas are common in this group of patients, as are the sequelae of high–risk-taking behaviors, such as drug abuse and indiscriminate sexual conduct. Nutritional deficiencies are common and aggressivity has been linked to low levels of trace elements. Imaging techniques have been used in small-scale studies to document specific frontal and temporal lobe dysfunctions, but they are in the early states of investigation and should not be routinely applied. Referral for psychometric testing is always indicated to ascertain the level of intellectual functioning, specific developmental disabilities, personality functioning, and of indicators of psychopathy.

Differential Diagnosis and Comorbidity Conduct disorder has to be distinguished first and foremost from antisocial behavior without underlying psychopathology, oppositional defiant disorder, antisocial personality disorder, and impulse-control disorders. Substance use disorders are extremely common in conduct disorder and can be the primary diagnostic reason for antisocial conduct. Attention-deficit/hyperactivity disorder is the next most common differential. The association with conduct disorder has been so frequent that there has been a debate over combining the diagnoses, but empirical data finds that the disorders differ in terms of premorbid risk and their respective predictive power for adult criminal outcomes. Divergent validity for conduct disorder from attention-deficit/hyperactive disorders is generally

considered as established. The latter disorder is considered the most virulent comorbid condition: it facilitates the early appearance of conduct disorder, which is a strong predictor of adverse outcome. Psychotic disorders, especially those with paranoid processes, can be mistaken for conduct disorder. Internalizing disorders, such as mood disorders, posttraumatic stress disorder, and dissociative disorder can be confused with conduct disorder, although less commonly. Age under 18 prevents the diagnosis of personality disturbances, but in some cases borderline, narcissistic, and antisocial personality disorders should be considered. DSM-IV allows for extensive comorbidities as no exclusion criteria are provided. Conduct disorder is usually accompanied by a wide range of comorbid conditions. These comorbidities contribute independently and interactively to prognosis and outcome. Internalizing and externalizing comorbidities become increasingly common as the disorder becomes more severe. Repeated studies have shown that complex diagnostic patterns are the rule and not the exception in this population, resulting in compound psychopathology that requires special management and treatment. Loeber's data provide an unique opportunity to examine the developmental unfolding of various comorbid states: prior to adolescence, attention-deficit/hyperactivity disorder is most frequently associated with conduct disorder, especially in boys, declining in importance thereafter. The typical sequence seems to be attention-deficit/hyperactivity disorder-opposition defiant disorder-conduct disorder; alcohol and substance abuse follows. Each additional comorbidity adds to the poor prognosis in boys. The picture is different for girls: they also have a higher chance of getting conduct disorder when they suffer from attention-deficit/hyperactivity disorder, but it is not clear that the prognostic implications are as grave. Internalizing disorders, most commonly mood and anxiety disorders, but also somatization disorders seem to appear during adolescence when conduct disorder is firmly entrenched. Depression, in particular, affects both sexes but especially girls, particularly after they have reached pubertal maturation. The evidence on the prognostic impact of internalizing comorbidity and conduct disorder is mixed.

Course and Prognosis There are several studies demonstrating the stability of conduct disorders over time. Although the precise manifestations of the disorder may change, the pattern of repeated violations of major societal rules and laws continues. Modern naturalistic and long-term results suggest that only approximately 40 percent go on to develop the most pernicious variant of the personality spectrum: antisocial personality disorder. The majority of the remainder, however, also lead problematic lives in which many domains of functioning continue to be affected significantly (e.g., interpersonal relationships, ability to maintain healthful styles of living, ability to support themselves). Whether such a poor outcome is attributable to lack of intervention by the penal system remains an open question.

Treatment There is only modest evidence that treatment of conduct disorder is effective. Several recent reviews of the literature and a meta-analysis of over 500 studies show that a wide variety of treatments have been tried and on the average only show modest effect sizes. There is consensus among experts that early intervention is better; prevention is more effective than treatment, (although the evidence for effective prevention programs is also incomplete); and extensive approaches in naturalistic settings are preferable over those who work intensively in special settings, which bear little or no resemblance to the patient's daily environment. Dramatic interventions such as shock, incarceration, or boot camps are not supported by the evidence and may even have negative outcomes. Realistic programs should be multimodal, addressing deficiencies in the multiple domains of functioning. Finally, treatment packages should reflect the developmental needs of the child because there is no one intervention that is effective across all ages.

Preschool Conduct disorder rarely is manifested in this age group, but there is important evidence that interventions may prevent future conduct disorder. Programs such as Head Start have as one of their byproducts the prevention of future delinquency. Programs consist of special stimulation packages for the child, parent education about normal development and maturation, and parental support in times of crisis. Identification of the temperamental characteristics of the child, the goodness of fit between the child and the parent, and the facilitation of parental efficacy, especially in handling normative coercive behaviors and tantrums are reasonable targets for intervention. Stimulants and other medications are used quite frequently in this age group for symptom control, but there is no convincing support that medication is effective in the short or long term.

School-Age Multiple studies show the effectiveness of parenting training and social skills training aimed at improving peer relationships and the child's ability to comply with demands from authority figures as well as the improvement of academic skills. The primary target for intervention should be the child and the family as well as the school environment, that is, teachers and peers. Behavioral techniques are superior to client-centered therapy in short-term outcome. Suitable targets are prosocial functioning and antisocial behaviors. Social competence can also be induced by other techniques, including television viewing of problem situations and fantasy play. Family therapy is one of the mainstays of intervention in this age group and can be used primarily to explore conflict and problems in parenting, but also secondarily as a means of building and maintaining a working alliance with these families. Individual therapy used in isolation is not considered to be an effective treatment approach. Psychopharmacological approaches are definitely indicated to treat significant comorbidities, but evidence that they are effective in cases of uncomplicated conduct disorder is limited. Medication is best used to control symptoms and crises, while the rest of the intervention package is allowed to take effect. A reasonable algorithm for the use of types of medication is discussed below.

Adolescence Youngsters are increasingly beyond parental control and rely on internal psychological structures and peer opinion to guide themselves in their daily conduct. Treatment needs to reflect this shift: individual treatment should probably be added to the package because there needs to be a specific alliance with the patient in order to maintain some compliance with treatment demands. In addition, most youngsters with conduct disorder in this age group will have charges pending or assessed against them, and there most likely will be some curtailment of their freedom in some rehabilitative setting. Furthermore, substances and alcohol play an increasingly prominent part of the patient's symptoms. Their adverse effects and interactions with prescribed treatment need to be considered at all times. The most promising approach with youth in this age group is multisystemic therapy, which aims at keeping delinquents in their psychosocial environments while coordinating family and multiple systems interventions. Outcome studies have shown the clear superiority of this approach over incarceration and other treatments at substantially reduced cost. Psychoeducational packages targeting social skills, conflict resolution, and anger management are available to augment treatment; some have better empirical support than others. Psychopharmacological management is increasingly being considered for this age group, but it is only very recently that we have evidence from double-blind placebo-controlled trials that lithium (Eskalith), selective serotonin reuptake inhibitors (SSRIs), stimulants, and antikindling agents might be effective against aggression and some forms of antisocial behavior, even in the absence of particular comorbidities. There is no evidence that drugs by themselves are helpful in cases of uncomplicated or comorbid conduct disorder in the long run. In addition, antipsychotics, lithium, and carbamazepine (Tegretol), clonidine (Catapres), and propranolol (Inderal) all have been studied to some extent. As there are no definitive data available, the current treatment guidelines recommend the following algorithm. In the presence of mental retardation or organic brain impairment, propranolol or a brief course of psychiatric drugs might be helpful. In the presence of clear danger to others, antipsychotic drugs become the first choice. In the presence of lability of mood or explosive outbursts, lithium, divalproex (Depakote) or valproate (Depakene), or carbamazepine might be helpful. Clonidine can also be considered for explosive outbursts. If all these drugs do not help, buspirone (Buspar) or trazodone (Desyrel) might be prescribed. If irritability is a major antecedent to violence and aggression, SSRIs should be considered.

DISRUPTIVE BEHAVIOR DISORDER NOT OTHERWISE SPECIFIED

This is a residual diagnostic category, intended to be used in those cases that do not fulfill all the criteria but suffer significant impairment in functioning in one of several domains (Table 40-5). No research data is available on the validity and utility of this category.

This category is for disorders characterized by conduct or oppositional-defiant behaviors that do not meet the criteria for conduct disorder or oppositional defiant disorder. For example, include clinical presentations that do not meet full criteria either for oppositional defiant disorder or conduct disorder, but in which there is clinically significant impairment.

CHAPTER 41. FEEDING AND EATING DISORDERS OF INFANCY AND EARLY CHILDHOOD

IRENE CHATOOR, M.D.

Because infants and young children cannot feed themselves independently, disturbances related to eating are frequently referred to as “feeding disorders” to emphasize the dyadic nature of the eating process in this young age group. The fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) lists three different diagnoses under feeding and eating disorders of infancy or early childhood: pica, rumination disorder, and feeding disorder of infancy or early childhood.

In the 10th revision of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10), feeding disorder of infancy and childhood (which also includes rumination disorder) and pica are included under the category of other emotional and behavioral disorders with onset usually occurring in childhood and adolescence.

PICA

In DSM-IV, pica is described as the persistent eating of nonnutritive substances for at least 1 month. The behavior must be developmentally inappropriate, not culturally sanctioned, and sufficiently severe to merit clinical attention. Pica is diagnosed even when these symptoms occur in the context of another disorder such as autistic disorder, schizophrenia, or Klein-Levin syndrome.

Pica appears much more frequently in young children than in adults; it also occurs more frequently in persons who are mentally retarded. Among adults, certain forms of pica, including geophagia (clay eating) and amylophagia (starch eating), have been reported to occur in pregnant women. In certain regions of the world and among certain cultures, such as the Australian aborigines, rates of pica in pregnant women have been reported to be high. According to DSM-IV, however, if such practices are culturally accepted, the diagnostic criteria for pica are not met.

History The term “pica” was first applied by the French surgeon, Ambroìse Páre. It was derived from the Latin word for magpie, a bird considered to have unusual appetites. Many attributions for pica that have been described over the past 150 years were summarized by Myra Cooper in the 1950s.

Epidemiology Since young infants mouth objects quite commonly, it is difficult to diagnose pica when the child is under the age of 2 years. A survey of a large clinic population with a wide range of ethnic backgrounds revealed that 75 percent of 12-month-old infants and 15 percent of 2- to 3-year-old toddlers were reported by their parents to put nonnutritive substances in their mouths. Among individuals with mental retardation, the prevalence of pica appears to increase with the severity of the retardation. The prevalence of pica among institutionalized mentally retarded individuals has been estimated to range from 10 to 33 percent.

Etiology Organic, psychodynamic, socioeconomic, and cultural factors have been implicated in the etiology of pica. Inadequate intake of iron and calcium induces pica in rats and has been considered to lead to abnormal cravings and pica in humans. Psychosocial factors such as poverty, maternal neglect and abuse, and disorganized family situations with inadequate nurturing and supervision of the children have been implicated in the etiology of pica. The cultural acceptance of pica in certain population groups is also considered to play a role in pica. Some authors have proposed a multifactorial model in which organic, familial, socioeconomic, and cultural factors interact.

Diagnosis and Clinical Features Young children with pica typically eat plaster, paper, paint, cloth, hair, insects, animal droppings, sand, pebbles, and dirt. Many of the children engage in other oral activities (e.g., thumb sucking or nail biting), which they seem to use for relief of tension and self-soothing. Pica may lead to anemia, diarrhea/constipation, worm infestation, toxoplasmosis, lead poisoning, and malnutrition. Intestinal obstruction may develop as the result of hair ball tumors. The DSM-IV diagnostic criteria are listed in Table 41-1, and the ICD-10 criteria are found in Table 41-2.

A. Persistent eating of nonnutritive substances for a period of at least 1 month.
B. The eating of nonnutritive substances is inappropriate to developmental level.
C. The eating behavior is not part of a culturally sanctioned practice.
D. If the eating behavior occurs exclusively during the course of another mental disorder (e.g., mental retardation, pervasive developmental disorder, schizophrenia), it is sufficiently severe to warrant independent clinical attention.

Table 41-1 DSM-IV Diagnostic Criteria for Pica

A. There is persistent or recurrent eating of nonnutritive substances, at least twice a week.
B. Duration of the disorder is at least 1 month. (For some purposes, researchers may prefer a minimum period of 3 months.)
C. The child exhibits no other mental or behavioral disorder in the ICD-10 classification (other than mental retardation).
D. The child's chronological and mental age is at least 2 years.
E. The eating behavior is not part of a culturally sanctioned practice.

Table 41-2 ICD-10 Diagnostic Criteria for Pica of Infancy and Childhood

Differential Diagnosis Before the age of 18 to 24 months, mouthing and sometimes eating nonnutritive substances is relatively common and should only be diagnosed as pica if it is persistent and inappropriate for the developmental level of the child.

Course and Prognosis Usually, pica lasts for several months and then remits. It may occasionally continue into adolescence or, less frequently, into adulthood. Several authors have pointed to the serious developmental impact of the disorder. The younger children showed delays in their speech and psychosocial development. Half of the adolescents suffered from depression, personality disorders, or both; engaged in other forms of disturbed oral activities (e.g., thumb sucking and nail biting), and abused tobacco, alcohol, or drugs. More recently, some authors found a strong relation of pica during early childhood and bulimia nervosa during

adolescence.

Treatment A variety of treatments have been proposed, ranging from physical restraints, aversive and nonaversive behavioral therapy, time out and overcorrection, to environmental enrichment, and individual and group therapy for the children and their mothers. One must conduct a comprehensive evaluation of the child, the caregivers, and their environment to develop an individualized treatment plan. This should include helping the adults become aware of the short- and long-term dangers of pica, providing a lead-free and childproof environment, facilitating a more-satisfying parent-child relationship, and applying behavioral techniques to extinguish the maladaptive behavior of pica.

RUMINATION DISORDER

In DSM-IV rumination disorder is described as an infant's or a child's repeated regurgitation and rechewing of food, after a period of normal functioning. The symptoms last for at least 1 month, are not caused by a medical condition, and are severe enough to merit clinical attention. The onset of the disorder generally occurs after 3 months of age. After regurgitation, the food may be swallowed or spit out. Infants who ruminate are observed to strain to bring the food back into their mouths and appear to find the experience pleasurable. The infants are often brought for evaluation because of failure to thrive. The disorder is rare in older children, adolescents, and adults. It varies in its severity, and it is sometimes associated with medical conditions, such as hiatal hernia, that result in esophageal reflux. In its most severe form, the disorder can be fatal.

Rumination has been recognized for hundreds of years. An awareness of the disorder is important for correct diagnosis to avoid unnecessary surgical procedures and inappropriate treatment.

Rumination is derived from the Latin word *ruminare*, meaning “to chew the cud.” The Greek equivalent is *merycism*, the act of regurgitating food from the stomach into the mouth, rechewing the food, and reswallowing it.

History As early as in the seventeenth century, rumination was described in conjunction with hiatus hernia by the Italian anatomist Fabricius ab Aquapendente. Paul Maas first described rumination disorder of infancy in 1907, and in the 1950s Reginald Lourie linked rumination to disturbances in the mother-infant relationship.

Epidemiology Rumination disorder is believed to be rare. It appears to occur more often in males than in females and also in individuals with mental retardation. A few reports describe adults with eating disorders who developed rumination.

Etiology Various causes have been proposed. Several authors have attributed rumination to separation or a disturbed mother-infant relationship (e.g., lack of responsiveness or neglect by the mother because of stressful family relations or life events). Others consider rumination a symptom of gastroesophageal reflux. Several authors have postulated that rumination is a learned behavior that is maintained by special attention to the regurgitation. More recently opiate receptor insensitivity or reduced endorphinergic transmission has been implicated in rumination.

The author has proposed a biopsychosocial model in which rumination is seen along a continuum in which an infant may have gastrointestinal pathology and little psychopathology at one end of the spectrum and no organic pathology and severe psychopathology in the mother-infant relationship at the other. Frequently, vomiting secondary to gastroesophageal reflux or vomiting associated with an acute illness precedes the beginning of rumination. Apparently at some point the infant learns to initiate vomiting and rechew the food to relieve tension, self-soothe, or self-stimulate. When the infant fails to elicit or loses caring attention or tension-relieving responses from the mother, rumination seems to become a means of self-regulation. Once the infant has experienced rumination as a means of self-soothing or self-stimulation, the rumination develops into a habit that is difficult to break.

Diagnosis and Clinical Features Some infants put their thumb or whole hand in the mouth, suck their tongue rhythmically, or arch their back to initiate rumination. Others ruminate after they have been placed in the crib to sleep and are frequently found in a puddle of vomitus, which is then attributed to an organic problem. The latter type of rumination is most commonly observed in infants who have received little emotional stimulation and have learned to stimulate and soothe themselves through rumination. Although initially most of the regurgitated food is vomited, some infants gradually learn to hold more of the food in their mouth and rechew and reswallow it. Experienced ruminators can bring up the food through tongue movements and reswallow it without losing any. Their rumination can only be discovered by observing the movements of their cheeks and the foul oral odor.

The DSM-IV diagnostic criteria for rumination disorder are presented in Table 41-3.

A. Repeated regurgitation and rechewing of food for a period of at least 1 month following a period of normal functioning.
B. The behavior is not due to an associated gastrointestinal or other general medical condition (e.g., esophageal reflux).
C. The behavior does not occur exclusively during the course of anorexia nervosa or bulimia nervosa. If the symptoms occur exclusively during the course of mental retardation or a pervasive developmental disorder, they are sufficiently severe to warrant independent clinical attention.

Reprinted with permission from American Psychiatric Association: *Diagnostic and Statistical Manual of Mental Disorders*, ed 4. © American Psychiatric Association, Washington, DC, 1994.

Table 41-3 DSM-IV Diagnostic Criteria for Rumination Disorder

Differential Diagnosis Rumination must be differentiated from vomiting secondary to organic conditions. Since reflux and rumination frequently coexist, one must observe the infant in different situations and actually see the initiation and rhythmic movements of the ruminatory activity.

Course and Prognosis The onset of rumination is frequently in infancy, most commonly in the first year of life. However, rumination may start at any point in life and has been reported to start later in childhood in individuals with developmental delays and in adulthood in individuals with eating disorders. In some individuals, the disorder remits spontaneously. However, some infants suffer serious complications such as electrolyte imbalance, dehydration, and weight loss. Earlier reports described mortality rates as high as 25 percent.

Treatment Different treatments have been suggested on the basis of different theories about the cause of rumination. Treatments range from the mechanical restraints described in the early literature and surgical interventions to prevent reflux to behavioral and psychodynamic treatments.

Based on the assumption that rumination is a learned habit that is reinforced by the increased attention given to the regurgitation, unlearning by behavioral techniques has been suggested. These treatments range from the use of aversive taste stimuli (lemon juice or hot sauce), oral hygiene, differential reinforcement of incompatible behaviors, to electric shock. Those who assume that rumination is based on an unsatisfactory mother-infant relationship have suggested a psychodynamic approach. Having a mother substitute feed the infant while the mother is helped through psychotherapy has been proposed.

After a thorough assessment of both infant and mother, the therapist needs to individualize the treatment. In severe situations, if the infant is malnourished and continues to lose most of the food through rumination, a jejunal tube may have to be inserted before any psychosocial treatment can begin. Frequently, a combination of psychodynamic and behavioral interventions to enhance the mother-infant relationship in general and to treat the symptom of rumination, in particular, is most effective.

FEEDING DISORDER OF INFANCY OR EARLY CHILDHOOD

According to DSM-IV, feeding disorder of infancy or early childhood is a persistent failure to eat adequately, reflected in significant failure to gain weight or in significant weight loss over at least 1 month. The symptoms are not better accounted for by a medical condition or by another mental disorder and are not caused by lack of food. The disorder has its onset before the age of 6 years.

The DSM-IV diagnostic criteria (Table 41-4) are broad and do not address the specificity of various feeding disorders not included in DSM-IV or ICD-10. Feeding disorder of infancy or early childhood serves as an umbrella diagnosis for the more specifically defined feeding disorders described in this chapter.

A. Feeding disturbance as manifested by persistent failure to eat adequately with significant failure to gain weight or significant loss of weight over at least 1 month.
B. The disturbance is not due to an associated gastrointestinal or other general medical condition (e.g., esophageal reflux).
C. The disturbance is not better accounted for by another mental disorder (e.g., rumination disorder) or by lack of available food.
D. The onset is before age 6 years.

Table 41-4 DSM-IV Diagnostic Criteria for Feeding Disorder of Infancy or Early Childhood

The ICD-10 diagnostic criteria for the disorder are listed in Table 41-5. Unlike DSM-IV, ICD-10's feeding disorder of infancy or early childhood subsumes rumination disorder. However, similar to DSM-IV, the criteria are broad and do not delineate additional specific feeding disorders.

A. There is persistent failure to eat adequately, or persistent rumination or regurgitation of food.
B. The child fails to gain weight, loses weight, or exhibits some other significant health problem over a period of at least 1 month. (In view of the frequency of transient eating difficulties, researchers may prefer a minimum duration of 3 months for some purposes.)
C. Onset of the disorder is before the age of 6 years.
D. The child exhibits no other mental or behavioral disorder in the ICD-10 classification (other than mental retardation).
E. There is no evidence of organic disease sufficient to account for the failure to eat.

Table 41-5 ICD-10 Diagnostic Criteria for Feeding Disorder of Infancy and Childhood

According to ICD-10, feeding disorder of infancy and childhood is “a feeding disorder of varying manifestations, usually specific to infancy and early childhood. It generally involves refusal of food and extreme faddiness in the presence of an adequate food supply and a competent caregiver, and the absence of organic disease. There may or may not be associated rumination (repeated regurgitation without nausea or gastrointestinal illness).”

History and Comparative Nosology Prior to the inclusion of the diagnostic category of feeding disorder of infancy or early childhood in DSM-IV, no nationally defined criteria existed for the diagnosis of feeding disorders. In the absence of a recognized standard, feeding problems were given various labels by different authors: food refusal, food phobia, food aversion, feeding resistance, picky eaters, problem eaters. The field of feeding disorders is further complicated by the use of *failure to thrive* as a diagnostic label primarily in the pediatric literature. *Failure to thrive* refers to inadequate weight gain on the basis of standard growth charts. Frequently, *failure to thrive* and *feeding disorder* are used interchangeably, although not all infants and children who fail to thrive have feeding problems and not all infants and children with feeding problems fail to thrive.

Because of the multiple causes of feeding problems, which may or may not be associated with growth deficiency, the author has developed clinical operational criteria for three developmental transactional feeding disorders associated with growth deficiency: (1) feeding disorder of homeostasis, (2) feeding disorder of attachment (described in the third edition of DSM [DSM-III] as reactive attachment disorder), and (3) feeding disorder of separation, later defined as infantile anorexia. Posttraumatic feeding disorder usually follows a traumatic experience related to feeding (e.g., choking or severe gagging) and may or may not be associated with growth deficiency.

Epidemiology It is estimated that between 15 and 35 percent of infants and young children have feeding problems. The more common feeding difficulties include eating too little, refusing certain types of food, objectionable mealtime behaviors, and bizarre food habits. Severe feeding problems associated with poor weight gain, such as refusal to eat or vomiting, have been reported in 1 to 2 percent of infants and toddlers. A few studies found that about 70 percent of infants who exhibit food refusal in the first year of life continue to have feeding problems when followed up to school age. Picky eating and gastrointestinal symptoms in early childhood have been linked to anorexia nervosa, and pica and problem behaviors during mealtime have been associated with bulimia nervosa during the adolescent years.

Other Feeding Disorders

Feeding Disorder of Homeostasis

DIAGNOSIS AND CLINICAL FEATURES Feeding disorder of homeostasis begins in the postnatal period and is characterized by irregular, poor feedings and inadequate food intake by the infant. Both infant and parent contribute to the feeding difficulties. The infant demonstrates poor regulation of state during feeding, expressed by irritability, easy fatiguability, and excessive sleepiness. The parent may be anxious or depressed or may exhibit more severe psychopathology. Feedings are characterized by infant irritability, sleepiness, or both; maternal tension; and poor engagement between mother and infant.

Feeding disorder of homeostasis can be seen in infants without any organic problems, but it is frequently associated with prematurity or dysmaturity, functional or structural abnormalities of the oropharynx or gastrointestinal tract, and cardiac or pulmonary disease.

DIFFERENTIAL DIAGNOSIS This feeding disorder needs to be differentiated from pure organic disorders which can interfere with the regulation of state of the infant. As described above, organic problems can trigger the feeding disorder and should always be addressed first before making the diagnosis of feeding disorder of homeostasis.

COURSE AND PROGNOSIS Mother-infant interactional patterns and the foundation for the regulation of feedings are established in the first months of life. Infants with feeding problems during the early months trigger anxiety in their mothers and frequently have difficulty self-regulating their food intake during the transition to self-feeding in the second year of life.

TREATMENT Treatment must be individualized and can be directed toward the infant, the mother, and the mother-infant interaction. If the infant tires easily and cannot take in adequate calories for growth, nasogastric tube feedings might be needed to supplement oral feedings. On the other hand, if the mother is exhausted,

overly anxious, or depressed, the mother's difficulties must be addressed to enable her to be more effective with her infant.

Videotaping the feedings and observing the tape with the mother frequently heightens the mother's awareness of the infants' cues and helps her consider alternative ways to facilitate the infant's regulation of state and ability to feed.

Feeding Disorder of Attachment

DIAGNOSIS AND CLINICAL FEATURES Feeding disorder of attachment is characterized by a lack of engagement between mother and infant that leads to inadequate food intake and growth failure. The onset of growth failure is usually between 2 to 8 months of age. The infant shows lack of age-appropriate social responsibility (e.g., lack of smiling response, lack of vocal reciprocity, lack of anticipatory reaching out when picked up, lack of molding and cuddling when held). The mother frequently presents with acute or chronic depression, drug or alcohol abuse, or high psychosocial stress that interferes with her care of the infant. Mother-infant interactions are characterized by a lack of mutual engagement and lack of pleasure in their relationship. The mother frequently appears detached and noncontingent in her responses to the infant's cues.

This feeding disorder has been referred to in the literature as “maternal deprivation” or “deprivation syndrome.” It has been postulated that lack of emotional nurture and infrequent feedings lead to the growth failure and developmental delays of these infants. Characteristically, infants with feeding disorder of attachment become engaging and gain weight when admitted to the hospital and put in the care of a nurturing nurse.

In DSM-III, this disorder was defined as “reactive attachment disorder of infancy” associated with failure to thrive; in DSM-IV this diagnosis was changed to encompass only problems in relatedness without growth failure. Several studies of infants with the diagnosis of “nonorganic failure to thrive” have demonstrated very high rates of insecure attachment, ranging from 50 to 90 percent of the infants studied. However, not all infants with insecure attachment fail to thrive. Apparently only a severe disturbance in the attachment process of the infant to the caregiver, what some authors describe as “nonattachment,” results in the severe disturbances in relatedness and growth failure seen in infants with this feeding disorder.

DIFFERENTIAL DIAGNOSIS Feeding disorder of attachment must be differentiated from organic conditions that lead to a lack of weight gain and weakness of the infant. However, in organic conditions mother and infant usually show better mutual engagement and the infant responds more readily to the examiner.

COURSE AND PROGNOSIS Children with a feeding disorder of attachment are at high risk for delayed cognitive and disturbed emotional development. When followed up to school age, deficits in behavioral organization, ego control, ego resiliency, and behavioral symptoms have been reported in these children.

TREATMENT Depending on the severity of the growth deficiency and the evidence of neglect, various interventions have been suggested. When no evidence exists of deprivational behavior by the mother and the parents have sought medical care in the past and have some support in the extended family or the community, an outpatient approach may be safe. However, if the growth deficiency is more severe, if there is serious hygiene neglect, if the mother is abusing drugs or alcohol, or if the mother has a chaotic lifestyle, immediate hospitalization is indicated.

During the hospitalization, a warm and nurturing nurse must be assigned to engage the infant during feedings. While the nutritional, emotional, and developmental rehabilitation of the infant takes place, a more in-depth evaluation of the mother and the mother-infant relationship must occur. Many of these mothers experienced unsatisfactory relationships with their own caregivers when they were growing up, and consequently they distrust and avoid professionals. It is helpful to identify and point out any positive behavior the infant shows toward the mother in order to see whether the mother has any potential to respond and to engage in a mutually satisfying relationship with her infant. In addition, the mother's support system and her ability to become engaged with a therapist must be explored before the infant is returned to her care. In some situations of severe neglect and associated abuse, Protective Services must be involved, and the infant must be placed in foster care.

Before discharge from the hospital all services must be in place to ensure adherence to the treatment plan. The treatment plan should be individualized and may include home visits by a health care professional, day care for the infant, mother-infant psychotherapy, and family therapy for the parents.

Infantile Anorexxia (Feeding Disorder of Separation)

DIAGNOSIS AND CLINICAL FEATURES Infantile anorexia is characterized by food refusal by the infant that leads to inadequate food intake and acute or chronic malnutrition. The food refusal causes high anxiety in the parents and leads to intense conflict in the parent-infant relationship over issues of autonomy, dependency, and control, with food being the battleground.

The food refusal by the infant usually begins or worsens considerably at the age of 6 months to 2 years, during the transition to spoon- and self-feeding. The food refusal may vary from meal to meal and with different caregivers. The infant may drink from the bottle or from the breast and primarily refuse solid food. This leads the parents to believe that the infant has a poor appetite and loses interest in food quickly. On the other hand, the infant is seen as very curious and demanding a lot of attention. The food refusal causes intense anxiety in the mother or both parents. Usually the parents resort to coaxing, cajoling, bribing, distracting, and offering different foods at all times, and when desperate, they may resort to force feeding.

Infantile anorexia interferes with the development of somatopsychological differentiation, the ability to differentiate physiological sensations of hunger and satiety from emotional feelings and needs (e.g., feelings of anger and the need for affection). The mothers are usually so anxious that they offer food, the bottle, or breast at any time, regardless of whether the infant is hungry or distressed. Frequently, the infants refuse to eat to control the parent, if they cannot have their way, if they cannot get out of the high chair, or if they are not offered the food they want. Eating or not eating becomes increasingly controlled externally by the interactions between the infant and the caregiver instead of internally by feelings of hunger and fullness.

DIFFERENTIAL DIAGNOSIS Infantile anorexia must be differentiated from another feeding disorder characterized by food refusal. Posttraumatic feeding disorder usually has a more sudden onset of food refusal following a traumatic event to the oropharynx or gastroesophageal tract (e.g., choking, severe gagging or vomiting, or the insertion of feeding or endotracheal tubes). The infant may refuse all food, only solid food, or only the bottle, depending on what mode of feeding the infant associates with the traumatic experience. Picky eaters may show the same behavior patterns as infantile anorectics, but their food intake is adequate for age-appropriate growth. In addition, infantile anorexia must be differentiated from food refusal caused by organic problems (e.g., gastroesophageal reflux, zinc deficiency, and metabolic disorders).

COURSE AND PROGNOSIS No systematic data from prospective studies are available. Studies from Sweden in which infants with food refusal in the first year of life were followed up to school age, showed that 70 percent of the children continued to have feeding problems at 4 years of age, and by 6 years of age the eating problems were noted not only in the home but in the school as well.

A follow-up study by the author of 20 children, 6 months to 2 years after they had received treatment, found that 17 children had changed considerably. The conflict in the parent-child relationship over the child's food intake was completely gone. The children had learned to recognize hunger and had increased their food intake, which had led to weight gain and improved growth. However, the parents reported that many of these children continued to lose their appetite when they were excited, had house guests, had a birthday party, or traveled. Once they calmed themselves, they would regain their appetite and usually make up for the lost meals. Three children continued to struggle with their parents over their lack of eating; in two cases, day care seemed to be too stimulating to allow these children to relax enough to eat, and in the third case, the home situation was very overcrowded and disorganized.

TREATMENT The author has developed a treatment model that is based on a transactional model for development of infantile anorexia. According to this model, the infant's emotional intensity, lower threshold for stimulation, and stubbornness evoke conflicts over issues of control, autonomy, and dependency in a vulnerable parent who is insecure about limit setting. The treatment addresses the infant's temperament and the parent's anxiety about limit setting to facilitate internal regulation of eating in the infant.

1. The infant's temperament is discussed with the parents to help them understand that the infant's curiosity and emotional intensity interfere with the awareness of hunger. Because these infants are strong willed and have learned that food refusal is a powerful tool to control the parents' attention, parental efforts to distract or entertain the infants to get them to eat only perpetuate the problem by getting the infants more excited.
2. The source of the parents' anxiety about limit setting is explored. Some parents have been sensitized by lost pregnancies, infertility problems, or the harshness or emotional unavailability of their own parents. Understanding the parents' sensitivity about limit setting is necessary to help them set limits more effectively with

their infant.

3. After this groundwork has been laid, the parents are trained to change their behavior to facilitate internal regulation of eating by the infants. To boost the infants biological rhythms of hunger and satiety, parents are encouraged to feed them only at regular 3- to 4-hour intervals and to offer nothing but water between these regular feedings. They are helped to understand the importance of encouraging the infants' self-feeding by commenting on their feeding skills (“you get the spoon in your mouth all by yourself”), but they are not to comment on how much or how little the infants eat. Infants must learn to regulate their food intake by their internal signals of hunger and satiety. Eating should not be a performance for the parents. There should be no distractions during feedings, no television or games, so that the infants focus on eating. If infants engage in inappropriate behavior during feeding (climbing out of the highchair, throwing food or feeding utensils) the parents need to learn to use the time-out procedure.

This three-step intervention is best accomplished in three double sessions, lasting 2 hours each, and grouped close together within a few weeks. The intensity of this brief intervention facilitates a close therapeutic alliance between the therapist and the parents and enables many parents to make major shifts in their interactions with their infants. Many of these parents need only a few follow-up sessions to deal with some specific questions that may arise. Frequently, after infants change their eating patterns, parents ask for help concerning the sleeping problems many of these children have as well. However, there are some families who are more deeply entrenched in maladaptive interactional patterns with their infants, and some infants are so severely malnourished that more intensive interventions or hospitalization may be required.

Posttraumatic Feeding Disorder

DIAGNOSIS AND CLINICAL FEATURES Posttraumatic feeding disorder may present with total food refusal, refusal to swallow solid food or refusal to drink from the bottle depending on what kind of feeding the infant associates with the traumatic event. The onset of food refusal is frequently rather sudden and follows a traumatic experience that involves the oropharynx or gastrointestinal tract (e.g., severe gagging, choking, vomiting, insertion of feeding or endotracheal tubes, or force-feeding). Frequently, the parents are not aware that the event was so frightening to the infant that it triggered the food refusal because other infants who undergo the same experience do not necessarily develop the disorder. Infants who develop a posttraumatic feeding disorder appear to be more prone to anxiety or are more sensitive to pain than the average infant. Older children who refused to eat solid food after an incident of gagging or choking reported being afraid that food would get stuck in their throat and choke them to death. Infants and young children express this fear by crying in anticipation of being fed when seeing the highchair, bottle, or spoon. Some infants or children are brave enough to put the food in the mouth but cannot bring themselves to swallow it. They keep the food in their cheeks or spit it out. Some infants and children may become more irritable and cling to their parents, others experience frightening dreams or even nightmares.

The parents frequently react with anxiety to the infant's food refusal. They worry about the infant's nutrition. Frequently, they try to coax and distract the infant, they offer various types of food, and they try to feed the infant day and night. Some infants who are afraid to drink from the bottle may drink when they are asleep and not be aware of what they are doing. However, if they wake up and see the bottle, they push it away and cry.

DIFFERENTIAL DIAGNOSIS Posttraumatic feeding disorder must be differentiated from infantile anorexia and from food refusal because of sensory aversions to certain types of food. Infantile anorexia is characterized by a more inconsistent pattern of food refusal, depending on the mood of the infant. Anorectic infants are not afraid to eat and can eat all types of food if they want to eat. Food aversions involve certain types of food with a certain taste, texture, or smell. Usually the food refusal is more selective and not as global as that in a posttraumatic feeding disorder.

COURSE AND PROGNOSIS No systematic longitudinal data on the course of posttraumatic feeding disorder are available. However, individual case studies indicate that many infants and children get locked into their fears of eating. Some drink milk from the bottle and eat only pureed food until they reach school age, when the social embarrassment of their eating behavior causes the parents to seek help. In extreme cases, when infants refuse all food, gastrostomy feedings have to be implemented. Some of these children depend on gastrotomy feedings to survive for years.

TREATMENT Because of the complexity of many cases, particularly those that result from trauma inflicted by unavoidable medical procedures (e.g., intubation, suctioning), a multidisciplinary team consisting of a pediatrician or gastroenterologist, nutritionist, occupational therapist, and a psychiatrist is best equipped to meet the needs of these infants.

Total food refusal puts the infant in acute medical danger of dehydration, and intravenous fluids must be given. It is important to determine whether the infant can be coaxed into accepting any form of food or whether nasogastric tube feedings need to be instituted. Unfortunately, the insertion of feeding tubes can intensify the fear of feeding, and if this is the case, the infant is better served by a gastrostomy tube. In any case, the infant's nutritional requirements must be addressed prior to the implementation of the psychiatric treatment.

The psychiatric treatment of infants who exhibit total or partial food refusal centers on desensitizing them to the fear of eating. Behavioral techniques of positive reinforcement of food acceptance and negative reinforcement of food refusal are instituted in the initial management of these infants. Encouraging self-feeding frequently helps these infants gain mastery over the anticipatory anxiety of eating. When the infant begins to accept food from the spoon, it is important to proceed slowly in advancing the texture of food, to avoid any incident of gagging that might set the infant back.

The behavioral manipulation of the infant's eating frequently leads to external regulation of eating in response to the reinforcers. Once the infant has overcome the fear of eating, the external reinforcers must be phased out and eating according to internal signals of hunger and satiety encouraged. The principles described above in facilitating internal regulation of eating in infants with anorexia should also be applied in this final stage of the treatment.

SUGGESTED CROSS-REFERENCES

The general topic of eating disorders is covered in Chapter 20. Psychological aspects of gastrointestinal disorders are discussed in Section 25.2. Regarding relevant treatment modalities see Section 3.2 on behavior therapy and Section 31.31 on electroconvulsive therapy. Normal child development is reviewed in Section 32.2. Psychiatric examination of infants and children is discussed in Chapter 33. Various other psychiatric disorders of childhood are the topics of Chapter 35, Chapter 36, Chapter 37, Chapter 38, Chapter 39 and Chapter 40 and Chapter 42, Chapter 43, Chapter 44, Chapter 45, Chapter 46, Chapter 47 and Chapter 48.

CHAPTER 42. TIC DISORDERS

JAMES T. McCRACKEN, M.D.

The tic disorders comprise a group of neuropsychiatric disorders that appear in childhood or adolescence, encompass a wide range of severity, and share the primary symptom of persistent and interfering tics. The most widely recognized and severest form of tic disorder is Gilles de la Tourette syndrome, or Tourette's disorder. The tic disorders are increasingly recognized as highly familial conditions involving disruptions of frontal, striatal, and subcortical brain circuitry and commonly accompanied by other forms of psychopathology. Treatment of patients with tic disorders usually involves multiple approaches and should be guided by a comprehensive assessment of current associated symptoms and impairment.

DEFINITIONS

Tics are defined as rapid, repetitive muscle contractions or sounds that usually are experienced as outside volitional control and which often resemble aspects of normal movement or behavior. Tics can be elicited by stimuli or preceded by an urge or sensation. They are usually beyond attempts at suppression. Tics are classified as simple or complex tics and as motor or phonic or vocal tics. *Simple motor tics* involve one or a small number of muscle groups (e.g., eyeblinking tic, facial grimace, or shoulder shrug). Simple motor tics can be further subdivided into clonic, tonic, or dystonic types. *Clonic tics* are very brisk movements; *tonic and dystonic tics*, on the other hand, can include more-sustained muscle contractions, such as arm extension and muscle tensing. Other dystonic tics are very common among individuals with Tourette's disorder and can involve oculogyric movements or torticollis.

Complex motor tics, on the other hand, may come close to mimicking normal movements of various kinds, through the synchronous contraction of several muscle groups, as in hopping movements, or the simultaneous extension of arms and legs, in knee bends, and rarely, obscene gesturing or copropraxia.

Phonic tics can also take simple or complex forms. Simple phonic tics include sniffing, grunting, or yelping. Examples of complex vocal tics include intelligible syllables or even phrases, such as “hi,” “I love you, I love you,” or (uncommonly) obscene utterances, defined as coprolalia. While simple tics are relatively easy to discern, complex tics may be mistaken for volitional acts.

As diagnoseable conditions, the tic disorders are currently grouped into four categories, transient tic disorder, chronic motor or vocal tic disorder, Tourette's Disorder, and tic disorder not otherwise specified. According to the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders*. (DSM-IV), both chronic tic and Tourette's disorder require that tic symptoms emerge prior to age 18 years and have a minimum duration of 12 months. The criteria for transient tic disorder require a duration of more than 4 weeks but less than 12 months. All of the categories require that the tics produce marked distress or impair functioning, which for many children and teenagers often is manifest in the social ridicule that they receive from peers. For other individuals, the distress of experiencing poorly controlled impulses generates considerable internal tension, dysphoria, frustration, and demoralization.

HISTORY

The formal history and discovery of Tourette's disorder and the tic disorders is credited to a nineteenth century French neurologist, Gilles de la Tourette (1857–1904), who in 1885 published a case series of nine patients afflicted with a disorder characterized by abrupt, involuntary movements, hyperexcitability, echolalia, echopraxia, and compulsive swearing, or coprolalia. de la Tourette had been led to examine and describe the characteristics of these patients by his mentor, Jean Charcot, who had earlier described a woman with abnormal movements and coprolalia. At the time, the classification and relation of tic movements to symptoms of several movement disorders, including the “jumping Frenchmen of Maine,” *latah, miryachit*, and Sydenham's chorea, was uncertain. Tourette accurately identified several integral features of Tourette's disorder still accepted today, such as the childhood onset, the likely hereditary nature of the condition, the distinction between the brisk tic movements and other abnormal movements, and the lack of association of Tourette's disorder with cognitive disability. However, the emphasis on coprolalia and echopraxia are now considered less central to the disorder. Likewise, the possibility that some cases of tic disorders may be associated with prior infections qualifies the earlier separation of Tourette's disorder and Sydenham's chorea in some patients. Indeed, other historians have pointed out an extensive older clinical literature on the role of infection and movement disorders that is being rediscovered in current research. Also of note, biographers have suggested that Samuel Johnson, Lev. Nickolayevich Tolstoy's Anna Karenina, and possibly Wolfgang Amadeus Mozart had tic disorders.

COMPARATIVE NOSOLOGY

The criteria from the 10th revision of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) includes the same tic disorder as does DSM-IV and adds one more, other tic disorders. A different classification has been endorsed by the Tourette Syndrome Study Group and the Tourette Syndrome Association. This system divides tic disorders into transient and chronic types. The chronic type is further divided into chronic single tic disorder, chronic multiple motor or phonic tic disorder, and Tourette disorder.

EPIDEMIOLOGY

In general, increased awareness of the wider range of expression and severity of tic disorders has led to their greater recognition and revised estimates of their prevalence and associated features in various populations. However, as with most mental disorders, changes in definitions influence estimates of prevalence. Although Tourette's disorder was previously considered rare, even this most severe tic disorder has recently been estimated to occur at a point prevalence as high as 0.05 to 5.2 per 10,000. Estimates of the other tic disorders are few, but one study, using the less stringent revised third edition of DSM (DSM-III-R) criteria, screened a sample of all 16- to 17-year-old Israeli military inductees and found point prevalences of 1.8 and 1.6 percent for chronic multiple tics and transient tic disorder, respectively. Similarly, chronic motor and vocal tic disorders were noted to occur in less than 1 percent of control families seen in a family history study of Tourette's disorder. Other surveys of the frequency of transient tic disorder find this disorder to be relatively common in community samples of school-age children, appearing in approximately 5 to 15 percent of children. In clinical samples, chronic tic disorders have been reported to be as frequent as 7 to 34 percent among children with attention-deficit/hyperactivity disorder in child psychiatric clinics. Although the overlap of disruptive behavior and tic disorders is viewed as a common comorbidity in children with chronic tic disorders, it is not shared by most other forms of child psychopathology. Tic disorders are much more common in males than females, by ratios of 1.5 to 9 to 1.

ETIOLOGY

Conclusive evidence of the pathophysiologic basis of tic disorders is lacking, but converging data support the notion that the tic disorders are genetic disorders involving abnormal dopaminergic–excitatory amino acid interactions in neural circuits bridging parts of frontal cortex, basal ganglia, and the thalamus. Additional neuropathological, neuroimaging, and molecular genetic studies under way should greatly advance our knowledge of these disorders and likely will also contribute to our understanding of other, more common forms of psychopathology.

Genetics While the familiality of Tourette's disorder was recognized in the earliest descriptions of the condition, it has proved a difficult disorder to fully understand using current techniques and models of genetic disorders. The inability to confirm a clear genetic basis for the condition may reflect some genetic and etiologic heterogeneity among families with members afflicted with Tourette's disorder. Nevertheless, twin and family studies convincingly demonstrate patterns of inheritance

in many families that are consistent with an autosomal dominant disorder with incomplete penetrance. Furthermore, careful screening of relatives with Tourette's disorder has consistently revealed a relation between Tourette's disorder, other tic disorders, and obsessive-compulsive disorder in some families, suggesting that obsessive compulsive disorder and less severe forms of tic disorders may reflect alternative expressions of a common genetic vulnerability. The high rate of comorbidity of tic disorders with disruptive behavior disorders such as attention-deficit/hyperactivity disorder provides some support for inclusion of attention-deficit/hyperactivity disorder as a possible alternative phenotype. Although some have suggested that tic disorders are part of a spectrum of psychiatric disorders that includes many other disorders with repetitive behaviors, preoccupations, and poor impulse control, evidence supporting a broader spectrum concept is lacking. The recognition that less than half of the offspring of individuals with Tourette's disorder will display Tourette's disorder or related phenotypes has led to the conclusion that epigenetic, or environmental, factors may also influence the expression, severity, and manifestations of tic disorders. These interacting epigenetic factors may include intrauterine experience, birth weight, and other pregnancy or delivery complications. Initial attempts at testing the possible association of candidate genes suspected of causal involvement with Tourette's disorder have had little success, although some positive findings have been reported including an association with the “seven-repeat” allelle of the dopamine type 4 (D_4) receptor subtype (*DRD4.7*). Additional progress in understanding the molecular genetics of Tourette's disorder is expected shortly from ongoing multisite genetic studies of affected sib pairs with Tourette's disorder.

Neurochemistry The potent tic-suppressing effects of drugs such as haloperidol (Haldol) that possess high affinity for D_2 receptors have long been inferred to support the involvement of abnormal dopamine neurotransmission in Tourette's disorder, often suspected to involve hypersensitivity of D_2. Similarly, the often more-subtle benefits of a-adrenergic receptor agonists such as clonidine (Catapres) have expanded notions of the role of other monoamines in the etiopathophysiology of Tourette's disorder. The difficulty directly measuring brain neurochemical systems has impeded researchers' ability to confirm or reject these theories. More-recent models of dopamine abnormalities in Tourettes's disorder include possible interactions between excitatory amino acids such as glutamate and dopamine systems.

A small amount of postmortem and neuroimaging research supports suggested monoamine and excitatory amino acid disturbances in Tourette's disorder. For example, differences in D_2 ligand binding with ^{123}I-benzamide in the caudate nucleus correlate with differences in symptom severity among twins with Tourette's disorder. Similarly, comparisons of dopamine reuptake transporter ligand binding with ^{123}I-b-carbomethoxy-3b-(4-iodophenyl)tropane (^{123}I-b-CIT) in Tourette's disorder patients and controls showed greater dopamine reuptake protein expression in the basal ganglia of Tourette's syndrome patients. In addition, postmortem analyses of brains from Tourette's syndrome patients have suggested higher concentrations of glutamate in globus pallidus and other striatal areas in these patients. Other neurotransmitters less central to tic genesis but probably also dysregulated in Tourette's disorder include serotonin, opioids such as dynorphin, and norepinephrine.

Neuroimaging Both structural and functional neuroimaging studies have contributed to understanding the etiology of Tourette's disorder. Studies examining structural brain differences in subjects with Tourette's disorder have found consistent volume reductions in the region of the basal ganglia as well as loss of normal asymmetries in these structures. Other regional volume differences reported include reductions in the corpus callosum. Taken together, these suggest the involvement of abnormalities in the corticostriatothalamocortical network and subtle disturbances of brain lateralization that may be related to both motor inhibition and information-processing deficits in patients with Tourette's disorder.

Functional imaging studies of Tourette's disorder patients have yielded less-conclusive information on patterns of disturbed brain activity but confirm that many of these patients show deviations from normal. Both hypo- and hypermetabolic regions have been identified by positron emission tomography (PET). In part, the greater variability in brain metabolic patterns in Tourette's disorder patients may reflect the extensive comorbidity common to the disorder.

Rediscovery of a possible link between exposure to infectious diseases and the appearance or worsening of tics has led to studies of immune parameters in Tourette's disorder patients. Overall, these studies have reopened the possibility of an autoimmune subtype of tic disorder, although the frequency of this subtype is far from clear. Support for the involvement of immune responses in tic disorders includes new onsets of tics and obsessive-compulsive symptoms following streptoccocal illnesses. Examination of symptoms of obsessive-compulsive disorder in patients with Sydenham's chorea found that up to one third meet criteria for obsessive-compulsive disorder during the height of the illness. Two studies in Tourette's disorder patients and related groups have found high concentrations of a lymphocyte antigen, the D8/17 protein, which earlier research associated with risk for development of rheumatic fever in response to stretococcal exposure. A possible mechanism for symptom production was suggested by apparent autoantibody binding to brain protein antigens in patients with tic disorders, obsessive-compulsive disorder, and other childhood hyperkinetic movement disorders. These intriguing studies await more-conclusive demonstrations of autoimmune abnormalities in patients with Tourette's disorder and related disorders.

DIAGNOSIS AND CLINICAL FEATURES

The clinical presentation of tic disorders in the psychiatric setting typically falls into one of two general categories: individuals with clearcut, often dramatic, hyperkinetic movements who frequently present during an exacerbation of an evolving or known disorder or patients who, during the course of evaluation or treatment for disruptive behavior or obsessions and compulsions, display more-subtle and possibly previously undetected tics. Both clinical situations require a comprehensive assessment of the child's functioning, range of symptoms, type and severity of impairments, current stressors, developmental issues, and family and school issues and supports.

The frequency and severity of tic symptoms typically wax and wane over weeks and months, which can greatly complicate attempts to gauge the response to treatments. Therefore, clinicians should avoid abrupt, multiple changes in treatment approaches and adopt a careful, longer-term view of treatment for the condition. While some increases in tic severity and frequency are often due to identifiable common stressors such as starting school, peer conflicts, academic challenges, fatigue, excitement, and illnessess, random exacerbations can occur. Another sometimes confusing element of Tourette's disorder and other tic disorders is the degree to which some patients can suppress tics for significant periods. Many children can so effectively suppress, hide, or postpone tic symptoms that even teachers are unaware of the child's disorder. Alternatively, some patients describe their tics as intentional but irresistible. Age influences symptom description and report; younger patients can less often describe mental and volitional aspects of their experience of tic phenomena.

Often the clinical picture is dominated by the common comorbid psychiatric disorders seen in high numbers of individuals with tic disorders, especially obsessive-compulsive disorder and attention-deficit/hyperactivity disorder. Epidemiological, family, and clinical samples display co-ocurring obsessive-compulsive disorder in as many as 20 to 40 percent of patients with Tourette's disorder. Many other Tourette's disorder patients complain of obsessive-compulsive behaviors that are below the threshold for diagnosis but cause internal preoccupations and worry. Recent phenomenological data support some distinctions between obsessive-compulsive symptoms associated with Tourette's disorder (tic-related obsessive-compulsive disorder) and obsessive-compulsive disorder without comorbid Tourette's disorder. Tic-related obsessive-compulsive symptoms are more likely to include more aggressive, sexual obsessions as well as more hoarding, ordering, and touching compulsions.

The association of attention-deficit/hyperactivity disorder and other disruptive behaviors such as aggression with Tourette's disorder is robust among clinic-referred children and adolescents, with 40 to 60 percent of children with Tourette's disorder meeting criteria for attention-deficit/hyperactivity disorder, possibly reflecting shared deficits in response inhibition affecting greater portions of corticostriatothalamocortical circuitry. Curiously, epidemiological samples of individuals with Tourette's disorder do not display the extensive comorbidity with attention-deficit/hyperactivity disorder, perhaps reflecting ascertainment differences. In most instances, the burden of symptoms created by the child's attentional problems, academic underacheivement, and impulsivity far outweigh that produced by tic severity. However, treatment of these associated comorbid conditions can be challenging because of the adverse effects of some treatments on tics, the temporal fluctuations in symptoms, and the frequent presence of other common associated problems such as learning disorders.

Estimates of the exact frequency of co-occurring learning problems in patients with Tourette's disorder and other tic disorders have varied widely, in part because of ascertainment differences, screening approaches, subject age range, and small sample sizes. Understanding learning difficulties in children with Tourette's disorder is complicated, since learning interference may be caused by the direct distracting effects of the tics themselves, by comorbid psychopathology, by specific learning disorders, or by the child's demoralization. Some reports note greater deficits in mathematical skills among Tourette's disorder children than among controls. In addition, interactions between comorbid attention-deficit/hyperactivity disorder, Tourette's disorder, and reduced performance in intelligence quotients (I.Q.) measures have also been reported. Assessments of children with tic disorders must include screening for possible learning disorders.

Other vexing problem behaviors are frequently encountered in patients with Tourette's disorder and other tic disorders, including forms of self-injurious behavior. These may range from skin picking to self-hitting and are clearly related to tics in some individuals. Other less common symptoms in individuals with tics include vomiting, freezing behaviors, rage outbursts, and depressive disorders. In assessing the treatment needs of patients with Tourette's disorder and other tic disorders, one must clearly separate the impact of tic severity on functioning from effects of other psychopathology, developmental stage, life goals, and family responses.

Tourette's Disorder To make a diagnosis of Tourette's disorder, clinicians must obtain a history of multiple motor tics and the emergence of at least one vocal tic at

some point in the disorder. According to both DSM-IV and ICD-10 the tics must occur many times a day nearly every day or intermittently for more than 1 year and cause impairment or distress (Table 42-1 and Table 42-2). The average age of onset of tics is 7 years, but tics may occur as early as the age of 2 years. The onset must occur before the age of 18 years.

A. Both multiple motor and one or more vocal tics have been present at some time during the illness, although not necessarily concurrently. (A tic is a sudden, rapid, recurrent, nonrhythmic, stereotyped motor movement or vocalization.)
B. The tics occur many times a day (usually in bouts), nearly every day or intermittently throughout a period of more than 1 year, and during this period there was never a tic-free period of more than 3 consecutive months.
C. The onset is before age 18 years.
D. The disturbance is not due to the direct physiological effects of a substance (e.g., stimulants) or a general medical condition (e.g., Huntington's disease or postviral encephalitis).

Table 42-1 DSM-IV Diagnostic Criteria for Tourette's Disorder

Table 42-2 ICD-10 Diagnostic Criteria for Tic Disorders

In Tourette's disorder, the initial tics are in the face and neck. Over time, the tics tend to occur in a downward progression or involve more complex movements of several muscle groups. The most commonly described tics are those affecting the face and head, the arms and hands, the body and lower extremities, and the respiratory and alimentary systems. In these areas, the tics take the form of grimacing; puckering the forehead; raising eyebrows; blinking eyelids; winking; wrinkling the nose; trembling nostrils; twitching mouth; displaying the teeth; biting the lips and other parts; extruding the tongue; protracting the lower jaw; nodding, jerking, or shaking the head; twisting the neck; looking sideways; head rolling; jerking the hands; jerking the arms; plucking fingers; writhing fingers; clenching fists; shrugging the shoulders; shaking a foot, knee, or toe; walking peculiarly; body writhing; jumping; hiccuping; sighing; yawning; snuffing; blowing through the nostrils; whistling inspiration; breathing exaggeratedly; belching; making sucking or smacking sounds; and clearing the throat.

Typically, prodromal behavioral symptoms—such as hyperactivity, attention difficulties, and poor frustration tolerance—are evident before or coincide with the onset of tics. The most frequent initial symptom is an eye-blink tic, followed by a head tic or a facial grimace. Most complex motor and vocal symptoms emerge several years after the initial symptoms. Coprolalia usually begins in early adolescence and occurs in about 15% of all cases. Mental coprolalia—in which a patient thinks a sudden, intrusive, socially unacceptable thought or obscene word—may also occur. In some severe cases, physical injuries, including retinal detachment and orthopedic problems, have resulted from severe tics.

Chronic Motor or Vocal Tic Disorders The onset of chronic motor or vocal tic disorder appears to be in early childhood. The types of tics and their locations are similar to those in transient tic disorder. Chronic vocal tics are considerably rarer than are chronic motor tics. The chronic vocal tics are usually much less conspicuous than those in Tourette's disorder. The vocal tics are usually not loud or intense and are not primarily produced by the vocal cords; they consist of grunts, throat-clearing, or sniffing or other noises caused by thoracic, abdominal, or diaphragmatic contractions. The DSM-IV diagnostic criteria are given in Table 42-3. The ICD-10 criteria are listed in Table 42-2.

A. Single or multiple motor or vocal tics (i.e., sudden, rapid, recurrent, nonrhythmic, stereotyped motor movements or vocalizations), but not both, have been present at some time during the illness.
B. The tics occur many times a day nearly every day or intermittently throughout a period of more than 1 year, and during this period there was never a tic-free period of more than 3 consecutive months.
C. The disturbance causes marked distress or significant impairment in social, occupational, or other important areas of functioning.
D. The onset is before 18 years.
E. The disturbance is not due to the direct physiological effects of a substance (e.g., stimulants) or a general medical condition (e.g., Huntington's disease or postviral encephalitis).
F. Criteria have never been met for Tourette's disorder.

Table 42-3 DSM-IV Diagnostic Criteria for Chronic Motor or Vocal Tic Disorder

Transient Tic Disorder The DSM-IV criteria for establishing the diagnosis of transient tic disorder (Table 42-4) are as follows: The tics are single or multiple motor or vocal tics. The tics occur many times a day nearly every day for at least 4 weeks but for no longer than 12 consecutive months. The patient has no history of Tourette's disorder or chronic motor or vocal tic disorder. The onset is before age 18. The tics do not occur exclusively during substance intoxication, and they are not caused by a general medical condition. The diagnosis should specify whether a single episode or recurrent episodes are present. Transient tic disorder can be distinguished from chronic motor or vocal tic disorder and Tourette's disorder only by observing the symptoms' progression over time. The ICD-10 criteria are listed in Table 42-2.

A. Single or multiple motor and/or vocal tics (i.e., sudden, rapid, recurrent, nonrhythmic, stereotyped motor movements or vocalizations)
B. The tics occur many times a day, nearly every day for at least 4 weeks but for no longer than 12 consecutive months.
C. The disturbance causes marked distress or significant impairment in social, occupational, or other important areas of functioning.
D. The onset is before age 18 years.
E. The disturbance is not due to the direct physiological effects of a substance (e.g., stimulants) or a general medical condition (e.g., Huntington's disease or postviral encephalitis).
F. Criteria have never been met for Tourette's disorder or chronic motor or vocal tic disorder.

Specify if: Single episode or recurrent.

Table 42-4 DSM-IV Diagnostic Criteria for Transient Tic Disorder

Tic Disorder Not Otherwise Specified According to DSM-IV, tic disorder not otherwise specified refers to disorders characterized by tics but not otherwise meeting the criteria for a specific tic disorder Table 42-5.

This category is for disorders characterized by tics that do not meet criteria for a specific tic disorder. Examples include tics lasting less than 4 weeks or tics with an onset after age 18 years.

Table 42-5 DSM-IV Diagnostic Criteria for Tic Disorder Not Otherwise Specified

Alan is a 11-year-old boy who lives with his parents and younger sister. His parents reported a long previous history of disruptive symptoms, especially noticeable in school, which led to the diagnosis of attention-deficit/hyperactivity disorder at age 7. His parents sought consultation because of the persistence of several ticlike muscle movements.

Alan was the product of a delivery complicated by breech positioning, leading to birth by casearean section associated with brief fetal cardiac decelerations. Early development was normal except for poor fine motor coordination, persisting into the present in poor handwriting. Preschool staff noted that Alan had difficulty sitting still and attending to class instruction. Poor school performance in the first and second grades improved considerably with the institution of psychostimulant treatment and behavior management.

About 12 months prior to evaluation, the parents had first noted Alan display frequent eyeblinking, which they ascribed to anxiety about restarting school. The eyeblinking persisted, although the frequency of the movements varied from week to week. About 2 months earlier, the parents noticed Alan begin to thrust his head forward violently. For the first time, Alan himself acknowledged these behaviors as outside his control and expressed his frustration over his inability to suppress them. When another movement appeared—repeated shoulder shrugging—the parents sought consultation. At the evaluation, Adam described his frustration and discouragement over his trouble controlling the increasingly frequent muscle jerks. The head thrusts often led to neck soreness and occasional headaches. The eyeblinking was frequent enough to interfere with reading and other activities requiring sustained effort. On examination Alan appeared cooperative but sad and displayed several frequent tic movements involving the face, neck, and shoulders. No vocal tics were noted. Psychomotor activity was increased. Results of the consultation were consistent with chronic motor tic disorder and attention-deficit/hyperactivity disorder. Recommendations included a trial of an a-adrenergic receptor agonist.

PATHOLOGY AND LABORATORY EXAMINATION

Tourette's disorder and the other tic disorders remain clinical diagnoses based upon clinical history and examination. No confirmatory or diagnostic tests exist at present. Brain imaging, electroencephalography (EEG), and neuropsychological testing may be indicated under specific clinical situations to rule out other diagnostic possibilities such as epilepsy or structural lesions or to evaluate for suspected comorbidities, but they should not be considered on a routine basis. Nonspecific EEG abnormalities have been reported to occur in up to 20 to 35 percent of patients with Tourette's disorder and have no clinical significance. Individuals with new onset of tics or a significant exacerbation who also have a recent history of infectious illness should receive throat cultures to test for group A b-hemolytic streptococcal infection, and if positive, serological screening for antistreptolysin O. Aggressive treatment of the infection and eradication of carrier status is advised.

DIFFERENTIAL DIAGNOSIS

Differentiating tics from other abnormal movements is generally straightforward by clinical history and examination (Table 42-6). Although more-complex tics, dystonic tics, and compulsive tics lack the rapidity of other tic movements, in general patients exhibit a mixture of simple and more complex tics, enabling discrimination between tic disorders and other movement disorders. Repetitive vocalizations are rare in nontic movement disorders, which also aids accurate classification. Additional features more strongly associated with tics are premonitory sensations, which are described by up to 80 to 90 percent of older patients. These sensations or experiences can take many forms, including an urge, an itch, a feeling of tightness, tingling, or the experience of irritation or worry. Other subjective features of tics include the experience of relief following the tic; conversely some patients note a buildup of an urge or tension prior to the activity. Other aspects associated with compulsive tics involve the need to repeat behaviors until relief is achieved or the individual feels “just right.” Similarly, the description of tic movements as intentional, or purposely performed, in response to an urge or sensation is uncommon among other types of abnormal movements. The complicated mental phenomena seen in some patients with tics often make the precise boundary between compulsive tics and obsessive-compulsive disorder difficult to define.

Table 42-6 Differential Diagnosis of Tic Disorders

Other features that distinguish Tourette's disorder and the tic disorders from other movement disorders include differences in age of onset (younger in autistic disorder, athetoid cerebral palsy, Pelizaeus-Merzbacher disease, Lesch-Nyhan syndrome, and status dysmyelinatus; older in Huntington's disease, Wilson's disease, spastic torticollis) and the lack of a frequent association of tic disorders with mental retardation or a dementing process (in contrast to autistic disorder, cerebral palsy, Lesch-Nyhan syndrome, Wilson's disease, and Huntington's disease). Occasionally, tics are an adverse effect of commonly prescribed psychostimulants. Generally these tics resolve promptly with dosage reduction or drug discontinuation.

Renee was a 7-year-old girl who lived with both parents and her older brother. She was referred by her parents because of worsening ticlike movements over the previous 12 months. Renee had seemed a healthy, normally developing child until about age 6, when her parents first observed the gradual emergence of several unusual muscle jerks affecting her face and neck.

An initial evaluation by her pediatrician noted the presence of multiple motor tics, but since no clear impairment existed, further monitoring was suggested. Her parents reported that since then, the frequency of tics had fluctuated considerably. However, soon after the most recent resumption of school, her movements had definitely worsened. Especially notable was Renee's difficulty in speaking clearly, which was reported by her teacher. Renee had also asked her parents if there was a medicine available for her “moves.” The parents and Renee denied teasing by peers.

On examination, Renee was a frail girl who was shy but able to engage the interviewer. Her behavior was marked by a number of frequent, vigorous movements that appeared to be involuntary. Renee's responses to questions were often difficult to decipher because of frequent forced exhalations that interfered with her vocalizing. Other behaviors included facial grimacing, head tossings, truncal flexing, and frequent squeaking vocalizations. Renee was tearful at one point while discussing her difficulty in controlling her movements.

Results of the consultation were consistent with the presence of Tourette's disorder and the possible co-occurrence of a specific learning disorder. Recommendations included referral to a local Tourette's disorder parent support group, education about tic disorders, educational and speech-language testing, and a trial of risperidone (Risperdal).

COURSE AND PROGNOSIS

Although the onset criterion in DSM-IV for Tourette's disorder allows symptom onset by age 18, prior reports describe tic onset prior to age 11 in 96 percent of patients. Initial symptoms most commonly involve the face, head, or neck, with eyeblinking being the most common first symptom. Phonic tics generally emerge years after the appearance of motor tics, although exceptions occur as well as cases with fulminant emergence of Tourette's disorder in which multiple motor and phonic symptoms appear within days or weeks. More-distal tics involving the trunk or limbs tend to appear later in the course of the condition; it is often suggested that tic symptoms emerge in a rostral-to-caudal fashion. Disruptive behavior symptoms in Tourette's disorder children frequently tend to precede the initial development of tics. Conversely, obsessions and compulsions generally arise later than the tics. The modal onset period of Tourette's disorder occurs during adrenarche in most children, raising questions about a possible relation between androgenic steroid sensitization and tic symptomatology. However, in experimental trials androgen antagonists have not consistently altered tic frequency or severity in patients with Tourette's disorder.

The course of tic symptoms varies from individual to individual. Tourette's original case descriptions included periods of tic remission followed by exacerbations. Recent follow-up data from small cohorts of children with Tourette's disorder tracked over 8 years found that tic severity reached maximum levels in early adolescence, followed by consistent falls in symptoms over the transition from late adolescence to young adulthood, with some patients reporting negligible or no tics. In other samples followed over time only about 25 percent of Tourette's disorder patients continue to experience moderate-to-severe tics in young adulthood. However, other comorbid conditions can persist and continue to produce significant morbidity.

TREATMENT

Children, adolescents, and adults with tic disorders should be healed from a longitudinal perspective guided by the patient's overall functioning, associated psychopathology, developmental challenges, and family and social adjustment rather than a narrow focus on tic suppression. Indeed, the goal of tic suppression is frequently secondary to improving classroom behavior or academic performance or relieving burdensome obsessions and compulsions. Thus clinicians should be prepared to use a variety of treatment modalities, depending on individual needs, including pharmacotherapy, behavioral treatments, psychotherapy, educational interventions, and family therapy. Treatment choice should be guided by a hierarchy of treatment goals for the individual.

Psychoeducation of the patient and family is required. Helping the patient and parents understand and anticipate periods of symptom exacerbation can reduce feelings of helplessness and frustration. Identifying sources of symptom fluctuations can aid efforts to reduce stressors and weather milder increases in tics. Additional information about resources available through support groups and other organizations can help families navigate complicated educational issues (eg., Tourette Syndrome Association).

If tic suppression is one of the primary goals of treatment, pharmacological approaches can be effective, but the risks and benefits of available agents should be carefully reviewed. High-potency neuroleptics with potent D_2 receptor antagonism such as haloperidol, trifluoperazine (Stelazine), and pimozide (Orap) possess robust tic suppressing effects and significantly reduce tic frequency and severity in 70 to 80 percent of patients at daily dosages of 1 to 8 mg. One study of haloperidol and pimozide found more than 70 percent tic reduction in 64 percent of patients receiving active medication. However, adverse effects may limit dosing in some patients. Among the neuroleptics, pimozide may be better tolerated, with less-frequent dysphoric effects, extrapyramidal symptoms, and cognitive dulling.

The more recent availability of atypical neuroletics such as risperidone and olanzapine (Zyprexa) has led to attempts to test the efficacy of these agents for tic control, with the hope of identifying better tolerated treatments. Initial reports indicate risperidone efficacy for tic suppression at dosages of 1 to 6 mg a day. In general, risperidone is well tolerated, with adverse effects of sedation and weight gain and fewer complaints of cognitive dulling or dysphoria. Despite their effectiveness as tic suppressing drugs, concerns over long-term risks of tardive dyskinesia, interference with learning, and dysphoric side effects often prompt use of nonneuroleptic alternative agents.

Although not fully approved for use in the treatment of tic disorders, the a-adrenergic receptor agonists clonidine and guanfacine (Tenex) are commonly prescribed to treat individuals with tic disorders. Some variability in the efficacy of these agents has been noted in controlled studies with clonidine, with only about 30 to 40 percent of patients showing significant improvements in tic severity. Another advantage of the a-adrenergic receptor agonists is their benefit on other symptom domains common to patients with tic disorders, including hyperactivity and disruptive behavior. While additional studies on the safety and efficacy of these agents in the treatment of tic disorders are still needed, these agents are frequently preferred because of better tolerability than the neuroleptics. At usual dosages (0.2 to 0.4 mg a day for clonidine and 1 to 4 mg a day for guanfacine), most-frequent adverse effects include drowsiness, fatigue, headache, irritability, and occasional hypotension.

A variety of other medications have been suggested as possible treatments for tic disorders. The addition of high-potency benzodiazepines such as clonazepam (Klonopin) to ongoing neuroleptic treatment may further improve tic control, especially in individuals with comorbid anxiety or pronounced internal tension associated with tics. However, treatment with benzodiazepines may risk disinhibition, particularly in younger patients with associated neurological symptoms.

Other suggested pharmacological treatments may be indicated by the comorbidity of tics with other disorders. The effects of stimulants on tic frequency and severity are variable, but most patients with comorbid attention-deficit/hyperactivity disorder and tics can benefit from the effects of stimulants on attention-deficit/hyperactivity disorder without experiencing intolerable increases in tic symptoms. Other alternative treatments for attention-deficit/hyperactivity disorder, such as the tricyclic drugs imipramine (Tofranil), desipramine (Norpramine), or nortriptyline (Aventyl, Pamelor) have both decreased disruptive behaviors and produced mild-to-moderate reductions in tic symptoms.

Other, more experimental treatments for tic disorders have been suggested but require additional study of their efficacy, safety, and tolerability in larger samples of tic disorder patients. In one case series the dopamine receptor agonist pergolide (Permax) benefited patients poorly responsive to standard treatments. The selective monoamine oxidase B inhibitor 1-deprenyl (selegiline; Eldepryl) has benefited a group of children with comorbid attention-deficit/hyperactivity disorder and tics, but conflicting reports exist. Other novel approaches under evaluation are nicotine as an adjunct to neuroleptics, as well as one report of the beneficial effects of mecamylamine (Inversine), a nicotinic antagonist. Other atypical neuroleptics may prove useful, with the promise of fewer adverse effects than currently available

medications.

Besides pharmacological treatments, behavioral interventions may have a role in the treatment of some individuals with tic disorders. Useful behavioral approaches for patients with a smaller number of persistent, bothersome tics include the use of habit reversal techniques, awareness training, and relaxation methods. Other behavioral approaches for patients with tic disorders may involve the use of behavioral management for disruptive behaviors, with application of contingencies for prosocial behaviors, clear expectations for behavior, and consistent environmental responses to challenging behaviors.

While traditional psychotherapy is not considered a primary treatment for patients with tic disorders, it can help educate the patient and family about the illness, help them identify and manage life stressors, develop a healthy acceptance of the disorder without loss of self-esteem, and encourage compliance with other interventions. Patients with demoralization or chronic depression due to peer rejection or other disappointments may benefit from focused psychotherapeutic intervention.

Overall, given the favorable course of symptoms for most patients, available and anticipated treatments, and expanding knowledge about these conditions, the outlook for patients diagnosed with Tourette's disorder or other tic disorders is quite positive. The overwhelming majority of patients with tic disorders can benefit from known interventions.

SUGGESTED CROSS-REFERENCES

Section 44.2 discusses stereotypic movement disorder. Obsessive-compulsive disorder is covered in Chapter 15, Section 2.6 discusses the neuropsychiatric aspects of movement disorders. Further discussion of various drugs used to treat tic disorders is given in Section 31.16 on clonidine. Section 31.17 on dopamine receptor antagonists, and Section 31.4 on medication-induced movement disorders.

CHAPTER 43. ELIMINATION DISORDERS

EDWIN J. MIKKELSEN, M.D.

ENURESIS

References to bedwetting have occurred almost since the beginning of recorded history. The modern term “enuresis” actually derives from the Greek word *enourein*, which means to void urine. Over the centuries the phenomenon of enuresis spawned a number of etiological theories, which carried with them differing approaches to treatment. Recent decades have seen substantial progress in the etiology of this disorder. The old observation that enuresis tends to run in families has evolved into sophisticated studies pointing to potential genetic loci. Progress in understanding the etiology of the disorder has been paralleled by the development of new treatment options. The particulars of these advances are detailed below. Viewed from a historical vantage, this progress is both impressive and gratifying.

DEFINITION

Enuresis is currently defined as the involuntary or intentional voiding of urine. The severity is determined by frequency of urination; quantity is not a diagnostic consideration per se. Quantity can become a factor in treatment decisions if a child emits only small quantities of urine; in actual practice, quantity usually does not figure heavily in the treatment plan. Frequency, however, can be important in planning a hierarchy of treatment approaches. The major diagnostic qualifier relates to age of onset. Finally, the definition precludes a physical cause for the disorder.

The length of time before continence is considered established varies in the literature between 6 months and 1 year. DSM-IV does not address that specific chronological issue but rather refers to “a ‘primary' type in which the individual has never established urinary continence, and a ‘secondary' type in which the disturbance develops after a period of established urinary continence.” In practical terms children who have never maintained continence for more than 1 year are referred to as having primary enuresis, whereas children who have achieved continence for 1 year or longer and then lost it are labeled as having secondary enuresis.

The disorder is further defined according to the timing of the episodes throughout the day. Episodes occurring only at night are referred to as nocturnal; daytime wetting is labeled diurnal. Most children display only nocturnal enuresis, but some manifest diurnal or nocturnal and diurnal patterns.

History Enuresis has been described throughout most of written history, with the earliest description being dated to the Papyrus Ebers of 1550 BC. Many treatment approaches prescribed in the past appear sadistic in retrospect. While those attempts may have been well intentioned at the time (as was leeching for other disorders), history underscores the anger that the disorder can engender in parents and clinicians who view the enuresis as voluntary or somehow under the control of the individual.

The modern era of research into enuresis dates from the development of polysomnographic recordings during sleep, which have enabled researchers to pinpoint the physiological correlates of nocturnal episodes. The modern era in treatment parallels the development of behavioral psychology and the application of those techniques to the disorder. The history of successful pharmacological treatments can be seen as dating to the initial description of the efficacy of imipramine (Tofranil) for the disorder in 1960.

Comparative Nosology The variety of differing nosological and diagnostic schemas seen with many disorders does not exist for enuresis. The behavior is concrete and definite: the child either wets or does not. That criterion makes it possible to integrate research data from different countries, cultures, and treatment centers with greater reliability than is possible for many other disorders. The efficacy of a given treatment is usually reported in terms of its impact on the frequency of enuretic events. The primary differences with regard to diagnosis concern the frequency required to make a diagnosis of enuresis as a pathological state and the period of continence necessary to separate primary from secondary enuresis, with a duration of 6 months occasionally being used instead of 1 year. Only slight differences exist between the 10th revision of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) and the fourth edition of *Diagnostic and Statistical Manual of Mental Disorder* (DSM-IV). ICD-10 states that enuresis “would not ordinarily be diagnosed in a child under the age of 5 years or with a mental age under 4 years.” This is slightly different from the DSM-IV cutoff of 5 years for both chronological and mental age. However, the tables that accompany ICD-10 indicate the same 5-year cutoff for both chronological and mental age as is found in DSM-IV. The ICD-10 also notes a change in required frequency of enuresis after age 7 (at least twice a month before and once a month after).

Epidemiology The most important data concerning the epidemiology of enuresis come from the Isle of Wight study. That study found that 15.2 percent of boys (7 years of age) were enuretic less than once a week, whereas 6.7 percent were wetting at least once a week or more. In 7-year-old girls the frequency was 12.2 percent for those wetting less than once a week and 3.3 percent with a frequency of once a week or more. By ages 9 and 10 years, 6.1 percent of the boys were wetting less than once a week and 2.9 percent were wetting once a week or more. The corresponding figures for 9- and 10-year-old girls were 3.5 percent wetting less than once a week and 2.9 percent once a week or more. The frequency for boys decreased considerably by age 14, at which time 1.9 percent were wetting less than once a week and 1.1 percent at a frequency of once a week or more. The rates also decreased or girls by age 14, with 1.2 percent wetting less than once a week and only 0.5 percent once a week or more.

A New Zealand study involving 8-year-old children found the prevalence of nocturnal enuresis to be 7.4 percent, with 3.3 percent labeled primary and 4.1 percent secondary. A similar large Scandinavian study involving 7-year-old children reported a prevalence of 9.8 percent, with most (6.4 percent) involving children with nocturnal enuresis, 1.8 percent with diurnal enuresis, and 1.6 percent with mixed nocturnal and diurnal enuresis.

The point prevalence figures cited in DSM-IV are 7 percent of boys and 3 percent of girls at age 5 years, dropping to 3 percent of boys and 2 percent of girls by age 10 years. Only 1 percent of boys are still wetting at age 18 years and still fewer girls. DSM-IV also cites a spontaneous remission rate of between 5 and 10 percent per year after age 5 years. Secondary enuresis may occur at any time but most commonly begins between 5 and 8 years of age.

Etiology Inclusion in the DSM-IV definition of enuresis of children who wet intentionally or involuntarily can be problematic. The vast majority of enuretic children do not wet intentionally or even on a subconsciously motivated basis. Increasingly, the research is pointing toward causal factors that may involve irregularities in physiological processes. Clearly, children who wet intentionally are in a different phenomenological grouping than those who do so involuntarily, even if they do meet the other diagnostic requirements. The most likely explanations for voluntary intentional wetting are either an oppositional defiant disorder or a psychotic disorder. A small number of children originally have enuretic events involuntarily and subsequently manifest the behavior on a voluntary learned basis as well.

There is a correlation between enuresis and psychological disturbance that increases with age. Children living in socially disadvantaged situations and experiencing psychosocial stress have a greater frequency of enuresis than those who are not. The type and range of behavioral disturbance seen in children with enuresis are broad, and no marker can reliably differentiate behaviorally disturbed from nondisturbed enuretic children. Thus, the associated behavioral disturbances are nonspecific and may represent a coincidental or secondary relationship rather than a causal correlation. Further supporting a secondary correlation are the repeated findings that children with enuresis have significantly more developmental delays than nonenuretic children, compared with both controls and other children attending a psychiatric clinic. One comprehensive study reviewed the psychodynamic literature concerning enuresis and encopresis to define the concepts conveyed in that literature and then determine empirically how often those concepts were verified and supported by the analysis of clinical material. The literature review yielded 24 generalizations that were consistently applied to enuretic and encopretic children. In subsequent statistical analysis of the clinical material, only 2 of the 24 generalizations reached statistical significance.

The association between behavioral disturbance and enuresis is stronger with secondary enuresis, and there are anecdotal reports of an association between the onset of enuresis and the loss of a father through divorce or death. The prevalence of psychodynamic factors in children with secondary enuresis is intuitively

reasonable as they have, by definition, demonstrated the physiological competence to maintain continence for a prolonged period of time before losing that ability.

There has been one innovative attempt to explore the possible relation between physiological and psychological factors. Specifically, it was postulated that children with enuresis who did not exhibit a concomitant behavioral disturbance would be those with dysfunctional or abnormal bladders, whereas those with a behavioral disturbance would be more apt to have normal bladders. The study found the converse to be true; the group with behavioral disturbance had more-dysfunctional bladders with lower volumes. The behaviorally disturbed group also had more developmental delays.

The observation that enuresis tends to occur in family members has been made for some time. A large Scandinavian study involving over 3000 children found that a child's risk for being enuretic was 5.2 times greater if the mother was enuretic and 7.1 times greater if the father was enuretic, lending further support to a genetic influence. DSM-IV notes that the concordance rate for the disorder is greater in monozygotic than in dizygotic twins, and 75 percent of children with enuresis have a similarly affected first-degree biological relative. Within the last few years, there have been tremendous advances in regard to the genetic transmission of enuresis. A Scandinavian group identified 11 families that manifested primary nocturnal enuresis over 3 generations in a pattern suggesting autosomal dominant inheritance with penetrance above 90 percent. Genetic linkage studies with these families indicated markers on chromosome 13q. Similarly designed studies have also implicated chromosomes 8 and 12, suggesting genetic heterogeneity.

One particularly important etiological hypothesis was that urinary tract obstruction frequently caused enuresis. The significance of that belief evolves around the related implications for surgery to correct the obstruction. Extensive review of the relevant literature found no basis for concluding that bladder neck repair or urethral dilation was a reasonable or effective treatment for enuresis. That generalization does not apply to patients with specific anatomical or pathophysiological findings.

Research into the association between sleep physiology and enuretic events has evolved steadily over the past three decades. The research can be seen as evolving through the following four stages. During the first phase of the research it was postulated that enuretic events were dream equivalents that occurred in deep sleep. The second major theory grew out of the observation that enuretic events originated in delta sleep and followed arousal signals. Thus, enuresis was seen as a disorder of arousal, which led to the hypothesis that enuretic children who were not psychologically disturbed did not produce arousal signals, whereas behaviorally disordered children did, but failed to respond to them.

The third phase of sleep research is represented by the two largest controlled studies, both of which found that when the time of night is also considered, enuretic events occur in all sleep stages in proportion to the amount of time spent sleeping in each. A fourth phase of investigation has attempted to couple cystometry with sleep studies in an attempt to identify subtypes.

The efficacy of desmopressin (DDAVP) as a treatment for enuresis has led to the theory that some children lack the ability to concentrate urine produced during the night and thus cannot reduce urine volume and manifest enuretic episodes as a result. That hypothesis has led to studies investigating the circadian variation of plasma atrial natriuretic peptide (ANP). Children with enuresis have not consistently been found to differ from controls with regard to ANP. In one study, 14 of 55 children with enuresis had lower ANP concentrations than controls, and 9 of the 14 had an excellent response to treatment with desmopressin. An investigation into the concentration of vasopressin in plasma and urine in 18 children with primary nocturnal enuresis and 20 matched controls found the concentration of vasopressin in plasma at 8:00 AM was significantly lower in the enuretic group. Total 24-hour urinary vasopressin excretion was also lower in the enuretic group but not significantly so.

Diagnosis and Clinical Features The DSM-IV diagnostic criteria for enuresis are listed in Table 43-1. The concreteness and simplicity of enuresis make the diagnosis relatively easy. As previously indicated, the diagnosis is not made in a child whose chronological or mental age is below 5. The wetting must occur at least twice a week for at least 3 consecutive months, or if less frequent, it must produce significant distress or functional impairment. Physical causes such as a bladder infection must be excluded. Qualifiers to the diagnosis indicate whether it is primary or secondary enuresis. The other qualifiers refer to the timing of the enuretic event. While most children exhibit only nocturnal enuresis, some have daytime (diurnal) patterns or a combined nocturnal and diurnal pattern.

A. Repeated voiding of urine into bed or clothes (whether involuntary or intentional).
B. The behavior is clinically significant as manifested by either a frequency of twice a week for at least 3 consecutive months or the presence of clinically significant distress or impairment in social, academic (occupational), or other important areas of functioning.
C. Chronological age is at least 5 years (or equivalent developmental level).
D. The behavior is not due to the direct physiological effect of a substance (e.g., a diuretic) or a general medical condition (e.g., diabetes, spina bifida, a seizure disorder).

Table 43-1 DSM-IV Diagnostic Criteria for Enuresis

Because DSM-IV includes children who wet intentionally and involuntarily under the same heading, the distinction between the two groups is currently not necessary for diagnosis. However, that distinction has significant clinical implications, as children who are wetting intentionally almost certainly are doing so as a manifestation of a psychological disturbance. There is also an association between behavioral disturbance and involuntary enuresis, but the nature of the correlation is less clear. Thus, although the coexistence of other behavioral problems is not a diagnostic issue per se, it is of clinical importance. The ICD-10 criteria for nonorganic enuresis are presented in Table 43-2.

A. The child's chronological and mental age is at least 5 years.
B. Involuntary or intentional voiding of urine into bed or clothes occurs at least twice a month in children aged under 7 years, and at least once a month in children aged 7 years or more.
C. The enuresis is not a consequence of epileptic attacks or of neurological incontinence, and not a direct consequence of structural abnormalities of the urinary tract or any other nonpsychiatric medical condition.
D. There is no evidence of any other psychiatric disorder that meets the criteria for other ICD-10 categories.
E. Duration of the disorder is at least 3 months.

Table 43-2 ICD-10 Diagnostic Criteria for Nonorganic Enuresis

John was a 10-year-old male who had consistently wet the bed throughout his life. He averaged three to four nocturnal episodes per week, and his longest period of continence was a few weeks. Thus, John warranted a diagnosis of primary enuresis. John's father had been enuretic until age 12, as was his father and a paternal uncle. Accordingly, he had always assumed that this was a genetic hereditary disorder that John could not control. In keeping with this perception, John's parents had never adopted a punitive approach to the bedwetting. The wetting was handled in a matter-of-fact manner, with John washing his sheets every morning and showering before going to school.

The family sought consultation at this time because John was increasingly being asked to sleep overnight at the homes of friends and also wanted to attend an overnight Boy Scout camp. These concerns led the family to meet with their pediatrician, who suggested a trial of the bell-and-pad method of conditioning. This approach was not effective, in part because the family lived in cramped quarters and the alarm that was meant to awaken John also woke his two brothers who shared the bedroom with him.

At this point, the family's pediatrician suggested that they meet with a child psychiatrist that she worked with. The child psychiatrist described the clinical literature on desmopressin. However, when John's father indicated that his health insurance did not cover prescriptions and that the family was having difficulty covering their household expenses on his income, which was only moderately above minimum wage, the psychiatrist felt compelled to discuss the relative costs of desmopressin and imipramine, which was only a fraction of the cost of desmopressin, since it was available in generic form. However, the psychiatrist also indicated that John would require a baseline electrocardiogram (which his insurance could cover) and that imipramine had more potential adverse effects.

Ultimately, the family decided that John would need medication only for brief discrete periods (overnights at friends and 1 to 2 weeks of summer camp), since they had worked out an acceptable plan for responding to the wetting on a day-to-day basis. Further, they reasoned that within approximately 2 years John would experience a spontaneous remission of his enuresis, as this was the family pattern. Thus, they decided that since desmopression has a rapid onset of action, they would pay out of pocket for the relatively small amounts of demopressin that would be needed for these discrete periods over the next 2 years.

Pathology and Laboratory Examination Because urinary tract infections can produce enuresis, a urinalysis should be part of every evaluation. Using radiographic procedures with contrast media to detect an anatomical or physiological cause for the enuresis is more problematic, as the procedures are invasive and painful, and the diagnostic yield is low. A large study carried out in a pediatric primary care setting found a 3.7 percent incidence of obstructive lesions in children with enuresis. Similar findings have been reported by others.

Differential Diagnosis As suggested above, the primary differential diagnosis is a urinary tract infection. This is especially true for girls, who are more prone than boys to urinary tract infections. With a girl who has been continent for a considerable period and has recently begun wetting, a urinary tract infection should be the first consideration. Although the diagnostic yield is smaller with boys, an urinalysis should still be carried out.

Enuresis can result from anatomical malformations or obstructive lesions, but the percentages are relatively low. If the history and interviews with the child suggest that the enuresis is intentional, then it is almost certainly related to an underlying psychological disturbance. The relation between psychological disturbance and involuntary enuresis is less clear. The coexistence of another behavioral disturbance should be noted and attended to clinically.

Course and Prognosis The natural history of enuresis is significant because it figures prominently in treatment decisions, since enuresis is a self-limited disorder that at some time will spontaneously remit. The fact that the diagnosis is not made until age 5 takes into account children who have delayed toilet training that is not outside the accepted range (between 2 and 5 years of age). The prevalence of enuresis is relatively high between the ages of 5 and 7 and then drops off substantially. The vast majority of enuretic children experience spontaneous resolution of the problem at some time, and only a few remain enuretic into adulthood. By age 14 years only 1.1 percent of boys wet once a week or more. The greatest rates of spontaneous remission occur after age 7 years and again after age 12 years.

Treatment The proved methods for the treatment of enuresis are primarily behavioral and pharmacological. Psychotherapy may be useful for ameliorating some of the associated behavioral problems that can be seen with enuresis, especially secondary enuresis. A particularly common clinical scenario for secondary enuresis is the development of wetting in boys following the loss of their father through death or divorce. In these patients, psychotherapy is the primary treatment modality. A review of the efficacy of psychotherapy for primary enuresis found a 20 percent success rate, which is probably not significantly above what would be expected by spontaneous remissions and random chance.

Behavior Therapy A comprehensive review of several studies determined the success rate for behavioral interventions to be 75 percent. Recent studies have yielded comparable response rates. The primary behavioral intervention is the bell-and-pad method of conditioning. A pad is placed on the bed with a wire running to a bell. When the child wets, the moisture completes a circuit in the pad, ringing the bell and waking the child. With repeated use the child learns to awaken before wetting occurs. Buzzer ulcers were a potential adverse effect of the treatment, but the frequency has decreased considerably with improved technology.

Recent behavioral studies have focused on embellishing the standard method and comparisons with different methods. A study that compared the basic bell-and-pad method with methods in which the bell and pad were coupled with more response contingencies for wetting versus not wetting found no statistical difference other than a slightly lower relapse rate with the adjunctive use of reward contingencies.

The relation between bladder capacity and response to behavioral treatment has also been investigated. One study found that bladder capacity did not affect outcome with the bell-and-pad method of conditioning, whereas another found that children with smaller bladder capacities tended to do slightly better when retention-control training was linked to the bell-and-pad method. In general, bladder capacity does not seem to significantly affect response to behavioral treatment. However, concomitant behavioral disturbance does appear to have a negative impact on the response to behavioral conditioning.

Pharmacotherapy Since the efficacy of imipramine for the treatment of enuresis was described in 1960, over 40 double-blind studies have confirmed that observation. Recent studies have focused on the relation between response and concentration of imipramine in the blood. While one study found no connection between positive response and imipramine concentration either alone or in combination with its metabolite desipramine, three studies found a significant relation between positive response and total concentration of imipramine and desipramine. More specifically, optimal response was found above combined concentrations (imipramine plus desipramine) of 60 ng/mL in one study and above 80 ng/mL in another. The most recent study also found that efficacy was related to increasing dosage but noted tremendous variation in serum concentrations among individual children receiving the same dosage. The adverse effect of dry mouth also correlates with concentration in blood, providing clinicians with a crude index of blood concentration in children who are extremely reluctant to have their blood drawn.

Clinically, when one encounters a history of a lack of response to imipramine, one must ascertain the specific dosage used, as nonresponse is frequently related to dosage: primary care physicians often prescribe only 25 to 50 mg a day. However, low-dosage responders do exist, and it is reasonable to start treatment at a daily dosage of 25 mg, titrating up by 25 mg every 4 to 7 days. This enables identification of the low-dose responders, as the response to imipramine occurs within a day or two. Most children exhibit a positive response in the 75- to 125-mg range. The standard maximal limit for dosage is 5 mg/kg body weight, and electrocardiographic (ECG) monitoring is recommended at dosages above 3.5 mg/kg. A pretreatment baseline ECG is also recommended. Blood concentration values may also be clinically useful if higher dosages fail to elicit a response.

There is the risk of overdosing both by the enuretic child and younger siblings. Children can engage in magical thinking, and there have been reports of children who believed that if taking a few pills would stop the wetting for a night then consuming the whole bottle would make it disappear forever. Thus, parents should be advised to control the medication carefully and to store it in a secure place. Severe overdoses may require treatment with physostigmine (Antilibrium), while more moderate overdoses may be treated by the symptomatic management of arrhythmias and seizures.

Because the vast majority of children at some point experience spontaneous remission of the enuresis it does not make sense to prescribe medication for years without checking for a spontaneous remission. One solution to that problem is to taper the imipramine dosage at 3-month intervals. Should enuresis reappear as imipramine dosage is tapered, it can simply be returned to the optimal level for another 3-month period. Clinically, one often finds that more children remain dry after 3 to 6 months of treatment than can be expected from spontaneous remission alone. In general, treatment with imipramine should be viewed as necessary until spontaneous remission occurs.

Three clinical subtypes of enuretic response to imipramine exist: true nonresponders; true responders who maintain a response over time; and transient responders, who respond for a few weeks and then resume wetting. Increasing the dosage for transient responders usually recaptures the response but only for another few

weeks, and ultimately one reaches a point at which the dosage cannot be increased further. However, the initial transient response can be replicated after a medication-free interval; thus one can use the medication for especially important, time-limited social events such as summer camp.

The most recent advance in the pharmacological treatment of enuresis involves the use of desmopressin. A thorough review of the literature on the use of desmopression for the treatment of enuresis revealed 18 randomized, controlled trials, including a total of 689 subjects. Many subjects had been refractory to previous treatment for enuresis. Desmopression reduced enuretic frequency from 10 to 91 percent in these studies. Positive prognostic factors were age above 9 years and lower pretreatment frequency of enuretic events. In most studies wetting resumed after the medication was discontinued. Follow-up studies indicated that 5.7 percent of children remained dry after cessation of medication, but many of those could have been due to spontaneous remission. The most common reported adverse effects were mild abdominal pain, epistaxis, headache, and nasal stuffiness. Several subsequent studies attempted to find factors that might predict or relate to an increased likelihood of a positive response to desmopression. No one factor appears to predict a positive response, but larger functional bladder capacity and a positive family history of enuresis appear to be positively correlated with treatment success. Factors that are not related to treatment outcome are urine osmolality, plasma osmolality, antidiuretic hormone (ADH) secretion, urine production and nocturnal arginine vasopressin concentration.

Studies have also specifically investigated the efficacy of desmopressin for children who were refractory to conditioning treatment and imipramine. One of these involving 52 children (dosage range, 20 to 40 µg intranasally) found complete cessation of wetting in 53 percent, partial response in 19 percent, and minimal or no response in 28 percent. A long-term follow-up study (mean length of follow-up, 13 months) of children treated with desmopressin found no hematological or hormonal adverse effects. However, there have been an increasing number of case reports of hyponatremic seizures with prolonged use. A review of 14 articles that reported data on serum sodium concentration in desmopressin-treated patients and 11 articles that reported individuals who developed altered consciousness or a seizure while taking desmopressin for enuresis concluded that hyponatremia is a potential adverse effect of desmopressin treatment. The authors also noted that excess fluid intake was a contributing factor in 6 of the 11 case reports. They concluded that patients receiving desmopressin for nocturnal enuresis should be advised not to consume more than 8 ounces of fluid on nights when desmopressin is administered. The data on hyponatremia also suggest that periodic monitoring of serum sodium concentration would be prudent.

Treatment with desmopression has been compared with the bell-and-pad method of conditioning. The difference in response rate was not statistically significant; 86 percent improved with the bell and pad and 70 percent with desmopressin. Another investigation comparing the combined use of the bell-and-pad method and desmopressin with placebo indicated that the combination achieved significantly more dry nights. Similar results were found in a study comparing alarm monotherapy with alarm treatment coupled with desmopressin. The combination proved superior, especially for children with severe, almost nightly, wetting.

The newest innovation in desmopressin treatment is the introduction of oral tablets, which were introduced for treatment of diabetes insipidus and are now used for primary nocturnal enuresis as well. A controlled multicenter study found no difference in response between oral desmopressin and the traditional nasal spray. A dosage of 400 µg produced more dry nights than did a 200-µg dose.

General Treatment Considerations The results of the studies reviewed in conjunction with the natural history of enuresis can help the clinician design a decision tree tailored to a given child. The first decision is whether to treat at all. That decision is affected by the frequency of the wetting, the age of the child, and the amount of psychological distress that the wetting causes the child. Enuresis has a negative impact on the self-esteem of affected children and self-esteem improves following successful treatment. One may choose not to treat a child who is wetting infrequently and is at an age in which a spontaneous remission may be expected.

If one does elect to treat, it makes sense to first use the bell-and-pad method of conditioning, because its efficacy has been repeatedly demonstrated, and because a behavioral technique is considered less invasive than pharmacological approaches. A study comparing observation, imipramine, desmopressin, and the bell and pad indicated that while all of the active treatments were significantly superior to observation alone, the positive response was much more likely to be sustained after treatment cessation with the bell and pad than with either pharmacological treatment. Despite these apparent advantages, one large population-based investigation revealed that only a relatively small number of enuretic children (38 percent) actually saw a physician, and of that number, only 3 percent were treated with the bell-and-pad method of conditioning, while over one third received pharmacological treatment. A more geographically restricted survey of primary care physicians yielded significantly different responses. Eighty percent of physicians indicated that they recommended the bell-and-pad method of conditioning. When the bell-and-pad method of treatment is unsuccessful or not feasible, it makes sense to proceed to pharmacological treatment, assuming that the enuresis is severe enough to warrant pharmacological intervention.

For decades imipramine was the first choice for pharmacological treatment. Although precise figures are not available for its relative use in the treatment of primary nocturnal enuresis, desmopressin appears to be emerging as the most popular pharmacological treatment. If studies continue to indicate that the oral tablet preparation is as effective as the nasal spray, this popularity will likely continue to expand.

Only recently, with the impact of managed care, have articles appeared that address the financial cost of the various treatments for enuresis. The bell-and-pad method of conditioning appears to be the most cost-effective treatment; it is as effective as the pharmacological approaches, is more likely to lead to sustained improvement after the cessation of active treatment, and requires only the initial expense of the apparatus. Other expenses to be considered are the time of the professional who counsels the parents on its use and the parental time involved. Imipramine is available generically, so its actual cost is quite modest. Recent wholesale prices of generic imipramine were $1.71 per 100 for 25-mg tablets and $2.38 per 100 for 50-mg tablets. Related costs are the physician's time and the costs of a baseline ECG, periodic monitoring, and blood concentration determinations. Desmopressin is not available generically. The recent average wholesale price for a 5-ml container of the DDAVP nasal spray was $131.16 and the average wholesale cost for 100 0.2-mg tablets was $260.60. Related costs are the physician's time and monitoring for serum sodium and urine osmolality.

ENCOPRESIS

The problem of fecal soiling, encopresis, has not yielded as well to research as has enuresis. Although there has been progress in understanding some of the pathophysiological elements of the disorder, so far these have not evolved into a unifying theory. As discussed below, this most likely represents the heterogenous psychosomatic nature of the disorder.

Definition DSM-IV currently defines encopresis with four related criteria: (1) the repeated inappropriate passage of feces, usually involuntary; (2) occurrence at least once a month for at least 3 months; (3) a chronological or mental age of 4 years; and (4) exclusion of a substance or medical condition as a cause.

For several years the clinical and research literature concerning encopresis has distinguished between retentive and nonretentive encopresis. Accordingly, DSM-IV lists two subtypes: with constipation and overflow incontinence and without constipation and overflow incontinence. The subtype with constipation and overflow incontinence corresponds to retentive encopresis and is described by DSM-IV as follows: “Feces are characteristically (but not invariably) poorly formed and leakage is continuous, occurring both during the day and during sleep. Only small amounts of feces are passed during toiletting and the incontinence resolves after treatment of the constipation.” The subtype without constipation and overflow incontinence corresponds to nonretentive encopresis and, as DSM-IV notes, “feces are likely to be of normal form and consistency and soiling is intermittent. Feces may be deposited in a prominent location.”

Some clinicians refer to a primary type in which the person has never established fecal continence and a secondary type in which the disturbance develops after a period of established fecal continence.

History The history of encopresis is not as richly detailed as is that of enuresis, possibly because encopresis affects fewer children and the events are less frequent. Unless the feces are particularly fluid it may also be easier for children to hide the symptoms. A high frequency of encopresis and enuresis was found in children who were separated from their parents in World War II, thus documenting the impact of environmental factors.

Comparative Nosology DSM-IV has adopted the widely held clinical distinction between retentive and nonretentive encopresis, although slightly different terminology is used. Although the current DSM-IV definition includes both voluntary and intentional encopresis, that is obviously a distinction of major clinical importance. DSM-IV states that nonretentive encopresis “is usually associated with the presence of Oppositional Defiant Disorder or Conduct Disorder or may be the consequence of anal masturbation.” This statement appears to negate the existence of a rather substantial subgroup of children with nonretentive encopresis who are encopretic because they cannot adequately control the anal sphincter or do not recognize the need to defecate in time.

The most comprehensive categorization of encopresis distinguishes three types of patients: (1) intentional—children who have bowel control but intentionally deposit feces in inappropriate places for psychological reasons; (2) involuntary—those who cannot adequately control the sphincter or lack an awareness of the process; and

(3) involuntary—those whose soiling is related to excessive fluid from retentive overflow (75 percent of this category), diarrhea, or anxiety. Thus, this classification schema incorporates both the retentive and nonretentive dichotomy and the distinction between voluntary and involuntary incontinence.

The ICD-10 diagnostic classification of encopresis essentially follows this schema and allows the notation of the three subtypes in DSM-IV. The primary differences with the DSM-IV criteria are the ability to code for three subtypes rather than two and a duration of 6 months at a frequency of at least once a month, as opposed to the DSM-IV duration of 3 months at a frequency of at least once a month. The ICD-10 also states that if encopresis coexists with enuresis "the coding of the encopresis should have precedence."

Epidemiology Two large epidemiological studies have yielded consistent results. The Isle of Wight study reported a prevalence of 1.3 percent for boys and 0.3 percent for girls ages 10 to 12 years soiling at least once a month. A large study involving 8863 children found a 1.5 percent prevalence rate for boys ages 7 and 8 years. In that study the ratio of boys to girls was more than three to one. A significant relation between encopresis and enuresis has also been found. DSM-IV cites a prevalence of 1 percent in 5-year-old children, with boys being more commonly affected than girls.

Etiology The dramatic nature of fecal soiling has contributed to psychodynamic speculation. The term "chronic neurotic encopresis" has been used to describe the small number of children whose encopresis is predominantly psychological. The clinical characteristics described in these children are (1) a distant father and neurotic mother, (2) early and often harsh bowel training, and (3) a history of neurological delay. The one systematic study that attempted to verify the clinical features usually attributed to enuretic and encopretic children in the literature by analyzing actual case material could not substantiate the existence of 20 of the 22 factors developed through the literature review.

As with enuresis, the distinction between primary and secondary encopresis relates to the issue of associated psychopathology. A study involving 63 boys with encopresis found that boys with primary encopresis were more likely to have developmental delays and associated enuresis while those with secondary enuresis were more likely to have experienced higher levels of psychosocial stressors and to be diagnosed with conduct disorder. A large study looked at several psychological and physiological variables in children with chronic constipation and children with encopresis unrelated to constipation. The group with constipation had significantly longer colonic transit times and both groups had relatively high frequencies of abnormal defecation dynamics. Both groups were significantly different from controls but were not significantly different from each other.

No correlation between encopresis and social class was reported in two independent studies. The issue of neurological competence as a contribution to encopresis has been investigated. One study found no abnormalities of anal-rectal motor or sensory function but did find that a significant number of encopretic boys had abnormal anal-rectal expulsion dynamics. A sophisticated physiological study using a triple-lumen catheter attached to a hydraulic manometry infusion system found that age of onset, frequency, and duration of encopresis were all highly correlated with the amount of anal sphincter spasm that occurred when defecation was attempted. The amount of pain reported with bowel movements correlated positively with frequency of encopresis and inversely with maximum squeeze pressure. An investigation involving the concentrations of gastrointestinal hormones in controls and children with retentive encopresis indicated that the latter had higher concentrations of pancreatic polypeptide after a meal and a lower motilin response. However, the authors noted that these abnormalities could be the result of, or the cause of the chronic constipation.

An extensive series of studies concerning physiological factors and the interplay of physiological and psychological factors was carried out. The principal physiological findings were (1) 56 percent of children with retentive encopresis could not defecate rectal balloons (research technique used to assess sphincter competency), and most had abnormal anal sphincter contractions; (2) only 14 percent of those who could not defecate the balloons had responded to treatment at 1 year follow-up compared with a 64 percent success rate for those who could; (3) at 1-year follow-up, 70 percent of children who could relax the anal sphincter at the time of initial evaluation were improved as opposed to 13 percent of those who could not; and (4) none of the children who initially presented with an abdominal fecal mass were improved at 1-year follow-up, regardless of other factors.

One subset of these studies physiologically compared constipated children with controls during the act of bearing down. All of the control children displayed decreased anal sphincter activity when bearing down, compared with 58 percent of the constipated children who could defecate a balloon and 7 percent of constipated children who could not defecate the balloon. The constipated children who could not defecate the balloon were also significantly less likely to respond to laxative treatment.

An attempt was also made to assess the relative impact of physiological and psychological factors. Specifically, anal-rectal manometric and electromyographic assessments were correlated with behavioral and social competence profiles as related to treatment outcome. Psychological variables were not found to predict outcome, but physiological variables were.

Diagnosis and Clinical Features The DSM-IV diagnostic criteria for encopresis are listed in Table 43-3. The rather objective and concrete nature of the encopretic event makes diagnosis relatively easy and uncomplicated from a phenomenological perspective, if the child meets the frequency, duration, and age requirements set forth in DSM-IV. The involuntary versus intentional dichotomy is neither a requirement nor a reason for subclassification according to DSM-IV, but it has important clinical implications. Similarly, the retentive versus nonretentive schema has clinical utility. Differentiating between primary and secondary encopresis is important, as one might expect medical or psychological factors to play a greater role in secondary encopresis. The ICD-10 criteria for inorganic encopresis are presented in Table 43-4.

A. Repeated passage of feces into inappropriate places (e.g., clothing or floor) whether involuntary or intentional.
B. At least one such event a month for at least 3 months.
C. Chronological age of at least 4 years (or equivalent developmental level).
D. The behavior is not due exclusively to the direct physiological effects of a substance (e.g., laxatives) or a general medical condition except through a mechanism involving constipation.

Code as follows:
With constipation and overflow incontinence
Without constipation and overflow incontinence

Table 43-3 DSM-IV Diagnostic Criteria for Encopresis

A. The child repeatedly passes feces in places that are inappropriate for the purpose (e.g., clothing, floor), either involuntarily or intentionally. (The disorder may involve overflow incontinence secondary to functional fecal retention.)
B. The child's chronological and mental age is at least 4 years.
C. There is at least one encopretic event per month.
D. Duration of the disorder is at least 6 months.
E. There is no organic condition that constitutes a sufficient cause for the encopretic events.

Table 43-4 ICD-10 Diagnostic Criteria for Nonorganic Encopresis

Henry was an 11-year-old male with almost-daily encopresis and a number of associated behaviors including hiding the feces around the house. He resided in a specialized foster care setting, having been removed from his biological parents at age 7, because of physical and sexual abuse. Both parents were involved with substance abuse, and his early history is not well documented. However, the parents did indicate that he had never exhibited sustained bowel continence for several months. Henry had also been enuretic until age 6, but this had resolved to an occasional nocturnal episode every 4 to 6 months.

Henry also qualified for a diagnosis of oppositional-defiant disorder. Although he had experienced physical and sexual abuse, he did not have flashbacks or other symptoms that would meet the criteria for posttraumatic stress disorder. Henry also had an attention-deficit/hyperactivity disorder and was being effectively treated with 10 mg of methlyphenitate (Ritalin) twice a day.

The foster family resided in an urban area that had access to a nationally recognized children's hospital. The Ambulatory Care Department had a specialized behavioral encopresis program that coupled the bowel training method with a psychoeducational component and psychotherapy. The psychiatric consultant to the specialized foster care program doubted that this program would be successful for Henry since he had so much associated psychopathology and the feces were often deposited around the house in a symbolic manner. Also, the encopresis was not of the retentive-overflow type, and the feces were always well formed. However, since no apparent harm could come from the referral, the consulting child psychiatrist agreed to it. Much to the surprise of the consultant, the several-week outpatient bowel training course coupled with the psychoeducational component and psychotherapy resulted in a complete cessation of the encopresis. On one of her visits to the home, Henry proudly showed his case manager a diagram of the functioning of the digestive system that was part of the psychoeducational program. In retrospect, it appeared that although there were symbolic aspects to Henry's encopretic behavior, the soiling was ego-dystonic, and he was highly motivated to change the behavior, although this motivation could not be prospectively detected by the treatment team because of his oppositional-defiant manner of responding to adults.

Pathology and Laboratory Examination The extensive, detailed physiological studies cited above suggest that physiological factors are important in many encopretic children as they correlate with treatment outcome at 6-month and 1-year follow-up. However, that does not imply that a physiological workup this thorough is required for every encopretic child who presents clinically. The clinician needs to rule out definite physiological illnesses, such as Hirschsprung's disease. Beyond that clinicians might consider more detailed physiological investigations, such as those used in the experiments described above, for children who prove refractory to conventional treatment. That type of specialized testing could be difficult to obtain outside an academic research center. A simple plain abdominal roentgenogram may aid in the diagnosis and confirmation of retentive encopresis. In one study 78 percent of children who met the diagnostic criteria for encopresis in the revised third edition of DSM (DSM-III-R) also met roentgenographic criteria, while 22 percent did not.

Psychological testing can be useful for children who exhibit concomitant behavioral problems or who are intentionally encopretic. Finally, clinicians should not overlook the importance of a detailed history obtained from both parents and the child that documents the time course, frequency, and circumstances surrounding the encopresis.

Differential Diagnosis Encopresis can be a symptom of other processes or be a syndrome in itself as described above. The medical illnesses that need to be ruled out include stenosis of the rectum or anus, endocrine abnormalities, smooth muscle disease, and Hirschsprung's disease.

The child's psychological profile should be considered, as children with mental retardation or pervasive developmental delay may have episodes of soiling related to those processes. Children with impulse-control disorders or attention-deficit disorder may at times have episodes of soiling related to lack of attention. A thorough history and psychiatric assessment should make it possible to identify both those children and children who soil on an intentional-oppositional basis. Extreme stress may also provoke encopretic episodes in children who otherwise function well.

Course and Prognosis As with enuresis, continued maturation provides increasing numbers of spontaneous remissions with time. That trend should be factored into the assessment of the efficacy of any long-term intervention. The results from relatively simple behavioral interventions involving educational, behavioral, and physiological components are striking (78 percent), suggesting that the disorder responds to treatment in most cases.

Treatment The first clinical approach to encopresis is primarily behavioral, with educational and physiological components. That method entails initial educational interventions with the child and family around bowel function. The process is meant to correct misconceptions the family may have and dissipate anxiety that may develop around the soiling. The physiological component is instituted next with an initial bowel catharsis followed by daily dosages of laxatives or mineral oil. The behavioral element of the program entails daily timed intervals on the toilet with success being rewarded. Follow-up studies have reported a 78 percent success rate for the method. The physiological research findings concerning abnormal defecation dynamics in children with encopresis led to interest in biofeedback training as an adjunctive treatment. Although this treatment received positive reports from uncontrolled studies, a review of controlled studies indicated that biofeedback training did not provide additional benefit over conventional treatment.

One element of the aforementioned physiological studies, namely the ability to defecate a rectal balloon, correlates with treatment outcome. A study involving 139 children with constipation and encopresis and 20 controls found that all of the controls could defecate the balloon but only 47 percent of the encopretic group could do so.

One year after beginning treatment, 51 percent of the children who could defecate the balloon at baseline were considered recovered but only 34 percent of those who could not. Although the group comparisons were considered significant, the balloon test alone could not predict response to treatment on a individual basis.

Psychotherapy may be useful for children who have concomitant behavioral problems and those with psychodynamic factors that appear to be especially strong and contributing to the disorder. Naturally, psychotherapeutic approaches are of primary importance for children who are intentionally soiling or depositing feces in inappropriate places around the home.

Pharmacological treatment for encopresis has not been as extensively studied as for enuresis. Six case reports (encompassing 15 individual patients) have described imipramine as effective for encopresis. Twelve of the 15 patients were boys. The therapeutic effect had relatively rapid onset (as it does with enuresis), occurring within a few days to 2 weeks, usually at dosages of 25 to 75 mg. Although the subtype of encopresis is not delineated in all of the case reports, one would anticipate that if imipramine were to be helpful, it would be in those with nonretentive encopresis.

The relatively high success rate of the combined educational, physiological, and psychological approach described makes it a reasonable first approach once other diagnoses have been ruled out. Psychotherapeutic and pharmacological approaches could be considered for children who prove refractory to that form of treatment.

CHAPTER 44. OTHER DISORDERS OF INFANCY, CHILDHOOD, AND ADOLESCENCE

44.1 REACTIVE ATTACHMENT DISORDER OF INFANCY AND EARLY CHILDHOOD

NEIL W. BORIS, M.D., AND CHARLES H. ZEANAH, M.D.

Reactive attachment disorder of infancy and early childhood is one of the few disorders in the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) applicable to children under the age of 5. Since this disorder first appeared in the third edition of DSM (DSM-III), the criteria have been substantially revised. The rationale for DSM-IV and the 10th revision of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) criteria for the disorder clearly arises from converging lines of research on institutionalized and maltreated infants and young children. However, no systematic research validates these criteria, and reactive attachment disorder of infancy and early childhood is rarely cited in the literature.

The normal development of the infant and young child's attachment system, first elucidated in John Bowlby's theory of attachment, is the marker against which behavior indicating disordered attachment is compared (Table 44.1-1). Two general patterns of deviant social responses have been described in published case studies and reviews of the literature on disturbances of attachment in institutionalized or maltreated infants and young children are reflected in current criteria for the disorder. Other less well studied or more subtle patterns also appear to exist. While the development of primary attachment relationships in early childhood is reciprocal, criteria clearly specify that this disorder occurs “as a result of grossly pathogenic care.”

	Birth to 2 months	3 to 7 months	7 to 12 months	12 to 18 months	Over 18 months
Phase of attachment	Limited discrimination	Discrimination with limited preference	Preferred attachment	Secure base	Goal-corrected partnership
Characteristics	Physical attributes of babies/news attract caregivers, but infant expressions of preference limited to olfactory and auditory realms and require experimental conditions to demonstrate	Infant differentiates among different interactive partners; may seem more comfortable with primary caregiver but willing to interact readily with other social partners	Clearly expressed preference for a small number of caregiving adults; separation protests and stranger wariness are normative	Use of the attachment figures as a secure base from which to venture out confidently and explore the world; and a safe haven to return to in times of danger; proximity to caregiver promotes internal feeling of security in infant	Cooperation with caregiver despite frequent conflicts; goal is to balance autonomous functioning with reliance on caregiver for help when needed; verbal relationships important including attention to emotional integration and fluency of discourse

Table 44.1-1 Developmental Features of Attachment in Early Childhood

A number of important issues regarding reactive attachment disorder remain unresolved. First, can the disorder be reliably diagnosed? Does the disorder exist within the child or within the relationship? Can the disorder exist when grossly pathogenic care cannot be documented? What other abnormal attachment patterns are disturbed enough to be considered disordered? What is the prevalence and natural history of the disorder? How is the disorder related to other disorders, particularly pervasive developmental disorders?

DEFINITION

Reactive attachment disorder of infancy and early childhood as described in DSM-IV is characterized by “markedly disturbed and developmentally inappropriate social relatedness in most contexts.” These findings must occur in the context of “grossly pathogenic care.” The disorder must begin before 5 years of age to meet criteria and cannot be “accounted for solely by developmental delay.” Children who are mentally retarded are thus difficult to diagnose; those who meet criteria for pervasive development disorder are explicitly excluded from consideration for reactive attachment disorder.

Two subtypes are spelled out in the DSM-IV criteria. The first pattern, generally linked in the literature to early childhood maltreatment, is characterized by inhibition of the normal developmental tendency to seek comfort from a select group of caregivers. Responses to social interactions are “excessively inhibited, hypervigilant, or highly ambivalent,” reflecting the overall inhibition of the attachment system in affected children. The second pattern, linked to institutionalization or exposure to multiple caregivers before age 5, is characterized by a relative hyperactivation of the attachment system, resulting in “diffuse” and unselective attachments, and patterned behavior labeled “indiscriminate sociability.”

Attachment and Development Attachment, as described by Bowlby in his influential trilogy, refers to a biobehavioral system whose goal is to coordinate the balance between the need for safety in proximity to a caregiver or set of caregivers with the tendency for exploration and autonomy in infancy and early childhood. Bowlby argued that human infants were motivated by this heritable attachment system to seek an external goal of safety in proximity to a small number of identified caregivers (usually with the infant's mother) and an internal goal of “felt security.” This internal subjective sense of security is influenced heavily by the experience of the caregiver's emotional and physical availability in times of need and modified by the infant's own temperamental makeup. From the usual biobehavioral shift at age 7 to 9 months through the first 3 years, infants are thought to begin to form internal representations of their relationships with important caregivers. These representations (Bowlby called them “internal working models”) form the basis for both the intense emotional bond between infants and their primary caregivers and behavior in later relationships. This link provides evidence that attachment is salient throughout the course of development. Although these representations are relatively stable, they may be modified by significant experiences or relationships later in life.

Bowlby's theoretical framework, refined from the early 1950s to the 1970s, has evoked much research in the last two decades on the development of patterns of secure and insecure attachment in early childhood. The normal developmental progression of attachment, captured in attachment-related behaviors, is summarized in Table 44.1-1. Though little of this research has been directed toward defining clinical disorders of attachment, much of it is germane to clinical medicine; assessment of attachment has become necessary for infant mental health professionals.

Deviant patterns of attachment like those reflected in criteria for reactive attachment disorder have been recognized in populations raised in environments marked by extreme deprivation. The normative tendency to seek comfort actively from a restricted number of familiar caregivers in times of distress, a hallmark of secure attachment, is commonly not apparent in many of these children. Moreover, a series of anomalous behaviors in these relationships are evident and are reflected in the criteria for reactive attachment disorder.

These anomalous behaviors are also the hallmark for a pattern of attachment labeled *disorganized/disoriented*. This pattern of attachment has been identified using standardized laboratory assessments. Recent longitudinal research suggests that disorganized/disoriented attachment in infancy is a risk factor for the development of psychopathology. Further, the antecedents of this pattern of attachment are primarily environmental factors that impact early relationship formation.

These findings suggest that subsyndromal disturbances of attachment such as disorganized/disoriented attachment exist on a continuum. The findings also suggest that clinicians should be familiar with risk factors impacting early caregiver–infant interactions that are related to the development of disorganized/disoriented

attachment. Maternal psychopathology, child maltreatment, family violence, and poor parental sensitivity to infant cues have been linked to the development of disorganized/disoriented attachment.

HISTORY

The importance of early experience on infant development was recognized as far back as the thirteenth century when the Holy Roman Emperor Frederick II ordered that no one should speak to, or interact with, a group of infants. His experiment, designed to see what language the children would learn to speak, ended with the premature death of all its subjects. Notes inscribed at the time by a Franciscan monk document the devastating social and emotional effects this lack of social interaction had on the infants.

This crude experiment was one of the first designed to test the relative importance of nature versus nurture in influencing development. The nature-versus-nurture theme is as evident in the history of philosophy as it is today in the field of experimental developmental psychology. The work of Aristotle and Plato includes reflection on the relative importance of biology and environment in influencing development. The Enlightenment in the seventeenth and eighteenth centuries brought more interest in the origins of personality; the eminent English philosopher John Locke argued that the mind of the infant was a tabula rasa on which layers of experience were imprinted to create a person with a unique personality. This view was countered by Jean-Jacques Rousseau, among others, who viewed infants as being endowed at birth with inherent goodness that would naturally develop except in circumstances marked by parenting deficiency. By the nineteenth century, Charles Darwin had suggested that complex individual traits, including intelligence, could be largely accounted for by hereditary factors.

The continued interest in the relative importance of nature and nurture has shaped much of the research in early childhood development in this century. The relatively common practice of institutionalization of infants in orphanages in the first half of the century unwittingly provided more evidence of the detrimental effects of what has been called “maternal deprivation.” Pediatricians had long argued against the practice of institutionalization, particularly because of the high mortality rates related to failure to thrive, but health care providers did not take notice of the effects of institutionalization on social and emotional development until René Spitz in the 1940s and James and Joyce Robertson in the 1950s conducted more rigorous studies (including control groups). Films that showed the effects of prolonged separations from caregivers and of institutionalization heightened interest in this social problem. These studies also led Spitz to propose a diagnostic entity he called “anaclitic depression,” which foreshadowed the DSM-III criteria for reactive attachment disorder and is consistent with some of the features of the DSM-IV inhibited subtype. Anaclitic depression seemed to follow prolonged separation of infants from their caregivers and was most severe if the infants were old enough to have developed a preference for that caregiver. The eventual recognition of the clinically meaningful consequences of institutionalization led to a marked decrease in state-run orphanages in many industrialized countries. However, the recent influx of young children from Romania and some Russian states has renewed interest in studying this population of children.

Recognition of the scope of the problem of child maltreatment, on the other hand, did not begin until relatively recently, spurred initially by C. Henry Kempe's classic 1962 article on the “battered child syndrome.” Since the early 1960s, there has been a great deal of research on the development effects of maltreatment on children. Though this research is confounded by the number of competing variables influencing observed outcome, disturbed attachment patterns have been consistently documented in a range of samples of young children. On the other hand, it is not yet clear what percentage of these children might meet criteria for an attachment disorder at any given developmental stage.

COMPARATIVE NOSOLOGY

The criteria for reactive attachment disorder have evolved markedly since the diagnosis was first introduced in DSM-III. This early version of the disorder included growth failure and lack of social responsivity as central features. The diagnosis had to start by 8 months of age (the age at which preferred attachment to a restricted set of caregivers is usually just beginning to be evident) and could not result from a diagnosable medical condition. Gross neglect of the infant's physical and emotional needs had to be evident, and, as with later criteria, presence of autism or mental retardation precluded the diagnosis. Pertinent behaviors cited in the criteria included poor tone, weak cry, excessive sleep, lack of interest in the environment, and weak rooting and grasping when feeding.

Though so-called nonorganic failure to thrive remains an important diagnostic entity in infant mental health, the restrictive age range of this set of criteria and the requirement for growth failure made the DSM-III definition difficult to apply in many cases. Further, it is rarely possible to rule out autistic disorder or mental retardation in severely malnourished infants under 1 year of age. The link between failure to thrive and reactive attachment disorder was dropped in the revised third edition of DSM (DSM-III-R), and the age of onset was changed to the first 5 years. The two subtypes of the disorder, inhibited and disinhibited, were introduced with DSM-III-R and have persisted in DSM-IV. The etiological link between the disorder and evidence of “pathogenic care” at the hands of the young child's primary caregivers and the exclusion of children whose symptoms might be accounted for by cognitive delay or one of the pervasive developmental disorders remained an emphasis of the criteria.

Though reactive attachment disorder was not included in the ninth revision of *International Statistical Classification of Diseases* (ICD-9), it does appear in ICD-10—in a form largely consonant with DSM-IV criteria. The ICD-10 criteria do not explicitly link the disorder to pathogenic care, but a warning against making the diagnosis without evidence of abuse or neglect is included in the clinical description attached to the criteria. ICD-10 lists the two subtypes from DSM-IV as separate disorders (Table 44.1-2), and neither explicitly excludes children with mental retardation or pervasive developmental disorders. However, the clinician is required to document that the child shows “elements of normal social relatedness” with “non-deviant adults.”

Table 44.1-2 ICD-10 Diagnostic Criteria for Disorders of Social Functioning With Onset Specific to Childhood or Adolescence

DSM-IV and ICD-10 criteria for attachment disorders have been criticized in the literature on a number of fronts. First, the implication that the disorder is reactive is problematic. A temporal association of factors like maltreatment and inhibition should not imply a causative link. From a practical perspective, one cannot always know what experiences children might have had with their caregivers, and the limits of what is or is not pathogenic care are unclear. Some children might meet criteria for reactive attachment disorder without having experienced extreme deprivation or abuse. Second, the exclusion of infants and children with pervasive developmental disorders and mental retardation ostensibly on grounds that each has a different cause suggests that these disorders cannot coexist. Certainly, children with a mental age below 8 months are unlikely to develop a focused set of attachments with caregivers. However, in children with milder cognitive impairment, the clinical distinction between these disorders is occasionally difficult, particularly when caregiving deficiencies are notable.

The criteria emphasize the general social behavior of affected children across relationships rather than more specific attachment-related behaviors. These latter behaviors might include comfort seeking, compliance with caregiver requests, exploratory behavior, and attempts to control the caregiver either by acting in a caregiving role or by being bossy and punitive. Responses to reunion, used successfully to classify patterns of attachment, may also reveal extreme affective responses (e.g., ignoring, fearful, angry, or affectless reunions) that are clinically meaningful.

A final concern is raised by the clear evidence that children act differently in different relationships. Both DSM-IV and ICD-10 criteria require that the aberrant behavior be evident across relationships, which excludes children whose behavior is clearly compromised in the presence of their primary caregivers but not in the few other relationships they might have. Changing this focus would compel the clinician to identify a relationship disorder rather than a pervasive pattern of abnormal

social behavior, which might identify more children and families requiring intervention. This approach, however, flies in the face of current conceptualizations of psychiatric disorders—namely that they exist within individuals, not between them.

These concerns about DSM-IV and ICD-10 criteria have led a group of researchers and clinicians to propose a series of alternate criteria designed to redress most of these concerns. Criteria have been proposed for six separate attachment disorders, beginning with disorders of nonattachment that can be diagnosed in any child with a mental age of 10 months or above (i.e., the age at which children typically show preferred attachments). These disorders follow DSM-IV criteria in including inhibited and disinhibited subtypes. However, the link to pathogenic care is dropped and evidence of less extreme social behavior in relationships with caregivers other than the primary caregiver does not disqualify the child for the diagnosis. A second general type of disorder is also proposed, disrupted attachment disorder, which applies when a child experiences the sudden loss of the caregiver; it includes behaviorally anchored criteria consistent with the descriptions Bowlby and others originally documented. The third general type of disorder, so-called secure base distortions, arises from clinical work with young children. Three types have been identified: attachment disorder with self-endangerment, attachment disorder with inhibition, and attachment disorder with role reversal. In each of these disorders, the child has a preferred attachment figure, but the relationship with this figure is markedly distorted in one of these three ways.

Unfortunately, none of the available criteria, including those from DSM-IV and ICD-10, have been subjected to research aimed at validation and reactive attachment disorder remains a little-used and poorly studied phenomenon.

EPIDEMIOLOGY

Virtually no data exist on the prevalence and clinical course of reactive attachment disorder. Retrospective chart reviews of consecutive patients suggest that the diagnosis can be made reliably in a clinic-referred population. Because pathogenic care is often associated with broad-risk factors like poverty, family disruption and low social support, in clinical samples, these may be considered frequent conditions associated with the diagnosis. However, reactive attachment disorder appears to exist across socioeconomic strata.

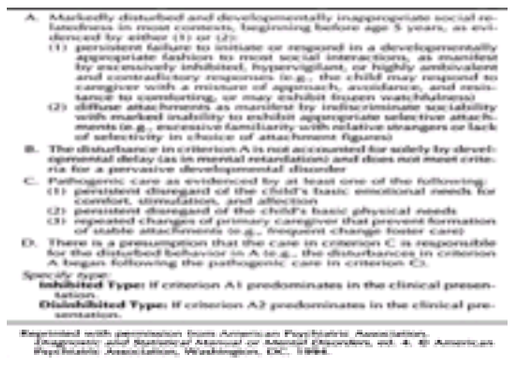
ETIOLOGY

While reactive attachment disorder typically occurs in the context of grossly neglectful or overtly abusive care, the critical elements of this care and their relation to the onset of the disorder are unclear. Certainly children institutionalized in the same facility or siblings raised together in a markedly disturbed family may have divergent outcomes. Individual temperamental or personality factors may combine with corrective experiences to yield a nonpathological outcome in some children who experience extremes of care. The individual fit between neglectful or abusive adults and their infants or children may be critical in determining which children develop symptoms consistent with an attachment disorder.

Though research on what causes caregivers to be abusive or neglectful is limited, caregiver characteristics from severe personality disturbance to psychopathology appear to be important. Parental mental retardation and poor basic parenting skills, particularly in the context of little social support, may also lead to pathogenic care. Infants who are cared for by multiple caregivers in succession, as is common in the foster care system in the United States, are also at increased risk for attachment disorders. The traumatic experience of prolonged separation from a caregiver in early childhood, documented by Spitz, the Robertsons and Bowlby, is itself enough to cause attachment disturbance. Repeated prolonged separations typically cause more severe symptoms, and when these separations are accompanied by abuse, neglect, or both, attachment disorders appear to be particularly likely.

DIAGNOSIS AND CLINICAL FEATURES

The diagnosis of reactive attachment disorder is contingent upon documenting clear evidence of pervasive disturbance in social relatedness that began prior to age 5 (Table 44.1-3). The pattern of behavior should fit one of the two different subtypes described in the criteria. The inhibited subtype is characterized by hypervigilant and fearful behavior (often recognized as a pattern of compulsive compliance with the abusive caregiver) or extreme ambivalence and contradictory behavior in relationships. Mixtures of approach and avoidance may be apparent, and frozen watchfulness may be noted. The disinhibited subtype is marked by a lack of selectivity in choosing social partners, resulting in diffuse attachments and a peculiar overfriendliness that has been labeled indiscriminate sociability. Caregivers may remark on their own subjective sense that the child is not truly attached to them.



A. Markedly disturbed and developmentally inappropriate social relatedness in most contexts, beginning before age 5 years, as evidenced by either (1) or (2):
   (1) persistent failure to initiate or respond in a developmentally appropriate fashion to most social interactions, as manifest by excessively inhibited, hypervigilant, or highly ambivalent and contradictory responses (e.g., the child may respond to caregiver with a mixture of approach, avoidance, and resistance to comforting, or may exhibit frozen watchfulness)
   (2) diffuse attachments as manifest by indiscriminate sociability with marked inability to exhibit appropriate selective attachments (e.g., excessive familiarity with relative strangers or lack of selectivity in choice of attachment figures)
B. The disturbance in criterion A is not accounted for solely by developmental delay (as in mental retardation) and does not meet criteria for a pervasive developmental disorder
C. Pathogenic care as evidenced by at least one of the following:
   (1) persistent disregard of the child's basic emotional needs for comfort, stimulation, and affection
   (2) persistent disregard of the child's basic physical needs
   (3) repeated changes of primary caregiver that prevent formation of stable attachments (e.g., frequent change foster care)
D. There is a presumption that the care in criterion C is responsible for the disturbed behavior in A (e.g., the disturbances in criterion A began following the pathogenic care in criterion C).

Specify type:
Inhibited Type: If criterion A1 predominates in the clinical presentation.
Disinhibited Type: If criterion A2 predominates in the clinical presentation.

Table 44.1-3 DSM-IV Diagnostic Criteria for Reactive Attachment Disorder of Infancy or Early Childhood

It is difficult to make the diagnosis of reactive attachment disorder without a multisession evaluation, particularly when the caregiver's behavior is not known to be abusive or the child's history does not include multiple placements. Ascertaining whether the child has less-deviant behavior in the presence of the clinician or another trusted adult is important and may take time. The child's relationship with the primary caregiver can be adequately assessed with a combination of free play, structured teaching tasks that stress the dyad, and a brief separation and reunion. Videotaping the assessment is a useful way to document social responses, and the introduction of a clinically trained person whom neither partner has met is often informative. Children who meet criteria for this disorder may look quite different depending on their developmental stage.

A 26-month-old girl, recently placed in foster care, was referred by state child protective services with her biological and foster families to assist with long-term case management. Her history included two admissions for failure to thrive in the first year of life and a third admission at 13 months that revealed retinal hemorrhage and a subdural hematoma from suspected shaken baby syndrome. No perpetrator was conclusively identified. When seen with her biological mother in a comfortable, toy-filled room, she stood completely still and maintained little facial expression. She complied completely and in rote fashion with her mother's often angry instructions, maintaining no sustained eye contact with either her mother or the examiner. When briefly separated from her mother, she showed little reaction, looking up briefly with an odd grimace when her mother returned to the room. Her mother confirmed that her behavior had been similar when she had lived in her home; the child spoke infrequently and rarely sought comfort when distressed. When seen with her foster mother of 3 months, she was markedly more animated, though frequently irritable. She engaged in play freely and referenced both her foster mother and the examiner during play. She stopped playing and stared blankly when separated from her foster mother, though she actively reengaged her foster mother upon her return. The biological mother's parental rights were eventually terminated and though the child was placed in two more homes, she showed the capacity to engage with her new caregivers each time. The girl was diagnosed with reactive attachment disorder, inhibited type.

A 6-year-old boy was referred by his adoptive parents because of hyperactivity and disruptive behavior at school. He had been adopted at age 5, after living most of his life in a Romanian orphanage where he received care from a rotating shift of caregivers. Though he had been below the fifth percentile for height and weight upon arrival, he quickly approached the tenth percentile in his new home. However, both his adoptive parents were frustrated by their inability to "reach him." They had initially worried about a hearing disturbance, though testing and his capacity to engage many adults and children verbally suggested otherwise. He showed interest in anyone and would often follow strangers willingly. He showed little empathy when others were hurt and blandly resisted redirection in school. He was frequently injured because of seemingly reckless behavior, though he had an extremely high tolerance for pain. Intensive intervention focused on problem behaviors at home decreased his self-endangering behavior, though he remained oddly overfriendly and unempathic both at home and in school. The boy was diagnosed with reactive attachment disorder, disinhibited type.

DIFFERENTIAL DIAGNOSIS

Children with marked disinterest in social interaction altogether may require cognitive testing for developmental delay or a neurological workup. Evidence of stereotypies, grossly restricted range of interests, and poor response to changes in routines suggest the spectrum of pervasive developmental disorders; cognitive impairment is frequently moderate to severe in these children. Interviews with the caregivers of these children usually yield little evidence of inappropriate care, and consistent blunting of social interactions outside the family unit is common. However, many children with pervasive developmental disorders or mental retardation form secure attachments with their primary caregivers despite an overall restriction in the range of attachment-related behaviors.

Children with severe receptive and expressive language delays may present linically with difficulty in social relatedness. Often the clinical picture includes externalizing behavior that heightens as unsuccessful attempts to communicate are made; rarely does this behavior fit the reactive attachment disorder subtypes, and grossly inappropriate care is uncommon in this population. As communication improves, social interactions improve.

Temporary or permanent loss of a primary caregiver to whom a young child is already attached is associated with significant disturbance. Bowlby described a common progression of reactions in this instance: protest, despair, and detachment. The clinical picture may mimic the inhibited form of reactive attachment disorder, though pathogenic care is not apparent in these cases. These children may quickly form new attachments to sensitive caregivers, particularly if they had some familiarity with the replacement caregiver before the loss. The clinician may diagnose depression in these cases, though the criteria for depression in infancy are not fully consonant with DSM-IV criteria for major depressive disorder.

The relationship between failure to thrive and reactive attachment disorder has not been well studied. If failure to thrive is not caused by a medical condition, then investigation of the child's relationships with the caregivers is necessary. In severe cases of neglect, reactive attachment disorder and failure to thrive may coexist. Prolonged lack of stimulation may lead to psychosocial dwarfism and many of these children would be expected to meet criteria for reactive attachment disorder. Worldwide, the interplay of kwashiorkor, lack of appropriate caregiving, and attachment disorders may be significant.

Comorbid psychiatric conditions appear common in older children whose history is consistent with reactive attachment disorder. Disorganized patterns of attachment behavior in the first 6 years appear to be associated with disruptive behavior disorders in later childhood; this may also be true for children with reactive attachment disorder.

COURSE AND PROGNOSIS

Because a sizable cohort of patients with reactive attachment disorder has never been followed, the typical course and prognosis for this disorder are not clear. It is likely that associated conditions from the nutritional and neurological sequelae of psychosocial deprivation to the stability of later relationships are critical in influencing the outcome. The possible range of outcomes include death in the most severe cases to relatively normal functioning with intervention leading to the establishment of healthy relationships. There have been several recent controlled studies of children adopted from international orphanages to Canada, England, and the United States. Despite the absence of a gold standard for diagnosing reactive attachment disorder and significant variation across samples (from age at adoption to conditions prior to adoption), these studies provide evidence that a subsample of adopted orphans have symptoms of indiscriminate sociability which continue for months or years after adoption. A smaller subsample appears to be at risk for externalizing disorders, and a handful of children from different samples have been reported to have chronic quasiautism. On the other hand, despite their histories of severe privation, it appears that a majority of these international adoptees rapidly assimilate after stable placement and have few ongoing psychiatric symptoms. Factors that are consistently related to these disparate outcomes have yet to be identified.

There are few long-term, controlled follow-up studies of children and adults who were raised primarily in institutional settings. The few available studies also suggest that indiscriminate sociability may persist and that the choice of marital partners in later life strongly influences eventual adult psychological functioning. The link between early disturbances of attachment and antisocial tendencies, particularly a lack of empathy, was first made by Bowlby; longitudinal studies of this association are needed to firmly establish this pathway.

TREATMENT

The first consideration in the assessment of children exposed to grossly inadequate care is the child's safety. Child maltreatment is associated with significant morbidity, and mortality is not uncommon, particularly in children under 24 months of age. Early involvement of child protective services is often warranted, and assessment of parental fitness may be a necessary part of the evaluation. In some cases placement of the child may be necessary, and reunification of parent and child may not be warranted. Children in this situation have often not had appropriate medical care, and medical referral is almost always indicated. Unfortunately, the foster care system and the family court system may lead to multiple placements in the first years of life and thus increase the likelihood of an attachment disorder. The clinician may play a crucial role in staying involved with the child who is placed in foster care, providing expert testimony in court and individual or family treatment.

Once the child is in a relatively stable placement and is medically healthy, full attention can be paid to psychosocial intervention, which must often be tailored to the individual. Possible interventions include individual psychotherapy for the child or caregiver; parent training with emphasis on developmental expectations; family therapy; or caregiver-child dyadic therapy, which is perhaps most specifically directed toward disturbances of attachment and in many instances is the treatment of choice. As described by Alicia Lieberman, this approach weaves together developmental training and guidance with an active attempt to address pressing instrumental issues (e.g., poor housing, inadequate medical care) and insight-oriented psychotherapy with the child present. The complexity of this approach reflects the complexity of the clinical problem. Long-term interventions are necessary in these cases, and psychiatric treatment should be bolstered by early intervention programs and ongoing medical care for the child.

SUGGESTED CROSS-REFERENCES

The role of early experience in development is discussed in different contexts in Section 4.1 on anthropology and psychiatry, Section 5.4 on animal research and its relevance to psychiatry, and Section 6.1 on psychoanalysis. The role of early experience in personality formation is discussed in Chapter 24 on personality disorders. Neuropsychological and intellectual assessment of children is discussed in Section 7.5. Mood disorders are presented in Chapter 14. Feeding and eating disorders of infancy or early childhood are discussed in Chapter 41. Aspects of physical and sexual abuse of children and neglect are reviewed in Section 49.4. Foster care is discussed in Section 49.3.

44.2 STEREOTYPIC MOVEMENT DISORDER OF INFANCY AND DISODERS OF INFANCY AND EARLY CHILDHOOD NOT OTHERWISE SPECIFIED

JOAN L. LUBY, M.D.

STEREOTYPIC MOVEMENT DISORDER OF INFANCY AND EARLY CHILDHOOD

Both the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) and the 10th revision of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) contain a category that includes a broad variety of etiologically unrelated stereotyped movements that do not form a part of any other recognized psychiatric or neurological condition.

Definition and Comparative Nosology The stereotypic movement disorder is described in DSM-IV as “repetitive, seemingly driven, and nonfunctional motor behavior” that “interferes with normal activities or results in self-inflicted bodily injury that requires medical treatment.” These movements may include hand waving, head banging, rocking, self-biting, picking at skin or bodily orifices, or hitting various body parts. ICD-10 contains a basically identical category called stereotyped movement disorders. In both systems, the diagnosis is given when the behavior is present for 4 weeks or longer. When the behavior is self-injurious this feature is specified; the ICD further elaborates on non-self-injurious, self-injurious, and mixed types. When the movement occurs as a part of another general neurological, medical, or psychiatric condition (e.g., pervasive developmental disorder not otherwise specified or autism) a comorbid diagnosis of stereotypic movement disorder is not deemed necessary. Lesh-Nyhan syndrome, the genetic deficiency of hypoxanthine-quinine-ribosyltransferase activity associated with choreiform movements and severe self-mutilating behavior, is perhaps the most dramatic example of a stereotyped movement that does not fall into this classification. One exception to this rule is that stereotyped movements that occur in conjunction with mental retardation warrant a separate diagnosis when the stereotypic or self-injurious behavior is severe enough to require treatment.

History Stereotypic movements were first identified as an important psychiatric symptom in the early 1900s by Emil Kraepelin, who described stereotypies as a characteristic of dementia precox. These movements have since become widely recognized as symptoms associated with psychotic disorders in general and with a number of neurodevelopmental disorders.

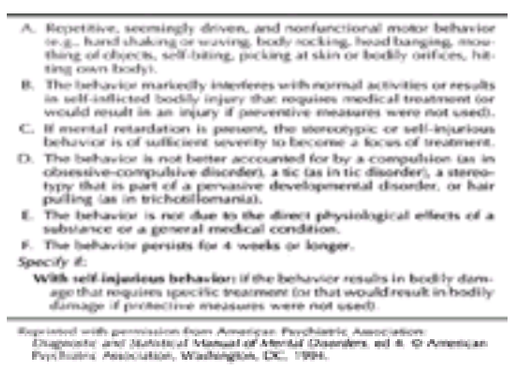
Stereotypic movement disorder has undergone some modification with the evolution of the DSM system. The third edition of DSM (DSM-III) contained a broader definition of the disorder than DSM-IV contains. The DSM-III criterion describes voluntary, nondistressing, nonspasmodic movements and goes on to specify that the behaviors were more likely to be associated with extreme psychosocial deprivation, mental retardation, or pervasive developmental disorder but could occur independent of these conditions. Stereotypy/habit disorder as it was called in the revised third edition of DSM (DSM-III-R), represented a broadened diagnostic category that included periodic and persistent nonfunctional behaviors such as nail biting. Also new in the DSM-III-R was the inclusion of functional impairment in the diagnostic criteria; the behavior had to either cause physical injury or interfere with normal activities. DSM-III-R also added exclusions; the diagnosis could not be made if the movements occurred in the presence of a tic disorder or a pervasive developmental disorder. In addition to new criteria described above, DSM-IV also excludes specific behaviors such as hair pulling (trichotillomania), tics, and compulsions since they are thought to fit more coherently into other diagnostic categories.

Epidemiology The prevalence of stereotyped movement disorders as a whole in the general population remains unknown; however, some data exist on the prevalence of individual stereotyped behaviors. The prevalence of self-injurious behaviors among individuals with mental retardation has been estimated to be between 2 and 3 percent in community samples of children and 25 percent among mentally retarded adults living in institutions. Head banging has been estimated to have a prevalence of approximately 5 percent in child populations, with males affected three times more frequently than females. The behavior is usually self-limiting, occurring in the first 3 years of life, with typical age of onset between 5 and 11 months. It is relatively rare after age 3 but persists longer in about 5 percent of cases. Similar statistics are reported for head rolling, a behavior that can result in significant hair loss. Similarly, breath holding is also rare after the third birthday and occurs most commonly between 12 and 18 months of age. This behavior is also more common among boys than girls. Bruxism (grinding the teeth) is estimated to occur in as many as 56 percent of the normal population in infancy, after eruption of the teeth.

Etiology Although many theories (behavioral, neurobiological, genetic, and analytic) have been proposed to explain the pathogenesis of various stereotyped movements, no clear understanding of the cause of the disorder has emerged. A number of genetic, neurological, and metabolic disorders are associated with stereotyped movements, and there is a much higher prevalence of these behaviors in individuals with mental retardation. In addition, twin studies have shown that a few stereotypic movement disorders (e.g., nail biting) have a familial inheritance pattern. For example, monozygotic twins had a 66 percent concordance for nail biting while dizygotic twins had a rate of 34 percent.

Stereotypic movements can be induced or exacerbated by a number of sympathomimetic pharmacological agents (e.g., amphetamine, cocaine). Similarly, both stereotypic movements and tics occur in children taking sympathomimetics (e.g., methylphenidate [Ritalin], dextroamphetamine [Dexedrine], pemoline [Cylert]). These movements generally disappear or diminish when the drug is withdrawn. Recent studies have also suggested that these behaviors have a rhythmic component.

Diagnosis and Clinical Features Although stereotypic movements may take a wide variety of forms, the most commonly observed forms include nail biting and onychotillomania (nail or cuticle picking), nose picking, hair pulling, head banging, head rolling, skin picking, poking or picking at other bodily orifices, bruxism, and breath holding. The behavior is repetitive and volitional. In younger children it may be more obvious on clinical examination, since they have less desire to suppress it; in older children it is more likely to be disclosed by a parent in the psychiatric history. In primary care settings, the diagnosis may be suspected when there is evidence of tissue trauma or damage or other physical signs such as anemia from chronic blood loss due to a self-destructive injury in extreme cases. No biological or physiological markers for the disorder are known, and thus no laboratory tests. Perhaps the most challenging aspect of the differential diagnosis is determining whether the movements are simply a part of another underlying disorder such as mental retardation, pervasive developmental disorder not otherwise specified, obsessive-compulsive disorder, or an underlying tic or neurological movement disorder. The DSM-IV diagnostic criteria for stereotypic movement disorder are listed in Table 44.2-1. Table 44.2-2 presents the ICD-10 diagnostic criteria for stereotyped movement disorders.



A. Repetitive, seemingly driven, and nonfunctional motor behavior (e.g., hand shaking or waving, body rocking, head banging, mouthing of objects, self-biting, picking at skin or bodily orifices, hitting own body).
B. The behavior markedly interferes with normal activities or results in self-inflicted bodily injury that requires medical treatment (or would result in an injury if preventive measures were not used).
C. If mental retardation is present, the stereotypic or self-injurious behavior is of sufficient severity to become a focus of treatment.
D. The behavior is not better accounted for by a compulsion (as in obsessive-compulsive disorder), a tic (as in tic disorder), a stereotypy that is part of a pervasive developmental disorder, or hair pulling (as in trichotillomania).
E. The behavior is not due to the direct physiological effects of a substance or a general medical condition.
F. The behavior persists for 4 weeks or longer.

Specify if:

With self-injurious behavior: if the behavior results in bodily damage that requires specific treatment (or that would result in bodily damage if protective measures were not used).

Table 44.2-1 DSM-IV Diagnostic Criteria for Stereotypic Movement Disorder

A. The child exhibits stereotyped movements to an extent that either causes physical injury or markedly interferes with normal activities.
B. Duration of the disorder is at least 1 month.
C. The child exhibits no other mental or behavioral disorder in the ICD-10 classification (other than mental retardation).

Table 44.2-2 ICD-10 Diagnostic Criteria for Stereotyped Movement Disorders

A white, 4½-year-old boy was brought to the clinic by his parents because of their concern about his persistent nail and cuticle biting that resulted in bleeding and tissue damage and his picking at scabs and moles on various parts of his body led to poor healing and recurrent infection. Parents described the behavior as ongoing for the past 4 to 6 months. They had hoped it was simply a bad habit and that the child would spontaneously "grow out of it." A comprehensive mental health evaluation revealed that in addition to the chief complaint the child also suffered from mild delays in expressive language as well as delays in gross motor control. On examination, the nails had been bitten down to the quick, and several cuticles appeared scabbed. During the 45-minute play observation, the child was noted to pick at moles and scales on his arms and upper body during his play. No other associated psychiatric or medical symptoms were noted. Family psychiatric history was negative for any major psychiatric disorder; however the mother was both a smoker and a nail biter herself. The diagnosis of stereotypic movement disorder was made, and a behavioral intervention program for the nail and cuticle biting was implemented. The child was also referred for a speech and language and occupational therapy evaluation. Given the tissue damage that had resulted from picking of moles, the primary care physician decided (in consultation with the child psychiatrist) to have the moles removed. The need to use large, impenetrable bandages to facilitate postsurgical healing was emphasized, and the procedure was successful.

Precautions Given the opportunity for early classification that the DSM-IV disorder of infancy and early childhood not otherwise specified category provides and the inherent lack of formal restrictions in using this classification, the responsibility to exercise caution in its application to very young children rests in the hands of the individual clinician. This is particularly important given the potentially detrimental social effects of applying psychiatric diagnoses or classifications to children. The infant-preschool clinician faces the additional unique challenge of distinguishing clinically significant phenomena from normal developmental vicissitudes known to appear so commonly in early childhood. Magda Campbell and others have expressed concern about the difficulty in distinguishing such developmental problems from clinically significant psychopathology in very young children. These investigators emphasize the importance of attention to symptom severity and the co-occurrence of other symptoms in determining clinical significance. A tangible example of the ambiguity in distinguishing developmental and clinical problems is seen when evaluating defiance or oppositionality in the preschool child. Here, the normative developmental move toward autonomy may alone produce these difficult behaviors. In these situations, the clinician must judge both the appropriateness of the giver's perceptions of and tolerance for the child's behaviors and the degree to which the behaviors deviate from developmental norms and occur in conjunction with other symptoms. The availability of the not otherwise specified category, with its inherent lack of constraints, makes this distinction particularly important to prevent over diagnosis in infants and preschoolers with only normative, transient developmental problems.

Course and Prognosis Stereotypic movements that occur in association with other psychiatric or neurological disorders generally follow the course of the core disorder. For example, stereotypic movements associated with a pervasive developmental disorder not otherwise specified are generally more severe when there is greater impairment from the underlying disorder and less severe when the underlying disorder is more controlled. Stereotypic movement disorder can occur at any age, but prevalence peaks in adolescence and declines in older age groups. Although the specific behaviors may change over time, the underlying disorder is generally quite stable.

Treatment No specific treatment has been shown to be effective for stereotypic movement disorder in general; however, a small number of double-blind studies have investigated the efficacy of pharmacological treatments for specific behaviors. For example, investigations have suggested the superiority of clomipramine (Anafranil) over desipramine (Norpramin) for severe nail biting. Although a wide variety of pharmacological agents have been used for stereotyped movements, with varying success, the standard neurolepics are perhaps most frequently used and demonstrate most clinical benefit. Both haloperidol (Haldol) and chlorpromazine (Thorazine) have demonstrated efficacy in placebo-controlled studies of patients with stereotyped movements associated with mental retardation and autistic disorder.

Behavioral modification techniques have been perhaps the most widely used interventions for the treatment of stereotypic movements. These techniques, which include both positive and negative reinforcement, have shown some success in diminishing the severity and frequency of the movements and in some cases extinguishing the disorder.

DISORDERS OF INFANCY AND EARLY CHILDHOOD NOT OTHERWISE SPECIFIED

The ongoing evolution of the DSM and International Classification of Diseases (ICD) is based on the recognized need to modify diagnostic criteria and add new diagnostic categories with advances in the understanding of psychiatric disorders. In keeping with this DSM-IV has a category disorder of infancy, childhood, or adolescence not otherwise specified (Table 44.2-3) so that clinically significant disturbances in children that do not meet criteria for specific, established disorders can be coded on Axis I. This is a residual category, intended for use only when the clinical characteristics cannot be adequately described by a more specific, established diagnosis.

This category is a residual category for disorders with onset in infancy, childhood, or adolescence that do not meet criteria for any specific disorder in the classification.

Reprinted with permission from American Psychiatric Association: *Diagnostic and Statistical Manual of Mental Disorder*, ed 4. © American Psychiatric Association, Washington, DC, 1994.

Table 44.2-3 DSM-IV Diagnostic Criteria for Disorder of Infancy, Childhood, or Adolescence Not Otherwise Specified

The ICD-10 included two residual categories for childhood mental disorders: (1) other specified behavioral and emotional disorders with onset usually occurring in childhood and adolescence, and (2) unspecified behavioral and emotional disorders with onset usually occurring in childhood and adolescence. However, inclusion of these categories implies that there are likely to be clinical disorders or variations of disorders that are not yet specifically described in the DSM-IV. These categories are intended for use throughout childhood. Unfortunately, they may be most frequently used by clinicians working with the youngest group of children, infants and preschoolers, for whom DSM-IV and ICD-10 include very few specific diagnostic categories. The greater need for not-otherwise-specified diagnoses in the youngest portion of clinical infant and preschool samples, to whom a specific DSM-IV diagnosis could not be applied, has been described by infant-preschool clinicians.

A NEW CLASSIFICATION FOR INFANTS AND PRESCHOOLERS

Over the last decade, advances in research on the socioemotional development and developmental psychopathology of infants and preschoolers and the clinical

application of these findings have contributed increased recognition and treatment of very early onset behavioral and emotional disturbances. This progress along with public health emphasis on early and potentially preventive intervention has catalyzed the growth of infant and preschool mental health into an increasingly practiced clinical subspecialty of child psychiatry. Although infant and preschool patients and their caregivers are seen in general child psychiatric clinics, increasing numbers of infant/preschool specialty clinics have been established across the nation. This led to the establishment of specific practice parameters for the clinical assessment of this age group. Along with this increase in clinical attention has come progress in developing a classification system specifically for these very young patients. The *Diagnostic Classification of Mental Health and Developmental Disorders of Infancy and Early Childhood* (DC:0-3), developed by a task force of the ZERO TO THREE/National Center for Clinical Infant Programs (NCCIP), represents the first diagnostic manual designed for children from birth through age 4. The system developed from the concern of a large group of experienced infant-preschool clinicians who agreed that DSM-IV and ICD-10 systems did not provide adequate descriptive criteria for this age group.

The DC:0-3 outlines a number of new diagnostic categories and developmentally modified DSM-IV categories. The manual is modeled after, but not identical to, the DSM-IV multiaxial system (Table 44.2-4). It is intended to augment and complement DSM-IV and ICD-10, not replace them. As in DSM-IV, clinical disorders ("primary diagnoses") are listed on Axis I. Physical, neurological, developmental, and mental disorders or conditions described in other classification systems (e.g., DSM-IV, ICD) are listed on Axis III. However, when a DSM-IV or ICD diagnosis is determined to best describe the clinical picture, these standard diagnoses are listed on Axis I. Also as in the DSM-IV, Axis IV is used to rate psychosocial stressors determined to affect the mental or developmental condition. Axis V rates the functional emotional developmental level. Given the developmental context of DC:0-3, this refers to the child's capacity for organizing "affective, interactive, communicative, cognitive, motor and sensory experience." In this sense it is similar to the DSM-IV Global Assessment of Functioning (GAF) Scale but more specific to emotional competence.

Axis I:	Primary classification
Axis II:	Relationship classification
Axis III:	Physical, neurological, developmental, and mental health disorders or conditions (described in other classification systems)
Axis IV:	Psychosocial stress
Axis V:	Functional emotional developmental level

Table 44.2-4 DC:0-3 Classification System

Relationship Classifications Unique to the DC:0-3 axial system and perhaps its most important contribution is the use of Axis II to describe classify relationships. Given the central importance of the primary caretaking relationship to the emotional development and mental status of the very young child, this axis is used in all cases to describe the quality of this primary relationship and (when indicated) to designate a relationship disorder. The Parent-Infant Relationship Global Assessment Scale (PIR-GAS) was developed to rate the quality of the relationship. The PIR-GAS ranges from 90 (well adapted) to 10 (grossly impaired). The clinical diagnosis of relationship disorders is made only when scores are below 39, while scores between 40 and 79 constitute "trend" or "tendency" levels of impairment similar to "trait" level personality disorders in DSM-IV Axis II. The PIR-GAS also constitutes a variant of the GAF Scale but is specific to the primary relationship rather than the individual. A number of specific relationship disorders described in the DC: 0-3 are outlined in Table 44.2-5.

901.	Overinvolved relationship
902.	Underinvolved relationship
903.	Anxious/tense relationship
904.	Angry-hostile relationship
905.	Mixed relationship
906.	Abusive relationships

Table 44.2-5 DC:0-3 Relationship Disorder Classifications

The use of Axis II for relationship disorders in infants and toddlers reflects the central importance of early caregiving relationships and environments as primary factors in the early manifestation of psychopathology. This theoretical model has been supported by both developmental child research and mental health research over the last two decades. At very young ages and in some circumstances (e.g., parental abuse or extreme neglect) the primary caregiving relationship is thought to be the unit of psychopathology rather than the individual child, particularly with children under 3 years of age, who remain fundamentally dependent on, and as yet undifferentiated from, their caregivers. Thus, early child assessment should involve assessing the child in interaction with the primary caregivers independent of the classification system used. Particular attention has been paid to this issue in the clinical assessment of attachment.

Regulatory Disorders While a comprehensive review of all diagnoses included in the DC:0-3 is beyond the scope of this chapter, several novel and developmentally modified diagnostic categories exist. The DC:0-3 regulatory disorders, specified by Stanley Greenspan in 1992, first described by Klaus Minde and Regina Minde in 1986 as "disorders of behavioral organization," have no corollary in DSM-IV. They represent the first attempt to categorize severe difficulties in sensorimotor organization or self-regulation in infants and preschoolers. Historically, children displaying these symptoms were likely described as extremely fussy or difficult temperamentally. An etiological basis for regulatory disorders is inherent in its definition: hyperreactivity or hyporeactivity to sensory stimuli occurring as a result of a core impairment in sensory motor processing and integration. Behavioral difficulties and problems in adaptation must be coupled with evidence of sensorimotor processing difficulties for the diagnosis to be made. Some physiological differences (i.e., changes in vagal tone) were noted in groups of children meeting criteria for the disorder, and evidence of later difficulty in school adaptation was found among a small group of children followed up after 4 years.

A 3-year and 2-month-old girl was brought to the infant-preschool clinic by her mother who was concerned about her extreme and chronic irritability, fussiness, and difficulty adapting to environmental change. She was described as a very difficult infant, the product of an uncomplicated full-term pregnancy, who was slow to develop a stable eating and sleeping cycle and very difficult to soothe. The mother was finding it increasingly difficult to leave her with alternate caregivers (i.e., babysitters) and was becoming concerned about her ability to make the transition to preschool. Further probing revealed that the child was extremely rigid in a number of areas that the family had unwittingly complied with. The child had a very small repertoire of food that she would eat, which appeared to be largely limited by texture. In addition, she refused to eat anything that was either too warm or too cold; all foods had to be at room temperature. The child was also extremely sensitive to tactile stimuli, tolerating only cotton fabrics and preferring not to wear clothing at all. She often comforted herself by stroking a fur blanket, which she seemed to find very soothing. Strikingly, she was drawn to articles of clothing of only a few colors. Family vacations were nearly impossible as the child would become extremely irritable and have tantrums when faced with the need to sleep in an unfamiliar bed, on unfamiliar sheets. She openly expressed her discomfort with the unusual smell of the new setting and was unable to enjoy herself, appearing distressed and whining throughout the trip. The child's verbal skills were within normal limits for her chronological age, and no core impairment in interpersonal relatedness was noted after a multiple session dyadic evaluation with both parents, at which time the diagnosis of a regulatory disorder was made. Previous clinicians had suggested the diagnosis of Asperger's disorder; however, her parents (who were quite savvy consumers) felt that she was simply a child with an extremely difficult temperament.

Mixed Disorder of Emotional Expressiveness In the area of affective disorders, the DC:0-3 includes another novel diagnosis, mixed disorder of emotional expressiveness. This disorder, unlike any mood disorder currently described in DSM-IV or ICD systems, identifies children who have an “ongoing difficulty expressing developmentally appropriate emotions.” This may be characterized either by the absence of the capacity to express discrete emotional states (e.g., shame, excitement, empathy) that would be expected for chronological age or by impairments in affect as evidenced by excessive inhibition or intensity of emotional reactivity. Although this category is based largely on clinical observations, it appears to be consistent with recent research findings on emotional regulation and affective development in infants and toddlers. This research supports the notion of affective development in infancy and early childhood and has helped identify and operationalize its multiple components. Normative developmental studies suggest that a core group of discrete emotions are present from birth and that others develop along a predictable trajectory. The development of both affective range and repertoire is thought to be a function of both constitutional and environmental factors. Although this new diagnostic category remains controversial (some forms could represent other nonmood disorders already included in the DSM-IV), it may be helpful to describe a subgroup of children who are not otherwise specified in DSM-IV.

In addition to novel diagnostic categories, the DC:0-3 also offers a reorganization that implicitly reconceptualizes some DSM-IV pervasive developmental disorders. DSM-IV includes autistic disorder, childhood disintegrative disorder, Asperger's disorder, Rett's disorder, and pervasive developmental disorder not otherwise specified in the broad category of pervasive developmental disorders. This categorization implies that these disorders are related, characterized by a core impairment in interpersonal relatedness, and associated with multiple developmental delays.

Disorders of Relating and Communicating In contrast to the DSM-IV organization, the DC:0-3 proposes a new general category of disorders of relating and communicating, which contains a new disorder, the multi-system developmental disorder. Multi-system developmental disorder can be described as a milder manifestation of traditional pervasive developmental disorder but is thought to result from a core impairment in sensory and motor processing that gives rise to deficits in social development. This new organization reflects the hypothesis that infants and preschoolers with milder impairments, who demonstrate a stronger capacity for interpersonal relatedness with primary caregivers, do not have a primary deficit in relatedness characteristic of autistic disorder. Rather, these more mildly affected children, who could also be classified in the currently very broad DSM-IV category pervasive developmental disorder not otherwise specified, are thought to have a primary deficit in sensorimotor processing and secondary impairments in relatedness that are not fixed and permanent but responsive to early therapeutic interventions. This new category is controversial as recent studies have demonstrated that early intervention in pervasive developmental disorders not otherwise specified also resulted in significant improvements. This new category and reorganization reflects another use of the DC:0-3, a template for scientific investigations of diagnostic classifications and treatment strategies in very young children.

Traumatic Stress Disorder The DC:0-3 also modifies criteria in established DSM-IV diagnoses to capture more age-appropriate manifestations. DC:0-3 traumatic stress disorder is a prime example of this. A modification of the DSM-IV posttraumatic stress disorder, the diagnostic criteria include several unique developmental manifestations of trauma such as posttraumatic play, interference or regression in development (e.g., temporary loss of previously attained developmental skills), and the onset of fears that were not present before the traumatic event. Outlining these age-adjusted criteria provides clear guidelines in lieu of the previous need to extrapolate from the more adult-based DSM-IV criteria. Support for this presumed need to modify the DSM-IV posttraumatic stress disorder criteria for infants and toddlers comes from empirical data showing that traumatized children under 48 months demonstrate these developmentally unique manifestations not included in the DSM-IV criteria.

Like a number of remaining unvalidated diagnoses in the DSM-IV, the current version of the DC:0-3 is based on the collective clinical observations of expert clinicians who treat infants and preschoolers. The manual provides an initial framework for further specification, definition, and controlled investigations into the validity of specific diagnostic criteria for infants and preschoolers. The DC:0-3 is currently in use in a number of infant and preschool centers worldwide, and preliminary testing in clinical samples has demonstrated its fundamental descriptive utility.

SUGGESTED CROSS-REFERENCES

Chapter 37 covers pervasive developmental disorders, and Chapter 34 covers mental retardation. Tic disorders are discussed in Chapter 42.

CHAPTER 45. MOOD DISORDERS AND SUICIDE IN CHILDREN AND ADOLESCENTS

CAROLY S. PATAKI, M.D.

Mood disorders in children and adolescents and their treatments have received increasing attention and clinical investigation over the last few decades. The core features of mood disorders are essentially the same across the life span. Developmental level, however, appears to influence the expression of certain mood symptoms with greater frequency than others within the framework of depressive disorders. For example, pervasive anhedonia and significant psychomotor retardation, typical of adults with depression, are not often observed as dramatically in children with major depressive disorder. Auditory hallucinations and somatic complaints appear with greater frequency among prepubertal children with major depressive disorder than among adolescents and adults, whereas delusions and psychomotor retardation are endorsed more often by depressed adolescents. Some depressive symptoms including suicidal ideation are equally prevalent at all ages. The manner of communicating depressive symptomatology such as irritability, sadness, and negative attributions is always subject to the child's developmental level.

Reports of suicide by children and adolescents have increased over the last decade. Suicide is the fourth leading cause of death in children between the ages of 10 and 15 years and the third leading cause of death among adolescents and young adults 15 to 25 years. Although the rate of death is significantly lower in children and younger adolescents than in older adolescents, the risk factors and methods of suicide need to be examined for each group. Recent findings indicate that psychiatric disorders have relatively less association with suicidal behavior among children and younger adolescents and that family conflict and peer difficulties may be more significant in the expression of suicidal behavior in this age group. Among older adolescents, although interpersonal conflict and loss are often reported to precipitate suicidal behavior, mood disorders and other psychiatric disturbance appear to be more important in the emergence of suicidal behavior. The task ahead is to identify both the psychosocial and the psychiatric risk factors to develop prevention strategies for suicidal behavior among these young persons.

DEFINITION

Major mood disorders comprised mood episodes including major depressive episode, manic episode, mixed episode, and hypomanic episode. Mood episodes, according to the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV), are not coded as separate entities, but they serve as the building blocks for many mood disorder diagnoses. The mood disorders include the depressive disorders (major depressive disorder, dysthymic disorder, and depressive disorder not otherwise specified); the bipolar disorders (bipolar I disorder, bipolar II disorder, cyclothymic disorder, and bipolar disorder not otherwise specified), mood disorder due to a medical condition, substance-induced mood disorder, and mood disorder not otherwise specified.

A *major depressive episode* consists of at least five depressive symptoms that have been present for at least 2 weeks and represent a change from previous functioning. Either a depressed mood or a loss of interest or pleasure must be present. In children or adolescents, an irritable mood may suffice for the depressed mood criterion. Significant weight loss or marked change in appetite may be substituted by a failure to make expected weight gains in children or adolescents. Insomnia or hyposomnia, psychomotor agitation or retardation, loss of energy, feelings of worthlessness or excessive guilt are mood symptoms for children and adolescents as well as for adults. Diminished ability to concentrate and recurrent thoughts of death are also depressive symptoms that apply to all ages. The symptoms must cause significant distress or functional impairment.

A *manic episode* consists of a distinct period of persistently elevated, expansive, or irritable mood for at least 1 week or of any duration if hospitalization is necessary. During the mood disturbance at least three additional symptoms (or four if the mood is only irritable) must emerge. These include grandiose thinking or inflated selfesteem, decreased need for sleep, pressured speech or increased verbalizations, racing thoughts or flight of ideas, distractibility, increase in goal-directed activities, or ideation and hopelessness, which seem to be equally likely at any age. The sepcific manner of excessive involvement in pleasurable activities is one of recklessness and thereby may lead to dire consequences. No modifiactions of manic episodes apply to children or adolescents according to DSM-IV.

A *mixed episode* consists of a combination of all the criteria for both a manic episode and a major depressive episode, except that they need only last for 1 week, not 2 weeks. The mood disturbance must be severe enough to cause functional impairment. The modifications within the major depressive episode for children and adolescents also apply in the mixed episode.

A *hypomanic episode* is defined in the DSM-IV as a distinct period of persistently elevated, expansive, or irritable mood lasting at least 4 days. During the mood disturbance, at least three symptoms of mood disturbance must be present or four symptoms if the mood change is only irritability. These symptoms include grandiosity, decreased need for sleep, talkativeness, flight of ideas or racing thoughts, distractibility, increased goal-directed activity, and excessive involvement in pleasurable activities. The episode is associated with an unequivocal change in functioning, but it is not severe enough to cause a marked deterioration in either social or occupational functioning. Hospitalization is not required, and there are no psychotic features. There are no modifications in the criteria for children or adolescents.

According to DSM-IV *dysthymic disorder* is defined by a depressed mood for most of the day, for most days, for a period of at least 2 years. The duration criterion is modified to 1 year for children or adolescents, and the quality of the mood may be described as irritable rather than depressed for youths. At least two additional depressive symptoms must be present in dysthymic disorder. These include change in appetite, insomnia or hyposomnia, diminished energy, low self-esteem, poor concentration or difficulty making decisions, or hopelessness. To meet the criteria for dysthymic disorder, the mood symptoms cannot be absent for more than 2 months.

Depressive disorder not otherwise specified includes disorders with depressive features that do not meet the criteria for other depressive disorders or adjustment disorders with disturbances of mood.

Bipolar I disorder requires a manic or mixed manic episode or a history of these episodes. The initial manic episode may be specified as mixed; that is, the criteria for major depression are also met. Bipolar II disorder is defined in the DSM-IV as recurrent major depressive episodes with hypomanic episodes. The criteria for bipolar II disorder require the presence or history of one or more major depressive episodes as well as the presence or history of at least one hypomanic episode. In bipolar II disorder, there has never been a manic or a mixed manic episode. The symptoms must cause functional impairment.

Cyclothymic disorder consists of at least 2 years with numerous periods of hypomanic symptoms and numerous periods with depressive symptoms that do not meet the criteria for a major depressive episode. In children and adolescents, the duration must be at least 1 year instead of 2 years. During the duration of symptoms (1 year for children and adolescents), symptoms cannot be absent for more than 2 months at a time. There cannot be a major depressive episode, a manic episode, or a mixed manic episode in the first year of the disturbance. After the initial year of symptoms, a manic or mixed episode may be superimposed in which case both disorders may be diagnosed.

Bipolar disorder not otherwise specified includes disorders with bipolar features that do not meet the criteria for the above-mentioned bipolar illnesses.

HISTORY

Mood disorders were recognized in ancient times. In the late 1800s and early 1900s Emil Kraepelin distinguished the syndromes of depression and mania from the deteriorating course of schizophrenic illness in adult populations. Although there was a rare report of a child or adolescent with serious mood alteration in the

literature, for the most part until recently, enduring mood disorders were not believed to occur in childhood.

One exception to this notion was the accepted syndrome of “anaclitic depression,” described by Rene Spitz in the 1940s among infants under 1 year of age who were separated from their primary attachment figure and placed in institutional settings. Spitz described a pervasive deterioration in the emotional and physical functioning of infants who experienced minimal interaction with the primary caregiver. The syndrome that developed over a period of months was characterized by expressed discontent and sadness in the deprived infants, which progressed to more overt distress, and then evolved into a withdrawn, apathetic, and dejected state. After 5 months of continued deprivation of interaction with an attachment figure, the infants failed to thrive and developed loss of appetite, weight loss, and diminished emotional reactivity. He called this syndrome hospitalism. Although this syndrome in infants had many similarities with depressive disorders among adults, the links between mood disorder in adults and during childhood remained dormant for several more decades.

The interpretations of mood disturbance in children and adolescents were constrained by the notion that children were developmentally too immature to mount true depressive responses. For some, this was supported by the belief that depression developed in a process requiring a harsh superego and the inward directing of rage, a chronological and developmental psychological process that could not have been accomplished by young children. Others held that since children were unable to engage in the adult psychological mechanisms generating depression, behavioral disturbances commonly seen among some troubled children must represent “masked depression,” that is, the childhood equivalents of depression. However, when children were assessed directly and standardized criteria for mood disorders evolved, it became evident that children of all ages met criteria for enduring and severe mood disorders.

The issue of developmental modifications of criteria for mood disorders in children and adolescents is still quite controversial. Early age of onset of a mood disorder introduces questions about whether this predicts a more severe, chronic, or recurrent illness and whether it is distinct from the adult form. Additionally, an illness that begins in childhood may differ from one beginning in adulthood with respect to efficacy of treatments and the subsequent pathophysiology of the disorder itself. Current research efforts are aimed at elucidating the relation of childhood mood disorders with those in adulthood, identifying genetic markers, and clinical treatment trials with pharmacological agents and psychosocial interventions.

COMPARATIVE NOSOLOGY

Although there were a number of alterations in the criteria for major depression and dysthymia between the third edition of the DSM (DSM-III) and the revised DSM-III (DSM-III-R), there were relatively few changes between the DSM-III-R and the DSM-IV. DSM-IV like DSM-III-R requires impairment for a diagnosis of major depressive disorder. There is one modification for youth in the DSM-IV for major depression: the criterion of depressed mood may be replaced by *irritable mood*, and in the dysthymic disorder criteria, the 2-years duration used for adults may be modified to 1 year for youths. In DSM-IV, the criteria for mania returned from a distinct period in DSM-III-R to a distinct period of at least a week or of any duration if hospitalization is necessary. Consistent with all of the diagnostic criteria in DSM-IV, there must be some impairment in social or occupational functioning. In DSM-IV, the diagnostic criteria for hypomania include a duration of 4 days and the same specific menu of symptoms given for a manic episode. In contrast to a manic episode, in which the symptoms must be severe enough to markedly impair occupational or social functioning, a hypomanic episode is not severe enough to cause marked impairment but must be associated with some unequivocal change in functioning that is uncharacteristic of the person when not symptomatic.

The 10th revision of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) divides depressive disorders into mild, moderate, and severe categories for single episodes of depression and for recurrent depression. There are no symptom modifications within the ICD-10 criteria for depression in children or adolescents. According to ICD-10, mild depression requires fewer symptoms than moderate or severe depression. The symptom of ‘loss of confidence and self-esteem,' listed as part of the criteria for depressive disorder in ICD-10, is not part of the criteria for major depressive disorder in the DSM-IV, but low self-esteem is listed as a symptom of dysthymic disorder in DSM-IV. ICD-10 does not list a category of depression that is exactly analogous to dysthymic disorder in so far as no depressive disorder requires persisting symptoms for 2 years (or 1 year for youths). ICD-10 does contain one other depressive disorder, depressive conduct disorder, within the broader diagnostic category of mixed disorders of conduct and emotions. Depressive conduct disorder (not contained within DSM-IV) may be particularly relevant to children and adolescents who often exhibit both a conduct disorder and a depressive disorder concurrently. To meet the ICD-10 criteria for depressive conduct disorder, the full criteria for both a depressive disorder and conduct disorder must be met. The most similar combined conduct disturbance and mood disturbance listed within DSM-IV is the category of adjustment disorders. Adjustment disorder with mixed disturbance of emotions and conduct in DSM-IV differs significantly from depressive conduct disorder in ICD-10, insofar as all adjustment disorders in DSM-IV must occur in response to an identifiable stressor within 3 months of the disorder. Furthermore, the disturbance must not meet the full criteria of another disorder such as a depressive disorder or a conduct disorder.

ICD-10 criteria for mania, hypomania, and bipolar I and bipolar II disorder are equivalent to the criteria in DSM-IV.

EPIDEMIOLOGY

The epidemiology of mood disorders and suicide among children and adolescents is complicated by their increasing rates with increasing age. Also, over the last few decades, the criteria for diagnosing the disorders have changed. Finally, the reported incidence of mood disorders among youths over the last few decades has consistently increased, and the age of onset has decreased. This phenomenon has been called the “cohort effect.” It is most evident in studies of mild-to-moderate depression, but it has not been noted for dysthymic disorder. More-severe melancholic depressions are less affected by the cohort effect. Although the mechanism of the cohort effect is not clear, genetic anticipation, in which a genetic disorder tends to worsen in successive generations, has been suggested to explain it.

Prevalence rates for mood disorders and suicide are often reported separately for prepubertal children and for adolescents. Rates of completed suicide are separated by gender as well as age. Large differences in sampling and measurement instruments make it not surprising that a range of prevalence rates were found by different studies. There is also some variation in rates of depressive illness depending on who the informant was. In most cases, patients reported higher rates of disorder than their parents. See Table 45-1 for prevalence rates.

Major depression	
Preschoolers	0.3%
Children	0.4–3%
Adolescents	0.4–6.4%
Dysthymic disorder	
Children	0.6–1.7%
Adolescents	1.6–8%
Bipolar I disorder	
Children	0.2–0.4%
Adolescents	1%
Attempted suicide	
Children	1%
Adolescents	1.7–5.9%
Completed suicide	
5–9-year-old boys	0.04/100,000
5–9-year-old girls	0
10–14-year-old boys	2.4/100,000
10–14-year-old girls	0.96/100,000
15–19-year-old males	18.25/100,000
15–19-year-old females	3.48/100,000

Table 45-1 Prevalence (Point or 1-year)

The lifetime prevalence rate of major depressive disorder in adolescents is estimated to fall between 15 and 20 percent, similar to that in adult populations. Epidemiological studies of mood disorders in children or adolescents support the notion that pure depression is rare among youths. Between 40 and 70 percent of children and adolescents have comorbid psychiatric disorders, and up to 50 percent have two or more comorbid disorders. Anxiety disorders and dysthymic disorder tend to be the most common comorbid diagnoses, major depressive disorder accompanying from 30 to 80 percent of the time. Disruptive behavior disorders co-occur with major depressive disorder 10 to 80 percent of the time, and substance abuse co-occurs 20 to 30 percent. Major depression often follows the other psychiatric disorder, although in general, substance use disorders occur after the onset of major depression. Approximately 70 percent of patients with early-onset dysthymic disorder have a secondary major depressive episode. A number of factors were found to be associated with depressive disorders among youths, including age. In most studies, adolescents had significantly more depressive disorders than children under 12 years of age. In studies comparing early and late adolescents, the older groups also reported higher rates of depressive disorders. Studies have found depression to be significantly associated with the patient's report of family dysfunction. Low self-esteem, not a core feature of major depressive disorder in DSM-IV (although a core feature of dysthymic disorders in DSM-IV), was associated with major depressive disorder in a number of studies. Stressful life events were associated with depression in at least one study. Results with respect to gender were

inconsistent; in children, depressive disorders were either equal in males and females or higher in males and among adolescents, they were either equal or higher in females. Race, poor school performance, and socioeconomic status were inconsistently associated with depressive disorders among youths.

The most frequent age of onset of bipolar I disorder (i.e., an episode of mania) is between 20 and 30 years, followed by 15 to 19 years. Mixed manic and depressed states in youth are often confounded by other diagnostic entities including attention-deficit/hyperactivity disorder and conduct disorder mixed with depression. Among adolescents, bipolar disorder appears to be equally distributed by gender, and 20 to 40 percent of adolescents with major depressive disorder develop a manic episode, either alone or concurrent with depression, within 5 years after the onset of the depression. In young adults with depression, development of hypomania has been associated with early-onset depression, atypical depression, seasonal affective disorder, protracted depressive episodes, mood liability, substance abuse, and significant psychosocial problems.

There have been reports of particular family pedigrees, for example, certain Old Order Amish families, in which bipolar I and II disorders were extremely prevalent. In these family pedigrees the prevalence of bipolar I and bipolar II disorder in family members 15 years or older was 46 percent.

Suicide in children and young adolescents is extremely rare in the United States and worldwide. Among 15- to 19-year-olds, suicide rates have quadrupled over the last four decades. The suicide rate for adolescents represents approximately 12 percent of the total mortality in this age group. Lifetime prevalence rates of suicide attempts among adolescents are reported to range from 3.0 to 7.1 percent. Male suicide rates in this age group are approximately 5 times higher than female rates. Suicide attempts are reported to occur approximately 3 times more often in female adolescents than in males in community samples. Protective factors for children and young adolescents may include less access to lethal means of suicide (firearms) and less realistic plans for suicide. Additional factors increasing the suicide risk, including substance use and depressive disorders, are more likely to be present in older adolescents than in children or younger adolescents. In the United States, the United Kingdom, and Europe, suicide is more common among males at every age, except the infrequent young childhood death by suicide. In Asia and some Latin American countries, suicide rates are equally distributed by gender or are higher in female adults. Ethnic and cultural factors also play a role in suicidal behavior. In the United States, suicide rates are more common among whites than among other ethnic groups, with the exception of certain Native American groups.

Suicide method is the most significant determinant of whether the attempt results in death. In the United States firearms and hanging are the two most common methods of suicide in males. Female adolescents who complete suicide are more likely to take a lethal ingestion or jump from a height. Asphyxiation by automobile fumes from a parked car (often in a garage) occurs in suburban areas, while jumping from a height is more common in urban areas that have tall buildings.

Suicide imitation and contagion, particular features of adolescent and young adult suicides, influence the suicide rate on a short-term basis but not on a long-term basis. Suicidal behavior increases in adolescents following exposure to well-publicized news stories of suicide or a film involving a teen suicide. The baseline suicide rate may increase for several weeks after such a dramatization. Suicide clusters also occur among adolescents within a community after a publicized suicide of a young person. The cluster consists of a larger-than-expected number of suicides taking place in a short period of time. The deaths are not more likely to be adolescents who were close friends or well known to the initial suicide victim. The adolescents who suicide as part of a cluster are those vulnerable to suicidal behavior, often with past histories of suicide attempts.

The great majority of suicide attempts among adolescents have little lethal potential. While use of a lethal suicide means (firearms, hanging) accounts for the outcome in most cases, severity of a depressive disorder, substance use, and persistent suicidal intent predict future lethality. Many adolescents who have survived a suicide attempt deny persistent suicidal intentions. In addition to mood disorders and their comorbid psychiatric disorders, additional predisposing factors for suicidality among adolescents include a family history of suicidal behavior or mood disorder, exposure to family violence, impulsivity, and availability of lethal methods.

ETIOLOGY

Genetic Factors Evidence from offspring studies, adoption studies, and studies of twins reared together and apart indicates that major depressive disorder and bipolar disorder aggregate in families. So far no twin studies have examined rates of depression among adolescents. In adult twin studies, rates of major depression range from 13 to 28 percent among dizygotic twins and from 53 to 69 percent among monozygotic twins. In one twin study in Denmark, concordance for bipolar illness was 19 percent in dizygotic twins and 69 percent in monozygotic twins.

Studies of rates of mood disorders in the offspring of adults with these disorders show at least a threefold increased risk of developing a mood disorder compared with the general population. The lifetime risk of depression in children of depressed parents has been estimated to range from 15 to 45 percent. Depression is also increased in offspring when both parents have depression. Significantly higher rates of depression emerge in adoptees who are offspring of a depressed parent and are reared outside the biological home. Relatives of adoptees with mood disorder have an eightfold increase in the rate of depression over nondepressed adopted controls. Children of depressed parents are also at higher risk for other psychiatric disorders, such as anxiety and disruptive behavior disorders. Other first-degree relatives of adults with mood disorder also show significantly increased risk of mood disorders. Genetic factors have been estimated to account for approximately 50 percent of the variance in the transmission of mood disorders in adult studies, with the other 50 percent attributable to nonshared familial and extrafamilial environmental factors. Offspring of bipolar I parents tend to appear well adjusted in early life, but they have significantly higher rates of bipolar I and bipolar II disorder.

An early age of onset of major depressive disorder, dysthymic disorder, or bipolar disorders predicts a higher family risk of mood disorders among first-degree relatives of the proband. Recent studies of early-onset depression indicate a higher risk of both depressive and bipolar disorders in family members and potentially the earlier onset of illness in these relatives. Lifetime prevalence rates for depression in first-degree relatives of depressed children and adolescents have been estimated to be from 20 to 46 percent. Adolescents with clear-cut manic episodes during adolescence who had prepubertal histories of complex psychiatric symptoms including mood disorders, attentional problems, and aggressive behavior were found to be less responsive to lithium (Eskalith) treatment and to have greater family loading for bipolar I disorder. Among genetic mechanisms considered for bipolar I disorder are preferential maternal or paternal transmission and mitochondrial inheritance (indicating maternal transmission). Studies of family members of children and adolescents with bipolar and depressive disorders have documented higher-than-expected rates of alcohol use disorders for both types of mood disorders.

There have been recent attempts to examine bipolar disorders or symptoms of bipolar disorders among children and adolescents with chromosomal disorders. These studies are preliminary and have not shown generalizability to most patients with bipolar disorder.

The ramifications of the age of onset of a mood disorder are still under investigation. Age of onset can indicate genetic heterogeneity of an illness, indicate a marker of etiology, herald a particular phenotype of the illness, or represent severity of an illness. Defining the age of onset of an illness is complicated by retrospective reporting, ascertainment bias (i.e., the ages present within the sample), and the cohort effect (i.e., an earlier onset of unipolar and bipolar illness reported over the last four decades). Various models have been proposed to explain the age delay in the emergence of mood disorders. One such model, taken from the observation that certain cancers seem to occur with greater frequency with increasing age, is termed the two-hit model. This model posits that to express a mood disorder, a gene carrier (demonstrating the “first-hit”) would need to be exposed to a second hit, thus explaining why some family members presumed to be gene carriers never manifest a mood disorder. The definition of a *hit* might include nongenetic adverse life events. On the other hand, a mood disorder in some individuals might be attributed to two noninherited hits. Thus, for bipolar disorders the age-specific incidence rises abruptly during midadolescence consistent with a model of an inherited mutation compounded by an environmental hit resulting in emergence of disorder. Since the incidence of major depressive disorder continues to increase over time, this disorder could fit a model in which one or more nongenetic hits occurring over time are responsible for the emergence of illness.

Several genetic mechanisms suggested in the literature could contribute to an age delay in the emergence of mood disorders. These include (1) triplet repeat expansion, (2) damage to mitochondrial deoxyribonucleic acid (DNA), and (3) age-specific changes in gene expression. Triplet repeat expansion is a type of mutation consisting of a repeating pattern of the same three nucleotides. The actual size of the triplet repeat expansion can influence the age of onset of a disease resulting from the mutation and the severity of the illness. This is one example of genetic anticipation, since a parent with a short expansion may exhibit a mild form of a disease, but if a longer mutation is transmitted, the offspring may exhibit a more virulent form of the disease with a younger age at onset.

Damage to mitochondrial DNA may play a role in age-dependent processes. Mitochondrial DNA is outside the cell's nucleus, but when damaged, it may exacerbate a cell's potential for dysfunction. Thus, mitochondrial damage can potentiate an already damaged cell, resulting in an earlier display of a disease process. It is not clear whether this process occurs in the emergence of mood disorders.

Age-specific changes in gene expression are related to the complex processes of transcribing genes into messenger ribonuclear acid (RNA) and then translating them into a protein product. Although all cells carry the same amount of DNA, mosaicism occurs (i.e., DNA varies qualitatively between cells). To be expressed, genes are

first transcribed into messenger RNA molecules, which undergo another process called splicing; then the spliced messenger RNA is translated into protein products. The splicing mechanism allows one messenger RNA precursor to generate different final messenger RNA molecules that will ultimately result in different protein products. Thus the DNA a cell starts with may eventually give rise to a variety of protein products. It is not well understood whether this mechanism can account for variation in the age of onset or severity of a mood disorder.

Adolescents who make suicide attempts have higher rates of psychiatric disorders including major depressive disorder, bipolar I disorder, and substance use disorders than nonsuicidal adolescents. A family history of suicide attempts is associated with suicide in adolescents, particularly when the rates are examined in second-degree relatives. Some studies have found higher rates of suicidality in the family members of suicide completers (23 to 38 percent) than in family members of suicide attempters (5 to 22 percent). In one recent study, a family history of depression was associated with an increased risk for completed suicide in adolescents, even after controlling for depression in the proband. This supports the hypothesis that both genetic and environmental contributions predispose an adolescent toward suicide. Twin studies (mainly in adults, but some in adolescents) have provided evidence of a genetic contribution to suicidal behavior. Studies of monozygotic and dizygotic twins showed concordance for suicide (both twins committed suicide vs. one twin) only in monozygotic pairs. In half of the cases, twins were concordant for the same psychiatric disorder. Another study compared 57 adopted probands who completed suicide with matched controls and found that 12 percent of biological relatives of the suicide victims had committed suicide whereas only 0.7 percent of the controls had relatives who had completed suicide. None of the adoptive relatives had completed suicide. The probands with diagnosed affective disorders had the ighest rates of biological family members who had completed suicide. Biochemical abnormalities found in suicide victims, particularly in the serotonin system (discussed below), may also imply a genetically determined vulnerability to suicide.

Cognitive Factors A number of theories have been developed to explain the relation between mood disorders, especially depression, and cognitive style. Cognitive distortions and negative attributions are commonly observed among depressed children, adolescents, and adults. Depressed children and adolescents exhibit higher levels of cognitive distortion and hopelessness and the tendency to attribute their experiences to uncontrollable external causes. How a negative cognitive style is developed is not clear; suggestions include a learned component (i.e., modeling of these styles at home or in the environment), experience with stressful unpredictable life events, and a temperamental component of perfectionistic traits that can enhance such cognitive patterns. The cognitive distortion theory, developed by Aaron Beck, hypothesizes that persons who seem to focus on negative information perpetually reinforce a negative view of about themselves, the world, and the future, and are at higher risk of becoming depressed. The distortions are negative catastrophic beliefs and overgeneralizations of negative events and beliefs. The notion of learned helplessness, first proposed by Martin Seligman describes the cognitive experience of a person who perceives unpredictable and uncontrollable events as the basis for feeling helpless and powerless. Another form of cognitive distortion observed in depressed persons is the belief that they are responsible for negative events that may be uncontrollable.

It is not well understood whether negative cognitions are more often the cause or the result of depression. A depression seems to exacerbate low self-esteem, a sense of being powerless over negative events, and negative attributions. When a depression resolves, persistent low self-esteem may linger as a scar and predispose a child or adolescent to future episodes. Recent reports indicate that a negative cognitive style predisposes children to more-prolonged mood disturbance in the face of a negative event. The cognitive-diathesis model proposes that the interactions of negative cognitive style with exposure to adverse life events are associated with development of depressive disorders.

Cognitive characteristics of children and adolescents of adults with bipolar disorders include a discrepancy between verbal and performance intelligence quotient (I.Q.). This discrepancy exceeds the variations expressed by normal controls. A recent report of school function among children stated that the children destined for bipolar I disorder showed a relative weakness in mathematics skills.

Cognitive patterns and attributional style in suicide attempters are shared with those in children and adolescents with mood disorders, since these two groups overlap. There is a subgroup of suicide attempters and completers who do not meet criteria for a mood disorder. Suicidal children and adolescents are less flexible in generating solutions for problems than nonsuicidal children. Suicidal children also predict more-negative consequences for their solutions than nonsuicidal psychiatric controls. Suicide attempters seem to be focused on the problem situation and unable to synthesize an effective strategy to deal with it. They tend to have less confidence that a solution will work. The adult literature reports a strong relation between hopelessness and suicidal behavior. Studies of cognitive features of suicidal children and adolescents have yielded contradictory results. Several recent studies of children and adolescents concurred that suicidal children and adolescents report lower self-esteem and more depression. One recent study examined both negative affect and cognitive biases in adolescents with suicidal ideation, suicide attempters, and nonsuicidal controls. The suicide ideators reported significantly greater hopelessness and poorer self-concept than psychiatric controls without suicidal ideation. Suicide attempters did not differ significantly from either group on any measure. The suicide ideators in this study reported the highest levels of hopelessness and the poorest self-concept. Negative affect and cognitive bias variables accounted for 48 percent of the variance in suicidal ideation. Among the measures of negative affect, only anxiety and depression were uniquely related to suicidal ideation and to each other. Several past studies have shown that impulsive adolescent suicide attempers report less depression and hopelessness than nonimpulsive suicide attempters. Some studies have found gender differences, with suicidal adolescent females reporting higher levels of depression and anxiety than suicidal males, but this is not universal.

Environmental Factors Family interactions with regard to the development of depression in a child or adolescent are complicated and difficult to interpret. In families in which one or both parents have a mood disorder, a child may be faced with an irritable or withdrawn parent whose reactions are inconsistent or hostile. These parenting factors are associated with disruptive behavior and (in some cases) aberrant attachment in the children, even in nondepressed populations. Children raised in family environments characterized by high levels of parental depression, conflict, less involved parents, or harsh parenting styles have increased risk for a variety of psychiatric disorders. More specifically, depressed parents may model negative cognitive styles and poor self-esteem, resulting in poor coping strategies in the child. Young children of mothers with unipolar depression exhibit observable anxiety and disruptive behavior, whereas toddlers of parents with bipolar illness do not. At slightly older ages, however, children at risk for bipolar illness showed higher-than-average rates of attentional and behavioral disturbances. Marital discord and lack of adequate support system for the family are additional risks for development of depression in the offspring. Overall, risk for depression in children of depressed parents is highest when parental illness is of earlier onset, is recurrent, and disrupts parental functioning.

Recent studies attempting to determine the relative roles of genetic endowment and family environmental factors in the development of depression and anxiety in childhood indicate that the greatest contribution to depression and anxiety is made by nonshared environmental factors affecting an individual child within the family, rather than genetic transmission or shared family factors. The mechanisms of these unique influences on a vulnerable child remain to be clarified.

Work with adult patients with schizophrenia and bipolar illness has shown that high levels of negative expressed emotion in families predict increased relapse rates. Preliminary evidence in studies of adults with bipolar disorders indicates that psychosocial interventions that educate families about these interactional styles may decrease relapse rates.

Family conflict is the most frequent precipitating event reported by adolescents with suicidal behavior. A recent study found that suicidal behavior in adolescents is independently associated with conflictual family relationships and depression. That is, lack of family warmth, family discord, and disturbed maternal relationships made an independent contribution to the risk of suicidal behavior. Among nondepressed adolescents, females with a history of conduct-disordered behavior were at increased risk of suicidal behavior. Family discord increased the risk for suicidal behavior in depressed adolescents. Disturbed family relationships may interfere with a child's acquisition of social problem-solving skills, creating a deficit in coping with stressful life events. Since family relationship problems make a contribution to the risk of suicidal behavior beyond that of depression, family interventions may play a major role as a strategy for diminishing suicidal behavior among youth.

Adverse Life Events The adult literature and a number of studies with children and adolescents document a correlation between stressful life event and depressive symptoms. Several studies have shown more stressful life events in depressed children and adolescents than in nondepressed controls. Based on life events inventories delineating the chronology of the events, perceived level of stress, and depressive symptoms, Ian Goodyer found that up to 70 percent of children and adolescents with new-onset depression reported an adverse life event in the 12 months preceding the depression, compared with 29 percent of controls.

Stressful life events that have been studied include interpersonal losses, relationship failures, divorce, bereavement, and exposure to a suicide. David Brent showed that exposure to a suicide was associated with a threefold increase in development of a depressive episode. The risk of developing depression is correlated with the relationship of the survivor to the suicide victim (i.e., the closer the relationship, the higher the incidence of a depressive episode).

A recent study by Douglas Williamson and coworkers found that depressed adolescents experienced more stressful life events during the depressive episode than nondepressed adolescents. A recent study by Boris Birmaher found that stressful life events in depressed adolescents were correlated with higher immune activity. It is not surprising that adverse life events are correlated with mood disorder especially in young children. One study of major depression in preschoolers found that 100 percent of the subjects had been victims of neglect or abuse. Finally, a past episode of major depression can produce a scar effect that results in heightened

interpersonal sensitivity and a persistent need for increased support.

A number of studies have investigated life events reported to precipitants of serious suicide attempts among adolescents. One such study concluded that adverse life events among adolescents during the preceding year (especially an interpersonal loss or discord with family, friends, or partners) significantly increases the risk of a suicide attempt. The predominant role of interpersonal life events in the suicide attempt could not be accounted for by antecedent family or life circumstances. Interpersonal adverse life events were experienced by one third to one half of adolescents with suicide attempts studied. A secondary category of adverse life event associated with suicide attempts among adolescents pertained to legal problems and difficulties with the police in the year preceding the attempt. In one recent study, 24 percent of adolescents who had made suicide attempts experienced legal problems within the year prior to the attempt, compared with less than 2 percent of the adolescent control group. These results are consistent with earlier studies that found strong associations between impending disciplinary crises and suicide attempts among adolescents. Other categories of life events associated with suicide attempts include work difficulties and financial problems. Personal illness and family illness were not significantly associated life events, but they may become more of a risk factor as the subjects age.

A recent study investigating the relation of physical abuse among adolescents to the risk of suicide attempts did not find a significantly higher number of suicide attempts among the adolescent group that was abused. The two groups did differ, however; the physically abused group had a cumulative higher number of risk factors for suicide and were believed to be more likely to make a suicide attempt in the future. Abused adolescent suicide attempters were characterized by higher rates of divorced parents and higher rates of comorbid psychiatric disorders, including depressive disorders, disruptive behavior disorder, and substance use disorders. The nonabused suicide attempters had less comorbidity and lower rates of psychiatric disorders altogether. Physically abused adolescents who made suicide attempts were more likely to perceive their mothers as noncaring than those who had never attempted suicide and they described their families as noncohesive and hostile. They were also more likely to carry a diagnosis of a disruptive behavior disorder, a substance use disorder, or both and were more likely to report exposure to a suicide in a peer or family member.

Biological Factors

Hypothalamic-Pituitary Axis Abnormal cortisol secretion in adults with major depressive disorders was demonstrated with overall elevation of 24-hour basal secretion, nonsuppression on a dexamethasone (Decadron) challenge test (DST), blunting of normal diurnal rhythms, and increased nocturnal cortisol secretion. It has been more difficult to document these changes systematically in depressed children and adolescents. Neither studies of 24-hour cortisol secretion nor nocturnal measurements have yielded robust differences between cortisol concentrations in depressed children and adolescents and those in normal controls.

DST studies in children and adolescents have been less robust in eliciting differences in cortisol secretion among children with depression from children with other psychiatric disorders. DST studies have also failed to show consistent differences among children with depression from children without any psychiatric disorders. A review of Connie Casat revealed a greater number of nonsuppressors with all types of psychopathology among hospitalized children and adolescents than among outpatients. DST appears to be a more specific test in adolescence compared to childhood, that is, in adolescents, a positive DST result was correlated with major depressive disorder 85 percent of the time, whereas for prepubetal children, the specificity was only 60 percent. The DST is not hightly specific, since 47 percent of hospitalized adolescents with major depressive disorder were nonsuppressors on the DST, and 20 percent of inpatients with other psychiatric disorders were also nonsuppressors.

Results of studies investigating hypothalamic-pituitary axis in relation to suicide have been inconsistent. In a study of hospitalized adolescents, nonsuppression of cortisol secretion after dexamethasone challenge was associated with patients who had made medically serious suicide attempts; those who exhibited less potentially lethal suicidal behaviors were less likely to have nonsuppression. Higher levels of suicidal intent existed among those who had made serious attempts. These results may be confounded by the potential association of serious depressive disorders with nonsuppression. Another study of prepubertal children showed an association between suicidality and nonsuppression of cortisol during a DST, independent of diagnosis.

Other measures of hypothalamic-pituitary-adrenal axis dysregulation found in adults with major depressive disorder include blunted secretion of adrenocorticotropic hormone (ACTH) after a challenge with corticotropin-releasing hormone (CRH). Cortisol concentrations remain normal. A recent study by Boris Birmaher found no significant differences in cortisol or ACTH concentrations in children with major depression and normal controls.

Sleep Studies Among adults with major depression, sleep abnormalities have included reduced slow-wave (delta) sleep, diminished latency to rapid eye movement (REM) sleep, increased REM density, and increased awakening during the night. Sleep studies with children and adolescents have provided variable results with respect to sleep architecture abnormalities. Prepubertal children with major depression have shown diminished REM latency and decreased slow-wave sleep in some studies; other studies have found no differences between depressed children's sleep and that of normal controls. Joaquin Puig-Antich followed sleep patterns of depressed children after recovery and noted that diminished REM latency persisted after recovery. This finding (not yet duplicated) has raised the possibility that the sleep abnormalities in these children were markers of risk for depression rather than changes based on the episode of depression. The persistence of abnormal sleep after recovery in some depressed children may also reflect a scar from the episode of depression. Among sleep studies in adolescents, Rao followed depressed subjects over time and found that those who went on to have recurrent major depressive episodes had shorter REM latency during the index depression than adolescents who had no recurrence. Adolescents with a single episode of depression or those who go on to have bipolar I disorder may have less consistent sleep-architecture abnormalities than more severe recurrent depressives, compared with normals.

Growth Hormone Children with depression hyposecrete growth hormone after pharmacological challenges with clonidine (Catapres), levodopa (Larodopa), growth hormone–releasing hormone, and desmethylimipramine. Growth hormone secretion is blunted in response to insulin-induced hypoglycemia during the depressive episode as well as after resolution of the depression. Nocturnal secretion of growth hormone has been reported to range from hypersecretion to hyposecretion. Growth hormone, secreted by the anterior pituitary, is secreted in greatest quantity during sleep throughout the life span, and during adolescence an increase in daytime growth hormone secretion results in an overall increase in 24-hour growth hormone secretion. Blunted growth hormone response may be a trait marker for depression (as opposed to a state marker), since it occurs among children who have had depression, even after the depression has remitted. Alternatively, after a depression has occurred, blunted growth hormone response may persist as a scar response.

There have been only a few studies suggesting that suicidality among adolescents is associated with a blunted growth hormone response to a desipramine (Norpramin) challenge. More studies are needed to differentiate whether this response is really just a measure of severity of depressive disorder or if it is associated with suicidality independent of the severity of mood disorder.

Serotonin Some evidence in adult studies indicates that a dysregulation of the serotonin system might contribute to the development of depression. This hypothesis is based on the blunted response of cortisol secretion to serotonergic agents used to challenge the system. One study to date has suggested that depressed children have a blunted cortisol response when challenged with an intravenous dose of L-5-hydroxytryptophan, a precursor of serotonin. Infusion of L-5-hydroxytryptophan increases serotonin turnover. These studies need to be replicated.

Most of the current investigations of biological correlates among suicide attempters and completers have involved adults. These studies have found significantly lower concentrations of the serotonin metabolite 5-hydroxyindoleacetic acid (5-HIAA) in the cerebrospinal fluid (CSF) of both suicide attempters and suicide completers. In postmortem studies, lower concentrations of serotonin itself and its major metabolite (5-HIAA) were found in the brains of suicide completers than in normal postmortem brains. These lower concentrations of 5-HT and 5-HIAA were localized to the brainstem and were not found in the cortex. Other studies have found that brains of suicide completers contain an increased postsynaptic number of serotonin (5-hydroxytryptamine [5-HT]) type 2 (5-HT_2) receptors in the prefrontal cortex, suggesting that this increase in receptors may be a mechanism to compensate for diminished serotonin release. Low concentrations of serotonin and its metabolites in CSF also characterize subjects with impulsive, labile, and aggressive behaviors across a variety of diagnoses. The postmortem studies of receptor density and serotonin concentration among suicide completers have led to controversial results; further studies are necessary to confirm some of these results. Several studies have demonstrated a higher number of platelet 5-HT_2 receptors in subjects with suicidal behavior across a range of psychiatric disorders. There is evidence (mainly from adult samples) of abnormal serotonergic function and possibly of changes in platelet 5-HT_2 receptors among suicide attempters.

Imaging Studies One open pilot study of magnetic resonance imaging (MRI) of children and adolescents with bipolar I disorder revealed enlarged ventricles and an increased number of hyperintensities.

Behavioral Genetic Studies Behavioral genetic research on childhood mood disorders investigates the causes of individual differences pertaining to genetic variability, shared environmental influences, and nonshared environmental influences. Environmental influences in this context include all sources of variation not explained by heritable genetic effects, including perinatal factors, psychosocial experiences, illness, and any developmental chromosomal influences that are not

inherited. This kind of investigation attempts to identify factors that are either shared or not shared within a family environment to explain variability in the emergence of depressive symptoms and disorders among siblings who share (1) no genetic material (adoptive siblings), (2) some genetic material (dizygotic twins), and (3) virtually all of their genetic material (monozygotic twins). One recent twin study of self-report of nonclinical depressive symptoms using dizygotic and monozygotic twin pairs found .20 for a heritability estimate, .27 for the shared environmental estimate, and .53 for the nonshared environmental factors relating to the symptoms. When the investigators looked only at the adolescents at the high end of reported depressive symptoms, however, genetics was estimated to account for 59 percent of the variation. Another study of twins who self-reported nonclinical depressive symptoms found a difference in the factors that accounted for the variation in depressive symptoms for children (8 to 11 years) and adolescents (11 to 16 years). For the children, shared environment accounted for 60 percent of the variation, nonshared environment accounted for 22 percent and genetics accounted for 18 percent. In the adolescent group, the variation in depressive symptoms was largely due to genetic factors, 78 percent, with shared environmental factors accounting for 4 percent, and nonshared environmental factors accounting for 18 percent of the variation.

Finally, in a recent large study of nonshared environmental factors in adolescents, shared, nonshared, and genetic factors accounted for 4, 62, and 34 percent of the variation in depressive symptoms for the entire group, respectively. When only the most depressed adolescents were analyzed, the shared environment accounted for 44 percent of the variation, the nonshared environment accounted for 33 percent of the variation, and genetics accounted for the remaining 23 percent. These results conflict with those of the first study mentioned, in which genetic factors accounted for more of the variation when the most depressed adolescent subgroup was analyzed.

Although there is much left to study in this area, several conclusions can be drawn. The most obvious but significant conclusion is that genetics clearly plays at least a moderate role in adolescent depression. Additionally, both shared and nonshared environmental influences appear to be important in the emergence of depression in adolescents. This means that differences experienced by siblings within family systems have a significant impact on the emergence of depressed symptoms in adolescents. Thus, the relative experience, in comparison to the experience of siblings, bears upon the development of depressive symptoms. Experiences outside the family, such as peer and school experiences, are also likely to have significant influence as nonshared environmental factors in the emergence of depressive symptoms. In general, assessment of an entire family is needed to understand the relative influences on an adolescent who presents with depressive symptoms.

DIAGNOSIS AND CLINICAL FEATURES

Major depressive disorder among children and adolescents presents as an enduring syndrome with the same core features manifested in adults. Often the two DSM-IV criteria that are modified for youth—(1) irritable mood in a child or adolescent may fulfill the depressed mood criterion, and (2) failure to attain expected weight gain may replace the weight loss and/or disturbance of appetite criterion for a child or adolescent—are not needed to make the diagnosis of major depressive disorders in children and adolescents.

Children with major depressive disorder may describe their predominant mood symptom as sad, mad, or bored. Children who exhibit an acute change in mood and functioning are most often identified, whereas children with long-standing sadness and irritability are sometimes overlooked. Among adolescents, certain features of depression such as guilt, hopelessness, and beliefs about their future are more likely to be experienced and described than they are among younger children. Currently no specific notations exist for subclusters of symptoms that occur more regularly in children of different ages in the diagnostic system. Clusters of symptoms within the criteria for major depression are more or less likely to occur depending on the age of the patient, from the very young child to adulthood. Table 45-2 summarizes the frequency of symptoms of depression on the basis of age.

Symptom	Adult (*N* = 54)	Adolescent (*N* = 92)	Child (*N* = 95)	Preschool (*N* = 9)
Felt sad	93	99	95	100
Appeared sad	74	47	64	89
Crying	50			89
Irritability	67	83	83	78
Social withdrawal	78	73	64	89
Anxiety, seasonal affective disorder	30	59	78	67
Somatic complaints	74	66	83	100
Fighting/disorder conduct	—	5	38	11
Mood-congruent hallucinations	2	10	22	—

Adapted from Carlson GA, Abbott SF: Mood disorders and suicide. In *Comprehensive Textbook of Psychiatry*, ed 6. HI Kaplan, BJ Sadock, editors. Williams & Wilkins, Baltimore, 1995.

Table 45-2 Frequency (%) of Depressive Symptoms Among Children and Adolescents

Additional symptoms that appear more frequently as age increases include anhedonia, delusions, psychomotor retardation, hopelessness, hypersomnia, and diurnal variation. Symptoms that decrease in frequency with age include somatic complaints, auditory hallucinations, poor self-esteem, and sad appearance. Some depressive symptoms seem to be represented equally at all ages, including suicidal ideation, poor concentration, depressed mood, and insomnia. While suicidal ideation occurs with equal frequency at all ages, the likelihood of a prepubertal child completing suicide is extremely low (0.04 per 100,000). Factors that protect prepubertal children from completing suicide include little access to lethal methods (firearms), limited ability to plan and carry out a lethal attempt, and the developmentally expected cognitive gap between having a thought (suicidal ideation) and following through behaviorally (a lethal attempt). In adult studies, hopelessness was often correlated with suicidal behavior. Hopelessness occurs more frequently in older children and adolescents with depression.

Specific signs of depression are especially salient in each developmental period. For example, major depression among preschoolers is often evinced by a lack of smiling, apathy toward play, and an overriding lack of involvement in all activities. These children may become tearful or irritable easily, and their activities may be destructive toward themselves, others, and property. Physical complaints are prominent, and physical aggression may be high. It is necessary to assess the family environment, because depressed preschoolers are at high risk for having been victims of some form of maltreatment.

Among school-aged children, deteriorating school performance and avoidance of peers may signal depression. Not infrequently, increased irritability, fighting, or argumentativeness may be associated features of a major depression in a child of this age. Exacerbation of anxiety symptoms and school refusal are not uncommon among children who are depressed. While vegetative symptoms are usually not predominant, mood-congruent auditory hallucinations that frighten and berate the child may emerge.

In adolescents, major depressive episodes occur with increasing frequency. As with children of all ages, the depression may be the primary psychiatric disorder, or it may be superimposed on a number of other behavior and anxiety disorders that generally emerge prior to puberty. Some adolescents recognize their state as depression, while others cannot identify the various components of the depressive state. More-severe depressions among adolescents that are characterized by mood-congruent auditory hallucinations and delusions, psychomotor retardation, and pervasive anhedonia have been recognized as the syndromes that more often are followed in the future by a period of mania and, consequently, a diagnosis of bipolar disorder. Adolescents with incipient schizophrenia may also present with social withdrawal, auditory hallucinations and delusions, and anhedonia. In the past, many adolescents who went on to develop bipolar disorder were misdiagnosed as having schizophrenia.

Several categories of specifications can be coded within the DSM-IV in relation to the current major depressive episode. These include severity, presence or absence of psychosis, presence or absence of melancholic features, presence or absence of catatonic features, and presence or absence of atypical features. *Melancholic features* include loss of pleasure in all activities or lack of reactivity to usually pleasurable stimuli or both in conjunction with three of the following symptoms: a depressed mood qualitatively different from the feeling of grief over loss of a loved one, depression that is worse in the morning, early morning awakening, marked psychomotor retardation, significant weight loss, or excessive guilt. *Atypical features* refer to mood reactivity in conjunction with two or more of the following: hypersomnia, heavy feeling in the extremities, long-standing pattern of interpersonal rejection sensitivity, or significant weight gain.

Another specified symptom within the description of a depressive illness pattern is seasonality. Winter seasonal affective disorder (mood disorder with seasonal pattern) affects between 3 and 4 percent of children. Relatively few studies have been done on children and adolescents with seasonal affective disorder even though more than one third of adults with seasonal mood disorders report that their symptoms began in childhood. Those studies that have been published describe

depressed states characterized by sadness, fatigue, hypersomnia, and carbohydrate craving. This constellation of symptoms has been categorized as atypical depression. Adult seasonal affective disorder studies have shown that disturbance in activity (i.e., circadian rhythm disruptions) were present. A recent study found that children with seasonal affective disorder displayed abnormal patterns of at-rest motor activity that are identical with patterns of depressed non–seasonal affective disorder patients, but different from patterns in adults with seasonal affective disorder.

Dysthymic disorder is described in DSM-IV as a less-severe depressive entity than major depressive disorder in certain respects, yet a more chronic form of depression with a longer recovery period than major depressive disorder. It consists of a depressed mood for most of the day or for more days than not for at least 1 year. In adults, the duration necessary for the diagnosis is 2 years. In addition to depressed mood, the criteria for dysthymic disorder may include low self-esteem, diminished energy level, feelings of hopelessness, insomnia or hypersomnia, poor concentration, and appetite disturbance. There is never a period of 2 months or more within the year of an absence of the dysthymic symptoms.

Mania in children and adolescents is currently controversial because of a lack of consensus among clinicians and researchers as to whether its identification requires a discrete episodic presentation. There are no modifications in the DSM-IV criteria for manic episode in children and adolescents, and yet there is considerable variation in defining a manic or hypomanic episode in a child who exhibits symptoms of the above but not in easily definable discrete episodes. Thus, a developmental viewpoint must be incorporated into future diagnostic criteria for bipolar I disorder in childhood. According to a recent review of bipolar illness in childhood and adolescence, childhood-onset bipolar illness may be more severe; it may have a chronic, nonepisodic course; and it may present in a mixed, or rapidly cycling, form that resembles the form seen in the most severely ill adult bipolar patients, who are relatively treatment resistant.

Children and adolescents with mania may present with infectious elation and interact in an amusing and silly manner. Children or adolescents with mania are likely to disclose age-appropriate grandiose delusions (e.g., they are that on the brink of achieving greatness in academia or in the arts), even in the face of impending failure. They may feel compelled to share solutions to world problems and instruct others in the meaning of life. Grandiose children may believe that they should be exempt from rules because of their more profound understanding of the laws of nature or the will of God. Adolescents with mania may also experience auditory hallucinations or visions of a grandiose nature. Children and adolescents with mania are well known for their extremely high energy levels, and they may manifest both high-risk behaviors with peers and hypersexual episodes far exceeding the comfort level of their friends. In contrast to adolescents with hyperactivity syndromes, manic adolescents are often illogical and driven to interact incessantly with peers and family members. Adolescents are often frightened and put off by a manic adolescent peer; however, when feedback is provided, it is often dismissed by the patient. Many adolescents do exhibit classic adultlike manic episodes. There is often no discrete episode in prepubertal children who exhibit hypomanic or manic symptoms that had an insidious onset and may not be increasing but are now impairing the child. In such cases, it is more difficult to make the diagnosis. There does seem to be a subgroup of children who present with hyperactivity in the preschool years and exhibit manic symptoms in the early grade school years.

Suicidal behavior can take many forms. Adolescent suicidal behavior usually occurs within the context of family conflict or recent perception of an interpersonal loss. Studies have also found that a subgroup of adolescent suicides took place during a disciplinary crisis within the family setting, with the law, or at school. Anticipation of punitive actions or social humiliation has precipitated teenage suicide. There is also evidence that suicidal behavior among adolescents has been exacerbated by exposure to media presentations pertaining to suicide, either in the form of news stories or television movies. Suicidal intentions can be in some patients recognized and identified. Psychological autopsy studies have found that up to 50 percent of adolescents with completed suicide had verbalized suicidal intentions within a day of the event. Thus, all suicidal threats by adolescents should be considered potential serious warnings. Clinical evidence of increased risk of suicide potential in a child or adolescent include previous attempts, a lethal plan, accessibility of lethal means (especially guns), probability of alcohol use, and a plan that includes precautions against being rescued. Additional features of high-risk clinical scenarios in a child or adolescent include suicide pacts with peers, desire to join a deceased friend or relative, inadequate parental supervision and support, and inability of the child or adolescent to agree to an explicit verbal or written no-suicide contract with the clinician.

Taylor, a 16-year-old eleventh grader was admitted to the adolescent inpatient unit from the emergency room where he had been brought by ambulance after he was found hanging in his bedroom, cyanotic, with a rope around his neck. He was found by his 17-year-old sister who had gone to his room looking for a cigarette. Since his mother was out for the evening, his sister panicked and then quickly called 911. According to his sister, Taylor seemed to be more secretive, less trusting, and more isolative since the beginning of the eleventh grade. Since his parents' divorce 4 years earlier, Taylor had taken care of things around the house because his mother was chronically depressed and alcoholic and his estranged father had a long history of being irresponsible and impulsive. Lately, Taylor seemed to forget what needed to be done, and he seemed preoccupied and distraught. Prior to the 11th grade, Taylor had been a good athlete, he had played on the school basketball team, and he had gotten along well with peers. This year, he had quit the team, and had become strangely isolated. Taylor's sister had mentioned to their mother that Taylor seemed to be sleeping all the time and was avoiding his friends in school. Although his mother was aware that his grades had dropped considerably, she thought he was just going through a phase and decided to leave him alone.

Once situated on the adolescent inpatient unit, Taylor admitted that he had been contemplating suicide off and on for several months. He felt extreme guilt for letting his mother and sister down by becoming more irresponsible around the house, just like his father. He didn't have the energy to get up in the morning or to get to classes. He was unable to concentrate when in school, and he began to feel that his friends were rejecting him. He realized that he was not being invited to parties or included in social activities with this friends. He believed that he was possessed by a satanic spirit that would whisper to him at night that he should kill himself. On the night of his hanging attempt, Taylor had decided that his mother and sister would be better off without him.

Taylor was given the diagnosis of major depressive disorders with psychotic features and treated with fluoxetine (Prozac), which was titrated to 40 mg over a 10-day period. On the seventh day the staff began to notice an increase in energy and a marked increase in his verbalizations. He was less and less isolative and appeared to be pressured with regard to conversing with patients. Several patients began to complain that Taylor was intrusive, irritable, and silly. Taylor began to believe that he had come to understand secrets of life that he felt compelled to share with others. He was speaking louder and was unable to sleep. He didn't understand why others were not fascinated by his revelations. He began to mistrust the other patients and staff, believing that he had been chosen by God to share his special knowledge. He was in constant motion, barely sitting down long enough to eat. Although he was overly active, intrusive, and silly, Taylor was emotionally labile, crying often and reporting that he felt depressed. Taylor's mother and sister had never seen him this way, but his mother reported that he reminded her of his father. Taylor continued in this manner for 4 days, and even after his fluoxetine treatment was discontinued, he continued to exhibit manic symptoms. Taylor was given the diagnosis of a mixed episode and was given divalproex (Depakote). The dosage was titrated to dose of 1000 mg a day, with a blood concentration of 80 µmg/mL. Taylor became subdued; he was able to converse more reasonably and reported that he was not suicidal. He still felt depressed and wondered if he would be able to make anything of his life now. A trial of sertraline (Zoloft) was added to his divalproex therapy, and within 2 weeks, he was somewhat less depressed. Taylor was discharged from the hospital and placed in a partial hospital program where he remained for another month before he returned to school. During this month family meetings were held twice a week, during which the family was given information about bipolar illness and the importance of family support. Taylor's mother entered treatment herself and vowed to drink less and be more available to Taylor and her daughter. Taylor's sister, who was exhibiting symptoms of depression and anxiety about caring for her brother, also entered into her own therapy. When he returned to school, Taylor was mildly depressed, nonsuicidal, and willing to participate in outpatient therapy. He remained concerned about how bipolar disorder would influence the rest of his life.

Brian is an 11-year-old boy who was transferred from his residential facility to the children's psychiatric unit after he had broken a window, threatened to run away, and stated that he was going to kill himself. Brian had a history of attention-deficit/hyperactivity disorder, and he had been treated with a variety of stimulants without great success. He had been placed in a residential treatment facility just 6 weeks prior to the admission, after he had tried to strangle his infant baby sister. Although Brian was quite bright, he had never done well in school because of his inability to follow directions, wait his turn, or get along with his peers. At times his mother and his teacher would describe periods in which his activity level seemed even more frenetic, and he had told his teacher that he would like to have sex with her. Although he was chronically hyperkinetic, at times he appeared giddy and grandiose in his thinking. He constantly made up stories, and he was continually rejected by his peers because of his absurd story telling. He also had another side, however, which was perpetually present but seemed to wax and wane in intensity. He was irritable and believed that nobody liked him or cared for him. When in this mood, he became inconsolable and reported that he was not going to listen to any adults and that life was not worth living. He was devastated when his parents put him into placement, and he had been defiant and irritable since his placement. On admission, Brian was tearful and hopeless. He reported that he wanted to die because he could not control himself and nobody would ever love him the way he was. He stated that he simply could not get his behavior under control even if he tried. He believed that there was definitely something wrong with his brain, and although he denied hearing voices, he felt that there was a noise in his head. Brian's mother carried a diagnosis of bipolar I disorder, as did his maternal grandmother. Brian believed that he always got blamed unjustly and that there was no reason to believe that things could ever get better. After a complete screening of Brian's blood chemistry, he was given a trial of lithium. The dosage was titrated to 1200 mg a day, with a blood concentration of 1.0 mmoL/L. On this medication, Brian seemed calmer, less irritable, and less aggressive. He still had poor concentration and had difficulty focusing on his school work. 10 mg a day of dextroamphetamine (Dexedrine) added to the lithium treatment resulted in some increase in vigilance and performance in the classroom. Although Brian did not exhibit clear-cut periods of pure mania or pure depression, his waxing and waning of mood symptoms seemed most consistent with a diagnosis of bipolar I disorder.

PATHOLOGY AND LABORATORY EXAMINATION

Since no specific laboratory tests serve as direct measures of mood disorders or suicide risk, the clinical history, medical history, and interview remain the most important sources of diagnostic information. A number of laboratory measures have been suggested as potential markers of past or present mood disorder or as influential in affective symptoms. The following paragraphs briefly review these tests.

A child or adolescent who complains of a significant change in energy level, appetite, motivation, or sociability may be experiencing both a medical condition and a psychiatric condition. Viral syndromes and other low-grade infections may produce symptoms that overlap with those of a mood disorder. Thus, a physical examination and a screening blood panel for blood count and (in some cases), electrolyte concentrations may be indicated. A pregnancy test or a reliable history of absence of sexual activity is needed before any adolescent female is given a medication that may have teratogenic effects.

The DST has been suggested to be a biological marker of depression. Nonsuppression of cortisol secretion during the DST has been associated with severe depression, more consistently with adults than with children or adolescents. Nonsuppression of the DST is not specific for mood disorders, however, and thus it does not help in making the diagnosis. DST also does not predict treatment choice or probability of response. Therefore, the DST is not a helpful diagnostic tool.

Thyroid function tests that measure serum thyroxine, triodothyronine resin uptake, thyroid-stimulating hormone (TSH), and triodothyronine may be useful with a child or adolescent with a psychiatric disorder because of the high frequency of thyroid dysfunction in this population and the potential overlap of mood disorder symptoms with those of thyroid disease. Thyroid function testing is not helpful as a diagnostic tool for the diagnosis of depression. The thyrotropin-releasing hormone (TRH) stimulation test has shown no differences in the responses of children and adolescents with depression and those of normal controls.

Toxicology screens for drugs of abuse including opioids, cannabinoids, amphetamines, barbiturates, and cocaine are advisable on admission for adolescent psychiatric inpatients. This battery may be useful in clarifying contributing causes of a new onset of psychosis, mood changes, and aggressive behavior. Positive urine toxicology reports should be confirmed by blood testing whenever possible. Toxicology screening may, however, reveal past exposure rather than current use (e.g., positive results several weeks after cannabis or cocaine use and 48 hours after use of amphetamines).

Brain-imaging techniques, including MRI, computed tomography (CT), positron emission tomography (PET), and single photon emission computed tomography (SPECT), are being used investigatively in child and adolescent psychiatry. Clinical indications for the use of MRI or CT are to rule out signs of intracranial pressure or other neurological condition. PET scans and SPECT have been used to study blood flow patterns in children with attention-deficit/hypersensitivity disorder, but there is no current indication for their use diagnostically for children and adolescents.

Electroencephalography is also not of use diagnostically, especially since up to 15 percent of the general population displays abnormal EEG findings.

Laboratory testing is used routinely to monitor medication concentrations and adverse effects of medications. For example, lithium concentrations are used routinely, although the therapeutic range for children and adolescents has not been definitely demonstrated. Saliva testing is not recommended because of the wide range of saliva to serum ratios in children. If the patient is about to begin treatment with a tricyclic drug, regular monitoring of the electrocardiogram (ECG), pulse, and blood pressure is required. Anticonvulsants such as carbamazepine (Tegretol) must not be given until results of a complete blood count with platelets and reticulocyte counts and serum iron concentration are known. Other psychiatric medications including divalproex and clozapine (Clozaril) are also monitored with blood concentrations, although there is no clear-cut therapeutic window.

Psychological testing, including tests of intelligence quotient, are not useful diagnostically, although they may help to identify a child's relative strengths and weaknesses. Projective testing, such as the Thematic Apperception Test (TAT) or the Rorschach test may confirm depressive themes but cannot be used as a diagnostic tool.

DIFFERENTIAL DIAGNOSIS

A striking component of the differential diagnosis of mood disorders in children and adolescents is the likelihood of associated symptoms and comorbid psychiatric diagnoses. Multiple psychiatric disorders coexist more frequently in children and adolescents than in adults. The emergence of major depression in a child or adolescent increases the risk of an additional psychiatric diagnosis ten- to twentyfold.

The main psychiatric disorders that major depression must be distinguished from include anxiety disorders, conduct disorders, and substance use disorders. The main entities requiring clarification from mania and hypomania are attention-deficit/hyperactivity disorder and disruptive behavior disorders.

Many studies have indicated that anxiety symptoms are universal among children and adolescents with major depression and, conversely, children with anxiety disorders also exhibit depressive symptoms. Major depressive disorder in childhood is commonly accompanied by increased irritability, more fighting, and aggression. There are three possible chronologies leading to this constellation that must be elucidated by history. First, a child with a preexisting conduct disorder may develop a major depression. In fact, children with conduct disorder are at increased risk to develop depression. Second, some children and adolescents become irritable and explosive when the major depressive disorder occurs but do not go on to exhibit the typical violations of human rights that characterize conduct disorder. In this case, the conduct disturbance is likely to resolve when the depression is treated. The third scenario consists of full emergence of a conduct disorder concurrent with the depressive episode. This may occur in up to one third of children with major depression. Approximately one half of children with chronic school refusal and separation anxiety disorder meet all of the criteria for major depression. Thus, comorbidity of anxiety disorders and depressive disorders is frequent among youth.

A line must be drawn between acute depression and bereavement reactions and adjustment reactions with depressed mood. No clinical boundary separates these entities. Thus bereavement (as described in DSM-IV) consists of a syndrome that may include sadness, insomnia, and appetite and weight changes. The bereaved individual considers the reaction to be “normal.” A diagnosis of major depressive disorder is usually not given unless the symptoms are still present 2 months after the loss. The presence of certain symptoms—including guilt, thoughts about death, morbid pervasive preoccupation beyond the realm of “survivor” misgivings—may be designated as major depressive disorder. Additional symptoms including pervasive functional impairment, hallucinations, and recurrent desire to die indicate a depressive syndrome beyond bereavement. In adjustment disorder with depressed mood, the symptoms develop within 3 months of the onset of the stressor but do not fulfill criteria for a mood disorder diagnosis. Once the stressor has terminated, the symptoms do not persist for more than another 6 months.

The boundary between attention-deficit/hyperactivity disorder and hypomania or mania in children has been difficult to delineate. Even oppositional defiant disorder can be construed as overlapping clinically with mania and hypomania. Although long-term follow-up studies of children with attention-deficit/hyperactivity disorder do not indicate higher-than-expected rates of mania, the converse is true. That is, data suggest that prepubertal-onset bipolar children exhibit hyperactivity more often

than expected in the population by preschool age, and it continues until mania emerges during the grade school years. Attention-deficit/hyperactivity disorder is more prevalent in prepubertal-onset bipolar disorder children than in adolescent-onset bipolar disorder youths. Among bipolar disorder youths referred for mania, approximately 90 percent of prepubertal and 30 percent of adolescent bipolar disorder youth exhibit attention-deficit/hyperactivity disorder. According to the work of Barbara Geller and coworkers, hyperactivity may be the first developmentally age-specific manifestation of a bipolar disorder in the prepubertal age group, and although bipolar disorders and attention-deficit/hyperactivity disorder may coexist, it is difficult to detect this in young patients with a bipolar disorder.

Similarly, long-term follow-up of conduct disorder has not detected higher-than-expected prevalence rates of bipolar disorder, yet conduct disorder occurs in up to 22 percent of bipolar disorder children and up to 18 percent of bipolar disorder adolescents. Conduct disorder may also be construed as an early manifestation of prepubertal mania or hypomania, since the disturbance of conduct in these patients is linked to grandiose thinking, poor judgment, and poor impulse control.

During adolescence, however, the main differential diagnosis for bipolar disorder is with schizophrenia. This is often difficult in an adolescent who is floridly psychotic. The decision is easier in an adolescent with multiple family members with bipolar illness.

Substance abuse is not an uncommon confounding variable in the evaluation of symptoms that are typical of mania or hypomania. Substance abuse may also coexist with mania, and the effects of both may interact.

COURSE AND PROGNOSIS

Multiple long-term follow-up studies of children who have experienced major depression, among clinical samples and in the community, lead to the conclusion that major depression among youth is a serious, relapsing disorder with lingering social impairment and a high risk of suicide. The work of Maria Kovacs has underscored the long and sometimes tortuous course of various mood disorders in children and adolescents. Children who exhibited dysthymic disorder had a mean episode length of of 3 years, while those with major depression had a mean episode length of 32 months. While 92 percent of prepubertal children diagnosed with a major depressive disorder had recovered at 18 months, 89 percent of those with dysthymic disorder had recovered after 6 years. Sixty-nine percent of children with dysthymic disorder had a major depression within 5 years of diagnosis, and there was a 72 percent cumulative risk of relapse for children initially diagnosed with major depressive disorder. The earlier the age at diagnosis, the more protracted the recovery was for either major depression or dysthymic disorder. In the adult literature, it has been proposed that an initial episode of a depressive disorder sensitizes an individual to future episodes. Episode duration among children and adolescents with mood disorders has been studied with respect to age at onset, gender, psychiatric comorbidity, presence of severity indicators such as delusions, and family history. In adults, presence of dysthymic disorder at the onset of a major depression, “double depression,” predicts decreased length of episode, with the baseline being the dysthymic disorder. In a recent investigation of multiple variables influencing recovery from depression among youths, none of the baseline variables including gender, social class, severity of depression as measured by presence of delusional symptoms, or nonaffective psychiatric diagnoses influenced length of a major depressive episode. When a major depression was superimposed on dysthymic disorder, the length of the episode (recovery back to dysthymic disorder) was shortened, as was found with adults. Recovery from the first episode of dysthymic disorder was influenced by the presence of comorbid conduct disorder, oppositional defiant disorder, or attention-deficit/hyperactivity disorder. Factors that predict relapse and recurrence of major depression among adults include the severity of the index episode, psychotic features, earlier age of onset, multiple past episodes, and a history of double depression. In a recent follow-up of major depressive disorder among youths, the risk of recurrence was highest in the first year after recovery. Most recurrences occurred within 2 years of the index episode. More-severe depressive symptoms, older age, and presence of psychotic features increased the risk of recurrence.

An important possible sequela of major depression among children and adolescents is the development of mania and diagnosis of bipolar illness. The switch from depression to mania among children and adolescents is significantly higher than it is for adults. In the adult literature, between 5 and 18 percent of patients with depression become manic. Among prepubertal children with severe major depression, the rates of eventual mania have been reported to be as high as 32 percent within a 2- to 5-year period. Among adolescents, rates of mania between 20 and 40 percent have been reported within 5 years of the index depression. Among adolescents, severe depression characterized by psychomotor retardation, delusional symptoms, and pervasive anhedonia is associated with the highest risk for future manic episodes. Among young adults, the development of future hypomanic episodes (bipolar II disorder) has been associated with atypical depression, early onset of depression, seasonal affective disorder, and comorbid substance abuse. Among adolescents, a switch to hypomania may sometimes be misconstrued as a disruptive behavior disorder.

Additional complications of major depressive disorder in children and adolescents are the persistence of social impairment and the perception of being socially isolated. While social disturbance is not unique to mood disorders, depression in youth is associated with increased risk of tobacco and substance use and continued negative attributions, all of which affect social functioning.

One recent study of depressed children followed up at 36 weeks found that 50 percent still met criteria for major depressive disorder; of those, 73 percent had remained depressed, and 27 percent had recovered and relapsed. In this sample, major depression at follow-up was predicted by more-severe depression at intake, comorbid obsessive-compulsive disorder, and being older at the time of the index depression.

The course and prognosis of bipolar disorders among children and adolescents are clearer in adolescents than in prepubertal children since diagnosis is more clear-cut. A number of studies have indicated that an earlier age of onset (i.e., adolescent compared with young adult) of bipolar I disorder is associated with an increased frequency of cycles as well as an increased likelihood of mixed states. Other studies have suggested that the relapse rate for bipolar I disorder patients whose first episode is in their teens or early twenties is lower than that of bipolar I disorder patients who experienced a first episode in their thirties. Adolescent bipolar I disorder patients appear to have a higher risk of experiencing psychotic symptoms than patients who developed mania as adults. In a follow-up of adolescent bipolar I disorder patients, those whose index episode was purely manic or mixed recovered from the episode more rapidly than those whose index episode was depressive. Of this sample, 44 percent relapsed within 5 years and 21 percent of the sample manifested at least two relapses following recovery from the index episode. The likelihood of multiple relapses was highest for patients whose index feature was mixed episode or rapidly cycling. Among adolescents who develop manic episodes, those with a premorbid history of psychiatric disorders, including disruptive behavior disorders, had significantly more first-and second-degree family members with a history of affective illness.

Most adolescents with bipolar disorders experience recovery, although the length of episode is influenced by its polarity. Both youths and adults recover more rapidly from a pure manic episode than from a mixed or depressive episode. Among adolescents, however, an index episode of pure depression appears to be associated with a poorer prognosis than it does for adults with bipolar illness. Current evidence suggests that adolescent patients may be slower to relapse than adult patients, at least after their initial diagnosis is made.

Prepubertal-onset bipolar disorder may not follow an acute episode model with interepisode recovery. It has been proposed that prepubertal bipolar disorder may manifest with a continuous, rapid cycling of multiple, brief manic episodes. Adults whose illness is characterized by mixed episodes or rapid cycling have a poorer prognosis than bipolar I disorder adults with more-discrete episodes.

It is not clear whether a switch from a bipolar II to a bipolar I diagnosis in children is similar to that in adults; so far, low rates have been found for both adults and children. The question remains, however, whether an eventual bipolar I disorder diagnosis in children who start out with a bipolar II disorder diagnosis represents a switch of diagnostic category or simply the manifestation of bipolar I disorder that was unexpressed previously for developmental reasons. This distinction could have implications for treatment, since mood-stabilizer treatment might be more appropriate than antidepressant treatment in a child diagnosed with bipolar I disorder.

Suicide is a considerable risk for children and adolescents with any category of mood disorder. In one follow-up study of 28 adolescents hospitalized for an index episode of either depression or mania and followed for 10 years, only 5 of the 16 depressive disorder adolescents recovered and remained well. The other 11 depressive patients had a relapsing course over the 10 years. Of the 12 bipolar I disorder adolescents, 3 committed suicide, and the other 9 continued to have cycling episodes with poor adjustment. Some additional data suggest that the suicide rate among bipolar adolescents is higher than that of adolescents with other psychiatric disorders. The addition of substance use further increases the risk of suicide among adolescents with depressive and bipolar disorders. A review of adolescent suicide reported depressive disorders present in 43 to 76 percent of suicide completers, substance abuse in 26 to 66 percent of completers, and antisocial behaviors in 6 to 70 percent of completers.

A recent study reviewed the different rates and risks of suicide for younger adolescents (below 15 years of age), and older adolescents (15 to 19 years old) in Norway. Of suicide completers under age 15, 43 percent had psychiatric disorders, compared with 79 percent of adolescents over age 15. All but one of the completers under age 15 used hanging as the suicide method, whereas the older adolescents used firearms and hanging equally. Older adolescents were more likely to have expressed suicidal intent. Twenty-nine percent of the younger adolescents and 68 percent of the older adolescents had either expressed suicidal ideation, made a

previous attempt, or left a suicide note. An identifiable precipitating event was present in 49 percent of the older adolescents, compared with only 29 percent of the younger adolescent suicide completers. None of the younger adolescent completers was intoxicated with alcohol or other substances at the time of death, compared with 50 percent of the older adolescent completers. The suicide risk relating to mood disorder and family situation was almost identical for the younger and the older adolescent groups. The lower rates of suicide in the younger group may reflect the decreased likelihood of having an affective disorder, less exposure to stressors, or increased resiliency in the younger group. Overall, lower exposure to the risk factors for suicide, including mood disorders, substance use, and accessibility of firearms, contributes to the relative protection of younger adolescents from completing suicide.

Adolescents Who Kill A disturbing number of reports over the last few years have depicted the tragic killings of both students and adults by adolescents. More than 200 deaths have occurred in school yards across the United States within the last decade. In more recent years, these killings have been more frequent in rural settings and have involved multiple victims. In the early 1990s many of the school-related killings were attributable to gang activities or disputes over money or romantic involvements. In the last few years, multiple homicides perpetrated by adolescents have related more to issues of revenge for being mercilessly teased or have been of enactments scenarios of violence by adolescents who appear to be obsessed with violence and destruction.

While no unifying profiles identify adolescents who may commit murder, some potential similarities can be noted retrospectively in the histories of adolescents who have killed. When pieces of the histories of adolescent murderers are disclosed, it appears that most of these adolescents had long-standing troubles, some with major depression, they were often socially isolated, and they had explicitly displayed a fascination with violence. Some of the adolescent killers disclosed their inner agony fueled by perpetual tormenting by peers who ridiculed and rejected them daily. Some had experienced clear family dysfunction or circumstances of abuse, neglect, or parental psychiatric history that influenced the adolescent negatively. Many of the adolescents who killed had expressed the desire for violent revenge to parents, teachers, or peers. All of the adolescent killers reported ease in obtaining firearms, and many were expert in using them. In most cases, adolescents acquired semiautomatic weapons that were unlocked and kept in their homes within easy reach. Some of the adolescents gave literal warnings a day or a few weeks before the killings, either stating that there would be a violent attack or warning certain peers to stay away from school on a certain day. Others wrote poems, compositions, or journal entries depicting the violent scenes. Most of the adolescents who left notes at the time of the murders were suicidal and assumed that they would also die during the attack.

Suicide rates among youths have been on the increase, and rates of depression have also increased in adolescents in younger age groups. A depressed, demoralized, socially rejected adolescent male preoccupied with violent fantasies, with easy access to semiautomatic weapons, is a potential disaster. Any violent threat must be taken seriously, and families must be taught to keep weapons away from these adolescents.

TREATMENT

Psychological Therapies

Cognitive-Behavioral Therapy Cognitive-behavior therapy is a problem-oriented treatment that targets cognitive distortions, faulty attributions, and poor self-esteem, all of which commonly plague children and adolescents with mood disorders. The treatment aims to diminish punitive attitudes and self-recrimination and focuses increased attention on positive attributes and improved social competence. Although negative attributional style is not unique to depressive disorders, it is pervasive among depressed adults and adolescents. Controlled outcome studies with adults have been promising, suggesting that cognitive-behavioral approaches may be effective in treating major depressive disorder in diminishing rates of relapse, and (perhaps) in preventing recurrence of depression. There have been relatively few efficacy studies of cognitive-behavioral interventions for children and adolescents with mood disorders.

A recent review of controlled cognitive-behavioral studies in children and adolescents led to the following conclusions. To be reviewed, the cognitive-behavioral intervention study must have met the definition of the treatment as an intervention promoting emotional and behavioral change by teaching children new coping styles and new thoughts in a problem-oriented manner. All but one of the six studies reviewed recruited their dysphoric subjects from schools and used a group therapy format. Two of the studies used adolescents formally diagnosed with major depression and used structured interviews as part of the diagnostic process. The period of treatment ranged from six to fourteen sessions, and the time periods ranged from 5 to 8 weeks. The control conditions included relaxation intervention, being placed on a waiting list, family therapy, supportive psychotherapy, self-control therapy, and self-modeling therapy. Each study used one or more of a number of depression rating scales given pretreatment and posttreatment, including the Beck Depression Inventory (BDI), the Reynolds Adolescent Depression Scale (RADS), the Children's Depression Inventory (CDI), the Children's Depression Scale (CDS), the Center for Epidemiologic Studies Depression (CESD) Scale, or the Mood and Feeling Questionnaire (MFQ). The total number of subjects in these studies was 217. The posttest ratings indicated significantly diminished symptoms of dysphoria and depression among adolescents. Follow-up posttreatment ranged from 1 to 24 months. Most studies were followed up for approximately 3 months. The overall posttest ratings at follow-up was also significant, indicating that the improvements made after the cognitive-behavior treatment was completed had been maintained. The study comparing cognitive-behavioral therapy with supportive psychotherapy found cognitive-behavior therapy to be superior. The studies that included a relaxation treatment, a self-control treatment, or a self-modeling treatment found that each of the active treatments was associated with improvement in depressive symptoms. In studies that included a wait-list group, all of the active treatments yielded better results than the wait-list group.

The improvements shown by adolescents after cognitive-behavioral therapy are similar to those of depressed adults. Cognitive therapy aims to modify maladaptive beliefs and attempts to enhance problem-solving abilities, social competency, and the ability to achieve a sense of mastery in social and occupational domains. Although the studies reviewed did not demonstrate a highly specific mode of employing these techniques, the positive yield was notable. The translation of these improvements into units of increased functionality and adaptability requires further study. Most subjects in these studies were “dysphoric,” and thus this review could not aid in determining whether cognitive-behavioral strategies are efficacious in more severely ill adolescents with major depressive disorder or bipolar I disorder. A recent report of cognitive-behavioral therapy for depressed adolescents did ask which patients are more likely to benefit from this modality of treatment. This study found that two variables predicted response to the cognitive-behavioral approach: age and severity. Younger patients and those with less severe depression responded better to a relatively brief trial of cognitive-behavioral therapy. The cognitive-behavioral strategy was not compared with some alternative treatments including pharmacotherapy.

A brief cognitive-behavioral treatment program called Successful Negotiation Acting Positively (SNAP) created by Mary Jane Rotheram-Borus and coworkers has been used in adolescent suicide attempters and is initiated at the time of their emergency room evaluation for the suicidal behavior. The treatment consists of a six-session, outpatient, highly structured program aimed at diminishing cognitive distortions and improving problem-solving strategies in families of adolescents who have attempted suicide. This program uses several operationalized components, including tokens given to each family member to pass to another whenever a positive feeling or an agreement has been reached. Role playing is used to practice problem solving from someone else's point of view. A schematic “feeling thermometer” is also used to help adolescents and their families identify their feelings. The therapist reframes family disagreements into forms that can be solved more effectively. Initiating this form of treatment at the time of the suicide attempt in the emergency room setting and with additional components of urgent treatment improved attendance at follow-up visits. Cognitive-behavioral treatment for adolescents and their families focuses on identifying and clarifying beliefs and notions regarding the roles and responsibilities of both parents and the adolescents.

Group settings often employ cognitive-behavioral techniques to treat depression in children and adolescents. Group therapy situations may focus on social skills improvement and social learning to diminish depressive symptoms. One protocol, called the Coping with Depression course for adolescents also uses a classroom format containing structured social learning tasks with assignments to be done at home. Although not every depressed child is willing to participate in such a treatment, participants have shown improvement, compared with waiting-list controls. A parallel intervention for parents led to a decrease in parental ratings of the child's behavior problems but was not associated with further decrease in depressive symptoms, as rated by the children.

Interpersonal Therapy *Interpersonal psychotherapy*, a brief individual intervention that focuses on the patient's social relationships and current evaluation of these relationships, was originally developed for adults with depression. The therapy aims to decrease depressive symptoms while improving interpersonal functioning. Interpersonal therapy emerges from the notion that depression is expressed within a social context and that interpersonal relationships with significant people influence the course of the depressive disorder. The assumption is that as communication improves within significant relationships, depressive symptoms diminish. At least five published controlled trials of interpersonal therapy used in depressed adults have found it efficacious in acute and maintenance treatment. There are no published controlled trials at this time of interpersonal therapy for depressed adolescents, but one controlled trial is in progress. In this trial, a standardized protocol consisting of 12 weeks of individual sessions is used. The first phase of treatment is aimed at identifying interpersonal patterns that promote depressive cognitions. During this phase, the therapeutic alliance is developed, with specific goals set for the treatment. In the second phase of treatment, strategies are developed to alter interpersonal communications. The final phase of treatment involves practical application of the interpersonal strategies. A recent publication reported the outcome at 1 year of depressed adolescents who received 12 weeks of interpersonal therapy using a manual. Sessions were held individually on a weekly basis. Of the 10 adolescents who were followed up, only 1 met the criteria for a mood disorder. In this follow-up, the improvements that had occurred by the end of the treatment period had been maintained for the next year, with only one subject depressed at follow up. The other subjects reported few depressive symptoms and consistent

social functioning. It remains to be determined whether interpersonal therapy can be protective with regard to responses to adverse life events. As mentioned above, interpersonal therapy presumes that whatever the cumulative causes of depression, improved significant relationships will diminish the depressive symptoms. Whether successful gains in interpersonal relationships are prophylactic for relapse or recurrence of depression remains to be seen.

There have been scant studies of a variety of additional psychotherapeutic interventions including psychodynamic therapy, supportive psychotherapy, and relaxation techniques. In most studies comparing any of the psychosocial intervention groups to a waiting-list control, the psychosocial interventions have been associated with greater improvement in depressive symptoms.

Family-Focused Psychoeducational Treatment The emotional attitudes of family members of psychiatrically ill adults, particularly those with schizophrenic disorder, influence the course and relapse rate of the disorder. Many studies of adults have found that schizophrenics whose families exhibit high expressed emotion (i.e., are highly critical, hostile, or overly involved) are at higher risk for relapse. At least two studies of manic and mixed episode young adults have shown that those residing with families showing high expressed emotion were more likely to relapse within a year and to show lower global functioning in the short term. Thus, family-focused psychoeducational treatment is aimed at helping families find an equilibrium after an affective episode in one family member and reducing the traumatic impact of the illness on the family. The components of this treatment include assessment of the family milieu, psychoeducation for the patient and the family about the course of bipolar disorder, and both communication enhancement and problem-solving-skills training. One model of this treatment proposes 21 outpatient sessions including 12 weekly sessions, 6 biweekly sessions, and 3 monthly sessions after an acute episode. Communication enhancement, the part of the treatment that approaches the expressed emotion in the family, consists of developing mastery in four areas: active listening, delivering positive feedback, delivering negative feedback, and requesting changes in other family members' behavior.

Psychopharmacotherapy Current antidepressant treatment of mood disorders in children and adolescents is still in the early phases of being validated with double-blind efficacy studies. Thus far, no studies have supported the use of tricyclic drugs in children or adolescents, and at least one published placebo-controlled double-blind study exists comparing fluoxetine's efficacy for depressive symptoms in adolescents with that of placebo.

The tricyclic drugs have shown efficacy in multiple adult studies of mood disorder, but since the advent of antidepressants with safer adverse-effect profiles (i.e., minimal risk of cardiac arrhythmias and considerably lower lethal potential), the tricyclic drugs are usually not among the first-choice antidepressants for children and adolescents.

Selective serotonin reuptake inhibitors (SSRIs) have become the drugs of choice for mood disorders in children and adolescents because of promising research findings and the favorable profiles of the drugs. Serotonin reuptake inhibitors include fluoxetine, paroxetine (Paxil), sertraline, fluvoxamine (Luvox), citalopram (Celexa), and nefazedone (Serzone). Nefazedone blocks norepinephrine receptors and serotonin receptors. These drugs all have a relatively mild adverse-effect profile, with low lethality after overdose. Dosage-related adverse effects include headache and nausea. Except nefazedone all these drugs can cause sexual dysfunction including diminished libido, delayed ejaculation, or anorgasmia. There have been no indications thus far that plasma level can be correlated to expected response. In the double-blind study by Graham Emslie, response to the SSRIs seemed to be equivalent in children and older adolescents. Additional potential adverse effects of these drugs include insomnia and a syndrome of restlessness and agitation that can be ameliorated by decreasing the dosage.

Additional antidepressants that can be used include bupropion (Wellbutrin), a dopaminergic drug; venlafaxine (Effexor), which blocks serotonin and norepinephrine reuptake, mirtazepine (Remron), a serotonin plus norepinephrine reuptake inhibitor; and the monoamine oxidase (MAO) inhibitors phenelzine (Nardil) and tranylcypromine (Parnate). Bupropion is an antidepressant with stimulant properties that has few anticholinergic side effects, produces virtually no sedation, and is much safer in overdose than the tricyclic drugs. Because of its stimulant properties, it has also been used to treat attention-deficit/hyperactivity disorder. Venlafaxine is a relatively new antidepressant that largely shares an adverse-effect profile with the SSRIs; the most common adverse effects include nausea, anorexia, nervousness, and sexual dysfunction. Despite its potential to induce nervousness, there have been anecdotal reports of its efficacy in the treatment of anxiety. There have been no studies of mirtazapine, a new antidepressant similar to nefazedone in mechanism of action. Mirtazapine is significantly more sedating than nefazedone.

MAO inhibitors have been sparsely studied in children and adolescents although they have been shown to be effective in adults with major depressive disorder and those with atypical depression. In one published open trial of phenelzine with adolescents who were refractory to treatment with tricyclic drugs the treating physician judged that up to 60 percent of these adolescents were improved by the phenelzine treatment. Since the monoamine oxidase inhibitors require strict adherence to a restricted diet (no cheese [except cottage cheese or cream cheese], processed meats, caviar, cured fish, overripe fruits, avocados, fava beans, yeast extracts, chianti or burgundy wine, beers containing yeast, or over-the-counter cold preparations, especially decongestants and inhalers). Aside from these restrictions (which potentially result in hypertensive crises and death if ingested), other adverse effects of the drugs include orthostatic hypotension and sleep disturbances. The MAO type A inhibitor moclobemide (available in Canada, but not in the United States) is a safer drug with a milder adverse-effect profile, but it has not yet been studied with children or adolescents. In children or adolescents with major depressive disorder there is a risk of precipitating a hypomanic or manic episode during the course of any antidepressant treatment.

Although there has been only one double-blind placebo-controlled study showing the efficacy of lithium for bipolar children and adolescents, pharmacokinetic studies of lithium in children and adolescents with behavior disorders indicate that lithium can be used with the same safety precautions used for adults. As with adults, electrolytes, renal function tests, thyroid function tests, and calcium and phosphorus concentrations should be monitored at least twice a year. Lithium has a shorter half-life in children than in adults, consistent with a higher efficiency of the kidneys in children. Treating hypomania or mania in adolescents applies the same basic strategies used for adults. Initiation of a psychopharmacological treatment in a manic adolescent often requires hospitalization if the patient cannot be contained or follow directions reliably. For adolescent patients with pure mania, lithium is generally the drug of choice. It has demonstrated efficacy in the treatment of manic states in adults and has shown some prophylactic efficacy for future mood episodes in adults, more strongly for manic episodes than for depressed episodes. Since there is controversy regarding inclusion of a variety of cycling and noncycling severe mood and behavioral disturbances in children and adolescents, the studies done in this age group have no doubt included a heterogeneous diagnostic group. Nevertheless, in the published open-trial reviews of lithium treatment of youths, the efficacy of lithium for behavioral improvement has ranged from about 50 to 66 percent. This is substantially lower than reported lithium efficacy in manic adults. Clinical features that may predict poor responsivity to lithium include mixed mood states and atypical features.

Prior to starting lithium treatment, a number of laboratory indexes must be documented to aid in monitoring adverse effects of lithium (Table 45-3). Lithium treatment should be initiated with 300 or 450 mg and be titrated up to achieve a concentration in blood of approximately 0.8 to 1.2 mEq/L. The most common adverse effects are nausea, diarrhea, stomach ache, fine tremor of the hands, polyuria, polydipsia, and weight gain. Signs of lithium toxicity include drowsiness, slurred speech, ataxia, muscle tremors, and hyperreflexia. Children on lithium also run the risk of cognitive slowing. The reliability of the family must be assessed regarding follow-up of lithium concentrations and laboratory studies before lithium treatment is initiated in a child or adolescent.

Laboratory Test	Reason
Serum electrolytes	Hypokalemia may increase risk of cardiac arrhythmias; hyponatremia can decrease lithium excretion resulting in lithium toxicity
BUN, creatinine	If renal function is impaired lithium may not be excreted
Blood count	Lithium may cause leukocytosis
ECG	Lithium can cause T-wave inversion or conduction abnormalities
Thyroid function tests (TSH)	Lithium can cause hypothyroid function or euthyroid goiter
Pregnancy test	Lithium is associated with first-trimester anomalies

Table 45-3 Laboratory Testing Prior to Lithium Treatment

Anticonvulsants have been shown to be efficacious in adult manic patients; there have been no double-blind studies to indicate efficacy in adolescents. Naturalistic follow-up data suggest that anticonvulsants may be efficacious for adolescents with mixed-state episodes or those with rapid cycling disorders. In studies of adult bipolar patients refractory to lithium treatment, a significant subgroup responded to carbamazepine, with or without adjunctive lithium. Hypothetical models of mood cycling exhibiting a brain-kindling effect support the use of anticonvulsants to interrupt this process. While carbamazepine and valproic acid have not been studied

systematically in children or adolescents with mania, they have both been used widely in the treatment of seizure disorders in children. There have been a few anecdotal reports of behavioral problems diminishing in epileptic children treated with carbamazepine. Several open clinical trials of both carbamazepine and valproic acid for adolescents with mania have suggested that these medications may be useful, especially in manic children or adolescents who do not respond to lithium. Both carbamazepine and valproic acid have potentially serious adverse effects. Carbamazepine requires weekly blood counts within the first month of treatment to follow the white blood cell count, since carbamazepine has been associated with aplastic anemia, thrombocytopenia, eosinophilia, and agranulocytosis. Valproic acid may be associated with a variety of adverse effects including nausea, rash, drowsiness, weight gain, and hair loss. Valproic acid is also associated with development of polycystic ovary disease in young women. Data comparing epileptic females taking valproic acid with those on other drugs indicate that the rate of polycystic ovary disease among young women on valproic acid was three times that of women who were not exposed to it, and rates of disease were close to 90 percent. These serious adverse effects must be considered before initiating a trial of valproic acid treatment in females.

Antipsychotic medications are sometimes indicated for mood disorders, including both depressive and bipolar disorders in adolescents with psychotic features. The newer antipsychotic agents such as risperidone (Risperdal), olanzepine (Zyprexa), and clozapine are often chosen as first-line adjunctive drugs, given their diminished extrapyramidal adverse effects. While clozapine has been suggested to be the most effective antipsychotic agent for pure mania, its risk for agranulocytosis and the need for weekly blood count monitoring make it less desirable. Antipsychotics are usually not effective as monotherapy for a mood episode, and additional strategies involving augmentation strategies and additional mood stabilizers are generally the next step for a refractory mood episode.

The use of multiple mood stabilizers has successfully controlled some resistant rapid-cycling disorders in adults. Lithium and carbamazepine have been reported to be adequately tolerated in the above situations. The addition of an anticonvulsant to lithium increases the probability of such effects as drowsiness, dizziness, and ataxia. On the other hand, the combination of carbamazepine with a smaller, adjunctive dose of lithium has also been successful in some patients with refractory bipolar disorders. Two open trials with adolescents have used lithium adjunctively in the treatment of major depressive disorder.

Additional agents reported to have efficacy in treating refractory mania in adults are calcium channel blockers (e.g., nimodipine [Nimotop]), other anticonvulsants (e.g., lamotrigine [Lamictal], gabapentin [Neurontin], and topiramate [Topamax]), and thyroid hormone augmentation. Open trials and several double-blind trials have reported L-type calcium channel inhibitors such as nimodipine to be effective in controlling mania in either refractory or rapid-cycling bipolar illness. Other calcium channel inhibitors such as verapamil (Calan, Isoptin) may not share the same antimanic properties. Lamotrigine has been used adjunctively in patients who are already on other mood stabilizers, and it has also been tried as monotherapy in adults. One double-blind study of lamotrigine as monotherapy reported a 48 percent response rate, with a placebo response rate of 5 percent. Lamotrigine is associated with pruritic rash in up to 10 percent of patients, which may be related to the rate of increase during drug titration. Of more concern is that 1 out of 500 patients may develop a potentially life-threatening skin condition called Stevens-Johnson syndrome or Lyell's syndrome. The metabolism of lamotrigine is influenced by other anticonvulsants being used; combined with valproic acid, lamotrigine's concentration may be doubled, and combined with carbamazepine, lamotrigine's concentration may be reduced by half. Although lamotrigine has been shown to be efficacious in mania, patients who responded to lamotrigine still required augmentation of the lamotrigine.

Gabapentin is an anticonvulsant believed to increase the concentration in the brain g-aminobutyric acid (GABA), the inhibitory neurotransmitter. A short-term double-blind trial of gabapentin indicated that it had an antimanic effect on approximately one third of patients, while placebo response was 5 percent. Gabapentin is reportedly well tolerated and has been used adjunctively as well as a monotherapy. Gabapentin is given in divided doses to maximize absorption and has been reported to improve sleep and anxiety symptoms.

Thyroid augmentation, using liothyronine (Cytomel) or levothyroxine (Levoxyl, Synthroid) has been used in combination with lithium in the treatment of both depressive and bipolar disorders. This strategy has also been used in refractory rapid-cycling bipolar disorder. Investigations are in progress to determine whether thyroid augmentation is effective in the prophylaxis of bipolar disorder. For levothyroxine augmentation, up to 70 percent of women showed improvement with the addition of the agent, compared with 20 percent of men, while for liothyronine augmentation, 44 percent of women responded, compared with 10 percent of men.

However, these augmentation strategies remain to be studied systematically in children and adolescents.

Electroconvulsive Therapy There have been a number of reports of electroconvulsive therapy (ECT) use in the adolescent population during the last decade. It has been described as a potentially efficacious treatment in adolescents for mood disorder characterized by catatonia, psychosis, and melancholic depression. A recent epidemiological survey of ECT among adolescents in the Australian state of South Wales found that only 42 patients between the ages of 14 and 18 years were administered a total of 49 courses of ECT comprising 450 treatments: 29 percent had major depressive disorder without psychosis, 29 percent met criteria for psychotic depression, 6 percent had mania, 12 percent had schizophrenia complicated by depression, 6 percent had schizophrenia without catatonic symptoms, 6 percent had schizophrenia with catatonia, 8 percent had schizoaffective disorder, and 4 percent had psychosis not otherwise specified. Several patients had neuroleptic malignant syndrome during the course of ECT. The number of treatments given ranged from 4 to 21. Electrode placement was unilateral on the right side in 64 percent of the courses, bilateral in 11 percent, and mixed in 25 percent. In patients who responded, response was evident in an average of 4.4 days, or after 2.8 treatments. The overall response rate to ECT in this review was 51 percent. Overall symptoms were rated significantly improved in 38 percent of patients with a diagnosis of major depression, 85 percent of patients with a diagnosis of psychotic depression, 100 percent of those with mania, 16 percent of those with schizophrenia complicated by depression, 33 percent of those with noncatatonic schizophrenia, 66 percent of schizophrenics with catatonia, and 50 percent of those with psychosis not otherwise specified. Depressive symptoms diminished irrespective of a diagnosis of major depression. Psychotic symptoms were more responsive to ECT in patients with mood disorders. Adverse effects consisted of headache in 65 percent of the courses, memory problems in 22 percent, confusion in 18 percent, muscle aches in 12 percent, and manic switch in 4 percent. Adolescents tended to have longer seizures than those reported for adults. Other reviews have indicated similar reports of adverse effects. Case studies of ECT among adolescents over a period of time at several university teaching hospitals corroborate the efficacy and overall safety of ECT in adolescents. Mood disorders in adolescents, characterized by psychomotor abnormalities, psychotic features, catatonia, and marked cognitive impairment may respond favorably to ECT. Given the rapidity of response and the relative safety of the procedure, ECT should be considered for treatment of severe mood disorders among adolescents.

Light Therapy Light therapy has been found effective in the treatment of depressive disorders with seasonal pattern in adults. There have been sparse reports of light treatment for children and adolescents with seasonal or other mood disorders. A recent double-blind placebo-controlled trial of light therapy was administered to 28 children and adolescents. The trial used a crossover design of 1 week of active treatment (1 hour of bright light and then 2 hours of dawn simulation) or placebo (1 hour of clear goggles plus 5 minutes of low-intensity dawn simulation, and then the reverse). Children initially underwent a baseline week in which they wore dark glasses for 1 hour a day. They were then randomized to active treatment or placebo. Following this, they entered another 1- to 2-week phase with dark glasses, before beginning the alternative phase. Active treatment consisted of bright light (2,500 lux for children under 9 years, and 10,000 lux for children older than 9 years) administered between 4 pm and 8 pm and dawn simulation (250 lux) at 6:30 am. Depressive symptom scores were significantly decreased from baseline and washout phases during the active treatment phase, according to parent report. Based on the parent report, 71 percent of the children had at least a 50 percent reduction of depressive symptoms during the active phase, while 25 percent reported reduction in the placebo phase. Although not significant, a trend toward diminished depressive symptoms during the active phase appeared in the child's report. Active treatment was not associated with more-frequent side effects than the placebo phase. At the end of the study, 78 percent of the parents and 80 percent of the children rated the active phase of treatment as the one in which they felt “best,” and almost all of the subjects opted to continue light therapy after the study had finished. The prevalence of seasonal affective disorder has recently been found to be between 3 and 4 percent, so it is important to continue investigation of light therapy.

CHAPTER 46. ANXIETY DISORDERS IN CHILDREN

46.1 OBSESSIVE-COMPULSIVE DISORDER IN CHILDREN

JOHN PIACENTINI, PH.D., AND R. LINDSEY BERGMAN, FH.D.

Until the last decade, obsessive-compulsive disorder (OCD) was thought to be rare in children and adolescents, and only limited attention was focused on this area. Over the past 10 years, however, several factors, including age-of-onset data from adult studies, the development of effective treatments, and more sophisticated assessment and screening methodologies, have led to significantly heightened professional and public awareness of childhood OCD and substantial upward revision in the prevalence rate for the disorder in this age group. Although significant strides have been made in advancing the scientific understanding and treatment of OCD in childhood, pediatric OCD remains less well studied than its adult counterpart. Like the adult disorder, childhood OCD is a chronic and distressing disorder that can severely impair social, academic, and family functioning. However, the continued refinement of current treatment approaches has increased the likelihood that many youngsters with OCD will be able to lead productive, satisfying, and relatively normal lives.

DEFINITION

According to the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV), *OCD* is defined as the presence of either obsessions or compulsions that "cause marked distress, are time consuming, or significantly interfere with the person's normal routine... or functioning." *Obsessions* are defined as "recurrent or persistent thoughts, impulses, or images" that are experienced as intrusive or inappropriate, are not simply excess worries about real-life problems, and which cause marked anxiety or distress. They must be recognized as products of one's own mind (to differentiate them from thought insertion). Common obsessions in childhood include fears of harm coming to self or others, fear of harming others, and contamination fears. *Compulsions* are repetitive behaviors or mental acts that are performed in response to an obsession or according to some other rigidly applied rules. Compulsions are meant to reduce anxiety or distress or prevent some dreaded event, but they are clearly excessive or are not realistically connected with the triggering stimulus. Typical compulsions in childhood include excessive handwashing, cleaning, checking, counting, and arranging.

HISTORY

Descriptions of one OCD variant, scrupulosity (e.g., groundless fears of moral, religious, or ethical transgression) date back to religious literature from the sixteenth century. In fact, the first survey of OCD symptoms in childhood was conducted in 1927 by the Catholic Church, which assessed 400 female Catholic high school students and identified 17 (4 percent) as overly scrupulous. The first description of OCD in childhood was provided by Pierre Janet in 1903 who reported on a 5-year-old boy with characteristic symptoms. Leo Kanner in 1935 noted the social isolation of OCD youngsters and the high degree of family overinvolvement in their child's rituals. In 1955, Louise Despert noted several key facts that remain characteristic of current thinking on the disorder: a male preponderance, children's recognition of their symptoms as abnormal and unwanted, and the tendency of these youngsters to hide their OCD symptoms from treatment professionals and others.

Early studies of both epidemiological and clinical samples supported the notion that OCD was rare in children and adolescents. The landmark Isle of Wight study of over 2000 English school children in the 1960s reported a 0.3 percent prevalence rate for "obsessional/anxiety disorder," and similar rates were derived from a handful of large, retrospective clinic-based chart review studies. In the mid-1980s, findings from the Epidemiologic Catchment Area (ECA) study that most adults with OCD report an onset of the disorder by mid- to late-adolescence significantly increased both the awareness of the disorder in childhood and research activity in this area. Much of the heightened professional and public awareness of childhood OCD was due to the efforts of a group of researchers at the National Institute of Mental Health (NIMH), led by Judith Rapoport. This group was also responsible for the first systematic studies of the epidemiology, phenomenology, and psychopharmacological treatment of OCD in this age group.

COMPARATIVE NOSOLOGY

The diagnosis of OCD has remained relatively constant from the third edition of DSM (DSM-III) to DSM-IV with minor exception. Compared with DSM-III, the revised third edition (DSM-III-R) provided stricter operationalization of the interference criterion (i.e., symptoms must take more than 1 hour per day). A more significant change was the reclassification of mental acts (e.g., praying, counting, mental organization) in DSM-IV from obsessions to compulsions. Although formerly considered obsessions because of their cognitive nature, these mental activities were reclassified as compulsions in DSM-IV to reflect their intended function as a means of reducing obsession-related anxiety. DSM-IV also added a specifier to code degree of insight and, consistent with the general DSM-IV framework, excluded disturbance directly due to a general medical condition.

The definition of the 10th revision of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) of OCD is phenomenologically similar to that for DSM-IV although less detailed and not as well operationalized. ICD-10 describes five subtypes of OCD: (1) predominantly obsessional thoughts or ruminations, (2) predominantly compulsive acts (obsessional rituals), (3) mixed obsessional thoughts and acts, (4) other obsessive-compulsive disorders, and (5) obsessive-compulsive disorder, unspecified. Unlike DSM-IV, ICD-10 does not preclude excess worries about real-life problems as obsessions or specifically address mental acts (as either obsessions or compulsions). Similar to DSM-IV, ICD-10 describes the function of compulsions as a means of preventing some objectively unlikely event. However, it does not go as far as DSM-IV in also noting that compulsions may further serve to reduce distress not associated with an untoward event (e.g., reducing vague discomfort associated with the "just-right" phenomenon). ICD-10 notes that compulsions are usually recognized as pointless or ineffectual providing some correspondence to the DSM-IV requirement that symptoms be recognized as excessive or unreasonable, but in contrast to DSM-IV, the applicability of this criterion to children is not addressed. Moreover, although symptoms are described as almost always distressing, ICD-10 does not provide other operationalized impairment criteria (e.g., time-consumption or interference with functioning). Finally, although noting that an OCD diagnosis "should be preferred only if ruminations arise or persist in the absence of a depressive disorder," ICD-10 does not specify the range of diagnostic exclusions found in DSM-IV.

EPIDEMIOLOGY

Recent epidemiological studies suggest a lifetime prevalence for OCD in children and adolescents between 2 and 4 percent, indicating that the disorder is approximately as common among youngsters as in adults. One recent community study of adolescents found a prevalence rate of 3 percent for "clinical" OCD, defined as symptoms severe enough to cause distress and interfere with functioning. The most commonly accepted 6-month prevalence rate is between 0.5 and 1.0 percent of the general pediatric population.

Most studies report a mean age of onset for childhood OCD between 6 and 11 years of age. Onset age appears to be bimodally distributed, with peaks in early childhood and early adolescence. Studies conducted at NIMH indicate that youngsters with an early onset of OCD (below age 7) are more likely to be male and to have a family history of OCD than those with later onset, suggesting that genetic factors may be more likely to play a role in development of the early onset subtype than the late-onset subtype. Although clinic-based studies of primarily younger patients suggest that the disorder is more common in males than females, this finding has not been replicated in epidemiological surveys of adolescent samples and may be a function of age or referral bias. Referral bias may also account for the underrepresentation of minorities and youngsters from lower socioeconomic strata in clinical samples of OCD youth, as this pattern has not been replicated in epidemiological studies with adult samples.

Comorbidity Comorbidity in children and adolescents with OCD is common, with up to 80 percent of affected youths meeting diagnostic criteria for an additional Axis

I disorder and as many as 50 percent experiencing multiple comorbid conditions. The most common comorbid disorders include other anxiety disorders (26 to 75 percent, depending on the sample), depressive disorders (25 to 62 percent), and disruptive behavior disorders (18 to 33 percent). The fact that depressive symptoms commonly appear after the OCD suggests that concurrent mood disturbance may be reactive. Obsessive-compulsive personality disorder has been reported in 11 to 14 percent of pediatric OCD samples. Motor and vocal tics are common in children with OCD, and 20 to 30 percent also suffer from Tourette's disorder. Youngsters with tic-related OCD (i.e., OCD with comorbid Tourette's disorder) are less likely to report engaging in ordering, hoarding, and washing compulsions than youngsters with OCD only.

ETIOLOGY

Neurobiological Factors The onset of OCD following encephalitis, head trauma, and epilepsy and the association between OCD and Sydenham's chorea and Tourette's syndrome support the notion of OCD as a neurobiological disorder.

Neurophysiological Factors Pharmacological and biochemical challenge studies suggest that abnormalities in central nervous system (CNS) serotonergic activity and sensitivity are related to at least a significant proportion of OCD cases. Primary support for this hypothesis (the serotonin hypothesis) is the fact that highly potent serotonin reuptake inhibitors are currently the most effective psychopharmacological treatments for OCD. Studies of both adult and adolescent samples have shown a relation between OCD severity and treatment outcome and peripheral markers of serotonergic functioning. A positive relation between decreased platelet serotonin concentration and decreases in OCD symptomatology in serotonin reuptake inhibitor-treated adolescents has been reported. Basal prolactin concentrations, an indirect measure of serotonergic activity, also correlated negatively with both duration and severity of OCD symptoms in a group of youngsters with severe OCD, and serotonin reuptake inhibitor treatment can significantly increase basal prolactin concentration over time.

Neuroanatomical and Neuropsychological Factors A number of neuroimaging studies of adults implicate abnormalities in corticostriatal-thalamocortical pathways in the etiology factors for OCD. Positron emission tomography (PET) studies show increased glucose metabolism in orbital frontal and prefrontal cortex, right caudate nucleus, and anterior cingulate gyrus. Moreover, successful treatment with either behavioral therapy or selective serotonin reuptake inhibitor (SSRI) medication decreases activity in these areas and attenuates the correlations of activity between these regions. Magnetic resonance imaging (MRI) and volumetric computed tomography (CT) scan studies also suggest frontal lobe and caudate nuclei abnormalities, and normalization of frontal and basal ganglia glucose metabolism was observed in OCD adults showing positive response to treatment.

In OCD patients, signals from an overactive orbitofrontal cortex may underscore feelings of danger and lead to ritualistic behavior, while the caudate nucleus and cingulate gyrus are associated with the more visceral and affective aspects (associated dread and worry) of the disorder. Some researchers believe that high intercorrelation of activity along the corticostriatal-thalamocortical pathway may lead to the circuit becoming “stuck,” resulting in an escalating pattern of doubt and checking characteristic of many OCD patients. Successful treatment may relieve symptoms by reducing the correlation in activity rates among these different brain areas.

Higher rates of neurological soft signs have been observed in both adults and children with OCD, and one prospective follow-up study found that the presence of neurological soft signs at age 7 predicted the occurrence of obsessive-compulsive symptoms in adulthood. Collective findings from imaging, neurological, and neuropsychological studies implicate greater right than left hemispheric dysfunction.

Immunological Factors Researchers have recently described a subgroup of youngsters whose OCD symptoms appear to be triggered or exacerbated by group A b-hemolytic streptococcal (GABHS) infection. The obsessive-compulsive symptoms in these individuals appear to stem from caudate swelling caused by a cross-reaction between caudate tissue and antineuronal antibodies formed against GABHS in a process similar to the development of Sydenham's chorea. This variation of OCD, *pediatric autoimmune neuropsychiatric disorders associated with streptococcal infection* (PANDAS), is characterized by sudden, dramatic onset or exacerbation of OCD or tic symptoms, associated neurological findings, and a recent streptococcal infection.

Family and Genetic Factors Several studies suggest that up to 50 percent of childhood OCD cases may be familial. Rates of OCD among parents of youngsters with OCD range from 17 to 19 percent, with some OCD symptoms reported in 52 percent of parents. Relatives of probands with early-onset OCD exhibit higher rates of OCD and tic symptoms. No significant correlation has been found between the type of OCD symptoms experienced by probands and their affected family members, suggesting that modeling may not play a primary role in the intergenerational transmission of the disorder.

Behavioral Factors Most behavioral conceptualizations of OCD are based on Hobart Mowrer's two-factor conditioning theory. According to this theory, a previously neutral stimulus becomes aversive (a conditioned stimulus) as a result of being associated with an unrelated aversive stimulus. Any actions associated with a decrease in the aversive response to the conditioned stimulus are then reinforced through higher-order conditioning (i.e., negative reinforcement). According to operant theory, compulsions become strengthened as a result of their anxiety-reducing properties. Because specific traumatic events responsible for the conditioned response are rarely identified, conditioning theories do not adequately explain the acquisition of obsessive fears. However, these theories are useful for understanding the maintenance of many OCD symptoms.

DIAGNOSIS AND CLINICAL FEATURES

Presentation of the disorder in children and adolescents is generally similar to that for adults. Compared with adults, however, children may be somewhat less likely to consider their OCD symptoms excessive, perhaps because of lower levels of cognitive awareness. Although a criterion for adult OCD, DSM-IV does not require that youngsters recognize their symptoms as senseless or unrealistic for the diagnosis to be made. However, DSM-IV does require that if another Axis I disorder is present, the content of the obsessions or compulsions are not restricted to that disorder. Examples of this include concern with appearance in body dysmorphic disorder, hair pulling in trichotillomania, and fears of harm befalling a loved one in separation anxiety disorder. Disturbance due to the direct physiological effects of a substance or general medical condition is also ruled out (see Table 15.6-10.)

The range of obsessions and compulsions experienced in childhood is quite similar to that found in adults with the disorder, although children are more likely to engage in compulsive reassurance seeking and involve family members in their rituals. Most youngsters with OCD have both obsessions and compulsions. The most common obsessions in this age range tend to focus on germs or contamination, followed by fears of harm to self or others, concerns with symmetry, and excessive moralization or religiosity. The most common compulsions include excessive washing, repeating, checking, touching, counting, ordering, and arranging. Compulsions in the absence of anxiety-related or otherwise distress-inducing obsessions are most commonly found in younger children, who often describe their rituals as being performed in response to an irresistible urge or an otherwise vague sensation (the “just right” phenomenon). Although the pattern and type of symptoms typically shift over time, the absolute number of symptoms generally remains constant. However, the disorder is stress sensitive, and many children experience acute symptom exacerbations during times of psychosocial stress or change (e.g., start of school year, moving to a new home, death of or separation from a family member).

Given the typically strange and senseless nature of many OCD behaviors, most children and adolescents with OCD attempt to camouflage or hide their rituals. With substantial effort, most children can inhibit or control their symptoms for short periods of time. In many cases, parents, teachers, and others close to the child remain unaware of the child's problem for months or years, learning of it only after the child can no longer control the symptoms or becomes too overwhelmed to cope.

Julie is a 10-year-old female who lives with her parents and two younger siblings. Julie reported a past history of OC behaviors including counting rituals dating to about first grade. These symptoms were moderate and remained manageable until 6 months prior to intake, when she began experiencing intrusive thoughts related to harm and subsequent near-constant performance of rituals. Julie's parents recognized her symptoms from a television program on OCD and scheduled an appointment for consultation and evaluation. For the past 8 months, Julie had been attending weekly supportive psychotherapy, although her OCD symptoms had not been addressed in this treatment.

At intake, Julie exhibited a range of obsessions primarily centered on harm befalling herself or her siblings, symmetry, and fears of forgetting things. Her compulsions included always making sure that if something touched one side of her body, she touched it with the other side as well, trying to hear things equally with both ears (causing her to frequently hold her head at an odd angle), and needing to see both feet as she walked. Julie's most severe ritual was related to walking through doorways. She felt that she needed to have a particular good thought in her head when walking through a doorway and would doubt whether she was having the appropriate thought. This would cause her to walk back and forth across doorways several times in an effort to ensure that she was having the good thought. She believed that if she wasn't having the good thought when walking through the doorway, it would be the last time that she would walk through any doorway because she would die. This symptom caused Julie to expend considerable time and energy and led to considerable interference with academic and social functioning at school. When she was unable to continue walking through doorways until satisfied, Julie would experience marked ongoing distress related to instrusive thoughts about her own death. This interfered with her ability to focus on her schoolwork, and her grades declined. In addition, the rituals had become very annoying to other family members and embarrassing to Julie when she was in public. Julie stated that although she still enjoyed being with her friends and playing basketball, her rituals were “getting in the way” and were very upsetting to her.

DIFFERENTIAL DIAGNOSIS

The DSM-IV requirement of functional impairment and distress differentiates obsessive-compulsive symptoms from benign habits or mildly excessive thoughts. Children and adolescents with OCD can be differentiated from those with other anxiety disorders in several ways. Although children with various anxiety disorders are often preoccupied or worried about issues related to their fears (e.g., a child with separation anxiety disorder worrying about harm befalling a parent, a child with dog phobia worrying about the presence of a dog), they do not typically engage in compulsions to reduce this anxiety. Although youngsters with generalized anxiety disorder typically experience recurrent intrusive worries, these worries tend to be focused on everyday matters, such as school, work, friendships, and future events. In contrast, obsessions usually involve some bizarre or seemingly magical content and are recognized by most children as unrealistic. Also, rituals or compulsions do not usually accompany the type of worry characteristic of generalized anxiety disorder.

Youngsters with Tourette's disorder typically exhibit motor and vocal tics that occur frequently and can appear behaviorally similar to compulsive actions. Tics are differentiated from compulsions, however, in usually being avolitional and not preceded by an obsessional thought. On occasion, children with OCD are mistakenly diagnosed with attention-deficit/hyperactivity disorder, since frequent intrusive obsessions can lead to inattentiveness, and ritualistic or avoidant behaviors can make the child appear overactive or impulsive. However, the purposeful nature of the OCD child's movements and their association with obsessive thoughts can be used to distinguish compulsions from motor hyperactivity. Perseverative and stereotypic behaviors are characteristic of pervasive developmental disorders such as autistic and Asperger's disorders. These can usually be differentiated from compulsions, since the former behaviors are neither distressing to the child nor performed in response to an obsession. In some cases, the fixed nature of bizarre or unusual obsessional beliefs can have a delusional quality and thus resemble schizophrenic symptomology. OCD can be distinguished from schizophrenia by the absence of other schizophrenic symptoms (e.g., hallucinations, formal thought disorder) and the ability to engage in reality testing. Several neurological disorders should be considered in the differential diagnosis of OCD, including temporal lobe epilepsy and complications secondary to CNS insults or tumors.

OCD must also be distinguished from developmentally normative ritualistic behaviors. These behaviors, which typically include bedtime or mealtime rituals and rigid or stereotypic rules for many activities, often serve to enhance the preschool child's sense of mastery and control. Although some have speculated that OCD represents the extreme endpoint along a continuum of normal developmental rituals, OCD can be distinguished from normal developmental phenomena on the basis of timing, content, and severity.

COURSE AND PROGNOSIS

Longitudinal studies attest to the chronicity of OCD in childhood. Follow-up studies have revealed that 43 to 68 percent of OCD youngsters continue to meet diagnostic criteria for the disorder up to 14 years after initial identification. Poorer outcome at follow-up is predicted by poor initial treatment response, a lifetime history of tic disorder, and a parental Axis I psychiatric disorder. The largest study to date reevaluated 54 participants in controlled medication trials at NIMH 2 to 7 years postintake. At follow-up, 43 percent of subjects still met diagnostic criteria for OCD, and only 6 percent were classified as complete remitters. On the whole, however, the group was significantly improved, with only 19 percent of subjects rated unchanged or worse. Substantial rates of comorbid psychiatric diagnoses have also been found at follow-up. Relatively few youngsters in the follow-up studies to date received an adequate trial of behavior therapy, which has been associated with positive long-term outcomes in adult samples. As behavior therapy becomes increasingly available for children with OCD, it is reasonable to expect the long-term outcome for these youngsters to improve.

TREATMENT

Several recent controlled trials with children and adolescents demonstrated the efficacy and tolerability of serotonergic agents for OCD in this age group. Fluvoxamine (Luvox), sertraline (Zoloft), and clomipramine (Anafranil) have all been approved by the Food and Drug Administration (FDA) for treatment of OCD in children and adolescents. Open trials of cognitive-behaviorial therapy (i.e., exposure plus response prevention) indicate that this treatment also benefits those with childhood OCD, with response rates similar to, or higher than, those for medication. In contrast, psychodynamic, supportive, and other psychosocial interventions have not proved effective when used alone for the treatment of OCD in either children or adults.

Pharmacotherapy

Selective Serotonin Uptake Inhibitors Large multicenter trials of fluvoxamine, sertraline, and paroxetine (Paxil) for childhood OCD have been completed. Fluoxetine (Prozac) showed similar benefit in two smaller controlled trials and several open trials. Response rates from the controlled medication trials average from 50 to 65 percent, although typical symptom reduction averages only 20 to 50 percent. Thus, the effectiveness of these medications in children is quite similar to that for adults. The most common adverse effects of the SSRIs include nausea, insomnia, hyperstimulation, agitation, headache, and sexual effects. These effects are typically transient, and most youngsters tolerate these medications well.

Clomipramine The earliest U.S. psychopharmacology trials for childhood OCD were conducted with clomipramine, a tricyclic drug. The largest controlled trial for childhood OCD yielded a 60 percent response rate for the medication group versus only 17 percent for placebo. Clomipramine adverse effects were typical of tricyclic drugs: dry mouth, somnolence, dizziness, fatigue, and tremor. Over the long term, however, tachycardia and electrocardiogram abnormalities are common in children treated with clomipramine and other tricyclic drugs; thus pretreatment and periodic electrocardiographic and therapeutic drug monitoring is warranted. Given the preferable safety profile and similar efficacy of the selective serotonin reuptake inhibitors, clomipramine should be considered a second- or third-line treatment option in most cases.

Medication Strategies Up to one-third of patients may not respond to monotherapy with a given serotonin reuptake inhibitor, and the likelihood of responding drops even further after a third serotonin reuptake inhibitor trial. Since many youngsters show a positive treatment response only after 2 to 3 months of treatment, one should wait at least 8 weeks and preferably longer before changing agents, adopting high-dose strategies, or undertaking augmentation regimens. A recent multisite fluvoxamine extension study found that many youngsters showed continuing improvement over the longer term, with maximum symptom relief occurring after 4 to 6 months of treatment (Table 46.1-1).

Generic Name	Brand Name	Typical Daily Dosage Range (mg)
First line		
Fluvoxamine	Luvox	50–200
Fluoxetine	Prozac	20–80
Sertraline	Zoloft	100–300
Paroxetine	Paxil	20–80
Citalopram*	Celexa	10–40
Second line		
Clomipramine	Anafranil	75–200

* Has not been well studied in children and adolescents. Clear dosing parameters for childhood OCD have yet to be established and are extrapolated.

Table 46.1-1 Primary Drugs Used for Childhood OCD

Combination drug therapy can be used for treatment-resistant patients or those with comorbid psychopathology. In most cases, the choice of an augmenting agent is determined by the comorbid condition, that is, busipirone (BuSpar) or clonazepam (Klonapin) with comorbid anxiety, lithium (Eskalith, Lithobid) with comorbid affective symptoms, and neuroleptics with comorbid tic disorder or refractory schizoobsessive symptoms. The use of combined medications for OCD has been poorly studied in children, and most current practice is based on clinical reports from the adult literature. Thus, a conservative approach must be taken when considering these strategies for OCD in children. In most cases, augmentation should only be considered for youngsters who have failed at least two monotherapy SSRI trials and a course of high-quality behavioral therapy.

Behavior Therapy Although both cognitive-behavioral therapy and SSRIs appear to be effective and well-tolerated treatments for childhood OCD, data from controlled trials with adults suggest that behavioral therapy may yield somewhat higher response rates, greater symptom reduction, and more-durable treatment gains than those obtained with medication alone. This, along with concerns regarding the long-term use of medication in children, has led to a preference by many clinicians to begin treatment with cognitive-behavioral therapy.

Behavioral therapy for childhood OCD is closely based on that for the adult disorder and is focused on exposure plus response prevention. The first step in exposure plus response prevention consists of developing a rank-ordered list of all of the child's obsessive and compulsive symptoms. Following this, patients are systematically exposed to these situations (the least difficult ones first), while being instructed not to engage in their ritualistic behaviors. Over repeated exposures, the associated anxiety dissipates through the process of autonomic habituation. In addition, when the feared consequences of not ritualizing fail to occur, patients' heightened expectations of harm disappear, reducing anxiety even further. Response rates from the open behavioral trials average from 75 to 80 percent, with mean symptom reduction in the 45 to 60 percent range. Preliminary data regarding predictors of outcome to behavior therapy for childhood OCD were provided by one recent study that reported an inverse relation between degree of symptom reduction and worse depression, anhedonia, and social functioning at baseline.

A number of developmental considerations complicate the behavioral treatment of childhood OCD. The most important complications stem from the cognitive and motivational limitations of young children for whom the motivating aspect of future improvement is likely to be outweighed by the high anxiety associated with the initial treatment exercises. These issues have been addressed by using psychoeducation to facilitate an understanding of the illness, cognitive strategies for dealing with anxiety, and behavioral rewards for compliance with treatment tasks, as well as an emphasis on graphic feedback of progress and family involvement in treatment.

Childhood OCD can have a significant negative impact on family functioning and relationships through both the disruption of normal family activities and the involvement of family members in rituals. As a result, inclusion of family members in the child's treatment is frequently warranted. Typically, family treatment provides psychoeducation about OCD to reduce blame and help the family distinguish OCD from non-OCD problem behaviors. Subsequent interventions facilitate family disengagement from the child's OCD behaviors and reinforce healthy patterns of family interaction.

Combined Therapy Even though concurrent behavioral and psychopharmacological treatment of pediatric OCD has not been well studied, evidence from the adult literature supports the use of a combined treatment approach. As noted, most medication and some behavior therapy responders experience continued significant OCD symptoms. In adults, combined treatment affords greater symptom relief than exposure plus response prevention or medication alone. Moreover, in adults, medication increases compliance with behavioral therapy, while the addition of behavior therapy minimizes relapse upon medication holiday and breakthrough symptoms associated with prolonged medication use. This latter point is especially significant for youngsters, in whom long-term medication effects are unknown.

Since symptom relapse follows cessation of medication, medication withdrawal should only be considered for youngsters who have remained symptom free for at least 1 year and must be done gradually. The typical strategy involves lowering the dosage in 25-percent increments at 2-month intervals in combination with cognitive behavioral therapy booster sessions to prevent relapse.

Other Interventions Case reports suggest that plasmapheresis and intravenous immunoglobulin are helpful for adolescents with presumed infection-triggered autoimmune OCD. The only published study of psychosurgery for adolescents with OCD reported significant symptom reduction in five adolescents following sterotaxic capsulotomy, although the course of postoperative rehabilitation was difficult. Scattered reports exist describing the use of electroconvulsive therapy, sleep deprivation, acupuncture, and biofeedback for adult OCD; however, no information is available regarding the utility of these techniques with children.

SUGGESTED CROSS-REFERENCES

Chapter 15 covers the anxiety disorders. SSRIs are covered in Section 31.25, and clomipramine is covered in Section 31.30 on tricyclic drugs. Cognitive-behavioral therapy in children is covered in Section 48.3. Compined psychopharmacology-psychotherapy is presented in Section 30.12.

46.2 POSTTRAUMATIC STRESS DISORDER IN CHILDREN AND ADOLESCENTS

LISA AMAYA-JACKSON, M.D.

Descriptions of child and adolescent victims of disaster and violence flash across television screens and newspapers with such growing frequency that more and more people are questioning the psychiatric consequences of direct, witnessed, and indirect traumatic experiences on the lives of youth. Research studies in recent years have confirmed that posttraumatic stress disorder and its inherent comorbidity occurs not only in adult victims of traumatic life events, but in children across the age spectrum. Delineating the many factors that influence the development of posttraumatic stress disorder as well as the best treatment outcomes within a pediatric developmental framework remains a pressing research agenda.

DEFINITION

The fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) defines posttraumatic stress disorder in six diagnostic criteria: (1) the person must have experienced, witnessed, or been confronted with an event involving death, serious injury, or a threat to the physical integrity of the self or others; (2) the traumatic event must be persistently reexperienced in the form of distressing images, thoughts, perceptions, dreams, or reliving, and intense psychological or physiological reactivity may be present with reminders of the event; (3) persistent avoidance of stimuli associated with the trauma and numbing of general responsiveness must be present following the trauma; (4) persistent symptoms of increased physiological arousal must be present; (5) the duration must exceed 1 month, and (6) some functional impairment must result. The related disorder, acute stress disorder, is not discussed in this section because the nosology of acute stress disorder is the same for children as for adults.

HISTORY

Accounts of emotional reactions accompanying human trauma can be traced throughout history. Pierre Janet's studies in the early 1880s are heralded as the first that contributed to the core set of symptoms that evolved into the current disorder. Following Janet, Sigmund Freud's conceptualization of psychic trauma had major underpinning for his contribution to psychoanalytic theory. “Traumatic neurosis” can be viewed as the earliest version of posttraumatic stress. The syndrome's evolution was primarily influenced by war trauma studies, particularly those on World War I and World War II veterans who suffered “shell-shock” and “combat fatigue”; Abraham Kardiner described it as a “physioneurosis” because of the notable autonomic hyperphysiology. Studies on the effects of traumatic events on children are primarily recent except for the noted work by Anna Freud and Dorothy Birlinghan that describes the reactions of children to the air raids of London. They noted that children's reactions often were mediated by parental response. Later studies of children's reactions found that when children are direct victims or witnesses to life threat (particularly when their developmental level allows them to understand the degree of threat), level of exposure is a stronger predictor of child distress than parental response.

The core symptoms of posttraumatic stress disorder were not actually applied to children until 1987, in the revised third edition of DSM (DSM-III-R). Research then confirmed that children's exposure across a wide range of traumatic life events can result in posttraumatic stress disorder.

COMPARATIVE NOSOLOGY

Prior to the third edition of DSM (DSM-III), specific reactions to trauma were called “gross stress reactions” (the first edition of DSM [DSM-I]) or “adjustment disorders of adult life,” with no application specified for children or adolescents. Posttraumatic stress disorder entered the nomenclature in DSM-III in 1980 as an anxiety disorder with an established stressor criterion, reexperiencing, numbing, avoidance, and general symptoms of distress. Not until DSM-III-R was there any application to children. DSM-III-R and DSM-IV refined the symptom groupings of the criteria in respect to the phasic nature of the symptoms (relative to both the physiological and psychological distress resulting from reminders of the event). The definition of a traumatic event (criterion A) evolved from something that would “cause distress in most people” (DSM-III), to “an event that is outside usual human experience” (DSM-III-R), to the current emphasis on the event's characteristics and the subjective distress response of the victim (DSM-IV). DSM-IV mentions several childhood stressors and emotional responses in children in criterion A in a nonspecific, nondevelopmentally derived way. Acute stress disorder is introduced in DSM-IV. DSM-IV attempts to be compatible with the 10th revision of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10). Disorders comparable to posttraumatic stress disorder and acute stress disorder appear in ICD-10; however, they are placed in a category of stress disorders rather than anxiety disorders.

EPIDEMIOLOGY

Prevalence rates for current and lifetime posttraumatic stress disorder were found to be 0.4 and 1.3 percent, respectively, in the Epidemiologic Catchment Area study. An additional 15 percent experienced posttraumatic stress disorder symptoms but failed to meet full criteria for the disorder. The only epidemiological study that looked specifically at the general population incidence or the prevalence of posttraumatic stress disorder in children and adolescents, done on a rural population of children in the Smokey Mountains, noted a 3-month prevalence rate of 0.6 percent. High rates of posttraumatic stress disorder have been documented in children exposed to such life-threatening events as combat and other war-related trauma, kidnapping, severe illness or burns, bone marrow transplantation, and a number of natural and man-made disasters. Studies on young victims or witnesses to criminal assault, domestic violence, and community violence have revealed high psychiatric morbidity (including posttraumatic stress) following exposure to violence.

Several incidents led to pioneering efforts in landmark studies in the area of sudden incident trauma. Lenore Terr's description of the Chowchilla school bus kidnapping described posttraumatic stress symptoms in all the children involved, regardless of their developmental, psychiatric, or prior trauma histories. Rosemarie Galante and Daria Foa followed young Italian earthquake victims and emphasized the inadequacy of non–trauma-specific measures. Robert Pynoos and investigators noted a higher than 90 percent incidence of posttraumatic stress disorder in child victims of a schoolyard sniper attack, and nearly 60 percent of exposed children continued to meet full criteria 1 year later. Posttraumatic stress disorder prevalence rates of 30 to 70 percent have been reported by other investigators studying disaster, community violence, and postwar adolescent refugee populations. These studies confirmed that posttraumatic stress disorder in children can become chronic and is highly comorbid with anxiety and depression. These and other studies have noted that parents and teachers may significantly underestimate both the intensity and the duration of the stress reactions in children. Furthermore, as in adult research, studies on child trauma reveal that exposure (proximity) is directly related to the risk of severe symptoms of posttraumatic stress disorder.

Only recently have posttraumatic stress disorder researchers turned to the more chronic forms of child trauma, such as domestic violence and child sexual abuse, despite long-standing public health concerns about their prevalence and impact on psychosocial functioning of affected young persons. A meta-analysis of the effects of sexual abuse revealed a mean prevalence of posttraumatic stress disorder in sexual abuse victims of 32 percent, and the rate increased to 53 percent when the analysis included studies of victims of severe ritualistic abuse.

ETIOLOGY

Posttraumatic stress disorder, by its first criterion develops in response to a stressor event. However, other variables contribute to development of the disorder,

including characteristics specific to the children and their environment, characteristics specific to the stressor, and posttrauma sequelae. The roles of risk factors, protective factors, and associated mediating variables of posttraumatic stress symptoms in children and adolescents are not well understood. Child variables of important consideration include demographic factors (e.g., age, sex, socioeconomic status), other life events (positive and negative), social and cultural cognitions, psychiatric comorbidity, and inherent coping strategies. Family factors (e.g., parental psychopathology and functioning, marital status, and education) play key roles in determining child symptoms. Parents' response to traumatic events particularly influence young children who may not completely understand the nature of the trauma or its inherent danger. Social psychologists have noted that traumatized young persons evidence a wide variety of social behaviors considered outside the norms, though which are risk factors and which are outcomes of the traumatic experience is less clear. Developmental psychologists have applied risk-analysis to studies of chronic adversity, and results suggest that multiple traumas, multiple risk factors, or both follow an additive-risk model. This has not yet been applied to posttraumatic stress disorder specifically.

Several frameworks attempt to conceptualize how the stressor actually causes the notable biological and psychological symptoms. While these frameworks have clear application to children and adolescents, none of the three were developed within a developmental psychopathology context. Cognitive-behavioral components probably have the strongest links to child-based developmental theory.

Neurobiological Factors Multiple physiological and neurochemical changes are implicated in the biology of posttraumatic stress disorder. Adult studies found prolonged autonomic sympathetic activity in trauma victims with the disorder. Using trauma-specific cues (e.g., combat films shown to war veterans), investigators found elevations in heart rate, blood pressure, electromyography, and sweat activity in veterans with posttraumatic stress disorder but not in those without the disorder (even when the latter had other anxiety disorders). Abnormal noradrenergic activity was found in studies using yohimbine (Yocon), a type 2 a-adrenergic receptor antagonist. Serotonin has been implicated in the stress response, with evidence suggesting better adaptation in animals with increased central serotonin functioning. Posttraumatic stress disorder patients experienced flashbacks and panic induction following administration of a serotonin receptor agonist. Studies investigating noradrenergic and serotonergic systems have not been replicated in children or adolescents; however, studies evaluating baseline levels of sympathetic tone and fear-enhanced startle responses in children with posttraumatic stress disorder have supported some of these findings.

The hypothalamic-pituitary-adrenal axis exhibits distinct changes in neuroendocrine functioning in patients with posttraumatic stress disorder. Changes in 24-hour urinary cortisol concentrations have been reported, as has dexamethasone (Decadron) suppression of cortisol in adult posttraumatic stress disorder patients. Neuroendocrine changes in maltreated children and adolescents were noted in a study looking at growth hormone and one assessing early pubertal changes.

Stress-induced analgesia in combat veterans exposed to combat films was reversed by naloxone (Narcan) administration, implicating abnormalities in the opioid system. Changes in sleep architecture in adult trauma victims with posttraumatic stress disorder include increased rapid eye movement (REM) latency, decreased REM sleep (reversed findings are noted in studies on patients with depression), and decreased stage 4 sleep (increased in those with panic states and night terrors). These sleep findings, and some of the neuroendocrine findings have important implications in differentiating posttraumatic stress disorder from depression and anxiety states. All these findings require further neurobiological research in children and adolescents to understand the developmental context of the stress response. Children, as developing organisms, may have distinct biological vulnerabilities to these neurobiological changes.

Psychodynamic Factors Sigmund Freud, around 1920, described psychic trauma (then referred to as “traumatic neurosis”) resulting from a traumatic stimulus intense enough to penetrate the stimulus barrier, overwhelm the ego, and render it helpless. This conceptualization, influenced by both Janet and Freud, posited that the dramatic loss of function resulted from the inordinate amount of energy trauma victims expended setting up every defensive mechanism they were capable of. Freud described “repetition compulsions” as unmastered themes of the trauma repeated in actions of everyday life that lead to the “fixation” on the trauma by the victim. Psychoanalytically defined defense mechanisms deemed important in trauma work include denial, dissociation, projection, and identification with the aggressor. Other theorists furthered psychodynamic interpretations by focusing on the (trauma-induced) emotion itself—so overwhelming that the traumatized individual experiences it as uncontainable.

Cognitive-Behavioral Factors Social learning theory applied to posttraumatic stress disorder uses the behavioral two-factor learning process in which both classical (factor one) and instrumental (factor two) conditioning apply. In classical conditioning, the stressor, or traumatic event, acts as an unconditioned stimulus that elicits an unconditioned response characterized by extreme fear and the cognitive perception of helplessness. Children note cognitive, affective, physiological, and environmental cues accompanying the traumatic event as conditioned stimuli. These stimuli become capable of eliciting a conditioned response through the process of stimulus generalization. The conditioned response is posttraumatic stress disorder, full blown or subsyndromal. In the second factor (instrumental conditioning), children quickly learn by trial and error how to reduce posttraumatic stress disorder symptoms through cognitive and behavioral avoidance. This model intertwines with both cognitive and information-processing models that note the inability to process and assimilate highly stressful experiences. Framed either as cognitive components that may follow higher-order conditioning patterns or as fear structures that remain easily activated, the individual adult or child would be unable to process memories beyond active memory storage. Hence these active memories repeatedly resurface, often rendering the trauma victim unable to modulate the arousal linked to the experience. Subsequently, the individual attempts avoidance and numbing.

DIAGNOSIS AND CLINICAL FEATURES

Stressor Diagnosis of posttraumatic stress disorder (see Table 15.6-12) requires meeting a stressor criterion. The stressor criterion A has been somewhat controversial in terms of defining a traumatic event. DSM-IV combines the qualifying aspects of life threat or association with serious injury or threat with the necessary subjective element of extreme fear and helplessness (which children may express as disorganized or agitated behavior). Clearly a child victim or witness to a life threat fulfills criterion A; instances in which chronic adversity plays a substantive role in a child's psychiatric presentation are less clear. Chronic physical and sexual abuse are considered potent stressors; however, their sequelae are not always adequately represented by the posttraumatic stress disorder symptom picture. The massive psychosocial adversities found in the inner city, terrorist countries, and third world child populations are traumatic by all standards, but they do not fit the sudden-incident nomenclature of posttraumatic stress disorder. Typologies such as type I trauma (sudden, single-incident trauma) and type II (ongoing or chronic trauma) have been suggested. Children also suffer posttraumatic stress as the result of “indirect” exposure—that is, the unwitnessed death or injury of a loved one, as in situations of disaster, war, or community violence.

Reexperiencing Children, like adults, reexperience the traumatic event in the form of distressing, intrusive thoughts or memories, flashbacks, and dreams. Reexperiencing phenomena, a unique feature of posttraumatic stress disorder, sets it apart from the other DSM disorders.

Children's nightmares may be linked specifically to a trauma theme or may generalize to other fears. Flashbacks occur in children as well as in their adolescent or adult victim counterparts. “Traumatic play,” a specific form of reexperiencing seen in young children, consists of repetitive acting out of the trauma or trauma-related themes in play. Depending on the nature of the play, it may be viewed as a positive or negative ability of the child to work through the experience of the event. Older children may incorporate aspects of the trauma into their lives in a process termed *reenactment*. Fantasized actions of intervention or revenge are common; adolescents should be considered at increased risk for impulsive acting out secondary to anger and revenge fantasies. Related behaviors in child and adolescent victims of trauma include sexual acting out, substance use, and delinquency.

Avoidance and Numbing Young victims of trauma, like adult victims, make the conscious attempt not to think about the event. Children not only cognitively suppress but also make conscious attempts to distract themselves via motor restlessness or impulsive behavior. This combined with the hyperarousal (criterion D) symptoms makes differentiation from attention-deficit disorder important but difficult.

Children often withdraw and show reduced interest in previously enjoyable activities. Loss of previously acquired skills is mentioned specifically in the C criterion and includes regressive behaviors such as enuresis or fear of sleeping alone. “Sense of foreshortened future” is another specific criterion C symptom that applies to children who may believe they will never grow up or who may lose motivation toward fulfilling a life goal because of a pervading sense of futurelessness.

Hyperarousal At least two symptoms of increased physiological arousal characterized by sleep disturbance, irritability, poor concentration, hypervigilance, and increased startle must be present. These manifest similarly in children and adults. Sleep disturbances are particularly problematic for children.

Associated Features Survival guilt was changed from a symptom to an associated feature in DSM-III-R, yet it remains highly prevalent in children with posttraumatic stress symptoms. DSM-IV struggles to accommodate the complex features of interpersonal violence and abuse (particularly when experienced in a prolonged manner during childhood) in the posttraumatic stress nomenclature. DSM-IV describes noteworthy associated symptoms of impaired affect modulation, self-destructive behavior, dissociative symptoms, somatic complaints, feelings of ineffectiveness and shame, feeling permanently damaged, constantly threatened, and a loss of

previous beliefs.

PATHOLOGY AND LABORATORY EXAMINATION

No laboratory studies presently help differentiate this disorder from other conditions. Psychological testing and the use of rating scales in children may help in data gathering for the differential diagnosis and treatment; however, they do not provide specific indicators that would make the diagnosis.

DIFFERENTIAL DIAGNOSIS

Children exposed to traumatic life events often exhibit symptomatology other than posttraumatic stress disorder. Furthermore, the symptoms of posttraumatic stress disorder may be confounded by their overlap with criteria symptoms for other disorders. For example, difficulty concentrating may be a symptom of posttraumatic stress disorder, depression, or attention-deficit disorder. Differentiating between likely comorbidities is particularly important since treatments may differ.

Anxiety disorders share symptoms (notably the criterion D set) with posttraumatic stress disorder as well as being highly comorbid conditions following trauma. Children experience fears about the safety of family and friends and not infrequently manifest full separation anxiety disorder. Generalized anxiety disorder is one of the most frequent comorbid diagnoses in both children and adults with posttraumatic stress disorder. Overlap with depressive symptoms is seen in the C and D criteria of posttraumatic stress disorder. These must be differentiated from major depression, which both the adult and child trauma literature show to be highly comorbid with posttraumatic stress disorder. Further complicating the picture, grief reactions and trauma-induced demoralization may also occur.

Disruptive behavior disorders or substance use may increase in children exposed to trauma—correlating with adult studies that found increased rates of antisocial behaviors after disaster and war. However, posttraumatic stress disorder must be ruled out as a cause of deteriorating school performance, concentration difficulties, irritability, or aggression that could mistakenly be attributed to disorder or attention-deficit/hyperactivity disorder. Sexualized behavior and suicidal ideation are often found in victims of child abuse. Dissociative symptoms may be particularly pronounced in abuse victims and victims of other interpersonal violence but are not uncommonly seen in child victims of other forms of trauma.

COURSE AND PROGNOSIS

High rates of symptomatology are seen immediately after a traumatic life event, and many children or teenagers are likely to meet criteria for acute stress disorder. A trauma victim is not eligible for the diagnosis of posttraumatic stress disorder until 1 month of symptoms has passed. Then it is not uncommon for rates of full-criteria symptomatology to be in the range of 60 to 90 percent of victims. Clinical lore suggests that trauma victims become more avoidant over time, which may negatively influence their willingness to seek treatment, despite the fact that some individuals' symptoms may worsen or may not fully arise until a substantial period of time has passed. Childhood delayed-onset posttraumatic stress symptoms have mostly been described in victims of severe physical abuse, sexual abuse, or both.

TREATMENT

The mainstay of both adult and child treatment strategies for posttraumatic stress disorder is cognitive-behavioral and psychodynamic psychotherapy used in combination with pharmacotherapy. Pharmacotherapy is less likely to be the primary treatment modality in children than in adults. Many fewer treatment studies have been done in children than in adult victims of trauma, particularly in clinical drug trials. Nevertheless, a growing number of clinicians who work with children are turning to trauma-based treatment strategies because of their increasing awareness of the impact of traumatic life events in their young patients.

Crisis Intervention When a traumatic event affects populations of children and their families, a crisis intervention plan should incorporate triage for acutely exposed victims, identify resources, and focus on supporting and strengthening coping skills necessary for dealing with the grief and trauma symptoms. The goal is preventing the development of chronic symptoms. Crisis centers and often schools serve as screening sites for children and families who may need further evaluations. Sessions called “critical incident stress debriefings” guide victims and caregivers to identify their reactions to the traumatic event. Outcome research on these debriefings have given them mixed reviews. Nevertheless, early preventive interventions are important in all acute trauma, when victims' symptoms are most prominent and they may be most amenable to contact with mental health professionals. Adult caregivers often need help dealing with resurfacing of prior losses or subsequent guilt over not being able to prevent what happened.

Psychotherapy The few treatment studies done in children emphasize cognitive-behavioral principles in targeting posttraumatic stress symptoms. Reexposure to traumatic reminders under safe conditions while incorporating mastery elements in a structured, supportive manner is a central theme for both group and individual trauma treatment. Systematic review of the traumatic event with children in a way that identifies their perception of the event and its meaning to them, their level of exposure, and their sense of “worst moment” becomes part of the working through of psychotherapy. Normalizing the children's reactions, acknowledging any actions that they did or wished they had done, identifying key traumatic reminders (conditioned stimuli), and clarifying their misunderstanding and predictable distortions of the event are important aspects of early treatment. Studies suggest that children may be particularly in need of contextual support in remembering, since proximity to life threat can influence memory. Children's detailed description of the trauma and their trauma response form the basis for narrative exposure that is strategically recalled in a play-by-play or moment-by-moment manner, to minimize avoidance mechanisms and habituate anxiety. Use of psychodynamic therapeutic principles allows development of the therapeutic relationship to sustain the discomfort of the exposure, facilitate an adequate holding environment, and attend to the meaning of the event that must be integrated into the child's experience. Cognitive restructuring, affective processing, and relaxation training are also used.

Psychotherapy must address the effect of the trauma and the resultant symptoms on the child's family life, peer relationships, and school performance and attend to the earlier described comorbidities. Treatment duration varies with level of exposure, and long-term treatment may be warranted for a child exposed to horrific violence, interfamilial homicide or suicide, or chronic abuse or when multiple risk factors (e.g., parental psychopathology, a chaotic living situation, and severe poverty) are present.

Group and family therapy are important treatment approaches that are used adjunctively or in place of individual therapy. Family members may need specific help in dealing with the child's distress and may suffer from trauma symptoms themselves that limit their ability to be in tune to their child's needs.

Parents benefit from psychoeducation about their child's symptoms and how to manage the symptoms. Working with nonoffending parents in maltreatment-related trauma cases has a strong empirical basis for improving a child's treatment outcome.

Group work can be specifically useful not only as a means to avail treatment when individual treatment is not available, but also when interpersonal difficulties need addressing or peer influences are important. Often victims express a need for support and understanding that only a fellow victim of trauma may understand.

Group treatment interventions in school settings tailor a public health approach in identifying children with symptoms and offering treatment when either shared exposure to single-incident violence or disaster occurs or multiple exposures to similar trauma such as widespread community violence occurs.

When a child's posttraumatic symptoms occur in the context of psychosocial adversity, including poverty, parental psychopathology, chronic abuse, lack of community support, and system failure, more systemic approaches that work with the family, community agencies, and the legal system may be necessary before trauma treatment strategies can be successful—given the rubric that most cognitive-behavioral treatment approaches stipulate the child is free from ongoing threat.

Psychopharmacology The neurochemical and physiological changes that accompany both short- and long-term posttraumatic stress symptoms indicate that medications may help to relieve the intense distress that so impairs trauma victims. Children, possibly more so than adults, may be unamenable to trauma-focused psychotherapy because of the intense hyperarousal and subsequent amplified avoidance. This is where psychopharmacological intervention would appear to be helpful. However, the clinical drug trial data on treatment of children and adolescents with posttraumatic stress disorder remains sparse, and clinicians who treat young people must rely on the results of research on adults. Medications are used to decrease intrusions and avoidance as well as hyperarousal symptoms; other target symptoms include impulsivity and sleep disturbance.

Clinical experience in children and adolescents supports many of the empirical findings from adult studies. Both tricyclic drugs (amitriptyline [Elavil] or imipramine [Tofranil]) and selective serotonin reuptake inhibitors (SSRIs) (fluoxetine [Prozac] and sertraline [Zoloft]) have efficacy on core posttraumatic stress disorder symptoms in adults that is not merely attributable to the drugs' antidepressant or anxiolytic effects. These drugs and others in their class have been used in children.

Concern about the lethality of tricyclic drugs and the necessity for careful electrocardiographic (ECG) monitoring may lead the treating physician to prefer the SSRIs over the tricyclic drugs; however, a posttraumatic stress disorder–induced sleep disturbance may be somewhat less responsive. Despite successful controlled trials using phenelzine (Nardil) in adults with posttraumatic stress disorder, clinicians have shied away from using monoamine oxidase inhibitors in children as a first-line drug.

Benzodiazepines, particularly alprazolam (Xanax), have only limited application in child posttraumatic stress disorder; clonazepam (Klonopin) may be an exception to this, although paradoxical disinhibition is a worry with it as with the rest of this class. Buspirone (BuSpar) may target anxiety and possible affective components, but as a single treatment it does not sufficiently relieve even the arousal symptoms on its own. Clonidine (Catapres) and possibly its counterpart, guanfacine (Tenex), target startle response in adults and children and are frequently used to treat intrusive symptoms and those of autonomic arousal. One study, using propranolol (Inderal), suggested that b-adrenergic receptor antagonist (beta-blockers) may reduce arousal symptoms in children. Carbamazepine (Tegretol) has been (case) reported to be helpful. Stimulants are often used unknowingly in child trauma victims to treat attention-deficit/hyperactivity disorder–like symptoms. Untangling the causes and overlapping criteria sets of posttraumatic stress disorder and attention-deficit/hyperactivity disorder is not easy; neither can one predict that a child's response to stimulants will determine whether attention-deficit/hyperactivity disorder is a true comorbidity or a misread stress response. Stimulants may exacerbate anxiety states and physiological hyperarousal. Alternatively, some patients with posttraumatic stress disorder who show the attention difficulties and impulsivity characteristic of attention-deficit/hyperactivity disorder may show improvement in impulse control, ability to stay on task, and activity level while on stimulants, though intrusive symptoms and sleep disturbances are unaffected. Only research that incorporates a developmental psychopathology view can untangle these and other child-specific factors in the psychopharmacological treatment of posttraumatic stress disorder in child and adolescent trauma victims.

B.C., a 5-year-old Asian boy living in New York City was brought by his mother to a university-based psychiatric clinic for evaluation and treatment of speech delays and psychological distress resulting from horrific family violence. B.C. and his two siblings aged 2 and 8 lived with his mother and her widowed father after fleeing their San Francisco home because of her husband's violent outbursts directed at her and her children. She reports that her husband of 12 years had a severe temper and when angered would verbally abuse her, or the children, or both, destroy furniture and the children's toys, and often physically abuse her and (more recently) the children. She stayed with her husband because her Chinese culture looked down on divorce, and she did not want her Chinese community to look down on her children's father. She left the home when the severe violence, which often left her with broken ribs and caused several episodes of loss of consciousness, extended to the children. The culminating episode was when the father—angry with his wife—stomped on the children's toys and then kicked B.C. in the stomach. Mrs. C. left with the children the next morning as soon as Mr. C. left for work. There was a 1-month period when the father took the children back to San Francisco and would not allow her even phone contact with them. When she was able to obtain sole legal custody, the children were returned to her. During the month with the father, the 8-year-old told her, the father told them daily that they must always stay and care for him when they grew up, otherwise his life would be ruined, and that he would take revenge against their mother and her relatives who were all to blame for the family being pulled apart. Mrs. C. reported that on their return from their father, all three children were more verbally and physically aggressive toward each other. Since living with the mother over the last 3 months their aggression has markedly decreased. Mrs. C. was worried about B.C. because of his terror of being separated from her—even if only for her to go to the bathroom—he would cling and cry inconsolably. B.C. had secondary enuresis of 2 years' duration. His mother reported that he had a severe sleep disturbance with frequent awakenings and nightmares throughout the night. School had gone surprisingly well with only mild separation problems upon being dropped off by his mother. Rating scales filled out by his teacher and his mother revealed no other striking behavioral concerns beyond those already described.

B.C. presented as an attractive, expressive 5-year-old whose speech was at times rapid, with some articulation problems. He was well behaved, without hyperactivity. He appeared to have a loving, close relationship with his mother and siblings that was observed both in session and in the waiting area. His mood was bright with no evidence of depression; his affect was clearly anxious. There was no evidence of thought disorder. He would often look out the window “to check”; he was clearly startled when a door down the corridor slammed shut as well as when he knocked several blocks off his worktable. He described nightmares of “blood on my mama and me” from a monster. He talked about liking school but feeling shy with the other children. He said he was not afraid at school “because there is a fence all around and no one could get me.” B.C.'s play over a two-session evaluation was either monotonous, clearly avoided any attempts of discussing family conflicts, or was full of aggressive themes. He wanted to blast the father doll to Mars because his older brother had told him there was no oxygen—“so he can't do any fighting.” He insisted on redrawing the face on his self-portrait multiple times because “I don't want the mouth to be mad.” He admitted he had trouble having fun when he played with his brothers at home because of frequent reminders of when his father would scream at them and “throw our toys at mama's head.” His mother described one particularly poignant episode in which B.C. ran into the yard with his hands covering his ears to try to keep a flashback “out of his head.”

B.C. was diagnosed with posttraumatic stress disorder and separation anxiety disorder. His was given multimodal treatment: individual and family therapy that included educational, cognitive, and behavioral interventions and adjunctive pharmacotherapy. Using stress management strategies (including relaxation training combined with clonidine to target his hyperarousal, startle, and sleep difficulties), B.C. used a narrative exposure task that combined drawing and narration to tell his “Scarytime in San Francisco” storybook—a detailed recounting of his traumatic experiences—in a gradual, desensitizing manner. This allowed him to target traumatic reminders of his father's rages and to habituate to both his painful recall of the traumatic events and his constant fear that his father would explode and kill his mother. Cognitive restructuring allowed him to process associated guilt feelings and horror at his revenge fantasies. Masterful actions taken by him and his family were integrated into his story. He and his mother were assigned homework to desensitize him gradually to being separated from her within, and later outside, their home. The family together designed “safety plans.” Within 6 months B.C.'s most severe symptoms of distress were ameliorated; he no longer met criteria for posttraumatic stress syndrome, and his separation anxiety had decreased significantly. He tolerated discontinuation of his medication without recurring symptoms. B.C. had some remaining self-esteem issues and was assigned a brief 8-week group treatment targeting peer relatedness and self-esteem concerns; afterward he no longer was considered to need treatment beyond occasional participation family therapy. His mother, who continued her own individual therapy (as did his older brother who had been diagnosed with posttraumatic stress disorder and major depressive disorder) was advised that B.C. would potentially need future interventions as he reached developmental milestones that could not help but be affected by his past relationship with his father (e.g., going through puberty or starting to date).

T.R., a 15-year-old white female had asked her maternal uncle to take her to the mall to meet her friends; he agreed, and they stopped at his local bank on the way. They inadvertently walked into a 4 PM bank robbery in progress, and her uncle was shot and killed. The robbers were apprehended 4 blocks away. T.R. had thrown herself to the ground at her uncle's instruction just before he was hit. Police initially thought T.R. had been shot because so much of her uncle's blood was on her clothes. T.R.'s parents kept her home from school several weeks after the funeral, viewing her as too fragile to handle school and fearing that unwanted questions would cause her distress. Her mother, grief-stricken and terrified that something could happen to T.R., would not let her out of her sight. Within a few weeks of resuming school a guidance counselor urged her mother to take T.R. in for a mental health evaluation. While her academics had suffered only mildly as a result of her trauma, the counselor noted that T.R. no longer ate lunch with her friends in the courtyard, cried every day during chorus, and no longer rode the school bus. A child psychiatrist, social worker, and psychologist team evaluated T.R. with rating scales (including parent and teacher child-behavior checklists and general symptom, anxiety, depression, posttraumatic stress disorder, and dissociation self-report checklists by the child) and interviews with both parents and T.R. T.R. had premorbidly been doing well though was temperamentally a bit shy and reserved. Since the traumatic death of her uncle, she displayed major sleep disturbance including difficulty falling asleep and nightmares with death themes. She reported intrusive recall of the robbery and the face of her uncle in death; numerous triggers caused flashbacks of the robbery including the autonomic response of going up the steps at school, which caused a full-fledged panic cascade reminiscent of her state while lying on the floor of the bank. She no longer would go into any commercial public place such as stores or banks. She felt tremendous guilt about her uncle's death—believing he would not have gone to the bank if she hadn't requested a ride to the mall. In fact, this guilt accompanied by the impairments from her anxiety caused tremendous demoralization that seemed to have bloomed into a full-fledged major depressive episode. Cognizant of the overlap in criteria, the team diagnosed T.R. as having posttraumatic stress disorder, major depression, and panic disorder. T.R.'s trauma avoidance strategies (e.g., not leaving her home) were reinforced by her mother, who herself appeared to have developed significant symptoms of posttraumatic stress disorder and separation anxiety. T.R. and her family began a multimodal treatment package consisting of individual therapy for both T.R. and her mother, adjunct psychopharmacological treatment for T.R. and her mother, and four sessions of family therapy. T.R. was guided through a detailed recounting of events preceding, during, and after the bank robbery. T.R. wrote out a timeline of events with accompanying thoughts and feelings describing the event step by step. The therapist carefully noted her current feelings and attributions (e.g., “that was so stupid of me”) about the original events and thoughts as well as stimuli that currently served as traumatic reminders. A series of “worst moments” was detailed along the way, often using drawings and colors in the drawings that identified the most terrifying aspects of the trauma—the ones that would come back to haunt her. Between sessions, exposure-response prevention homework tasks were done (often in conjunction with her mother), beginning with the easiest tasks and moving up a hierarchy to more difficult ones such as separation from her mother and going to a movie with friends. Medication management of T.R. began with paroxetine (Paxil); guanfacine was added after 1 month, and nicely reduced her remaining sleep disturbance and autonomic hyperarousal. Guanfacine dosage was tapered after 3 months of treatment (6 weeks after resolution of symptoms). T.R's individual psychotherapy consisted of approximately 25 to 30 sessions. Her medication (paroxetine) management continued for over 1 year.

46.3 SEPARATION ANXIETY DISORDER AND OTHER ANXIETY DISORDERS

CARRIE SYLVESTER, M.D., M.P.H.

Anxiety disorders have peak ages of onset in childhood and adolescence, although only two, separation anxiety disorder and selective mutism, occur solely in childhood. Anxiety symptoms are also quite common in normal children of normal parents. Thus, early development of these disorders in vulnerable children and adolescents is not surprising. They remain classified as adult disorders, however, because many patients do not come to treatment until they can seek help for themselves as adults.

COMPARATIVE NOSOLOGY

Child psychiatric disorders first appeared in the second edition of *Diagnostic and Statistical Manual of Mental Disorder* (DSM-II) with two child anxiety disorders, withdrawal reaction and overanxious reaction. The former was similar to avoidant disorder in the third edition (DSM-III), the latter to overanxious disorder. Separation anxiety disorder, which first appeared in DSM-III, is the only child anxiety disorder in the fourth edition (DSM-IV). The only significant change in criteria was a duration change from 2 to 4 weeks. Avoidant disorder was subsumed under social phobia and overanxious disorder under generalized anxiety disorder. Elective mutism did not appear as an anxiety disorder of childhood in DSM-III but appeared as selective mutism in DSM-IV. Now viewed as a form of social phobia, it may not survive to another edition of DSM as an independent disorder of childhood.

The International Classification of Diseases (ICD) is a categorical system that has developed parallel to the DSM. Although separation anxiety disorder is essentially the same in both, the 10th revision of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) has some differences from DSM-IV as shown in Table 46.3-1. Phobic anxiety disorder of childhood and generalized anxiety disorder of childhood are specific diagnoses, but descriptions of the disorders are similar to DSM-IV adult diagnoses. Selective mutism retains the older nomenclature of elective mutism in ICD-10.

Table 46.3-1 ICD-10 Diagnostic Criteria for Emotional Disorders With Onset Specific to Childhood

COMORBIDITY

Discussing the anxiety disorders as discrete entities is a heuristic exercise for many patients. Half the children and adolescents with either generalized anxiety disorder or separation anxiety disorder have at least one other anxiety disorder. Specific phobia, in contrast, confers little risk for another disorder. Studies of community samples have found anxiety disorder comorbidity rates from 14 percent in adolescents to 39 percent in children. Depression, attention-deficit/hyperactivity disorder, and conduct disorder or oppositional-defiant disorder are commonly diagnosed in anxious children. Anxiety causes distractibility and inattention so that the diagnosis of attention-deficit/hyperactivity disorder must be approached with caution. Oppositional behavior or the impression of such can be created by the stress of an anxious, impatient parent rushing an anxious child who is unable to decide rapidly or to enter novel situations easily.

Although a specific anxiety disorder diagnosis may not be longitudinally stable, anxious children often develop another anxiety disorder or an affective disorder. Thus, statements about remission of a particular disorder cannot be taken to mean that risk for another anxiety disorder or an affective mood disorder has abated.

SEPARATION ANXIETY DISORDER

Definition The primary feature of separation anxiety disorder is developmentally inappropriate anxiety sufficient to cause clinically significant distress or impairment when faced with separation from home or major attachment figures.

Epidemiology The prevalence rate drops from 4.1 percent in 7- to 11-year-old children, to 3.9 percent in 12- to 16-year-olds, and 1.3 percent in 14- to 16-year-olds. The mean age of onset for this disorder is 7.5 years. Although DSM-IV accepts onset up to 18 years, symptoms of separation anxiety (e.g., school refusal) after 13 years of age usually suggest another major psychiatric disorder. Gender differences in prevalence of separation anxiety disorder are uncertain in children, but in adolescence girls outnumber boys with this disorder. These children commonly come from single-parent homes, which probably explains the association with lower socioeconomic status. No studies specifically implicate genetic factors in the development of separation anxiety disorder discrete from other anxiety disorders or depression.

Etiology Interplay of temperament, attachment, and parenting style is believed key to the development of separation anxiety disorder. A parenting style combining lack of affection and maternal care interacting with overprotection and excessive control has been implicated in school refusal. Lack of parental care and intrusive overcontrol may lead to anxious, insecure attachment as a substrate for separation anxiety disorder and related disorders. Stressful transitions such as moves, changes in schools for other reasons, and hospitalization of children or attachment figures, may precipitate acute onset of separation anxiety disorder.

Diagnosis and Clinical Features Table 46.3-2 lists the eight criteria, of which at least three must be met for at least 4 weeks. Onset before age 6 years warrants the specification of early-onset disorder. The most common age at presentation to a mental health facility is 10.3 years, usually with school refusal. Refusal to participate in other activities that involve separation is more apparent in school-aged children. Younger children are more likely to report preoccupation with thoughts of harm befalling attachment figures and to have somatic complaints that cause them to present to the pediatrician. Parents may complain that the child is intruding on their marriage by insisting on sleeping in their bed.

A. Developmentally inappropriate and excessive anxiety concerning separation from home or from those to whom the individual is attached, as evidenced by three (or more) of the following:
(1) recurrent excessive distress when separation from home or major attachment figures occurs or is anticipated
(2) persistent and excessive worry about losing, or about possible harm befalling, major attachment figures
(3) persistent and excessive worry that an untoward event will lead to separation from a major attachment figure (e.g., getting lost or being kidnapped)
(4) persistent reluctance or refusal to go to school or elsewhere because of fear of separation
(5) persistently and excessively fearful or reluctant to be alone or without major attachment figures at home or without significant adults in other settings
(6) persistent reluctance or refusal to go to sleep without being near a major attachment figure or to sleep away from home
(7) repeated nightmares involving the theme of separation
(8) repeated complaints of physical symptoms (such as headaches, stomach aches, nausea, or vomiting) when separation from major attachment figures occurs or is anticipated
B. The duration of the disturbance is at least 4 weeks.
C. The onset is before age 18 years.
D. The disturbance causes clinically significant distress or impairment in social, academic (occupational), or other important areas of functioning.
E. The disturbance does not occur exclusively during the course of a pervasive developmental disorder, schizophrenia, or other psychotic disorder and, in adolescents and adults, is not better accounted for by panic disorder with agoraphobia.

Specify if:
Early onset: if onset occurs before age 6 years

Table 46.3-2 DSM-IV Diagnostic Criteria for Separation Anxiety Disorder

Tony was a 6-year-old boy referred by his school because of persistent refusal to attend school. He had always been a somewhat “clingy” child, but his difficulties had intensified in the past 4 months. He would follow his parents around the house and refuse to leave their sides in playgrounds or other situations where separating would be age appropriate. That behavior was worse if he could not keep them in clear sight. He said that he might be kidnapped or lost if he ever got out of their sight. He would tantrum whenever they would try to go out for the evening, saying that they were not coming back. When forced to engage in any of the distressing activities, he would complain of various somatic symptoms until one of his parents remained.

He was the product of a pregnancy marred by caesarean section for premature rupture of membranes at 34 weeks gestation. The perinatal course was complicated by moderate respiratory distress necessitating hospitalization for more than 3 weeks. Evaluation of the recent somatic symptoms revealed a child who was normal except for the psychiatric complaints.

His early development had been normal. He attempted preschool, but his mother had removed him because he cried at the beginning of each day, followed by aggression toward smaller peers. She participated as a parent aide in his kindergarten classroom, stating that she was trying to help him adjust to school. He was in grade school with peers who were after-school playmates in his home but would only go to their homes with a parent.

Family history was positive for maternal recurrent major depressive disorder, in remission, and a history of panic disorder in Tony's maternal grandmother. His maternal grandfather and a paternal uncle had alcoholism. Tony's parents were both in their early 30s with some college education. His father worked as an assistant manager in a small service firm; his mother had worked as a bookkeeper until Tony was born. They said that his mother would have returned to work if he had liked preschool. His difficulties were straining their marriage, as he frequently insisted on sleeping in their bed. His mother insisted that she wanted to return to the workforce and that Tony's separation anxiety prevented it. There was no suggestion of domestic violence.

Mental status examination revealed a thin, nicely attired boy who had great difficulty allowing his mother to go beyond a chair outside the office door. He insisted on checking twice whether she was there. He was fidgety and admitted feeling very worried about his mother leaving. He said that kind of worry was bad enough that he has trouble thinking. He denied depressed mood or symptoms including irritability. He denied hallucinations and did not voice any delusional ideas. He said that he enjoyed his friends and that his teacher was “nice” but that he worried about his mother when he was away from her.

Further exploration of the family situation revealed that his maternal grandfather had died 2 years earlier. His grandmother, who lived nearby, had been very agoraphobic until recently and had been dependent on the patient's mother, which had caused significant marital friction. Father had hoped that mother would return to work so that he could complete college and leave a job he hated. When mother tried to force Tony to go to school, grandmother would come to the home to help and would then encourage mother to “go easy on the child.” Mother would become angry, relent, and feel guilty about her interactions with her mother and her child. Grandmother further lectured mother that she needed to stay at home to care for her needy and delicate child because he had been premature.

Treatment focused on bringing the adults together to develop a supportive program for the child and to enlist grandmother in an appropriate role helping her daughter and son-in-law move forward with their lives. Grandmother supported Tony's return to the classroom once she understood the issues and approach. That was accomplished without directly addressing or interpreting her significant identification with her separation-anxious grandchild. Mother returned to work, with grandmother providing after-school care. Tony also responded well to a simple reward program for sleeping in his own room. Unfortunately, he presented again 7 years later as a popular, very good student and athlete who developed major depressive disorder. He responded well to fluoxetine (Prozac) and cognitive therapy.

Differential Diagnosis Social phobia, posttraumatic stress disorder, other anxiety disorders, and adjustment disorder each can present with some features of separation anxiety disorder. Depressed or psychotic children may cling to attachment figures. Inappropriate academic placement, fear of gang violence, or simple truancy due to conduct disorder are other reasons for school refusal. Additionally, culturally determined expectations about separation during the preschool years vary considerably.

Course and Prognosis The 96-percent remission rate for separation anxiety disorder is the highest for a childhood-onset anxiety disorder. The relation between separation anxiety disorder and later onset of panic disorder or depression remains conjectural because the evidence is retrospective. The previously held belief that early separation anxiety disorder is a prodromal symptom of schizophrenia has not been substantiated.

Treatment Parent education is the basis for development of an individualized behavior-modification program. The parents must become comfortable with a structured approach that includes systematic, gradual desensitization and rewards for improvement. Some mildly affected children respond rapidly once parents insist that they attend school or sleep in their own bed with appropriate praise and reward for their efforts. Others need some relaxation training and much support as they spend increasing time at school or move first to a cot in the parents' room and then to their own room.

Children who are unable to respond to support and behavioral management may benefit from pharmacological intervention. Although imipramine (Tofranil) was long the treatment of choice for separation anxiety disorder presenting as school refusal, attempts to replicate the studies have been unsuccessful. Current treatment recommendations include the serotonin reuptake inhibitors in dosages similar to those used for depression. Benzodiazepines or buspirone (BuSpar) may also be useful adjunctive treatments.

GENERALIZED ANXIETY DISORDER

Definition Overanxious disorder in DSM-III and the revised third edition of DSM (DSM-III-R) highlighted preoccupation with future and past events in contrast to generalized anxiety disorder characterized by poorly controlled, excessive worry. Overanxious disorder has been subsumed under generalized anxiety disorder in DSM-IV. Overanxious disorder emphasized concerns about competence and self-consciousness that were vague and commonly found in children of normal parents. Only one of six symptoms of restlessness, fatigue, difficulty with concentration, irritability, muscle tension, and sleep disturbance is required to make the diagnosis of generalized anxiety disorder in children. Affected older children and adolescents have more symptoms than younger children.

Epidemiology Rates of overanxious disorder in children and adolescents ranged from 2.9 to 4.6 percent. Symptoms of generalized anxiety disorder are usually overlooked by parents until their child is in school. Thus, data currently available on peak age of onset are suspect. The sex distribution is probably equal in early childhood, but the ratio of adolescent girls to boys with generalized anxiety disorder is 6 to 1.

Children of anxious parents are more likely to have an anxiety disorder than those with normal parents or parents with other psychiatric disorders. First- and second-degree relatives of children with overanxious disorder have increased rates of generalized anxiety disorder, separation anxiety disorder, and panic disorder. Monozygotic twins are more similar in fearfulness, emotional tone, and approach and withdrawal behavior than dizygotic twins.

Etiology The relations among temperamental aversions to novel situations, attachment, and parenting behaviors as contributors to the development of anxiety

disorders are foci of investigation into the etiology of the anxiety disorders.

Temperament Temperamental traits of passivity, avoidance, fearfulness, and shyness or reticence in novel interpersonal situations may be related to development of anxiety disorders in children, especially when at least one parent has an anxiety disorder or a depressive disorder. These traits have also been correlated with signs of increased autonomic nervous system activity, including tachycardia, laryngeal tension, pupillary dilatation, increased salivary cortisol concentration, and elevated urinary catecholamine concentrations. Also, a genetic trait of high reactivity has been proposed as an animal model for part of the hereditability of anxiety. Rhesus monkeys with that trait react to stressors such as forced separation with retreat, diminished exploration, and increased physiological arousal.

Attachment Infants who are insecurely attached may have more anxiety disorders in childhood and adolescence. Mothers of insecurely attached infants also have poor current and past attachments.

Parenting Parents of anxious children tend to interpret ambiguous situations as threatening; the same response has been shown in anxious children. Their parents provide more-negative responses and are more restrictive; they usually encourage avoidance as a way to handle stressful situations. As a corollary, parenting behaviors may be due to the child's distress. More likely, the family system strikes a dysfunctional balance between child and parent factors.

Diagnosis and Clinical Features These children are referred because of somatic complaints, insomnia, social impairments, or comorbid depression and suicidality. They are often well behaved and eager to please but may intrude on parents with undue concern about finances or minor family problems. Excessive, intrusive reassurance seeking or procrastinating with school work may show their anxiety. They may attempt to limit their families' activities because of difficulty with novel situations.

The two most common measures of childhood anxiety are the Revised Children's Manifest Anxiety Scale (RCMAS) and the State-Trait Anxiety Inventory for Children (STAIC). The RCMAS has an advantage of providing a scale suggesting whether the child is misrepresenting symptoms or misunderstanding the instrument. Neither instrument is useful in making a differential diagnosis. Both are useful in gauging severity and treatment response.

Barney was an 8-year-old boy who was referred by his parents in the first month of third grade because of a 1-year history of increasing anxiety during transitions. He stated his problem as “being nervous about things” and said that he had been “worse” in the past few weeks. He had had difficulty falling asleep and nightmares as long as he could remember. An example was that Frankenstein's monster was chasing him to turn him into a rock. His insomnia increasingly included waking during the night and sleepiness in the morning. He said that he was always a “picky eater” and stated that he did not like to try new things. His parents noted that he cried easily and complained about feeling nervous about going to school. He compared himself unfavorably with other children and expressed much performance anxiety regarding academic achievement. He also described much anticipatory anxiety about not doing well enough at things and worrying about how tired he would be in the morning. He had multiple fears including that “nobody will be nice to me,” spiders, snakes, people breaking into the house, bombs, heights, big dogs, the dark or “stuff under the bed,” getting sick or hurt, and speaking in class. He was preoccupied with fearful thoughts at bedtime. He worried about being kidnapped by robbers and never seeing his parents. However, he could go to camp and tolerate a parent being away for several days on a business trip. The parents usually avoided being away at the same time. There was no suggestion of abuse and no history of recent or significant past losses or trauma.

Barney was the healthy product of a normal pregnancy, labor, and delivery. Early temperament and developmental milestones were normal. His medical history was uneventful, and his most recent physical examination was entirely normal. He changed schools in second grade after having attended a small private school for preschool through first grade. He was in an excellent neighborhood private school and was earning mostly above-average grades. He excelled at basketball and enjoyed competitive team play.

Family history was positive in that mother had recurrent mild major depressive disorder. Maternal grandparents both had severe recurrent major depressive disorder, but their siblings and their children were thus far normal. Barney's parents were successful professionals in their late 40s. Both were in good health and considered this first marriage an important, positive relationship. They enjoyed a lifestyle that included a second home in another region of the country that Barney said he enjoyed.

Mental status examination revealed an attractive, charming, cooperative boy who was developmentally appropriately dressed and groomed. His interactions with his parents were affectionate, and he separated easily from them. His speech was articulate and spontaneous. He described some sad mood, but anxiety predominated. His affect was appropriate to the content of the discussion. He smiled readily and could relax during the interview. The remainder of the examination was entirely normal.

Further discussion over a brief course of therapy revealed that he would read for long periods at night to try to distract himself from his thoughts so he could go to sleep. His parents had stopped reading to him when he achieved early reading proficiency. He also revealed that he would go from one parent to the other when they had differences over his rules. He would then feel overwhelmed by anxiety and guilt about mild parental dissension. He particularly found himself in that situation when he wanted to avoid homework. Treatment included teaching him and his parents relaxation techniques, using basketball game imagery to help him when fears and worries became intrusive. His parents resumed holding him and reading to him at night as a soothing bedtime ritual. He expressed great relief, saying that he could go to sleep easily and that his nightmares dramatically diminished. He and his father, in particular, worked on a variety of cognitive strategies to deal with his fears. An important change in family dynamics was that he adopted a rule of leaving the room if his parents needed to discuss one of his requests. He also stopped making requests of both parents without telling each what the other had said. He admitted to feeling much better having eliminated the main reason his parents would be upset in front of him. Fortunately, his second year in the school went well academically, and his basketball team (on which he had an important starting position) had an excellent season. These external events reinforced the work done in 10 therapy sessions. His parents said that they would return for further evaluation and treatment if new symptoms developed.

Differential Diagnosis Generalized anxiety disorder is distinguished from the other anxiety disorders on the basis of persistent symptoms and a lack of a specific focus for the anxiety. The real worries of children who are ill, poor, or with impaired parents must not be confused with generalized anxiety disorder.

Most substance-related and other medical causes of tension and autonomic reactivity are not seen until adolescence. Relatively common causes are caffeinism and bronchodilator overuse. Uncommon causes include hyperthyroidism, lupus, hypoglycemia, and pheochromocytoma.

Course and Prognosis Eighty percent of children and adolescents with the disorder have remitted at 4-year follow-up. Early age at onset and older age at diagnosis are related to slow remission.

Treatment

Education and Family Therapy Parent education and family therapy are important in the treatment of anxiety disorders in children and adolescents. Understanding which family stressors may be aggravating anxious symptoms in the child is essential. If school performance and test anxiety are prominent features of a child or adolescent's generalized anxiety disorder, consulting with the school may be helpful.

Behavior Therapies Behavioral treatment may be indicated if the child's anxiety is circularly causing and responding to inconsistent limit setting. It also organizes family contexts in which an anxious, depressed, or simply inexperienced parent has difficulty setting priorities for expectations, fails to reward attempts at appropriate behavior, or does not allow a child adequate time to respond. Behavioral programs must emphasize simple, positive statements of desired behaviors rather than prohibitions of undesired behaviors. Negative (“do not”) goals increase ambiguity and anxiety; clear statements of positive expectations coupled with social rewards and encouragement reduce ambiguity and anxiety. Punishment may be included, but the emphasis must be on rewarding even small efforts and one must avoid expecting rapid, error-free improvement.

Pharmacotherapy The current standard of care is that pharmacotherapy must be viewed as adjunctive to other interventions. Results of double-blind controlled studies document the efficacy of selective serotonin reuptake inhibitors (SSRIs) in the treatment of depressive disorders in children and adolescents. Many have wellknown anxiolytic effects and the advantage of treating common comorbid conditions. No comparable data exist for the tricyclic drugs, but they may play a role in management of children with comorbid attention-deficit/hyperactivity disorder or enuresis. Experienced clinicians caution against starting treatment of children and adolescents, especially those with anxiety disorders or risk for bipolar disorders, with more than the equivalent of 2 to 5 mg daily of fluoxetine, with gradual increases

every 2 to 4 days, because younger or anxious patients are particularly at risk for agitation.

The benzodiazepines also have a role in the short-term treatment of anxiety disorders in children, but the risk for behavioral disinhibition is greater in younger patients (Table 46.3-3). Open trials have suggested that buspirone may be efficacious in some young anxious patients without risk for habituation or disinhibition. The starting dosage of buspirone for children and adolescents is 2.5 mg daily or twice a day, with an increase every 3 to 4 days up to a maximum of 20 mg daily for children and 60 mg daily for adolescents. The usual total daily dosage is 0.3 to 0.6 mg/kg. Antihistamines and neuroleptic drugs are no longer recommended anxiolytic agents for children and adolescents.

	Dose Equivalency mg	Starting Dose mg q.d.)	Rate of Increase	Usual Daily Dosage mg*	Maximum Daily Dose mg
Prepubertal Children					
Lorazepam (Ativan)	1.0	0.25–0.5	0.25–0.5 mg q.3–4d.	0.25–3	4
Diazepam (Valium)	5.0	0.5	0.5 mg q.5–7d.	1–10	10–15
Alprazolam (Xanax)	0.5	0.25	0.25 mg q.3–4d.	0.25–2	1–4
Clonazepam (Klonopin)	0.25	0.125	0.125 mg q.3–7d.	0.125–0.25	0.2 mg/kg
Adolescents					
Lorazepam (Ativan)	1.0	0.5–1	0.5–1 mg q.3–4d.	0.5–6	10
Diazepam (Valium)	5.0	0.5–1	0.5–1 mg q.5–7d.	1–20	20–30
Alprazolam (Xanax)	0.5	0.25–0.5	0.25–0.5 mg q.3–4d.	0.75–4	8–10
Clonazepam (Klonopin)	0.25	0.5–0.75	0.5 mg q.5–7d.	1–3	4

*Daily dosage is usually divided for b.i.d., t.i.d., or q.i.d. administration.
Children overmetabolize benzodiazepines faster than adults, therefore they may need a higher mg/kg dosage and more frequent dosing.

Table 46.3-3 Benzodiazepine Dosage Regimen for Children and Adolescents

SPECIFIC PHOBIA

Definition Unlike adults, children are not required to acknowledge their fears and worries as unreasonable or excessive to make a diagnosis of a phobic disorder. It is sufficient that the fear causes avoidant behavior that interferes with some aspect of childhood functioning.

Epidemiology Specific phobia occurs in 2.4 to 9.2 percent of children and adolescents, with usual onset between 5 and 13 years of age. Specific phobia occurs equally in young boys and girls, but 9- to 12-year-old girls have more fears than boys. The sex distribution of this disorder favors girls in adolescence. One study of specific phobia probands found that 15 percent of their children had specific phobia; 8 percent of the children of normal controls had it.

Etiology Twin studies suggest that specific phobia has the lowest genetic contribution of any of the anxiety disorders. Psychodynamic theorists extended Sigmund Freud's original conceptualization of phobic displacement of Oedipal urges to emphasize aggressive and social conflicts, but their ideas rest on anecdotal case studies. In contrast, empirical studies have implicated indirect experience of trauma and information transmission as most important in the early development of specific phobias. Direct exposure is a less common pathway for children, in contrast to adults, who more typically acquire phobic avoidance after direct exposure to feared objects.

Diagnosis and Clinical Features Heights, loud noises, injections, insects, dogs, and other animals are among the more common phobias. School phobia, however, is a misnomer for school refusal. School refusal is a symptom of disorders including separation anxiety disorder, social phobia, depressive disorder, and conduct disorder.

Kathy was a 10-year-old girl referred by her pediatrician. Her worsening, nearly lifelong panic response to dogs was interfering with peer relations and apparently causing family conflict. She denied excessive fear of other animals including insects, except for a healthy respect for creatures that her parents had warned her carry rabies. She had a guinea pig for which she provided most of the care. Neither she nor her parents could recall a traumatic incident involving a dog, but barking had always frightened her. She was somewhat afraid of the dark but could fall asleep with a small light in her room.

Medical and developmental history was normal. She was a very good student and was popular despite limits imposed by her fear of dogs. She had, however, recently been subjected to some teasing by peers about her phobia.

Family history was positive in that Kathy's mother recalled that her brother had an excessive fear of the water that took considerable effort to overcome so he could swim. Kathy was the middle of three children of a rural carpenter and homemaker in their mid-30s. Her father and 12-year-old brother wanted a large dog suitable for hunting. Her mother was unenthusiastic, but believed that denying them a dog because of Kathy's phobia was unfair.

Mental status examination revealed a pleasant, attractive, intelligent girl who related easily and had no evidence of a disorder other than specific phobia. She expressed regret that her fear was interfering with her friendships. Kathy was somewhat angry that her father and brother were forcing her to confront this; nevertheless, she added that keeping them from having a dog was unfair and made her sad.

Treatment consisted of a gradual desensitization procedure that began with looking at pictures of dogs while practicing relaxation techniques. We then arranged to have a small, friendly puppy visit three sessions. She gradually could tolerate and finally hold and pet the puppy. Her father and brother agreed to have her work with them to raise a puppy. They chose a gentle, intelligent retriever with a predictable temperament. The remainder of her desensitization included playing with the family puppy and accompanying her father and brother to puppy obedience training. She later attended similar training for dogs with their dog and adult dogs of other breeds so that her reduced fear could generalize. This family fortunately wished to own a large, easily trained dog who provided an optimal experience for Kathy. It also helped that her mother grew to love him too.

Differential Diagnosis Persistence for at least 6 months is required to avoid misdiagnosis of developmentally normal fears. The disorders most easily confused with specific phobia in children include panic disorder, social phobia, obsessive-compulsive disorder, and posttraumatic stress disorder. Delusional disorders mimicking phobias are rare in children.

Course and Prognosis Mild specific phobias are transient, probably because fears are a normal part of childhood. The longitudinal course is affected by the presence of comorbid disorders and the response of important individuals in the child's environment.

Treatment Gradual desensitization is the supportive behavioral treatment of choice. Implosion treatment is contraindicated in children. Guided imagery using relaxation techniques is useful in preparing a child with particularly distressing somatic symptoms for gradual in vivo exposure. Family therapy is useful when parental factors such as shared persistent fears or impatience with systematic desensitization are compromising the child's progress. Medication is rarely recommended in uncomplicated specific phobia. Careful reassessment of the diagnosis and consideration of occult family factors is usually indicated rather than use of an anxiolytic medication.

SOCIAL PHOBIA

Epidemiology Social phobia occurs in 1 percent of children and adolescents, with typical onset in early to midadolescence. Avoidant disorder, now childhood onset social phobia, occurs between 2½ years old and the early school years. Sex distribution is equal in childhood and probably throughout adolescence.

One approach to elucidating familial disposition to social fears is controlled study of the families of behaviorally inhibited children. Although they do not exhibit social phobia when examined at a young age, their parents have very high rates of social phobia, avoidant disorder, and generalized anxiety disorder with considerable comorbidity.

Etiology The factors that lead from avoidant, inhibited temperament to social phobia are poorly understood. As with specific phobias, a combination of real or

vicarious exposure, parental attitudes, and information transmitted to a vulnerable child is a likely pathway to the disorder. No information exists to clarify the relative contribution of genetic variables.

Diagnosis and Clinical Features To subsume DSM-III avoidant disorder, the criteria for DSM-IV social phobia now include fears of unfamiliar people and fear of social evaluation. Children with social phobia report distressing events occurring approximately every other day. They complain of a variety of somatic symptoms and use illness to avoid embarrassing situations. Young children and early adolescents with social phobia report a sense of being scrutinized.

Differential Diagnosis In middle school and high school, children with social phobia may be willing to participate in activities with their close friends while avoiding school when they cannot be in classes with children they know well. Selective refusal of school, while being willing to go away from parents to participate in pleasurable activities with friends, can be easily misinterpreted as oppositional behavior or an aspect of conduct disorder. Misdiagnosis of developmentally normal shyness and normal anxiety engendered by public speaking must be avoided. Severe disorders that may initially seem to be social phobia include major depressive disorder, panic disorder, and (rarely) childhood-onset schizophrenia.

Course and Prognosis Childhood-onset social phobia is the most stable childhood anxiety disorder. The lifelong effects of interference with school attendance or participation in developmentally important activities are obvious. The proclivity for using alcohol to disinhibit shy or avoidant adolescents is another risk of social phobia.

Treatment Systematic desensitization and family therapy are initial treatments aimed at improving support for the child. Social skills training including group therapy and peer mentoring are effective adjunctive treatments.

Medication may have a role in the management of social phobia, especially if the child is refusing to attend school or is self-medicating with alcohol. No placebo-controlled studies of benzodiazepines or antidepressants have been reported for this indication. Studies of children with selective mutism indicate that SSRIs, such as fluoxetine, may benefit these children and adolescents.

PANIC DISORDER

Epidemiology The prevalence of panic disorder in childhood and adolescence is approximately 0.6 percent. There have been anecdotal reports of panic disorder symptoms in children and retrospective reports of childhood onset of panic disorder. It is uncommon before puberty, but the peak age of onset for panic disorder is between 15 and 19 years. The sex distribution is equal in childhood, but the adult female predominance of this disorder rapidly appears after puberty.

Etiology There are no studies that clarify etiological factors for an early onset of panic disorder as opposed to early onset of other anxiety disorders. The genetic and familial nature of panic disorder is well documented.

Diagnosis and Clinical Features The diagnostic criteria for panic disorder are the same for children and adolescents as for adults. As with less psychologically minded adults, children may focus more on somatic symptoms or may express panic as acute separation anxiety if symptoms occur while they are stressed and away from familiar surroundings. They may not tell anyone about the psychological symptoms or discrete panic attacks without systematic inquiry. Because younger children become easily confused about time lines, gathering unbiased interview data is difficult.

Differential Diagnosis Spontaneous panic attacks must be differentiated from specific phobia, social phobia, or generalized anxiety disorder. Associated agoraphobia, fear of going out or fear of crowds, may be confused with separation anxiety disorder in younger patients. Children may develop panic disorder when depressed, especially when separation or loss precipitates depression.

Most medical disorders known to mimic panic disorder have onset in childhood and adolescence. These include asthma, cardiac arrhythmias, thyroid disorders, misuse or abuse of substances including caffeine, and rare tumors such as pheochromocytoma or insulin-releasing tumors. Distinguishing seizure disorder from pseudoseizure secondary to panic is important because brain tumors are the commonest solid tumors of childhood.

Course and Prognosis Panic disorder with onset in childhood and adolescence has the poorest outcome of the childhood-onset anxiety disorders, with a remission rate of 70 percent. Careful monitoring for comorbid depression and associated increased risk for suicide is crucial.

Treatment Education and relaxation training are fundamentals of management of this disorder. Behavioral treatment of associated agoraphobia may be necessary. Supportive or cognitive therapy may be needed to overcome the pathological explanatory models for the frightening experience of spontaneous panic attacks.

Ample open-trial and anecdotal evidence supports the use of SSRIs or high-potency benzodiazepines to treat this disorder in children. Children, adolescents, and individuals with panic disorder are, however, particularly sensitive to rapid increases in either class of medications, and may exhibit agitation, worsening panic, or disinhibition.

SUGGESTED CROSS-REFERENCES

Anxiety disorders are discussed in detail in Chapter 15. Benzodiazepine receptor agonists and antagonists are covered in Section 31.9 and buspirone in Section 31.11. Selective serotonin reuptake inhibitors are explained in Section 31.25. Tricyclic and tetracyclic drugs are further discussed in Section 31.30. Normal child development is covered in Section 32.2. Selective mutism can be found in Section 46.4. Mood disorders of childhood and adolescence are discussed in Chapter 45. Behavior therapy is discussed in Sections 48.3 and Section 30.2 and family therapy in Section 48.5.

46.4 SELECTIVE MUTISM

HENRIETTA L. LEONARD, M.D.

Selective mutism is a disorder of childhood characterized by a total lack of speech in specific situations even though the individual has the ability to speak as demonstrated by speech production in other (usually familiar) settings. Recently, psychodynamic etiological factors have been deemphasized in lieu of a possible reconceptualization of selective mutism as an anxiety disorder. A focus on biologically mediated temperamental and anxiety components currently drives ongoing research on the phenomenology, etiology, and treatment of selective mutism.

DEFINITION

Selective mutism appears under “Disorders Usually First Diagnosed in Infancy, Childhood, or Adolescence” in the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV). DSM-IV defines selective mutism as a persistent failure to speak in specific social situations (e.g., school) where speaking is expected, despite speaking in other situations. The name was changed from elective mutism to selective mutism with changes from the revised third edition of DSM (DSM-III-R) to DSM-IV. Although the DSM-IV definition is essentially unchanged from that given in DSM-III-R, duration (at least 1 month, not the first month of school) and severity (interfering with social communication or educational or occupational achievement) diagnostic criteria were added in DSM-IV.

HISTORY AND COMPARATIVE NOSOLOGY

The latter part of the nineteenth century saw the first description of a disorder in which people would not speak in some situations, despite having the ability to speak. The use of the term *aphasia voluntaria* in the German literature emphasized the conceptualization of this phenomenon as a voluntary decision not to speak. The nomenclature shifted to *elective mutism* in the 1930s, with the prevailing belief that children were electing not to speak, thereby assigning oppositional characteristics to these children. With the change from DSM-III-R to DSM-IV, the more descriptive term *selective mutism* (implying that children do not speak in select situations) was adopted. This replacement is consistent with new theories of etiology stressing temperamental inhibition, shyness, and anxiety. In the 10th revision of *International Statistical Classifications of Diseases and Related Health Problems* (ICD-10), elective mutism is characterized by a marked, emotionally determined selectivity in speech and is usually associated with social anxiety (see Table 44.1-1).

EPIDEMIOLOGY

Few systematic studies exist to support the claim that selective mutism is a rare disorder. Even with a current (weighted) prevalence rate estimated to be below 1 percent in psychiatrically referred samples, selective mutism may not be so uncommon, as most cases do not come to medical attention and do resolve with age. In one epidemiological study using strict diagnostic criteria, a prevalence rate of 0.06 percent was found in a city cohort of 7-year-olds. Another study reports that transient mutism upon entry to school is much higher, 0.69 percent, with the rate falling to 0.02 percent after 56 weeks.

Selective mutism seems to be more prevalent in females than males, although some clinical reports found only slightly higher frequency in girls. No epidemiological data have been reported on the sex distribution of selective mutism. Onset is usually insidious, but the diagnosis is often first made when the problem is noticed upon entry to school, about age 5 or 6. Boys may present to treatment at an earlier age than girls, which may be attributable to greater tolerance of this behavior in girls.

ETIOLOGY

Various etiological explanations have been proposed. Historically, the disorder has been seen as a child's response to family neurosis, usually characterized by overprotective or domineering mothers and strict or remote fathers. Unresolved psychodynamic conflicts, trauma, divorce, death of a loved one, and frequent moves have all been postulated to play a role in symptom development.

Recently, several investigators have likened selective mutism children to socially phobic adults. Immense discomfiture in social situations and chronic avoidance of interaction seen in socially phobic adults can be compared with selectively mute children's apprehension about speaking to people outside the immediate family or of hearing their own voice. Furthermore, family histories were remarkable for the presence of anxiety disorders, parental public-speaking anxiety, and parental childhood shyness. Nearly all descriptions of selectively mute children have alluded to their shyness, inhibition, or anxiety. Reframing selective mutism as an anxiety disorder or as a symptom of social anxiety may be salient.

Although by definition the diagnosis of selective mutism cannot be made if the symptoms are better ascribed to developmental, organic, or sociocultural obstacles to adequate language acquisition, linguistic factors may be contributory. Despite the lack of systematic speech and language assessments, speech delays or difficulties in clinical samples have been reported. Delayed speech onset, articulation disorders, expressive language disorders, and mixed expressive-receptive language disorders are not uncommon in selectively mute children. The rates of speech and language disorders in this population and the impact of such problems merit further investigation.

Some children who have immigrated into a new linguistic environment have been reported to be selectively mute. Obviously, the diagnosis is precluded in children who have not yet attained fluency in their new language; however, selective mutism may result from resistance to the nondominant language or a sort of culture shock. Children from multilingual homes may display selectively mute behaviors upon starting school where a nondominant language is exclusively used. Familial and community isolation may play a role in such cases.

DIAGNOSTIC AND CLINICAL FEATURES

The hallmark of selective mutism is the failure to use speech in a situation where it is expected despite demonstrable expressive and receptive language competency in other circumstances. Most commonly, children will not speak in school and to unfamiliar adults. Sometimes the child will speak to strangers (e.g., ordering in a restaurant) but not to teachers at school. Some children can speak on the telephone with someone to whom they will not speak face-to-face. Speech is commonly present in the home, and the affected child may be quite talkative around family members. There is usually a distinct hierarchy of people to whom the child will and will not speak.

Usually, selectively mute children are completely silent when mute, but some use whispers or monosyllables in the nonfluent situation. These children vary in their degree of verbal and nonverbal inhibition. In unfamiliar environments, some selectively mute children are shy and anxious, others will interact in some way (e.g., gesturing, nodding their head, smiling) even if they will not talk. The diagnostic criteria for selective mutism are given in Table 46.4-1.

A. Consistent failure to speak in specific social situations (in which there is an expectation for speaking, e.g., at school) despite speaking in other situations. B. The disturbance interferes with educational or occupational achievement or with social communication. C. The duration of the disturbance is at least 1 month (not limited to the first month of school). D. The failure to speak is not due to a lack of knowledge of or comfort with, the spoken language required in the social situation. E. The disturbance is not better accounted for by a communication disorder (e.g., stuttering) and does not occur exclusively during the course of a pervasive development disorder, schizophrenia, or other psychotic disorder.

Table 46.4-1 DSM-IV Diagnostic Criteria for Selective Mutism

Amy is a 5-year-old girl who was brought by her parents because she was not speaking at preschool. The parents reported that this was her second year of preschool and that she had not yet spoken to the teacher or any child at school. She does not use the bathroom at school, because she cannot ask to go. Although she has not spoken to any of the children in her class, she will participate in the class activities. She sits in the group at circle time, and she participates in all the general activities. She will not verbalize if called upon or if she needs anything. In contrast, the parents report that Amy is a “chatterbox” at home. She speaks easily and loudly to her parents and her older and younger sisters. On occasion, she will speak to her grandparents, but she will only consistently talk to one grandmother, whom she knows the best. Amy speaks with her two girlfriends with whom she plays regularly. Even though one of her friends is in her class, she will not speak with her in the classroom. Amy will not answer the phone nor speak out loud in public. She does not order her food in a restaurant nor talk to other children on the neighborhood playground. Her parents describe her as shy with strangers and new situations but quite happy and comfortable with familiar settings. The parents chose this time for seeking an assessment for Amy because they are concerned that she may not speak in kindergarten next fall and that this may be a difficult situation for her.

The parents report that Amy “has always been this way.” Nothing about her behavior at home is particularly concerning. She eats well at home, and she does not have difficulty going to bed at night. She is a “little shy” in new settings, but they don't think that this is particularly unusual. She is not temperamentally difficult, and she is not easily frustrated. On occasion, she may worry about something she has heard or seen. Sometimes she may fear that there is “someone downstairs,” but she has no persistent worries or obsessions. The parents do not feel that Amy is depressed or particularly difficult. They know that she enjoys playing with her good friends. The parents have not noticed any immaturity in her speech and language at home. There was no concern about physical or emotional trauma.

Amy's developmental history was unremarkable. Her developmental milestones were on time, including those for speech and language. She has no significant medical history, and she has never been hospitalized. Amy's mother recalled some separation issues when she was a child, and Amy's father was reportedly “shy as a child.” There is no family history of selective mutism. Amy has never had any formal evaluation for her behavior or her speech. Screening showed that her hearing was within normal limits.

On interview, Amy was inhibited and shy. She did not want her mother to leave the room, and after her mother left the room, she was reluctant to engage in the process, even nonverbally. She did not answer any direct question aloud. Toward the middle of the assessment, she was able to draw pictures with the interviewer. However, she was reluctant to play with the toys in front of the interviewer. There was no evidence of motor hyperactivity, abnormal movements, or thought process or content abnormalities. She appeared shy and slightly apprehensive but was able to draw with the interviewer and participate in some play activities. She appeared more inhibited and shy than one would expect for her age. Her reluctance to engage in the process appeared consistent with her behavior at school. She did not appear depressed or withdrawn.

At the time of the assessment, Amy's presentation was most consistent with a diagnosis of selective mutism.

Associated Features Immaturity, developmental delays, and emotional and behavioral symptoms have been associated with selective mutism, although the older reports may have included a more heterogeneous population than that currently described. Reports on these children in the literature have consistently pointed to their shyness, inhibition, or anxiety. Often emotionally characterized as timid, socially withdrawn, or clinging, selectively mute children exhibit a wide variety of comorbid psychiatric conditions including enuresis, encopresis, obsessive-compulsive features, phobias, school refusal, and depression. The literature reports aggression, hostility, temper tantrums, and oppositional behaviors—more likely manifested at home than elsewhere—but it is most authors' impression that these children are unable to speak in the specific social setting. It is unclear whether an oppositional stance truly exists in even a subgroup of children with selective mutism.

DIFFERENTIAL DIAGNOSIS

A child under consideration for a diagnosis of selective mutism should have a comprehensive evaluation. Many other psychiatric disorders (including pervasive developmental disorders and mental retardation) can incorporate speech inhibition as a secondary symptom, so the differential diagnosis for selective mutism can be complex. Since most selectively mute children will not speak with clinicians, a speech sample recorded on audiotape at home may provide valuable clues. Parents should be interviewed to obtain the child's symptom history, with particular attention to type of onset (sudden or insidious), which may help establish the diagnosis of selective mutism. The child can be evaluated through nonverbal interactions with the diagnostician, direct observations, and adaptive structured interviews and standardized tests to which the child may nod in response.

Other neurological or psychiatric problems (e.g., autistic disorder, and other developmental disabilities, aphasia) should be ruled out in a child presenting with patterns of behavior that deviate from the classic traits of selective mutism, such as not talking to immediate family members, abrupt cessation of speech in one environment, or absence of speech in all settings. Children with Asperger's disorder, right hemisphere deficit disorder, or social-emotional learning disorders may resemble selectively mute children because of their shyness and social isolation, but research suggests that their symptoms are based on an inability to process social cues. A history of neurological insults, developmental delays, neuropsychological deficits, or atypical speech and language difficulties (e.g., prosodic problems) should be sought during the parental interview, as such difficulties may exacerbate speech inhibition. Review of the child's medical and psychiatric history is critical, as physical conditions may underlie the child's mutism. As mentioned, some comorbid diagnoses (e.g., pervasive developmental disorders, schizophrenia) may prelude assignment of the diagnosis of selective mutism. Auditory testing should be performed, especially if the child has a history of frequent ear infections, because hearing problems are sometimes associated with learning and language delays.

A complete family psychiatric and medical history should be obtained. Specifically, the diagnostician should explore with the parents any selective mutism, extreme shyness, or anxiety disorders (e.g., social phobia, panic disorder, obsessive-compulsive disorder) in the family that may predispose the child to developing similar problems.

Distinguishing symptoms due to a communication disorder and symptoms due to selective mutism may be especially problematic. A comprehensive speech and language evaluation is essential; it is a misconception that nonverbal children cannot be evaluated for speech and language functioning. Possible determinants of a child's language delay include a parent with identified speech and language problems or inadequate exposure to the dominant language (as in some bilingual homes), and the influences of these factors should be considered. Children from immigrant families who have had adequate exposure to the language and yet exhibit persistent mutism in school may be given the diagnosis of selective mutism.

Additionally, transient shyness upon entry to school, social phobia, major depressive disorder, and adjustment disorder may produce short-lived speech inhibition in specific social situations; in selective mutism, speech inhibition is protracted.

COURSE AND PROGNOSIS

Selective mutism usually has an insidious onset between 3 and 6 years of age. Parents commonly report that their child has “always been this way.” Identification and referral peak during the first and second grades, when speech expectations at school are continually not met.

Most selective mutism cases are transient and spontaneously resolve. It is not known what (if any) sequelae follow untreated but self-limited selective mutism. In the more severely affected children, disability may last from several months to years. Older children who have not improved by age 10 years may be suffering from a more intractable form of the disorder. Some reports have revealed a few cases in which a chronic, unremitting course ended in pervasive psychiatric disorder.

Children who are symptomatic for longer than 6 months should be evaluated and treated. The long-term outcome of children treated for selective mutism is not clear. Most are improved at follow up, but some speech, behavioral, and emotional symptoms may remain. In light of the new theories on temperamental and anxiety components in selective mutism, systematic research is warranted to determine whether these remnants of shyness or anxiety persist and fulminate into an anxiety disorder in adulthood. Early identification and intervention, with cooperation from both home and school, indicate the best prognosis.

TREATMENT

Although many different approaches have been taken, treatment for selective mutism has long been considered difficult. Case studies, often with only a single subject, dominate the treatment reports. Methodological issues obscure the efficacy and generalizability of various behavioral, psychodynamic, family, speech or language, and pharmacological interventions, since few systematic studies have been conducted with any of these modalities. A literature is now emerging on the pharmacotherapy of selective mutism.

Behavior Therapy Behavioral techniques based on the principles of learning theory have been used most frequently to treat selective mutism. Reinforcement (often combined with an absence of reinforcement for the mute behavior), stimulus fading (gradual stepwise desensitization), shaping (increasing approximations to the desired behavior), and self-modeling (audio or video " *dubbed adaptive* behaviors") have all been tried with variable success. Unfortunately, only one controlled study of behavioral therapy exists to date. Subjects in this study who were randomized to receive active treatment had significantly more vocalizations than untreated subjects at 5 weeks, but the improvement was not significant at 1-year follow-up. Behavioral therapy is usually an important component of the treatment plan.

Psychodynamic Therapy Once the preferred treatment for selective mutism, psychodynamic therapy focused on identifying and resolving underlying intrapsychic conflicts. Art and play were frequently incorporated into sessions to facilitate communication with the selectively mute child, although the therapeutic process was often arduous and time consuming. Presently, cognitive-behavioral approaches are being used with increasing frequency in the psychotherapeutic relationship.

Family Therapy The role of family therapy has shifted somewhat in light of the contemporary clinical perspectives. Family therapy was once used to identify and treat dysfunctional patterns thought to be a causal factor in the development and preservation of selective mutism, but more recently family members have been engaged in designing and implementing the child's treatment plan. Family pathology is no longer seen as the (primary) cause of the symptoms; however, if family problems are affecting the child, a more traditional, insight-oriented family treatment approach could be warranted.

Pharmacotherapy Some medications that have been effective for social phobia have been reported for the treatment of selective mutism. One patient reportedly responded to phenelzine (Nardil), up to 2 mg a day; others reported improvement with 20 mg a day of fluoxetine (Prozac) or fluvoxamine (Luvox). In a double-blind, placebo-controlled 12-week trial of fluoxetine, the six children on active medication showed significant improvement on some, but not all, ratings of mutism and anxiety, but subjects in both groups remained symptomatic at 12 weeks. An open trial of fluoxetine in graduated doses was conducted by other investigators, and 16 of 21 children (76 percent) were improved at the end of the 9-week study. A longer trial, flexible dosing, or multimodal interventions may be appropriate. If pharmacotherapy is prescribed, it is usually accompanied by behavioral therapy. The efficacies of fluoxetine and fluvoxamine for the treatment of selective mutism are currently under study. If anxiety is a prominent factor or if treatment-resistant symptoms exhaust other options, a medication trial should be considered.

Individualized Educational Plan A multidisciplinary, individualized educational plan can be implemented with the cooperation of parents, clinicians, and teachers. Teachers can carry out simple interventions in the classroom to decrease speech anxiety and encourage the student to interact and communicate. With the increased prevalence of speech and language problems noted in the literature, speech and language therapy may help the selectively mute child. Intensive speech therapy focusing on articulation and language training can provide structured practice whether or not the child has an identified speech and language disability. An integrated approach to treatment with the coordinated efforts of all involved may produce the best outcome. Since the comparative efficacies of these different methods are obscure, further systematic research is needed.

The author thanks Mai Karitani and Sara P. Dow for their help.

SUGGESTED CROSS-REFERENCES

Chapter 37 on communication disorders describes some differential diagnoses for selective mutism. Children with pervasive developmental disorders (Chapter 38) and mental retardation (Chapter 34) may exhibit mutism. Lack of speech output may also occur in mood disorders, discussed in Chapter 45, or in anxiety disorders, considered in Chapter 46.

CHAPTER 47. EARLY-ONSET SCHIZOPHRENIA

JON M. MCCLELLAN, M.D.

Schizophrenia is a neurodevelopmental disorder with deficits in cognition, affect, and social relatedness. Although it rarely occurs in children, the incidence of schizophrenia increases steadily after the onset of puberty. It is often a chronic condition, with significant long-term morbidity and functional impairment. Therefore, clinicians who work with children and adolescents need to be familiar with the phenomenology, clinical course, and treatment of this disorder.

DEFINITION

Schizophrenia is diagnosed in children and adolescents using the same criteria as for adults. The disorder is defined by the presence of positive and negative symptoms. Positive symptoms consist of hallucinations, delusions, or bizarre and disorganized thinking and behavior. Negative symptoms consist of paucity of speech, paucity of thought content, apathy, avolition, and flat affect. These symptoms are coupled with a significant deterioration in functioning, including the failure to achieve expected levels of social development.

HISTORY

Although schizophrenia is primarily considered an adult disorder, its occurrence in children has been described since the time of Emil Kraeplin. However, as the concept of childhood psychoses evolved, autistic disorders and pervasive developmental disorders became classified as childhood schizophrenia. As a result, much of the early literature regarding childhood schizophrenia is actually about autistic and psychotic disorders.

Israel Kolvin and others challenged this nosological construct by demonstrating that autistic disorder was a discrete disorder, distinct from schizophrenia. Thus, beginning with the ninth revision of the *International Statistical Classification of Diseases* (ICD-9) and third edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III), childhood schizophrenia was differentiated from pervasive developmental disorders and diagnosed using the same criteria as for adults. Subsequent research has generally validated this decision.

There is a paucity of research examining schizophrenia in youth. Treatment studies are generally lacking. Although the incidence of the disorder increases after the onset of puberty, much of the existing literature focuses on childhood onset. Other methodological problems include retrospective designs, lack of standardized assessment tools such as diagnostic interviews, small subject pools, and lack of comparison groups. However, despite these limitations, reasonable conclusions can be drawn from the existing studies regarding the diagnosis of schizophrenia in youth. Furthermore, because schizophrenia in youth appears to be essentially the same heterogeneous disorder as in adults, the adult literature can generally be extrapolated to children and adolescents as long as developmental issues are taken into account.

Although schizophrenia in children under age 13 years has often been described as prepubertal, most studies have determined this by age, not by physical development. To avoid ambiguity, early-onset schizophrenia has been defined as onset prior to 18 years of age, with a subgroup of very early-onset schizophrenia defined as onset before age 13 years.

COMPARATIVE NOSOLOGY

The conceptual notion of schizophrenia, including what are considered characteristic symptoms, remains basically unchanged. Since the recognition that childhood schizophrenia and autistic disorder were distinct conditions, only minor modifications have been made within the specified diagnostic criteria. The revised third edition of DSM (DSM-III-R) required that the active psychotic symptoms last at least 1 week, whereas in the fourth edition of DSM (DSM-IV) these symptoms must persist for at least 1 month. The other significant change is that DSM-IV added negative symptoms as one of the characteristic symptoms of the active phase of the disorder.

The diagnostic criteria defined by the ICD-10 are similar to DSM-IV. The only difference is that ICD-10 only requires a total duration criterion of 1 month, compared to the 6-month duration specified by DSM-IV. A high rate of diagnostic agreement was found between DSM-III-R, DSM-IV, and the 10th revision of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) in hospitalized psychotic adolescents.

EPIDEMIOLOGY

The prevalence of schizophrenia in youth has not been adequately established. Clinical experience suggests that schizophrenia with onset prior to age 12 years is rare. It has been estimated that 0.1 to 1 percent of all schizophrenic disorders present before age 10 years, with 4 percent occurring prior to 15 years of age. The rate of onset increases sharply during adolescence, with the peak ages of onset generally ranging from 15 to 30 years.

A study examining young adults during their first episode of schizophrenia (*N* = 232) found that 47 percent had displayed the first sign of their illness before age 21 years. However, only 21 percent developed psychotic symptoms prior to this age. There are reported cases of onset prior to age 6 years. However, a diagnosis of schizophrenia in young children must be carefully scrutinized.

Schizophrenia in youth, especially in children occurs predominantly in males. As age increases, this ratio tends to even out. Since the adult literature suggests that the age of onset in males is significantly younger than that in females, the male predominance may be a cross-sectional effect.

ETIOLOGY

Schizophrenia is a heterogeneous disorder of unknown cause. Etiological mechanisms are undoubtedly complex, and remain to be elucidated. However, at least three potential causal mechanisms have been identified: genes, neurodevelopmental insults, and viral exposure. It has been hypothesized that a multifactorial polygenic model best explains the development of schizophrenia. In this model a variety of risk factors, genetic and environmental, interact in an additive fashion to produce a vulnerability towards schizophrenia. If a threshold is reached, the individual will develop the illness. Subthreshold cases may present with related conditions, such as schizotypal personality disorder. The relative risks of different etiological mechanisms, and how these factors interact, remain an important area of future research.

Genetic Factors There is substantial evidence that genetics play an important role in the development of schizophrenia, including data from both twin and adoption studies. The lifetime risk of developing schizophrenia is 5 to 20 times higher in first-degree relatives of affected probands when compared to the general population. In early-onset schizophrenia the genetic risk appears to be at least as high as for the adult-onset form. Moreover, some studies have found that an earlier age of onset is associated with an increased familial risk.

Despite this evidence, no single model of genetic inheritance has been identified. Although some studies have identified potential sites on the genome that were linked to schizophrenia, these associations have not been consistently found or replicated. Because schizophrenia is a heterogeneous disorder, it is likely that multiple genes are involved. Moreover, the risk conferred may not be always expressed as schizophrenia, but rather as related traits such as a schizoid personality. Finally, some cases are assumed to be sporadic and as resulting from environmental causes rather than genes. The current evidence suggests that the development

of schizophrenia is best explained by a multifactorial polygenic model.

Neurodevelopmental Factors Schizophrenia may be a neurodevelopmental disorder with early central nervous system lesions affecting normal maturational processes. Thus, premorbid abnormalities and developmental delays may represent the early neuropathological manifestations of the disorder. Perinatal complications, alterations in brain structure and size, minor physical anomalies, and disruption of fetal neural development, especially during the second trimester of pregnancy, have been correlated with schizophrenia. An earlier age of onset (before age 22 years) has been associated with an increased rate of obstetrical complications. It has been hypothesized that early neurological trauma may interact with genetic risk factors to produce schizophrenia in at-risk individuals.

Viral Exposure Viral exposure has been implicated as a risk factor for schizophrenia. Individuals with schizophrenia have a higher than expected rate of being born during winter months, which suggests the involvement of an infectious agent. Furthermore, several studies have found an increase in viral titers, or immunological markers, or both, in schizophrenic patients. Finally, birth cohorts who were in the second trimester of pregnancy during an influenza epidemic have been shown to have an increased risk for schizophrenia. However, efforts to directly link schizophrenia to maternal influenza infections have produced mixed findings. Further research is needed to clarify what role, if any, exposure to viral infections has in the development of schizophrenia. One proposed mechanism is that viral exposure produces the illness in some at-risk individuals by an autoimmune process.

Psychological Factors There is no evidence that psychological factors alone cause schizophrenia. Rather, psychological factors interact with biological risk factors, primarily influencing the course of the disorder. Psychosocial stressors, including expressed emotion within the family setting, influence the onset or exacerbation of acute episodes and relapse rates. However, these interactions are complex and bi-directional. The presence of difficult family interactions may not be “causal”, but rather a reaction to the collection of difficulties the patient brings to the family setting.

DIAGNOSIS AND CLINICAL FEATURES

Diagnosis The diagnostic criteria for schizophrenia are outlined in the DSM-IV, (see Table 12.7-1). Diagnostic tools, such as structured interviews, symptom scales, and diagnostic decision trees, help to ensure the reliability and veracity of diagnosis. Because schizophrenia is a serious disorder with ominous prognosis and social stigma, it is important that the criteria be adequately assessed before a diagnosis is made. However, that is not tantamount to saying that schizophrenia should not be diagnosed when present because that potentially denies the child and family access to appropriate treatment and psychoeducational resources.

Characteristic Symptoms At least two of the following are needed for a period of at least 1 month; delusions, hallucinations, disorganized speech, grossly disorganized or catatonic behavior, and/or negative symptoms. The duration of these symptoms may be less than 1 month if they have been alleviated by treatment.

Social or Occupational Dysfunction The level of social, occupational, and self-care functioning has markedly deteriorated below the highest previously obtained level. In children and adolescents, this includes the failure to achieve expected levels of social development.

Duration The disturbances must be present for a period of at least 6 months. This includes an active phase of overt psychotic symptoms (criterion A) with or without a prodromal or residual phase. A prodromal phase involves the deterioration in functioning prior to the onset of psychotic symptoms, while the residual phase follows the active phase. Symptoms characteristic of both prodromal and residual phases include marked social isolation, deterioration in occupational functioning, peculiar behavior such as food hoarding, poor hygiene, blunted or inappropriate affect, disordered thought processes (tangentiality, circumferentiality, poverty of speech or speech content), odd beliefs or perceptions, and anergia.

Exclusion of Mood Disorder Schizoaffective disorder and mood disorder with psychotic features must be ruled out. If mood episodes are present, their duration must be brief relative to the course of the schizophrenic symptoms. These exclusion criteria are especially pertinent for adolescents with bipolar I disorder, since manic episodes in this age group frequently include schizophrenia-like symptoms at onset.

Substance and General Medical Condition Exclusion The symptoms are not due to either the direct effects of a substance or to a medical condition.

Relationship to a Pervasive Developmental Disorder If there is a history of autism, or another pervasive developmental disorder, prominent delusions or hallucinations (for at least 1 month unless successfully treated) are required to make a diagnosis of schizophrenia.

Clinical Features Although this disorder is diagnosed using the same criteria as are used for adults, some specific developmental characteristics have been noted.

Premorbid Functioning Schizophrenia in youth generally has an insidious onset, with a longstanding history of developmental and personality abnormalities. An age of onset before age 12 years is associated with highest rates of premorbid problems. The abnormalities most frequently described include (1) being socially withdrawn, odd, and isolated; (2) behavioral disorders; and (3) multiple developmental delays, including lags in cognitive, motor, sensory, and social functioning. Autistic disorder and pervasive developmental disorders have been reported.

These premorbid features are not equivalent to a diagnosis of schizophrenia. Many children are considered odd, or have multiple developmental problems. However, most will not have the prerequisite psychotic symptoms required to make the diagnosis.

Symptomatology In studies of early-onset schizophrenia hallucinations, thought disorder, and flattened affect are consistently found; systematic delusions and catatonic symptoms are less common. Developmental differences in language and cognition may influence the spectrum and quality of symptom presentation. Children tend to have less complex delusions, with the content reflecting childhood themes.

Most hallucinations in children lack the persistence and associated symptomatology required for schizophrenia. These diagnostic issues have led to high rates of misdiagnosis, especially in children. A child's report of hallucinations may represent: imagination; misinterpretation of normal intrapsychic experiences; misunderstanding of the clinician's question; developmental phenomena; dissociative phenomena; factitious symptoms; or symptoms of another psychotic illness (i.e., a mood disorder). These issues must be examined prior to diagnosing a child with schizophrenia, given its long-lasting treatment and prognostic ramifications.

Significant rates of formal thought disorder, including loose associations and illogical thinking, have been found in children with schizophrenia. It is important, however, to differentiate the thought disorder of psychosis from that of either developmental delays or language disorders.

Rapidity of Onset Schizophrenia with very early onset generally has an insidious onset. Conversely, reports of onset in early adolescence describe high rates of acute or subacute onset, defined as less than 1 year; other reports found a predominance of insidious onset.

Subtype Reports of schizophrenia with childhood onset vary as to whether the paranoid type or the undifferentiated type are more common. At this time sufficient evidence is lacking to justify categorizing early-onset schizophrenia as a separate diagnostic group.

Cognitive and Language Dysfunction Approximately 10 to 20 percent of youth with this disorder have a low intelligent quotient (I.Q.) scores. Language and communication deficits are common. Children with schizophrenia have deficits in their information-processing capacities, a finding also noted in adults.

Caution must be used in making the diagnosis of schizophrenia in children who have severe language impairments. Since the standard presentations of hallucinations and delusions involve language, assessing a child with severely impaired language for psychotic symptoms can be a diagnostic challenge. In these cases, the clinician is dependent on observations of behavior. Psychotic symptoms may be identified when their emergence is associated with a deterioration in mental status and global functioning.

Mortality In follow-up studies, the risk of suicide or accidental death directly due to psychosis appears to be approximately 5 percent. However, this estimate needs to be further studied given the small number of subjects examined and the limited length of follow-up periods.

An 11-year-old white male presented with a greater than 1-year history of increasingly bizarre behavior, including: confused and tangential thinking, seeing ghosts, hearing voices, and taking on the identity of fictional media characters (Teenage Mutant Ninja Turtles). He had no noted major episodes of mood symptoms. He also had a chronic history of behavior problems, including decreased attention span, poor impulse control, severe oppositional behaviors, aggression, and sexually inappropriate behaviors. He was socially odd and isolated, and avoided interacting with peers unless it was in an aggressive or intrusive fashion.

Developmentally, his first 4 years were chaotic. He was intermittently exposed to domestic violence, possibly physical abuse, and a lack of structure and supervision. There was no documented history of sexual abuse. His developmental milestones were slightly delayed, with onset of speech at age 18 months and of walking at age 15 months. By the time he entered school, cognitive and academic delays were apparent. Intellectual testing at age 8 years displayed a full-scale I.Q. of 71. When retested at age 10 years, his intellectual functioning had deteriorated, with an I.Q. of 58.

He had no significant medical problems. An organic workup was unremarkable, including normal chromosomes, a metabolic urine screen, an electroencephalograph (EEG), and a computed tomography (CT) scan of the head. He had a family psychiatric history of substance abuse in second-degree relatives. However, much of his paternal family psychiatric history was unknown.

His mental status examination was significant for tangential and disorganized thinking, loose associations, and perseverative speech patterns. His moods were labile, his affect silly and inappropriate. He was preoccupied with the belief that he was a Teenage Mutant Ninja Turtle. He also reported auditory hallucinations, for example, hearing God, the devil, and the turtles. Socially, he was awkward and immature; behaviorally, he was oppositional and intermittently aggressive.

Since the initial referral, his psychotic symptoms have partially responded to various trials of antipsychotic medications, in addition to mood stabilizers for his explosive behaviors. However, his intermittent aggression, sexualized behaviors, and developmental delays have necessitated several long-term hospitalizations. At age 15 years he remained severely impaired, with ongoing delusions (e.g., the Teenage Mutant Ninja Turtles have a computer chip controlling his brain), disorganized thinking, and impaired social relationships.

PATHOLOGY AND LABORATORY EXAMINATIONS

There are few studies examining the biological markers of schizophrenia. In an ongoing study of youth with schizophrenia with very early onset at the National Institutes of Mental Health (NIMH), neurobiological abnormalities have been noted. These include deficits in smooth pursuit eye movements and autonomic responsivity, which are similar to those reported in the adult literature. Using magnetic resonance imaging (MRI) subjects with schizophrenia had larger left frontal ventricular horns, larger left caudate regions, and a lack of normal caudate asymmetry when compared to normal controls. A progressive increase in ventricular size was seen in these subjects over a 2-year period. Smaller total cerebral volumes were correlated with negative symptoms. In a separate study, magnetic resonance spectroscopy showed frontal lobe dysfunction in 13 children with schizophrenia.

These neurobiological findings are important research efforts to understand the underlying etiological mechanisms of the disorder; however, none are diagnostic. Laboratory evaluations and neuroimaging techniques do have a role in the standard assessment of the condition, but primarily for ruling out other medical disorders.

DIFFERENTIAL DIAGNOSIS

When assessing a child or adolescent with symptoms suggestive of schizophrenia, a comprehensive diagnostic evaluation is needed to rule out other conditions that present with similar symptomatology. A thorough review of presenting symptoms, course, premorbid functioning, adherence to DSM-IV criteria, how psychotic symptoms present in this age group, and family psychiatric history all will help improve the accuracy of diagnosis. However, discriminating between these various disorders still may be difficult, especially at the initial presentation. Therefore, the diagnosis needs to be periodically reassessed.

Mood Disorders Both schizophrenia and psychotic mood disorders (especially bipolar I disorder) typically present with a variety of affective and psychotic symptoms. This overlap in symptomatology increases the likelihood of misdiagnosis at the time of onset. Approximately one-half of adolescents with bipolar I disorder may be originally misdiagnosed as having schizophrenia. Longitudinal reassessment is therefore needed to ensure accuracy of diagnosis. Family psychiatric history may also be a helpful differentiating factor, although it is important to note that studies also have found an increased family history of depression in young people who have schizophrenia.

Schizoaffective Disorder Early-onset schizoaffective disorder has not been well defined in this age group. Twenty-eight percent of a sample of schizophrenia with childhood onset at follow-up had schizoaffective psychoses, which is an ICD-9 diagnosis that overlaps with DSM-III-R diagnoses of bipolar disorder and schizoaffective disorder. Other follow-up studies of psychotic youth have also found this disorder, but at lower rates.

Nonpsychotic Behavioral or Emotional Disorders (Including Dissociative or Personality Disorders) Youth with conduct and other nonpsychotic emotional disorders may report psychotic-like symptoms, and thus be misdiagnosed as having a primary psychotic disorder. When compared to children with psychosis, these children have lower rates of delusions and thought disorder. At follow-up, an increase in personality dysfunction, including personality disorders, but not psychotic disorders, has been found. When there is a history of abuse or neglect, the psychotic-like symptoms may represent dissociative symptoms. It is important that these children be accurately characterized because a misdiagnosis of schizophrenia may unnecessarily expose them to the long-term adverse effects of antipsychotic medications.

Pervasive Developmental Disorder Autistic and other pervasive developmental disorders are distinguished by the absence or transitory nature of the required positive psychotic symptomatology, that is, hallucinations and delusions, as well as by the predominance of the characteristic deviant language patterns, aberrant social relatedness, and other key symptoms that characterize these disorders. The earlier age of onset and the absence of a normal period of development are also indicative, although some children with schizophrenia do have a lifelong history of developmental delays. However, compared to pervasive developmental disorder the premorbid abnormalities in schizophrenia tend to be less pervasive and severe.

Childhood disintegrative disorder resembles autistic disorder except that the onset occurs after 2 or more years of normal development. Children with Asperger's disorder lack the marked language disturbances associated with autistic disorder but present with deficits in social relatedness, contextual communication (especially with social cues), and a restricted (and possibly bizarre) range of interests. The lack of overt hallucinations and delusions distinguishes both these conditions from schizophrenia.

Communication Disorders Children with developmental speech and language disorders may be mistakenly diagnosed as having a thought disorder. Such children do not, however, have other prerequisite symptoms of schizophrenia such as hallucinations, delusions, or odd social relatedness.

Other Disorders Other disorders that need to be differentiated from schizophrenia include schizotypal and schizoid personality disorders and other psychotic disorders (e.g., delusional disorders and schizophreniform disorder). Finally, there are children with multiple developmental lags, including disturbances in affect modulation, social relatedness, and thinking, whose symptoms do not fit well within the current criteria for schizophrenia.

Organic Disorders It is important that all children and adolescents with a psychosis receive a thorough pediatric and neurological evaluation. The possibility of an organic psychosis needs to be considered when obtaining the history, completing the physical examination, and in selecting initial laboratory investigations. The list of potential organic etiological agents is exhaustive; however, conditions that must be considered include (1) delirium; (2) seizure disorders; (3) central nervous system lesions (e.g., brain tumors, congenital malformations, head trauma); (4) neurodegenerative disorders (e.g., Huntington's chorea, lipid storage disorders); (5) metabolic disorders (e.g., endocrinopathies, Wilson's disease); (6) toxic encephalopathies (e.g., substances of abuse such as amphetamines, cocaine, hallucinogens, phencyclidine, and solvents; medications such as stimulants, corticosteroids, or anticholinergic agents; and other toxins such as heavy metals); and (7) infectious diseases (e.g., encephalitis, meningitis, and human immunodeficiency virus [HIV]-related syndromes). Also, it is important to examine for comorbid medical or developmental disorders. For example, there is an increased risk for psychotic disorders associated with the genetic condition velocardiofacial syndrome.

Given the significant rates of comorbid substance abuse with schizophrenia and psychotic mood disorders in adolescents (as high as 50 percent comorbidity in some studies), it is not uncommon for a history of drug abuse to be obtained at the first onset of the psychotic disorder. If the psychotic symptoms persist for longer than a

few days despite documented detoxification from abused substances, a primary psychotic disorder should be diagnosed, with substance abuse as a comorbid condition and exacerbating agent (rather than a primary etiological agent).

COURSE AND PROGNOSIS

There are few studies examining the course of early-onset schizophrenia. Most are retrospective and none factor out the influence of treatment. The adult literature suggests that schizophrenia is a phasic disorder, although there is a great deal of individual variability. Diagnostic and therapeutic decisions depend on the recognition of these stages. The phases include:

Prodrome Prior to the overt development of psychotic symptoms, most patients will experience some degree of functional deterioration. This may include social withdrawal, odd or schizotypal preoccupations, deteriorating academic performance, worsening hygiene and self-care skills, dysphoria, and idiosyncratic or bizarre behaviors. Some youth will present with an increase in aggressive behaviors or other conduct problems, including substance abuse. These symptoms may confuse the diagnostic picture.

The prodromal phase varies greatly in time, from an acute change (days to weeks) to chronic impairment (months to years). The symptoms may represent a marked change from baseline functioning, or alternatively, a worsening of premorbid personality or behavioral characteristics. Many youth, especially those with schizophrenia with very early onset, have an insidious onset. In such cases it may be difficult to distinguish between the premorbid personality or cognitive abnormalities and the onset of the disorder.

Acute Phase During the acute phase positive symptoms predominate (i.e., hallucinations, delusions, thought disorder and disorganized behavior), and are associated with a significant deterioration in functioning. This phase generally lasts 1 to 6 months, although it may persist for over a year. Symptoms may shift from positive to negative over the course of treatment, and the length of this phase is in part determined by treatment response.

Recovery Phase As the acute psychosis remits, there is generally a period lasting several months in which the patient continues to experience a significant degree of impairment. This is most often due to negative symptoms (flat affect, anergia, social withdrawal), although it is common for some positive symptoms to persist. In addition, some patients will develop a postpsychotic depressive disorder of schizophrenia, characterized by dysphoria and flat affect.

Residual Phase As they recover, patients may have prolonged periods (several months or more) without active positive symptoms. However, most patients will continue to experience some degree of impairment due to negative symptoms.

Chronically Ill Patients Some patients will remain chronically symptomatic, despite adequate treatment, over a period of many years. These patients are among the most severely impaired and require the most intensive treatment resources. The advent of the serotonin-dopamine antagonists (atypical antipsychotic) agents offers some promise for these individuals, since clozapine (Clozaril) has been effective for treatment-refractory schizophrenia.

Longitudinal Course Schizophrenia generally follows a pattern characterized by increasing deterioration after each cycle until, after approximately 10 years, the disorder tends to wane, leaving a residual state of varying disability typified predominantly by negative symptoms. There are insufficient data to determine whether this long-term pattern holds for early-onset schizophrenia. Some youth with schizophrenia may only have one cycle, although this is not common. Recovery is incomplete in approximately 80 percent of cases where patients have had more than one episode.

Long-Term Outcome There are very few studies examining long-term outcome in early-onset schizophrenia; most studies are retrospective. In addition, there are potential problems in interpreting the existing literature. Outcome studies may be influenced by diagnostic errors, given that historically bipolar I disorder was frequently misdiagnosed as schizophrenia. Also, because schizophrenia is a phasic disorder, ratings of outcome will vary depending on the phase during which the assessment occurs.

Premorbid characteristics, treatment response, and adequacy of therapeutic resources invariably predict short-term outcome. Of 113 adolescents and young adults (mean age 18.3 ± 3 years) with schizophrenia, only 14 percent were found to have a complete remission of symptoms during the index hospitalization. The same study also reported on a cohort of 64 individuals with schizophrenia (ages 12 to 22 years) who entered a special rehabilitation program. This sample was followed at 3-month intervals over a 1-year period. Significant improvement was noted in symptomatology and cognitive functioning; subjects with higher levels of cognitive abilities and premorbid functioning did better at outcome.

There are some differences found between studies that have examined outcome over approximately a 5-year period. Two separate retrospective studies found that the majority of subjects displayed moderate to severe impairment at outcome. Eighty to 90 percent had two or more episodes during the follow-up period whereas only a few had a complete remission; outcome was best predicted by premorbid and intellectual functioning.

Eighteen children with very early-onset schizophrenia were followed over 2- to 7-year periods; 44 percent showed minimal improvement or a deteriorating course. After 1 year, only two children displayed no evidence of symptoms. However, between 2 and 7 years, one-third of the sample no longer met criteria for either schizophrenia or schizoaffective disorder; four children had no psychiatric disorders at outcome. The children in this study received extensive pharmacological and psychosocial treatment, which may have influenced the findings.

There are two sets of studies that have examined long-term outcome. One study followed up on 40 subjects with early-onset schizophrenia (mean follow-up period 14.8 years, mean age of onset 14.0 years); only two subjects had a complete recovery. Most (74 percent) were moderately to severely impaired. Premorbid functioning and the severity of positive and negative symptoms during acute episodes best predicted outcome.

Fifty-seven patients with childhood schizophrenia (onset between 7 and 13 years of age) were followed over a mean follow-up period of 16 years. At outcome, 28 percent had schizoaffective disorder. Overall, 50 percent of the sample were significantly impaired at outcome, 30 percent had good to satisfying social adaptation, and 20 percent had a complete remission. Those with schizoaffective disorder had a more favorable course. They also tended to have less premorbid difficulties, which was also a significant prognostic factor. Onset before age 10 (N = 11) was uniformly associated with a poor outcome.

Within this same sample, 44 subjects were reassessed after a mean follow-up period of 42 years. The outcome ratings were similar: 25 percent had complete remission; 25 percent partial remission, and 50 percent had chronic impairment. An insidious onset (over more than a 4-week period) and an age of onset before age 12 years were both associated with greater disability at outcome.

In general, the available follow-up studies are consistent with the adult literature. There are few studies that have compared early-onset schizophrenia versus adult onset. Onset before 15 years of age was found to be associated with higher ratings of negative symptoms in adulthood, while another study reported greater social impairment in patients with onset before age 21 years. These two studies support the clinical observations that the disorder may have a more insidious and chronic course, with less favorable outcome.

TREATMENT

There is little research addressing the treatment of early-onset schizophrenia. Therefore, treatment recommendations must be extrapolated from the adult literature. In general, therapeutic strategies should be tailored to the developmental characteristics of the patient, the needs of the family, and the different stages of the disorder. Comprehensive multimodal interventions are needed that incorporate psychopharmacological as well as psychosocial therapies. An array of therapeutic resources are needed, including inpatient/day patient psychiatric units; medication management; psychoeducational services; intensive case management; family interventions; vocational and rehabilitative assistance; special education programs, and in some cases, residential programs.

Psychopharmacology The efficacy of antipsychotic agents for the treatment for schizophrenia has been firmly established. However, there are few studies examining their use in youth. In children with schizophrenia, 0.02 to 0.12 mg/kg of haloperidol (Haldol) was found to be superior to placebo in reducing symptoms of thought disorder, hallucinations, and persecutory ideation. Loxapine (Loxitane) was superior to placebo in a study of adolescents with schizophrenia. Youth may experience the same adverse effects noted in adults, for example, extrapyramidal symptoms, sedation, tardive dyskinesia, and neuroleptic malignant syndrome. The long-term

use of antipsychotic drugs in this disorder has not been studied.

The most significant recent advance in the pharmacotherapy of schizophrenia is the advent of the serotonin-dopamine antagonists, including clozapine, risperidone (Risperdal), and olanzapine (Zyprexa). These agents are considered atypical since they are not primary type dopamine 2 (D_2) antagonists like the traditional antipsychotic medications (i.e., dopamine receptor antagonists), but instead are serotonin receptor antagonists, with some D_1 activity. Clozapine is more effective than traditional agents in reducing both positive and negative symptoms; however, its use is limited by the potential for neutropenia or seizures. Although the other atypical agents need to be further studied, they all have a lower risk for extrapyramidal symptoms and may be more effective for negative symptoms. These agents are likely to replace the traditional drugs as the primary medication for treating schizophrenia.

There are few studies examining the use of atypical agents in youth. Clozapine has been shown to be effective for treating schizophrenia with childhood onset. In the ongoing NIMH study, clozapine (mean dose 176 mg ± 149 mg a day) was superior to haloperidol (16 ± 8 mg a day) for treating both positive and negative symptoms in 21 youth (mean age 14.0 ± 2.3 years) with schizophrenia. However, while on clozapine, five youth developed significant neutropenia (this resolved spontaneously in three of subjects), and two had seizures. Therefore, although potentially more efficacious, clozapine's apparent increased risk for adverse reactions in youth raises concerns. The other atypical agents have not been systematically studied with this age group and further research is needed.

Other medications with some reported efficacy for schizophrenia in adults include lithium (Eskalith), benzodiazepines, and anticonvulsants. However, the evidence supporting the antipsychotic activity of these agents is limited, and their use in youth with schizophrenia has not been studied.

Treatment varies dependent on the phase of the illness and the patient's history of medication response and adverse effects. Except clozapine, antipsychotic drugs can be considered first-line agents; clozapine is recommended for treatment-resistant cases.

Baseline Assessment Prior to initiating a medication trial, the targeted psychotic symptoms should be adequately documented. The patient and family should be provided with adequate information regarding diagnosis, medication options, and adverse effects.

A thorough medical assessment is also needed. Evidence of neurological dysfunction warrants further evaluation, including consideration of an EEG, neuroimaging studies, and a neurology consultation. Any preexisting abnormal movements should be documented to avoid later mislabeling them as medication adverse effects. Routine laboratory screening tests to be considered include blood counts, serum chemistries, thyroid functions, and urinalysis and toxicology screenings. Testing for HIV should be done if the risk factors are present. Chromosomal analysis may be indicated for patients with clinical presentations or features suggestive of a developmental syndrome.

Acute Phase Antipsychotic drug therapy should be implemented for a period of no less than 4 to 6 weeks, using adequate dosages, before efficacy of the medication choice is determined. The immediate effect of the medication is generally sedative, with the antipsychotic effects becoming more apparent only after the first week or two. Large dosages during the early part of treatment generally do not hasten recovery, and more often result in unnecessarily excessive adverse effects. If no results are apparent after 4 to 6 weeks or if adverse effects are not manageable, a trial of a different medication should then be undertaken.

Recuperative Phase This generally occurs after 4 to 12 weeks provided the acute phase can be controlled. As positive symptoms improve, the patient may have persistent confusion, disorganization, and dysphoria. During this period antipsychotic medication should be maintained. Attempts to gradually lower the dosage may be indicated to decrease adverse effects, including exacerbation of negative symptoms. This is especially true if high dosage was needed to control the acute psychotic phase. However, any lowering of the dosage must be carefully monitored to avoid relapse.

Residual Phase In this phase, antipsychotic therapy has well-documented efficacy in preventing relapse. Approximately 65 percent of adult patients on placebo will have a relapse within 1 year of their acute psychotic phase, compared to 30 percent of patients on psychiatric drugs. However, in newly diagnosed patients who have been stabilized for at least 6 months, a medication-free trial may be advisable because a small percentage of patients will not relapse and therefore should not be exposed to the risk of the long-term adverse effects of drugs. In patients with relapses or chronic illness, or in newly diagnosed patients with persistent psychotic symptoms, the maintenance medication should be maintained indefinitely at the lowest effective dose. Longitudinal monitoring is needed, with gradual lowering of the dosage as tolerated.

Nonresponders to Antipsychotics Many patients with schizophrenia do not respond adequately to traditional antipsychotic drugs. The atypical agents may be more effective for treatment-resistant cases, although at this time clozapine is the only antipsychotic drug with clearly documented superiority in efficacy. Given clozapine's potential adverse effects, it is only used in cases where patients have failed to respond (or have had significant adverse effects) to at least three adequate trials of different antipsychotic agents.

Psychosocial Therapies In the adult literature most traditional psychotherapies have not been effective for treating schizophrenia. However, psychoeducational interventions directed at family functioning, problem-solving and communication skills, and relapse prevention have been shown to decrease relapse rates.

The family interventions stem in part from research regarding expressed emotion. Expressed emotion refers to attributes of overprotectiveness or criticism expressed towards the patient. The relapse rates for patients with schizophrenia are higher when living in families characterized as having high expressed emotion. Family intervention programs, in conjunction with medication therapy, have been shown to significantly decrease schizophrenia relapse rates.

Another important psychoeducational modality is social skills training. These programs focus on improving the patient's strategies for dealing with conflict and avoidance; identifying the correct meaning, content, and context of verbal messages within their families; and enhancing their socialization and vocational skills. The combination of family treatment, social skills training, and medication therapy also has been shown to decrease relapse rates.

The effectiveness of a psychoeducational treatment program was compared to the standard community treatment in a sample of adolescents with schizophrenia (12 subjects per group). The psychoeducational treatment program included parent seminars, problem-solving sessions, milieu therapy (while the subjects were hospitalized), and networks (reintegrating the subjects back into their schools and communities). These interventions were used in conjunction with medication therapy. The standard treatment group received a mixture of individual psychotherapy, milieu therapy, and medications; outcome was assessed after 2 years. The psychoeducational treatment program had lower rates of rehospitalization and was more cost effective. Subjects with poor premorbid psychosocial functioning benefited the most from the psychoeducational interventions. Clinical improvement was associated with the families' expressed emotion ratings changing from high to low. Although more research is needed in this area, family treatment and social skills training should be considered helpful adjuncts to medication treatment for children and adolescents with schizophrenia.

Further research is needed to delineate the course, phenomenology, response to treatment, and outcome of schizophrenia with early onset. Because schizophrenia in youth appears to be the same disorder as in adults, studying the progression of its neuropsychiatric manifestations against the backdrop of normal developmental maturation may potentially provide clues to underlying etiological mechanisms. Moreover, because schizophrenia in youth may be a more homogeneous form of the illness, research examining this population may be more likely to identify potential biological and genetic markers.

SUGGESTED CROSS-REFERENCES

Chapter 12 reviews the adult literature on schizophrenia; antipsychotic medications are discussed in more detail in Section 12.8, Section 31.17, and Section 31.21. Medical conditions that may mimic psychotic disorders are reviewed in Chapter 10. Other pertinent sections include the psychiatric treatment of children (Chapter 48), mood disorders (Chapter 14), and pervasive developmental disorders (Chapter 38).

CHAPTER 48. CHILD PSYCHIATRY: PSYCHIATRIC TREATMENT

48.1 INDIVIDUAL PSYCHODYNAMIC PSYCHOTHERAPY

OWEN LEWIS, M.D.

Psychodynamic psychotherapy is conceptualized and organized as an individual psychotherapy. What distinguishes psychodynamic psychotherapy from other therapies is that it seeks to treat not only the individual symptoms, disabilities, and vulnerabilities of the child, but the meanings of those symptoms, disabilities, and vulnerabilities and their role in the overall functioning of the child's personality. In its classical format, it was derived from psychoanalysis and did not usually involve other modalities of treatment. In modern applications, it may include a variety of modalities in an overall psychodynamic framework. It is used to treat a wide variety of disorders and developmental circumstances.

Central to psychoanalytic theory is the role of the unconscious fantasy life. Not only are symptoms viewed in regard to the unconscious, but also patterns and quality of relationships, modulation of affects, and personality traits are related to unconscious functioning. Of concern, too, are the patterns of defense mechanisms, the presence of traumatic experiences, the level of psychosexual functioning, and the evolution of the superego and conscience. Modern adaptations also look at the presence of biologically determined disorders (such as some forms of depression or anxiety) and biologically determined cognitive patterns (such as attention-deficit disorders or learning disorders) and the meaning of these to the child. Modern adaptations also address those factors that maintain problematic behaviors of the child in the family.

The inner world of the child is understood through several pathways. Children can and do speak about themselves. Reports about the child from parents and teachers can suggest points of difficulty. Free play serves as an important expressive modality for many children, especially younger children. Older children may be given to playing games, and their conduct in such games is often revealing. Children of all ages may benefit from a variety of creative techniques such as drawing, storytelling, story writing, or playacting. The therapist's own reactions to the patient can also serve as an important source of information about the subjective world of the child.

In contrast to adult psychotherapy in which great emphasis is placed on the importance of interpretations of the unconscious, the child's experience with the therapist in the therapy can exert a powerful influence toward change. The child not only uses the therapist as a transference object, but also readily uses the therapist as a real figure offering important new identifications.

In general, children with internalizing symptoms (e.g., depression or obsessive-compulsive disorder) are more accessible to individual psychotherapy as they become able to locate the source of distress as internal and desire to find help. Children with externalizing symptoms (e.g., conduct disorder or oppositional defiant disorder), on the other hand, tend to blame others, are less able immediately to see their own role in the genesis of their difficulties, and may therefore be less accessible to individual work. This tends to be a problem in the initial phase of treatment. Current research supports the application of individual psychodynamic psychotherapy to a wide variety of disorders.

HISTORY

Child psychotherapy begins with Sigmund Freud's case of Little Hans, a 5-year-old phobic boy. Published in 1909, it was the first description of the psychotherapeutic treatment of a child. The treatment in this case was actually rendered by Han's father who reported to Freud and received guidance from him. Significant interest in the mental and emotional lives of children was generated by Freud's theories of psychosexual development that posited that symptoms in adulthood could be traced to conflicts arising at earlier stages of development. Sandor Ferenczi was one of the first to attempt to analyze children, but he quickly became frustrated with the endeavor, finding that children only wanted to play. Hermione Hug-Hellmuth published the first report of actual play therapy with children suggesting that play and drawings were valid modes of communication used by children.

However, two psychoanalysts, Anna Freud and Melanie Klein, developed the field of child psychoanalysis. While they worked in different ways, they undertook the analyses of many children and spurred the work of many others. Klein understood play to be the actual equivalent of adult free-association. She was interested in the earliest object relations; the importance of unconscious fantasies at each stage of development; the role of primitive defenses such as projection, projective identification, and omnipotent control; the process of early identifications; and the role of envy and guilt in these early relationships. Freud looked at play from a psychoanalytic perspective and learned about the child from play but, for a number of reasons to be elaborated later, did not view play as a substitute for free-association. Her work concerned the development of the ego, the evolution of defenses, and the developmental pathway of various ego functions. In one example of a developmental pathway, she described a continuity from the child's capacity to play to the adult's capacity to work.

There were several other major early contributors to field. Donald Winnicott, a psychoanalyst and pediatrician, emphasized the importance of the mother-infant relationship. His understanding of the transitional object, for instance, as playing a role in the child's ability to separate from the maternal figure infused a new appreciation of the meaning of commonly observed childhood behaviors. Margaret Mahler observed mother-toddler interactions in a more systematized way and described the evolution of early object relations from the perspective of separation and individuation. Winnicott's and Mahler's ideas had great impact on the issues dealt with in children's psychotherapy. August Aichorn first extended the work to delinquent adolescents. Finally, the work of Jean Piaget focused on children's cognitive development and this subsequently influenced the practice of psychotherapy.

Another early influence on the development of child psychiatry and child psychotherapy came in the child guidance clinic movement. William Healey settled in Chicago in 1909 and turned his attention to the care of delinquent, abandoned, and abused children appearing before the Cook County Court. The Juvenile Psychopathic Institute (later becoming the Institute for Juvenile Research) was founded to evaluate and treat these children. Healey stressed the importance of psychologists for testing and social workers for making home visits. By 1917 a number of other child guidance clinics had been established, Healey went to the Judge Baker Guidance Clinic in Boston. Then and through the 1920s, the work with children in these settings was largely environmental. These clinics established the practice of intervention with troubled children. The influx of European psychoanalysts in the 1930s turned this work in a psychodynamic and psychotherapeutic direction.

CLASSICAL PSYCHODYNAMIC PSYCHOTHERAPY

Classical psychodynamic psychotherapy evolved from an approach to child psychoanalysis rooted in drive theory, in which symptoms are viewed as a compromise formation of the various agencies of the mind (id, ego, superego). The approach relies on interpretation of defenses and conflicts and strives to make these unconscious processes conscious. The principle of multiple causation holds that any given behavior, emotion, or communication has multiple meanings. The approach should not be confused with the aims of psychotherapy. Hansi Kennedy has noted that the most basic aim of any child's psychotherapy is to restore that child to a path of normal development; this end-point must be kept in mind.

Freud noted that what distinguishes child psychoanalysis from other forms of therapy is that it relies chiefly on interpretation of resistance and transference and attempts to avoid coercion, the use of authority, suggestion, abreaction, and manipulation. This also holds true for classical psychodynamically oriented psychotherapy. She notes several features that distinguish child psychoanalysis from adult psychoanalysis. First, children, unlike adults, do not as a rule voluntarily bring themselves to therapy; rather, they are brought. Thus, forming a task-oriented working alliance is more difficult. Resentment at having been brought to a psychiatrist may also interfere with the work. In her earlier writing she proposed using many nonanalytic means to induce children into treatment, such as feeding them or promising actual help with difficult parents and teachers. She later reversed this position and advocated instead an approach of interpretation from the

beginning. Such approaches may nonetheless be useful with the resistant child at the start of treatment. On the other hand, the curative tendencies may be more easily tapped since the child's urge to complete development is immeasurably stronger than the adult's.

Many significant differences in technique exist; chief among them is the relative absence of free association in the child. The child tends to act instead of speak and possesses an innate resistance to regression. In addition, children preferentially express aggressive drives over libidinal drives. Play, drawing, and the staging of fantasy games, according to Anna Freud, cannot be accepted in place of free association because they introduce the uncertainty of symbolic interpretation. They serve only as an arena for psychoanalytic observation.

While interpretation, principally of resistances and transferences, remains the primary vehicle of the therapy, verbalization plays a specific role in the process leading to interpretation. First emphasized by Annie Katan, verbalization is an indispensable prerequisite for secondary process thinking, and it promotes reality testing and ego control over id impulses. *Verbalization* refers to the therapist's active narration of the child's play, behavior, moods, and affects. While verbalization is important in the treatment of children of all ages, it is particularly important in the treatment of early school-age and preschool children and children who have more-extreme developmental delays and defects.

While the curative tendencies can be seen as stronger in children, so too can the resistances. The various sources of resistance in children, according to Freud, include the following:

1. Children do not enter treatment on their own and are therefore not bound by the analytic rules
2. Children cannot take a long-term view of treatment
3. Acting-out takes precedence over talking
4. Children's egos are relatively weak and defenses are kept up more rigidly
5. Primitive defenses remain present, even as more mature ones evolve
6. The urge to grow up and reject the past is stronger, so the infantile (conflictual) past is often not accessible
7. Children prefer environmental solutions to internal ones.

These various resistances must be dealt with in the therapy. Because children cannot be counted on to maintain an independent alliance with the therapist, throughout treatment the alliance with the child's parents must be maintained and fortified.

Psychoanalytically oriented treatment has traditionally been divided into a beginning phase, a middle phase, and a termination phase. The beginning phase depends on establishing a strong working alliance with the parents. After this, an initial session must indicate the nature of the work without overwhelming the child with a sense of having problems or with anxiety. Finding a comfortable mode of communication, whether in play, games or being able to talk about one's current life, ensures that conflictual communication can occur in a predominantly nonthreatening setting.

The middle phase involves an intensification of transference reactions as well as play sequences. Here, basic conflicts are worked through via interpretation of both transference and the play.

PLAY

Play has had a central place in the psychotherapy of children from its inception. Play is a natural means of child communication. Play serves many functions in a child's development including socialization, motor development, development of imagination, integration of emotions, and the development of autonomy. Anna Freud described a line of development from a child's capacity to play to the adult's capacity to work. While the use of play in child psychotherapy may draw on these functions, there are special considerations regarding play and psychotherapy. Whether play is used ultimately for the purposes of therapeutic interpretation or whether play itself has a primary therapeutic benefit in the context of ongoing psychotherapy is controversial.

Play in the context of psychotherapy takes on special characteristics. While children's play usually occurs either in a social context (which after the age of 4 usually involves a high degree of reciprocity) or in a solitary setting (in which all the play is elaborated from the child), the context of therapeutic play is neither social nor solitary. While the therapist may choose to be more or less involved in the play, the therapist will attempt to encourage the elaboration of play by children. The therapist can attempt to redirect the play towards areas of conflict and can help children overcome resistance. Because the therapist will show interest in all areas of the play and will not express judgments about what is good or bad, permissible or prohibited, children come to understand that playing with their therapist is different from playing with anyone else. Children are thus encouraged to express more and more material that might otherwise be repressed.

What is also unique about the play therapy situation is the balance between the control children have over the play and the safety provided by the presence of the adult. In a play enactment, for instance, children may assign parts to themselves and other parts to the therapist. While the therapist will make some comments spontaneously to facilitate the play, the therapist will also occasionally defer to the children, asking what a given character should say. The children retain ultimate control over the script and may terminate a scene at will. Yet, the presence of the therapist confers a certain safety. Children who would not dare play out a certain theme alone not only feel encouraged, but also may feel that the presence of the therapist creates what Donald Winnicott has termed the *holding environment*, in which security, if it existed in the child's development in the first place, is ensured.

In this way, children come to communicate more and more in therapeutic play. Facilitation of communication, as described above, depends on the constellation of internal object relations. Security can only develop if there is an internal source of security to draw on. The same consideration applies to all affects and emotions. The seductiveness, punitiveness, or negligence of the primary caretakers comes to bear in the evolution of the therapy.

> A 3½ year-old boy was brought to treatment because he regularly objected to visiting with his father who had left the family 6 months previously. His father practiced a strict fundamentalist religion and required practices and prayers of the boy that he little understood. His father felt that the mother was turning the boy against him. In the first three sessions, he layered the roof of a small doll house with strips of black tape, as if he were reshingling the roof. On the fourth session, he had a father figure walk along the pitch of the roof, stumble, and fall. With each fall, he clapped his hands with glee. At first, he looked to the therapist for permission to go on with this play. When this was given, he repeated the sequence over and over again with delight. Some weeks later, at a session after another child had removed some of the pieces of tape from the roof, the boy looked up with great alarm, saying, “Who's been playing in my house?”
>
> This case illustrates the way a child will express thoughts and feelings not permitted in other contexts, the importance of the permission and facilitation of the therapist, and finally, the sense of privacy and security of the play situation. After the initial anxiety, the child became anxious again only when he perceived that his play space had been entered.

Other Considerations Several other aspects of play in a therapeutic context must be considered. These include play as defense, traumatic play, the use of games, and what Eva Sperling has called “play as a medium of exchange.”

Play can often be used for defensive purposes. In such cases, play becomes repetitious, rote, and unadventurous. Avoidance of interpersonal contact or revelation of personally threatening matters is thus achieved. It is not uncommon for a therapy to go through periods of such defensiveness. At these times, neither therapist nor patient may realize that the patient may be testing the therapist in various ways. Is the therapist really interested? Is the therapist really patient, accepting, or nonjudgmental? Eventually, the therapist must challenge the repetitious nature of the play or undertake maneuvers to introduce new activities.

Repetitious play must be distinguished from posttraumatic play. In the latter, a traumatic situation is repeated with no particular elaboration or use of the imagination. Often the play situation is devoid of expressed emotion. What distinguishes this type of play from defensive play is the nature of the traumatic situation portrayed, which will have been unusually and severely stressful. Examples of such trauma include natural disasters, witnessing or participating in accidents or crimes, or kidnappings. In these cases, the technique differs from that used in defensive play. One aim of the therapy here is to connect the displaced emotion to the traumatic situation.

Latency-age children tend to use an admixture of games and free play. Their interest in games reflects the Piagetian stage of concrete operations in which children are becoming capable of understanding the rules that govern external reality. In this regard, their preoccupation with rule-bound games reflects an exercise of the new

capacity of the developmental stage. Games, however, often flow into play. As John Meeks has noted, when children obviously cheat at a game, they are often at the point of moving from the realm of games into the world of play. If one understands play as a situation in which the unconscious fantasy life dominates reality in the play sequence, the same situation occurs when cheating overtakes the rules of the game. The children are motivated by what they want reality to be, not what they currently perceive it to be. The therapist must note that a new set of rules is being invoked to help the children perceive their cheating and support the development of superego functions, but noting this change in rules is not judgmental.

A 10-year-old boy was brought to treatment because of his disillusionment with his learning disabilities. These had been appropriately diagnosed, and he was receiving adequate remedial work. His emotional reactions to these difficulties had been overlooked for some time. Early in treatment, in the midst of a game of checkers, and somewhat annoyed that the therapist had achieved two kings, he moved his king back across the board, added a third checker on top of the two, and declared that this was an emperor, more powerful than a mere king, and able to move diagonally. Soon his emperor retraversed the board and became an arch emperor with a fourth checker on top. The archemperor had all the emperor's powers plus the ability to enter red squares. So the game went. With pieces soon piled six and seven high, his need for strength and his sense of powerlessness were revealed.

Finally, play in therapy is often used as a medium of exchange between patient and therapist. Here, the play is neither being used in the process of self-disclosure nor is it specifically defensive. Rather, because children may not be able to sustain a conversation for the full session, the play activity serves to structure the interaction between the therapist and the patient. Conversation then need not carry the full weight of the interaction and can start and stop and then proceed again as motivated by a true desire for communication. Drawing, constructing, or games may serve this function.

TRANSFERENCE

Most psychodynamically oriented psychotherapists agree that the emergence of transference is considered central to the process of psychotherapy. Through the interpretation of the emerging transference, the conflicts that are central to both the particular presenting symptoms and the particular organization of the personality can be resolved. Transference has been regarded as a window on psychic organization; through it, past relationships become visible particularly as they color and shadow the current, actual relationship with the therapist.

The application of the concept of transference to the treatment of children needs modification. As first described by Freud, children use the therapist differently from adults. Children's hunger for new experiences is often stronger than the repetition compulsion. Thus, therapists are experienced as new persons in their own right, and the children are drawn to what is new in the relationship with them. This does not preclude repetition of elements of the past, but these exist alongside the new experiences. Child therapists, however, must distinguish between the two. In addition, the fact that a child will approach the therapist as a new object provides other opportunities for the therapist via new identifications.

Other factors are associated with transference in children. Most importantly, most children are living with their parents. They have neither physically nor psychologically separated from them. This, of course, is the psychological task accomplished by the end of adolescence. Because of this retained connection, many other modes of interaction occur that look like transference but must be differentiated from it. Robert Tyson and Dayllis Tyson have distinguished these reactions: habitual modes of relating, transference predominantly of current relationships, transference predominantly of past experiences, and transference neurosis. *Habitual modes of relating* are characteristic ways of relating to others that may occur in the therapy but are not specific to the therapy. *Transference of current relationships* refers to “spill-overs” of interactions currently occurring with the parents. Children and adolescents often see the therapist as an extension of their parents, so they are prone to these types of displacements with the therapist. *Transference of past experiences* refers to a type of limited transference reaction that occurs after some period of treatment. Children are usually aware of some qualitative change in their feelings about, or attitudes toward, the therapist. A *transference neurosis* involves both a qualitative and quantitative shift so that much (if not all) of the patient's interactions with the therapist are dominated by conflicts from the past, however strongly felt in the present. When a transference neurosis is established, the neurotic elements in the children's lives become specifically focused on the therapist, thus freeing the children from the influence of these conflicts in other areas of their life. Not all intensive child psychotherapies, however, progress to the development of a transference neurosis; in fact, some question whether a true transference neurosis can emerge at all with children. A transference neurosis is more likely to occur when there have been discontinuities in the child's essential object relationships. At such times, the children may see the therapist as the basic cause of their difficulties and desire to flee the therapy. Understanding the various sources of the vacillations in children's treatment of their therapist is essential for effective interpretation.

An 8-year-old boy was brought to treatment because of behavioral difficulties in school, infantile behaviors at home, and a recent onset of stealing or, as he called it, “borrowing” toys from his friends. He had been adopted at birth. At the age of 3 his mother contracted cancer and was slowly dying, principally at home, over the next 2 years. The year after her death his father fell into a depression and remained home much of the time with the boy. The boy was indulged throughout the mother's demise and during the year of mourning. A kindly housekeeper saw to all his needs and continued to feed and dress him. At the age of 6, the father married a woman with no children who made it her business to whip the boy into shape. She installed herself as mother and first informed the boy about his original adoption indicating that his mother had not really been his mother. She replaced his bedside picture of his mother with one of herself.

In therapy, a particular play sequence emerged over several weeks and was repeated regularly for almost 6 months. The boy went into an imaginary time machine and crawled out as a baby. The therapist as “Daddy” would make him cookies and bottles out of paper and feed him. Sometimes he did not like swallowing the cookies and spit them out. After this, the therapist had to read him three juvenile stories. Then both would have to feign sleep with the lights dimmed. Soon it was morning, but neither the boy nor the therapist were supposed to feel like getting out of bed and would lounge, either pretending to watch television or reading the stories again. Once this sequence was established, the child's stealing, infantile behaviors at home, and disruptive behaviors at school subsided. Eventually, the child replaced this sequence with a new enacted story that concerned a little puppy who needed training.

These play sequences fit the description of a transference neurosis. The enactments were both intense and comprehensive, with a behavioral improvement outside of the therapy. Clearly the boy needed to revisit the lost, merged relationship he had experienced with his father after his mother's death, which had been abruptly taken away from him. When he was ready to be “trained,” he indicated so.

INTERPRETATION

Interpretation historically referred to a set of communications from analyst to patient to bring about dynamic change in the structure of the personality. Specifically, interpretations were aimed at making the unconscious conscious and were usually centered on either the defenses or an explanation of the transference. The variability of children's development has required modifying the use of these interventions with children.

Melvin Lewis has proposed that interpretation with children must occur over a range of six types of interventions that proceed from less to more comprehensive statements. *Setting statements* are aimed at creating the conditions necessary for therapeutic work; for example, telling children that therapy is unique because it lets them understand their feelings and actions. *Attention statements* focus children on the facts of their actions or statements. This involves direct labeling; for example, a certain character is speaking nicely but doing mean things. *Reductive statements* attempt to identify themes that have occurred in a variety of settings. If children have been reacting with sadness to the departures of friends in their actual life and characters in play, this might be pointed out. This requires that the children's cognitive capacities allow them to generalize across situations. *Situational statements* follow from reductive statements. Building on the ability to recognize an affect or reaction arising in different settings, the children's role in the generation of the affect or reaction can be highlighted. *Transference interpretations* are considered to be the essential interpretation. As noted in the section on transference, transference may not exist as discretely in children as it does in adults. Nonetheless, to the extent that transference is manifested, whether completely as a transference neurosis or incompletely, statements that elucidate the nature of an earlier object relationship are considered to be at the heart of the conflict. *Etiological statements* attempt to connect earlier developmental events with current behaviors and feelings through recall and reconstruction. While the children's cognitive limitations may make this aspect of the work difficult, at termination children can often recall earlier phases of the treatment. This makes some aspects of reconstruction possible.

Paulina Kernberg has described the hierarchy of verbal interventions differently. She discusses various levels of statements moving from surface consciousness to the unconscious, including (1) statements of ordinary social behavior, (2) statements relating to treatment, (3) questions about factual information, (4) supportive statements, (5) facilitating statements, (6) clarifications, (7) confrontations, and (8) interpretations. Psychotherapy, then, is formulated on those interventions that are both possible and desirable in a given situation. Broadly speaking, psychotherapy ranges from supportive-expressive psychotherapy to expressive psychotherapy to

psychoanalysis.

In supportive-expressive psychotherapy, resolution of conflicts is not expected. Symptoms are expected to resolve but without character change. The therapeutic alliance is seen as an end in itself, with emphasis on identification with the therapist and a corrective emotional experience in the therapy. The usual types of interventions include clarifications, confrontations, and supportive interventions. Transference interpretations are generally limited to negative transference to facilitate the treatment. Other interpretations are limited to the manifest content. The therapist actively chooses topics to be discussed and gives information and advice.

In expressive psychotherapy, the goal includes resolution of conflicts from some, but not all, levels of development. Symptoms are expected to resolve but without character change. Children are given greater autonomy in the elaboration of the treatment. Interventions include some supportive statements, clarifications, and confrontations, though some transference and reconstructive interpretations are possible.

In child psychoanalysis, the goal is not only symptom resolution but also character change. Resolution of conflicts from all developmental levels is expected. The pace and unfolding of materials is left entirely to the children. A full transference neurosis is expected to develop, and full use of it is made in interpretation. Other types of verbal interventions are used only as preliminary steps en route to transference and reconstructive interpretations.

RESEARCH

Most research on the evaluation of outcome in intensive psychoanalytic treatment of children has been flawed by poor definitions of the disorders, poor specification of treatment procedures, and unreliable outcome measures. Several studies do support the efficacy of intensive psychoanalytic treatments and have led to a reconsideration of certain aspects of psychoanalytic treatment of children and its application.

Peter Fonagy and George Moran compared two groups of 11 children hospitalized for poorly controlled diabetes. One group received hospital care plus three to four sessions of psychoanalytic psychotherapy a week for an average of 15 weeks; the control group received only hospital care. The treatment group showed significant improvement in diabetic control, which was maintained for over 1 year at follow-up. The control group returned to pretreatment levels of diabetic control after 3 months. In a study with single-case design, Fonagy and Moran investigated growth rate changes in three children who exhibited growth retardation. All three children showed an acceleration in growth and several biological growth indicators.

Mary Target and Fonagy undertook a retrospective chart review of 763 patients treated at the Anna Freud Center. Patients had received either psychoanalysis four or five times a week or psychotherapy one to three times a week. The authors used standardized psychological and psychiatric descriptions of the children to allow comparison and used diagnostic change and changes in social and emotional adaptation as outcome indexes. Three broad studies were undertaken: children with emotional disorders, children with disruptive disorders, and the impact of age.

There were several notable findings. Of the 352 children with emotional disorders, only 24 percent had a diagnosable disorder after 6 months, regardless of the intensity of treatment, and 72 percent showed reliable, clinically significant improvement. In this group, both the more- and less-frequent treatment groups showed more improvement with longer treatment, but the more-frequent treatment group showed greater improvement. Intensive treatment was significantly more helpful for children with more severe disturbance in terms of multiple diagnoses or pervasive impairments.

The 135 children with disruptive disorders showed lower overall rates of improvement than the matched children with emotional disorders, and nearly one-third dropped out of treatment after 1 year. Of those who remained in treatment, 69 percent were no longer diagnosable at termination. Predictors of improvement included younger age, more-intensive treatment, longer treatment, concurrent treatment of mother, and history of foster care placement.

Children were grouped by age: below 6 years to 12 years, and above 12 years. The youngest group showed the most benefit. The 6- to 12-year-olds showed most benefit from more-intensive treatment. Adolescents did not show any benefit from increased frequency of treatment.

These studies have several important results. Younger children benefit more from treatment, which underscores the need for early intervention. Adolescents did not benefit from the more intensive treatment, which suggests that a frequent treatment should not generally be prescribed for this age group. Children with simple or single emotional disorders, the assumed ideal patient for psychoanalysis, appeared to benefit equally from intensive and nonintensive psychotherapy. The children with severe, entrenched, complex psychosocial problems, which included conduct disorder and at least one emotional disorder, only benefited from psychotherapy that was intensive.

CRITIQUE OF CLASSICAL PSYCHOTHERAPY

Classical psychotherapy, according to its own theory, relies predominantly on interpretation as the vehicle of psychic change. Interpretation is a verbal intervention. The emphasis on verbal intervention is based on the concept that verbalization places wishes, affects, and fears under the rational control of the ego. Thus, in Kemberg's schema, treatment progresses from less complete treatment (supportive-expressive) to more complete (psychoanalysis). Complete treatment involves character change. Symptom abatement, change in diagnosis, or improvement in social and adaptive functioning are presumed to follow character change. Character change is made possible through verbally derived insight into conflict.

That children can and do change through psychoanalytically oriented psychotherapy or analysis is substantiated by the studies of Fomagy and Moran and Target and Fomagy. Their demonstration that the more pervasively disturbed children in the emotion disorders group benefited from more frequent (but not less frequent) treatment and that children with disruptive disorders benefited more from intensive, longer treatments suggests that the application of intensive psychoanalytic treatment to these groups (formerly presumed not to benefit from intensive psychotherapy) should be reconsidered. The assumption that these groups did not benefit from intensive psychotherapy derives from their apparent inability to use an interpretative approach. Are these children changing because of verbally mediated interpretations or is some other process at work?

Kennedy, very much in the classical psychoanalytic tradition, described developmental limitations on children's capacity for insight at each developmental stage. The egocentric, non-reality-based orientation of school children precludes their gaining objective insight. Their needs and wishes dominate the moment. The problem for the latency-age child is exactly the opposite. The Piagetian stage of concrete operations of cognition is essentially an interest in exploring the external world and the rules by which it operates. Here, there is a resistance to exploring the inner world. Thus, while objectivity is possible, subjectivity is resisted. For the adolescent, other factors work against the attainment of insight. While adolescents are developing the capacity for abstract thinking, which should facilitate the attainment of insight, their increased tendency toward introspection is based on a defensive narcissism, which (in ways similar to the preschool situation) precludes an adequate perception of the external world and works against the attainment of full insight.

Cognitive studies reveal that many operations that are part of the interpretative process are difficult, if not impossible, for children at certain stages of development. S. Harter notes that while preoperational children can generate free association, their cognition limits their ability to distinguish fantasy from reality, their ability to take in what the therapist may articulate for them, and their difficulty in appreciating connections and inferences. Free association in the latency period is resisted as regressive, and the external orientation is maintained. While the expression and understanding of emotion is basic to the process of psychotherapy (particularly the experience and understanding of ambivalent emotion), the child's capacity both to experience contradictory emotions and to experience these emotions directed toward the same person may not emerge until the end of the latency period. Similarly, an appreciation of the difference between manifest and latent feelings emerges later in latency. Here a belief that emotions cannot be hidden progresses to an understanding that emotions can be hidden, to a realization that mental operations can put feelings out of one's mind, to an understanding, in adolescence, that certain thoughts and feelings are not always consciously available. Much interpretative work requires some understanding of latent feelings. The recognition and appreciation of feelings in parents also develop later. Some emotions (e.g., fear and happiness) lag behind others (e.g., anger and sadness) in being differentiated from parental feelings. The sense of self, often invoked in the language of interpretation, also undergoes development into adolescence. The self is defined first by concrete behaviors and attributes and then by increasingly abstract and differentiated attributes. Finally, an awareness of dreams as the product of the child's own mind again emerges throughout latency. Thus, these various mental operations that are invoked in the interpretative process are not well established at the ages when many children undergo psychotherapy.

In considering the cognitive level of children and attempting to determine what types of interventions are possible for their individual level of understanding, one must remember that when children are confronted with intense emotion or unusual stresses (as often occurs in psychotherapy), they are likely to experience both emotional regressions and cognitive regression. In fact, all regressive behaviors have both emotional and cognitive components. Thus, although a child may have recently achieved more-advanced cognition in a certain area, this achievement will most likely be lost when it is most needed, namely at crucial points in therapy when

emotion reaches a certain pitch. Possibilities of interpretation are then correspondingly diminished.

Finally, as first highlighted by Anna Freud, children use the therapist equally as a new object in their lives and as a transference. They are interested in the new experiences provided by therapy and are open to developing new identifications with the therapist. This means, for instance, that while therapists may think they are interpreting children's anger at a parent, the children perceive an entirely new way of someone reacting to their anger and talking about it. This new experience itself may well be internalized. If and when the anger emerges in the transference, the children can then replace their identifications with their parents (who may themselves have reacted angrily, critically, or punitively to the children's anger) with an identification with the therapist who is reacting in a benign manner.

ALTERNATIVE FORMULATIONS

P>While maintaining a belief in an unconscious determination of many types of symptoms and an unconscious motivation for many behaviors, a number of authors have recognized that even within the process of psychotherapy, factors other than interpretation may account for much change that occurs. While such considerations apply to the resolution of dynamically based conflicts, these authors also attempt to balance dynamic factors with other etiological sources of pathology such as biologically based deficit, biologically based constitutional trends, and social learning.

Enhancing Mentalization Efrain Bleiberg, Peter Fomagy, and Mary Target have presented a partial reformulation of child psychoanalysis that is developmentally based rather than relying on conflict resolution. It attempts to enhance the skills of self-reflection and perception of others, or *mentalization*, and derives from recent research findings on the outcome of intensive psychoanalytic treatments. In the large group of children with complex psychopathology who benefited from intensive psychoanalytic treatment in these studies, there appeared to be two clusters of patients. Cluster A patients showed unstable reality contact and thought disorganization in situations without structure, impoverished relationships, communication difficulties, and poor affective regulation. These patients had diagnoses from the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) that included schizotypal and schizoid personality disorders and milder forms of pervasive developmental disorder. The Cluster B group patients showed intense hunger for social reponsiveness, a variety of reactions to separation, affective lability, and significant self-centeredness. DSM-IV diagnoses included attention-deficit/hyperactivity disorder, conduct disorder, separation anxiety disorder, and mood disorders. Despite the obvious heterogeneity of these groups, they either pervasively (Cluster A) or intermittently (Cluster B) lacked the ability to be aware of their own and other's mental states.

In light of these deficits, the child analytic approach focused on enhancing mentalization includes the following goals: (1) facilitating verbalization and differentiation of feelings, (2) helping the child to master manageable units of anxiety, (3) to appreciate cause and effect within relationships, (4) to develop better reality testing, (5) to understand limit setting, (6) to increase frustration tolerance, (7) establishing internal representations of affect that can lead to self-regulation, and (8) expanding the child's appreciation of ambivalent and conflicting thoughts and feelings.

A number of techniques are proposed to achieve these goals. Enhancing reflective process is achieved by improving children's observation, labeling feeling states, and tracing sequences of behaviors. Strategies that allow children choices before action, consideration of alternative actions, and possibilities of verbal instead of physical action will strengthen impulse control and self-regulation. Becoming aware of others requires attention to the smallest indicators of a child's awareness of other's feelings or thoughts. Attempts to make reparations are often seen in play. The experience of guilt, however displaced, may also indicate that children have some early awareness of their effect on another. Attention to the therapist's countertransference may serve as a guide. Transference considerations differ in the two clusters. Cluster A patients require an active use of the therapist to integrate these new processes. Cluster B children adhere to a rigid, often hostile, organization of the relationship that usually tests the therapist's ability to remain empathic and requires patience, bargaining, and cajoling on the part of the therapist to help these patients find other ways of relating.

Many of the above techniques may appear to be techniques used in cognitive therapy, but this approach to psychoanalytic psychotherapy is less prescriptive and anticipates resistance to change that is psychodynamically based. Furthermore, here the actual therapeutic relationship is the tool of integration, rather than prescriptive exercises or reinforcements.

Integrated Psychodynamic Psychotherapy Owen Lewis presented integrated psychodynamic psychotherapy, an approach to dynamic psychotherapy based on four clinical principles. The first of these, the dual purposes of psychotherapy, holds that psychotherapy proceeds in two sometimes contradictory directions. Psychotherapy must function as a specific treatment for a specific disorder in a child at a specific developmental stage. With these parameters, specific techniques are used to treat the condition. On the other hand, psychotherapy also functions as an open-ended exploration of the unconscious factors that may have a role in the child's problems. Even if the disorder is developmentally or biologically based, it will be understood and incorporated by the child in unique ways that must be elucidated. These factors cannot be known in advance and are discovered in the course of psychotherapy.

The second principle, the use of all modalities of treatment, follows from the first. The complexity of most psychiatric disorders and the inherent limits of any one approach warrant the use of any combination of modalities of treatment. While certain approaches (e.g., classical psychoanalytic treatment) were seen as incompatible with other modalities of treatment, integrated psychodynamic psychotherapy finds a positive synergistic interaction between modalities. Integrating treatment approaches requires innovation to create the best comprehensive treatment plan for a given child.

The various modalities of treatment (e.g., behavioral, cognitive, familial, psychopharmacologic, and educational) are organized through a basic psychodynamic understanding. The third principle involves tracking the psychodynamic process. How these various modalities interact is monitored through shifts in the material presented by the patient. Does alleviating an anxiety symptom through a behavioral intervention make the patient more or less interested in pursuing its cause? Do the effects of an antidepressant make a patient more or less able to talk about troubles? Intervention by intervention, session by session, the flow of material is watched. The therapist also notes positive interventions that soon yield negative results. If the dynamic meaning of change is not appreciated, the patient will resist change.

The fourth principle holds that psychotherapy proceeds through the therapeutic relationship. In this interpersonal perspective, all therapy is ultimately organized within the relationship with the therapist, and without that relationship, there is no therapy. While transference is a necessary component to this relationship, patients are also bound by their developmental capacity for relatedness. This capacity is determined not only by developmental stage, but also by the patient's accumulated experience. A therapist who offers a child help with anxiety symptoms through a relaxation technique can simultaneously and symbolically expose a deficit in care by a parent (transference) and provide new opportunities for care (new identifications). From this point of view, the therapist must equally note transferences and the patient's resistance to these transferences as well as the real relationship and the patient's resistance to this.

Change, for the child, comes from a variety of sources. Specific behavioral techniques will shape behavior. Family interventions can modify parenting approaches. School consultations can help create an environment for children that is more conducive to their learning and social environment. All these interventions (which may or may not be accepted by the child), are processed through the therapeutic relationship and color that relationship in ways that have dynamic meaning. While classic interpretation may be used, interpretation per se often formulates for the child change that has already occurred. This change ultimately evolves from the new emotional, cognitive, and interpersonal integrations achieved within the therapeutic relationship.

A 4½-year-old boy was brought to treatment because of his persistent use of a diaper and other infantile behaviors. Up to the age of 3 he was developing normally, if not precociously, when his sister was born. He now clung to his bottle, diaper, and changing table, and resorted to baby-talk with his parents. After a year and a half of trying various ways to eliminate these behaviors, the parents sought consultation.

A series of behavioral rewards was established for the elimination of the infantile behaviors, the use of the bathroom for changing diapers, and finally sitting on the toilet seat after defecation.

Play initially involved the boy playing the part of a drill sergeant with a shrill whistle and harsh commands. One day the child devised a game in which he climbed inside a cardboard box, declared himself to be “Mr. Duty,” and had the therapist speak to him through a vaccum hose. After a brief discussion of his cramped quarters, he rumbled out, and therapist and patient changed roles. This game went on for several weeks.

One day, he announced to his father that he might want to use the toilet. His father, himself now well trained, gave him his choice. From that point on the child used the toilet.

A new game evolved shortly after this. Playing the part of a mother kangaroo with a baby kangaroo stuffed into his “pouch,” he hopped around the office telling the baby it was not yet time to come out.

Both the behavioral and the dynamic treatments contributed to this boy's improvement. Of particular note, the dynamic meaning of his encopresis was not revealed until after the symptom improved, namely equating the feces with the baby (sibling).

Other combinations of treatments have shown similar synergistic effects. Medication, for instance, often serves as an emotional probe. What does the medicine mean to the child? What does illness mean to the child? What improvement is attributable to the child, what to the pill? Similarly, family therapy and individual therapy have important interactions. Not only can family therapy improve communication, it can also challenge or confirm views the patient has of other family members, and thus hasten improvement.

SUGGESTED CROSS-REFERENCES

Section 7.2 discusses the psychiatric report and medical record, and Section 7.6 discusses psychological and intellectual assessment of children. Section 30.1 covers psychoanalysis and psychoanalytic psychotherapy, Section 30.7 covers interpersonal therapy, and Section 30.12 covers combined psychotherapy-psychopharmacology. Short-term psychotherapy in children and adolescents is discussed in Section 48.2, cognitive-behavioral therapy in children and adolescents is discussed in Section 48.3, and family therapy is discussed in Section 30.5 and Section 48.5. Section 48.10 covers the psychiatric treatment of adolescents.

48.2 SHORT-TERM PSYCHOTHERAPY

EUTHYMIA D. HIBBS, FH.D.

Short-term therapy with children and adolescents flourished in the last two decades in response to several factors. Long treatment experience and frequency of premature termination and drop-outs suggested that most children and their parents could not sustain long-term commitments. Second, because short-term therapy addresses a specific problem or behavior and not the overall functioning of the child, a limited number of sessions may suffice to correct the problem. In the last decade managed care limited the number of sessions, based on the results of the efficacy studies, forcing clinicians to short-term treatments regardless of the needs of the patients or the extent of the problem. Finally, medication has replaced long-term treatments to a significant extent, but because of the lack of pharmacological trials, the public is currently concerned about the extensive use of medication for the quick treatment of children.

Short-term therapy may be appropriate for a number of children. Surveys indicate that outpatient treatment with children is by default time-limited for several reasons. Children are usually brought to therapy by adults. When the recommendation to enter treatment comes from outside sources (e.g., schools, courts), parents may not be motivated to follow through. Further, children sometimes may not be available for long-term commitments, or they may not be interested (or cooperative) in entering open-ended therapy. Financial constraints and managed care's limits on treatment length also mitigate against long-term therapy.

Since the late 1980s psychotherapy research with children and adolescents has expanded, especially in modalities that claim to be of short duration, such as behavioral, cognitive, and cognitive-behavioral therapies. These studies have reported success rates, but problems remain. Not many children benefit to the same degree from these short-term therapies, and the benefits they derive are not always stable. Manuals are useful in efficacy studies to standardize treatment across subjects, therapists, and settings and secure the validity of the treatment, but manuals do not ensure the generalizability of treatments. Further, nonspecific effects of treatments such as moderators, mediators, and the role of the therapeutic alliance are not considered in efficacy studies with children. Managed care companies misinterpret the results of studies on the efficacy of short-term treatment and request uniform therapy for all conditions.

However, research on short-term therapy enhanced the scientific theory and understanding about the ways people change and adapt to their environment. Short-term therapy may benefit children during periods of developmental reorganization and may contribute to a sense of continuity, relational patterns, acquisition of particular skills, and environmental disruptions.

This chapter discusses only the four major short-term therapies that are most commonly used in the clinical field: psychoanalytic/psychodynamic psychotherapy, behavior therapy, cognitive therapy, and cognitive-behavioral therapy. These treatments, with the necessary adjustments, may be applied in individual or group therapy with children and adolescents.

DEFINITION

Short-term psychotherapy is defined as any intervention that is guided by a core set of principles, based on the theoretical model of choice, and uses techniques essential for the specific treatment. Short-term psychotherapy is limited to 1 to 30 sessions (as opposed to open-ended treatments), depending on the theoretical basis of the therapy. Psychodynamically oriented psychotherapy aims to develop a limited psychogenic understanding of the focal problem. The major therapeutic technique, interpretation, is adapted to the brief format. Behavioral, cognitive, and cognitive-behavioral therapies aim to identify the primary problem and the discrete behaviors that maintain the disorder. The main therapeutic techniques used are verbal or cognitive mediation to bring about behavior change. Therapists maintain a consistent focus on the goals of therapy and allow little deviation from the problem at hand.

HISTORY

Short-term therapies for children and adolescents are derivations or downward extensions of adult treatments. Therefore, their history is blended with the development of brief therapies for adults. Only a few specific techniques such as play therapy and parent management skills have been specifically developed to treat children.

Short-term therapies began with Sigmund Freud who sought a quick cure for neuroses. He believed that once the etiology of the neurosis was known, it would lead to a quick solution and resolution. For example, Freud treated the composer Gustave Mahler in a single 4-hour session and the conductor Bruno Walter in six sessions. Freud's book *Studies on Hysteria* indicates that in some cases, once the problem was identified and discussed, it was also solved. However, as Freud sought a solution for the problem of resistance, psychoanalytic therapy lengthened considerably.

Otto Rank may be considered the forerunner of contemporary brief therapies. His theory on separation and union postulates that in the course of human development, individuals move between emotional attachment and dependency and separation and independence. He emphasized that in therapy, the patient learns to deal with separation from an ambivalent love object through engagement, attachment, and eventual loss. Thus time-limited therapy, at least with some patients, may be the treatment of choice because it requires them to deal with the dread of time and its implications for loss. This theoretical concept, though, is quite different from the reasons why short-term therapies were established. In reality, the movement toward short-term therapies was principally a response to long waiting lists, limited resources, other public health needs, and (in the last two decades) economic factors.

During World War II the need for short therapeutic interventions became crucial, to address the stress-related symptoms developed by soldiers. The psychosocial changes and traumas resulting from the war pressured the psychotherapeutic community to explore briefer, more direct methods of treatment. The earliest short therapy was crisis intervention aimed at stress reduction, symptom relief, and prevention of greater breakdown. The goal was to restore self-esteem and avoid retreat into more serious maladjustment. These short-term interventions were based on psychoanalytic principles and the transference phenomena, regardless of the length of the therapy. The work of Franz Alexander and Thomas French, which clarified a path toward a briefer therapy, was also based on the psychoanalytic understanding of the personality and the process of psychotherapy. They tried to define the basic principles that make possible a shorter and more efficient means of psychotherapy. They advanced the concepts of “corrective emotional” experience that focused on emotional change based on the reexperiencing of old conflicts in the therapeutic relationship and the “principles of flexibility” in which the therapist creates an interpersonal climate.

Originally, the psychoanalytic thinking was that a specific diagnosis was not necessary to treatment. However, as early as 1941, Abraham Kardiner indicated in his book *The Traumatic Neuroses of War* that a precise diagnosis must be linked to a specific intervention. Kardiner may have been at the vanguard of the diagnostic systems. George Kriegman and Harlan Wright in 1947, for example, studied a specific diagnostic problem—enuresis among soldiers—and evaluated several techniques such as suggestion, reassurance, hypnosis, and reeducation as interventions.

The impetus to use effective treatment methods comes principally from supply-and-demand pressures. World War II generated a need for short-term interventions, and the psychotherapeutic community responded appropriately. The Veterans Administration initiated the development and adoption of short-term therapeutic methods by assigning veterans to private psychiatrists for treatment and contracting for a limited number of sessions. Otto Fenichel described brief psychotherapy as the “child of bitter practical necessity.” Short-term interventions thereafter became a reality. In 1958, Leopold Bellak opened the Trouble Shooting Clinic in Queens, New York. About the same time the emergency clinic at Bronx Municipal Hospital was created. In 1962 the Benjamin Rush Center for Problems of Living was

established in Los Angeles. Other centers and training programs burgeoned in the country in response to lengthening waiting lists of patients. Most short-term therapies at that time were based on psychoanalytic principles, and the therapists were psychoanalysts who tried to adapt to the demands of their time.

Another turnabout that helped to establish short-term therapies was the social movement of the 1960s with its political counterculture activities, availability of drugs, and change in moral standards. Many individuals at that time experienced situational and personal turmoil that often led to a need for psychological help. In response, many counterculture “rap” centers, drop-in clinics, other alternative centers, and free clinics were established. These interventions, however, were often delivered by nonestablishment volunteers who offered nontraditional short-term support and counseling.

While the brief therapies based on psychoanalytic principles were unfolding, behavior therapy was being developed and established. Behavior therapy focused on addressing specific treatment to specific problems. Treatments were established to be short term, with a proposed systematic assessment of the diagnostic status, treatment process, and treatment outcome. Behavior therapies also redefined the role of the therapist by ignoring the alliance issues and the therapist's creativity. The therapist was required to take direct charge, assume an active role in the process, and direct the client.

Short-term therapies for children and adolescents also surfaced in the 1940s. The expense and time-consuming nature of longterm psychiatric care became prohibitive because of broken appointments, dropouts, and the inability of children and parents to sustain long-term commitments. There was also an urgency to offer services to many more children and families who required care. Brief service was developed by the Philadelphia Child Guidance Clinic whose goal was to assess the dynamic elements that could be used in short clinical services. In 1949 the Buffalo Children's Hospital developed a new structure for short-services cases. Specific patients were initially selected to try out the new therapeutic model that was later extended to all possible patients. All child short-term therapies that followed were based on the adult model of psychoanalytic-psychodynamic therapy. During the first two sessions children were helped to clarify their emotions, feelings, concept of self, wishes, desires, and expression of needs via symbolic play, imagery, and fantasy. Today, the first two sessions of almost all therapeutic modalities are used to assess the child and determine the problem to be addressed in the short-term therapy. Several childhood problems (e.g., school phobia, misbehavior, internalized disorders) were then treated with either psychoanalytic psychotherapy or behavior therapy. In the 1970s a major shift toward cognitive therapies took place and a combination of cognitive-behavioral therapies is most commonly used today.

Research on short-term therapies for children and adolescents is scanty. Besides the treatment of Little Hans by Freud, one of the earliest short-term therapy efforts with children appeared in 1946 in a study by Evelyn Alpern. He compared the outcomes of two approaches: seeing parents and children separately or seeing them together. The outcome measures were clinicians' evaluations of the child's progress—no statistical analyses were used. The emphasis on empirical research on the treatment of childhood disorders started in the early 1980s and intensified in the 1990s with the National Plan for Research on Child and Adolescent Disorders, a plan generated in response to a congressional mandate.

TECHNIQUES

Most short-term psychotherapies share some basic characteristics. They are very selective about the problem to be treated and the patients to be involved; that is, the problem or symptom must be circumscribed, with careful selection of inclusion and exclusion criteria. The first two or three sessions are dedicated to the assessment of the child and the problem. In addition, the principles of the short-term therapy are explained, emphasizing the immediacy and urgency of the change process, as well as the time limits, and techniques to be used. From this point on, both therapist and patient concentrate on working on the core symptoms. Each therapeutic modality follows its own theory-based principles of treatment. The therapist takes a direct and active role in promoting client functioning while simultaneously encouraging the child's capability for change. The cognitive-behavioral therapist assigns tasks or homework, and the patient is expected to be an active participant in the therapeutic process.

SELECTION CRITERIA

Children with less severe psychopathology are usually selected for short-term therapy. For short-term psychoanalytic/psychodynamic psychotherapy children need to possess object relational capabilities, basic trust, ego defenses that are functioning adequately, flexibility, and the ability to rapidly enter and then leave a meaningful relationship. Children who can profit from behavior therapy and cognitive-behavioral therapy are those whose problem is circumscribed, such as specific phobias, symptoms of the anxiety spectrum disorders, symptoms of affective disorders, disturbance of conduct and other well-defined childhood problems. Excluded are children with chronic psychopathology, such as psychotic symptoms, developmental disabilities, traumatic abuse, and comorbidity and those who lack sufficient cognitive and verbal skills. Also excluded are children with a history of severe loss, such as parental loss, maternal deprivation, and severe family pathology.

Indications Short-term therapies, in general, are indicated for specific, well-delineated problems. Psychodynamic psychotherapy is recommended for children with relatively simple problems and basically healthy personalities who have difficulty relating to parents or other important figures in their lives or who suffer from mild phobias, mild anxiety disorders, or dysthymic disorder. They must have above average intelligence and be motivated to feel better. For developmental reasons (i.e., childhood plasticity in the unfolding of the personality) children with less severe psychopathology may profit from a short-term intervention to remove the obstacles and permit resumption of the development process. Behavior therapy is indicated for specific, well-delineated behaviors of children and aims to ameliorate the symptom or behavior. Like the other short-term therapies, cognitive therapy is indicated for children with a prescribed problem who are intelligent and verbal and can understand the focus of the therapy. In addition, the child must be aware of the problem and the emotional fluctuations and be able to establish a working relationship with the therapist.

Limitations Short-term therapies have many limitations, but the main limitation is that severe conditions or syndromes are excluded. Short-term psychodynamic psychotherapy is not indicated for highly resistant children or those with antisocial behaviors, developmental disorders, or other serious psychopathology. The same is true for children with severe psychopathology whose families are of low educational level. Behavioral treatments can address only one behavior at a time; therefore, they are not recommended for clinically dysfunctional populations and those with comorbid conditions. Cognitive therapy also may not be the treatment of choice for children with comorbid disorders and those with severe psychopathology. In general, short-term therapies for children may be effective for some distinct problems, but they do not address the overall functioning of the individual.

SHORT-TERM PSYCHOANALYTIC-PSYCHODYNAMIC PSYCHOTHERAPY

Definition Definition of psychoanalytic-psychodynamic psychotherapy is difficult because it has evolved and been modified throughout its 100-year existence. There are some underlying treatment assumptions: (1) a continuity exists between the mental states of “normality” and “abnormality,” as well as the belief of a causal continuity between the mental states of infancy, childhood, and adulthood. Within these continuities, motivational instinctual drives and conflicts affect all aspects of mental life. (2) The observable actions, behaviors, or verbal communications are the sources of information about the subjective experience. (3) Organisms strive to reach a steady state (adaptation, homeostasis) in the face of pressures from external environmental sources, internal physiological sources, and powerful sources within the mental apparatus itself. Defense mechanisms are short- and long-term adaptational forces in the control and modification of conflicting motivational tendencies. (4) Most mental events are outwardly expressed because they originate in multiple converging psychological processes. (5) The unconscious aspects of thought that are for the most part inaccessible to the conscious mind can be brought into consciousness to introspective awareness. These unconscious aspects become accessible only under specific circumstances such as dreams or some psychotic states or are implied in the symbolic meanings of symptoms, parapraxes, and slips of the tongue, and above all they can be constructed by the clinical method of psychoanalysis.

Short-term psychodynamic psychotherapies, therefore, focus on the underlying personality processes, the expression of feelings, the development of insight, and the identification and (eventually exploration) of new ways of functioning. The therapeutic relationship, or therapeutic alliance, is accorded a special role and serves as the central agent for therapeutic change.

Theoretical Issues In psychoanalytic-psychodynamic psychotherapy, developmental impasses are considered to result from the interaction of limitations of structural adaptive capabilities in the child and environmental stressors such as losses, familial inadequacy, illness, or other psychosocial strains. Symptoms may be understood in terms of the child's unsuccessful efforts to cope with the experience of being overwhelmed by traumatic or chronic stress. Psychodynamic concepts addressing personality structure (e.g., ego strength, reality testing, tolerance for frustration) are seen in the context of essential adequate external support. Character structure is deemphasized, and the adaptive fit of child and environment becomes the locus of attention. Short-term psychotherapy relies on formulating a clinical focus to organize the therapeutic activity and keep it on track. The central issue is formulated on the basis of the presenting symptoms, the developmental history, and the current family situation. The termination addresses the child's ambivalence issues of loss and separation.

Therapy uses the basic principles of psychoanalytic theory, which include diagnosing the problem with consideration of the developmental context and the

psychoanalytic concepts of development, including the notions of regressions, fixation, and the possibility of a developmental breakdown. The defense mechanisms used and the concepts of transference and resistance are also examined. This occurs typically in 10 to 30 sessions, and the therapy is focused on the problem at hand. The aim is not to restructure the child's personality but to modify the existing balance of internal and external forces to address some observable life stressors, both in therapy and in the extended environment, to reactivate the developmental imperatives. Therefore, classifying the child in a categorical diagnosis is not as helpful in predicting outcome as the assessment of interpersonal, intrapsychic, and object relational capacities required by short-term therapy. The decision to use a brief treatment must weigh the child's social and familial milieu, since the child remains within the influence of the family, which thus has a great impact on the outcome of treatment.

Techniques Several theoretically based models of long-term psychodynamic psychotherapy techniques have been adapted to short-term treatments with children. They all follow a systematic process. Therapists maintain the focus of the treatment, are more active, sometimes give directives, are flexible, and address termination. During the assessment phase, therapists take a complete history and form a clinical opinion about operating dynamics and symptomatology. In addition, a clinical opinion is also formed on the basis of the history given by the children and their parents concerning the problem; the children's relationships with siblings, peers, and parents are examined; and their behavior during the interview is considered. The children's motivation is also assessed. From the onset, therapists are supportive, empathetic, and reassuring and show that they care about the child's feelings and problem. An effort is made at the initial phase to establish a good working relationship, and the time of termination is decided.

The next step is to help the children acquire insight into what is behind their problem. This can be achieved through the use of dreams, play, or transference interpretations. Sometimes interpretations go beyond the phenomenological material and include unconscious defensive operations, suppressed instinctual tendencies, and hidden meanings of behavior patterns. Interpretations are accompanied by warm, empathetic, and emotionally available therapists who help the children understand the basis of the problem, how it is related to the presenting dysfunction, and how it may affect their development.

The ensuing stage is devoted to helping the children resolve the conflict that brought them to a therapist, by encouraging them to use the new insight or understanding of the problem at hand and then putting the insight into action. That is, to challenge their fears and engage in actions that are anxiogenic but hold promise of rewards. Therapists and children discuss the strategies and possible consequences of the actions, with repetition encouraged until the children feel comfortable doing so, then they test and expand their repertoire to other challenges in life. The final task, termination, is to integrate what has been learned so that the children realize that only they can control anxiety and tension about events precipitated from the environment and recognize that they can find different ways to address a stressful situation.

Some specific therapeutic techniques are used with children such as finger-painting or painting, puppets, and other games. All aim at releasing children's internal or fantasy world to understand it, be less afraid of it, and guide it in reaching age-appropriate functioning.

Play therapy, the technique of choice for young children ages 4 to 12, includes age- and gender-appropriate activities such as games, painting, building, and puppets or dolls that allow children to “play out” their feelings, their fears, anger, loneliness, and their feelings of failure or inadequacy. In play therapy children are given the opportunity to learn about their problems and their relationships with others and work on the issue that brought them to therapy. The aim is to ameliorate clinically relevant domains of functioning and learn to cope better with the problem at hand. Play therapy also promotes the development of trust and confidence in communicating feelings. Several techniques based on different theoretical concepts are used for that purpose.

Mutual story telling is a technique in which first children tell a story. The therapists then infer its psychodynamic meaning and tell a story of their own, that contains the same characters in a similar setting but introduces healthier adaptations and resolves the conflicts exhibited in the children's story.

Story making consists of therapists writing stories using the children's expressed concepts and their knowledge of the children's problems. The aim is to enter the children's world and facilitate the children's expression of their fantasies while suggesting avenues in which the children can overtly express their feelings and involving them in the world beyond fantasy. The stories are adjusted to reflect the individual needs of the children.

No short-term treatment with children is conceptualized without involving the parents or the family as whole. One-on-one sessions with the child are supplemented by family sessions. The child is often best helped by assisting the parents in handling the changes brought about by therapy and the maturation of their child. Therefore, parents are usually actively engaged in individual or conjoined therapy sessions. They are involved at the outset of treatment, both for information gathering and in the development of a therapeutic process. If necessary, parents are helped to recognize and resolve their own conflicts and their conflicts toward their children. The techniques used for parents are mainly psychoeducational approaches, support, clarification, and direction.

> John, a bright 14-year-old, was treated with brief (25 sessions) psychotherapy. The initial complaint was that his grades had dropped during the academic year, he had withdrawn from sports, was anhedonic, had difficulty relating to his peers, and whined a lot. His parents divorced when John was 7 years old. He had two younger sisters, ages 12 and 9. John “hated” his father, therefore he missed many visitations with him, pretending that he was sick or too busy to see him. His sisters kept close contact with the father. Mother had a live-in boyfriend who moved in the year that John became symptomatic. John also “hated” the boyfriend. He felt miserable, and he reproached every one in his environment. During the first two therapy sessions, two issues to be addressed in the brief therapy were delineated: John feeling rejected by his father and mother (who had found another man) and rivalry. During the following treatment sessions, an empathetic and supportive therapist helped John acquire insight into his feelings through interpretations of his defenses, transferential manifestations, and clarifications. John and the therapist discussed strategies and activities to be carried out during the treatment period to alleviate his discomfort. By session 16 John had reestablished regular contact with his father and was able to tolerate mother's boyfriend. The termination phase included the integration of what had been discussed, learned, and practiced, and gave control to John to find ways to understand his internal conflicts and find more appropriate ways of managing them. His rivalry issues had diminished since he was also able to share his father with his sisters. Biological parents and mother's boyfriend were seen in parallel. The sessions consisted of psychoeducational approaches concerning John's developmental level of functioning and the way he perceived and experienced his environment. Parents were helped to recognize and handle John's problems as well as their own conflicts, and strategies were proposed for facilitating John's development. At termination it was agreed that John would return to see the therapist for one follow-up session every 3 months in the first year and every 6 months in the following 2 years. At the 2-year follow-up, it was apparent that John had improved academically and had resumed his outside activities such as sports. He remained sensitive to rejection, but he was able to use the skills he had learned to manage those feelings.

Research and Evaluation To date there are few empirical, manual-driven studies on time-limited psychodynamic psychotherapy with children and adolescents. The few existing studies have methodological problems. Therefore, the efficacy of the short-term psychoanalytic/psychodynamic treatments remains untested. Success with short-term psychodynamic therapy usually appears in case reports.

BEHAVIOR THERAPY

Definition *Behavior therapy* (behavior modification) is a generic term that embraces many different techniques used to treat a variety of clinical problems. Therefore, it is difficult to provide a simple definition. Behavior therapy has eight main principles: (1) it concentrates on behavior rather than an underlying cause; (2) it assumes that maladaptive behaviors are learned; (3) it assumes that learning principles can be effective in modifying behaviors; (4) it sets specific, clearly defined treatment goals; (5) it rejects the classical trait theory; (6) the therapist adapts the method of treatment to the child's problem; (7) it concentrates on the here and now; and (8) therapists place great value in obtaining empirical support for their technique. In general, behavior therapy focuses on promoting adaptive prosocial behaviors and aims to decrease maladaptive behaviors. Behavioral treatments give primary attention to behavior as a means of dealing with clinical problems.

Theoretical Issues Behavioral interventions include many different theories about how clinical problems emerge and how they are maintained. These theories vary in their explanations of behavior and in the role they accord to the influences of processes within the individual (thoughts, beliefs, and perceptions) or processes resulting from events in the environment (cues, feedback, and consequences that behavior produces). Behavior therapies have their roots in the seminal work of Joseph Wolpe, B. F. Skinner, and later on Albert Bandura.
