Wolpe's work on the experimental development of neurosis in cats led to a most important and enduring clinical technique known as systematic desensitization. Wolpe presumed that anxiety underlies most neurotic or maladaptive behaviors. His theory relies on the Pavlovian model and assumes that anxiety has been classically conditioned to harmless stimuli. Based on this postulate, several treatment techniques such as systematic desensitization, in vivo desensitization, and reciprocal inhibition have been developed to decondition the autonomic nervous system responses to key stimuli in the individual's environment.

Another influence on behavior therapy was Skinner's work that proposed that the principles derived from his study of operant conditioning and in particular the effect of learning the consequences of behavior could be applied therapeutically. Operant conditioning assumes that most emotional problems are reactions to overcontrolling, punitive environments, lack of control, or both. Therefore, therapies based on operant conditioning aim to change the frequency of overt behaviors and control the consequences that follow behaviors to increase or decrease those behaviors. Behavioral techniques based on this model that are used frequently in short-term behavior therapy with children include positive reinforcement, negative reinforcement, punishment, extinction, shaping, token economy, and contingency contracting.

Bandura's work relies heavily on social learning theory, which greatly influenced behavioral interventions. Bandura emphasized that behavior change involves cognitive symbolic processes, as evidenced by observational learning. The premise is that behavior can be altered by providing new learning experiences. For example, social skills training includes modeling (a form of role playing), behavioral rehearsal (practice duplicating a behavior), correction feedback (from therapist), coaching, and reinforcement. Bandura's work was the forerunner of the cognitive-behavior therapies.

In general, behavior therapy assumes that people become who they are through both learning from interaction with the environment and genetic loading. Difficulties occur when learning is inadequate or faulty. Problems can be corrected by offering necessary learning experiences.

Techniques Behavioral interventions combine treatment techniques from all behavioral schools. The main characteristic is that they focus directly on overt behaviors and give primary attention to behavior as a means of dealing with the clinical problem. They do not rely on the therapeutic relationship or the development of psychological insight. Rather, they rely on directive and active treatments using problem-oriented approaches. Children and parents play an important role in developing the plan of action to change the behavior.

There are five stages in the behavioral interventions.

1. Detailed analysis of the child's problems and factors related to them. That is, the behaviors to be altered are carefully identified and assessed, using mostly (in the case of children) multiinformant techniques. Significant people in the child's life (e.g., parents, teachers, and others affected by the child's behavior) are involved in evaluating the extent and nature of the problem.
2. Determination of the specific goals for treatment. That is, the goals, the means for reaching them, and procedures are discussed and specified with the child and parents.
3. Development of a treatment plan involving the use of the techniques of behavior therapy that are applicable to the child's problem.
4. Implementation of the treatment plan. Explicit training experiences may be prescribed, such as homework assignments, to facilitate learning new behaviors to be used in everyday life. The actions or activities are carried out both within and outside the treatment sessions (rehearsals).
5. Objective evaluation of the results of treatment to determine whether the desired outcome has been realized. Although treatment is time limited, it is possible, depending on the outcome, to extend and modify the treatment plan based on the feedback provided by such evaluation.

The following are some of the behavioral techniques most commonly used in therapy.

Systematic desensitization involves relaxing all the muscles of the body, followed by practice sessions. The therapist and child construct an anxiety hierarchy. During relaxation the therapist asks the child to imagine the least anxiety-producing item. The process continues by introducing higher anxiety level stimuli until anxiety is eliminated.

Self-control desensitization is an active mediational process in which the child learns to interrupt maladaptive thinking through relaxation. It consists of four steps: directing the child's attention to the sensations associated with both tension and relaxation, incorporating a variety of stressful situations in the anxiety hierarchy to promote generalization, having the child continue imagining the anxiety-producing scene while practicing relaxation, and encouraging the child to practice in all anxiety-producing situations.

Exposure consists of imaginal or in vivo desensitization, is highly structured, and involves the actual confrontation of the fear-producing stimuli.

Positive reinforcement refers to the application of a positive reinforcer following a response or behavior to increase the occurrence of that response or behavior.

Token economy involves establishing an environment in which appropriate behaviors are consistently reinforced by generalized conditioned reinforcers (tokens) that can be exchanged for backup reinforcers. It involves defining the target behaviors to be reinforced, selecting the tokens and backup reinforcers, developing a system of monitoring and assessing token economy, and developing a plan for phasing out the contingencies.

Response cost is associated with the token economies and involves the withdrawal of money or tokens for inappropriate behaviors. Response cost is more effective when it is used in conjunction with positive reinforcements for alternative behaviors.

Punishment refers to the application of an adverse stimulus (e.g., withdrawal of privilege) after a nonacceptable response or behavior has occurred. The goal is to reduce the probability that the behavior will recur.

Contingency management refers to a formal agreement between two or more individuals (therapist, child, parent) that defines what behaviors are to be changed and what consequences will follow performance of those behaviors. An effective contingency contract must explicitly define the role of each party and the reward for meeting the responsibilities. The behaviors included in the contract must be capable of being monitored. A system of sanctions for failure to meet the contract's terms should be in place, and the contract should define “bonuses” for consistent compliance. A record-keeping system should be established to provide constant feedback to the parties about the frequency of target behaviors and the delivery of reinforcers.

Time out refers to the removal of positive reinforcement for a specific period of time following the performance of an undesirable behavior. Ideally all sources of reinforcement are removed. Isolation is common (i.e, the child is removed from all sources of positive reinforcements). This technique has been successfully used in classrooms and home environments.

Indications Behavior therapy has been applied with considerable success to a wide variety of problems including phobias, obsessive-compulsive disorders, generalized anxiety, depression, enuresis, encopresis, substance abuse, aggression, delinquency, and eating disorders. One behavioral technique is rarely used for the treatment of childhood disorders. The following examples show how a combination of techniques is used.

Childhood Anxiety Disorders The main therapeutic procedure for the treatment of phobic disorders is exposure. In this technique the youth confronts anxious phobic objects or events so that anxious phobic symptomatology can eventually diminish. Exposure can involve in vivo or imaginal forms or sometimes both. Exposure is usually accompanied by systematic desensitization. Self-control strategies are used to teach the child how to use appropriate cognitive strategies to facilitate exposure or approach behavior toward feared objects.

Since parents are an integral part of the treatments involving children, they are offered training in contingency management that defines what behaviors are to be changed and what consequences will follow performance of those behaviors. A detailed contract is established between therapist, parents, and child, instructing the parents to administer a specific reward to the child when the behavior is performed.

Attention-Deficit/Hyperactivity Disorder Operant and social learning principles are mostly used in the treatment of children with attention-deficit/hyperactivity disorder to shape more appropriate academic and social behaviors and reduce defiant, aggressive behaviors. Self-control procedures, self-monitoring, and anger management (recognition of cues that provoke anger, strategies to counteract anger, and choice of plans to address provocation that results in anger) are the main behavioral techniques used. Parental and school or teacher involvement is a prerequisite. Contingency management procedures are established that use reward and response cost at home and in the classroom. Behavior management procedures are taught to parents and teachers who implement targeted strategies in the child's natural environment (i.e., using positive attending or ignoring skills to promote appropriate behavior, setting a home or classroom token system, and using time out).

Conduct Problems Parent management training involves working primarily with parents, with little or no contact with the children. The aim is to develop specific skills

in the parents so they can implement procedures effectively at home. Parents are trained to identify, define, and observe behaviors in new ways. When the behaviors of interest are identified, parents are taught how to reinforce or punish these behaviors. Methods include use of social praise and tokens for prosocial behaviors or mild punishment, such as time out, and loss of privileges for unacceptable behaviors.

Mary, a 16-year-old girl, presented with social phobia. She was afraid to stand up and talk in front of the other children in her class. She perspired profusely, panicked, and forgot the topic she was supposed to talk about. If she knew in advance that she had to give a presentation, she stayed home sick. For the assessment phase both Mary and her parents were interviewed to determine the nature and extent of the problem. The therapist explained the procedures and the length of the treatment, which consisted of 16 sessions. The technique of choice for social phobia is exposure. Twelve of the sessions were dedicated to gradual desensitization and imaginal and in vivo exposure. Mary and the therapist constructed the public speaking anxiety hierarchy. Four treatment sessions were devoted to systematic desensitization and imaginal exposure. Mary was asked to pay attention to the sensations associated with anxiety and relaxation while imagining anxiety producing scenes and practicing relaxation. The next sessions consisted of gradual in vivo exposure; that is, Mary was asked to give a presentation to a person in the family that she trusted most, then gradually to other family members, then to a stranger, and eventually to more strangers and familial individuals. Sessions 15 and 16 were devoted to termination and evaluation of the treatment results. Mary's symptoms were eliminated. She was able to give class presentations by the end of the 12 sessions. A 12-month follow-up indicated that Mary had maintained the gains and functioned at the premorbid level.

Research and Evaluation By the 1960s behavior therapists had begun systematic research on the applications of behavioral techniques to emotional and behavioral problems of children. Operant conditioning programs have produced dramatic behavior changes in settings such as classrooms, institutions, and at home. Parent management training, in which parents are trained to alter the child's behavior at home, is probably the child treatment technique investigated most in controlled outcome studies. It has been used successfully to treat children with disruptive behavior disorder, attentiondeficit/hyperactivity disorder, pervasive developmental disorders, mental retardation, learning disorders, eating disorders, and other childhood psychological problems. Parent management has been proved beneficial except with dysfunctional families in which parents are unwilling or unable to participate and follow through with the treatment. Many manual-driven, empirical studies exist today that support the use of behavior therapy for the treatment of various childhood problems. However, neither the long-term effects of treatment nor the rates of relapse have been reported.

COGNITIVE THERAPY

Definition *Cognitive therapy* uses an active, directive, time-limited, structured approach in a family of techniques that seeks to produce change of the child's cognitive processes by altering affect and behavior. The approaches differ in both process and procedure. The premise is that thoughts and faulty learning determine the behavior; therefore, children misconceive their environment. The focus of change may include perceptions, self-statements, attributions, and expectations. Some approaches emphasize modifying distorted beliefs. Others attempt to compensate for perceived deficits in cognitive skills.

Theoretical Issues Three theories have strongly influenced the development of cognitive therapy. Albert Ellis suggested in 1962 that psychopathology arose from faulty, maladaptive, and irrational beliefs. This theory led to rational-emotive therapy whose objective is to substitute adaptive thoughts for maladaptive ones. In 1973 Donald Meichenbaum's self-instructional theory emerged. The aim of the therapy based on this theory is to teach individuals to increase their coping skills through education, controlling physiological arousal, rehearsing, and physical relaxation. Following these theories, in 1976 Aaron Beck developed a treatment for depression based on the findings that depressed people have negative views of themselves, their experiences, and the future. This therapy's objective is to alter distorted thinking by helping the individual consider alternatives.

In general, the theoretical premise of cognitive therapy is that cognition is a significant variable in the development and maintenance of psychopathology. Models of cognition maintain that to understand human functioning, one should recognize not only the role of the environment in directing the individual's experiences but also the role of the individual in interpreting that environment. The cognitive models of psychopathology suggest that the individual's construct of the experiences largely determines the emotional reactions to events and future behaviors in similar situations. There is an essential interaction between the way individuals feel and behave, which in turn influences the way they define their world, their self, and their way of viewing the future. The assumption is that children with a deficiency in particular processes and those unable to use or apply cognitive skills, exhibit deviant behaviors.

The cognitive perspective takes into consideration the contributions of innate propensities or prior experience in which thinking plays a role in determining subsequent affect and behavior. Although not exclusively, cognitive theory suggests that thinking plays a causal role in generating and maintaining at least some disorders, in concert with other factors. Cognitive therapy thus seeks to relieve distress by providing new information-processing skills to changing maladaptive beliefs.

Techniques Cognitive therapy is an active and directive short-term intervention. It is a collaborative endeavor in which therapist, child, and parents work as a team. The goal is to help children to discover their dysfunctional and irrational thinking and to reality test their thinking and behavior. The therapist proposes hypotheses, models for coping and adaptation, and strategies for testing them, to alleviate the presenting symptoms and help the patient develop more adaptive and functional behavior. Cognitive therapy focuses on the cognitive processes believed to underlie disordered behavior, and it often uses specific techniques to change these processes. Following are some of the cognitive therapy techniques.

Problem-solving techniques are most frequently used for children who appear unable to generate alternative solutions to interpersonal problems, focus on ends or goals, and foresee the consequences of their actions. Problem-solving training is defined as a process that provides a variety of potentially effective response alternatives for managing problem situations and increases the likelihood of selecting the most effective response. George Spivak and Myura Shure have identified different cognitive processes or interpersonal cognitive problem-solving skills that underlie social behavior: alternative solution thinking (the ability to generate different options for solving problems in interpersonal situations), means-ends thinking (awareness of the intermediate steps required to achieve a particular goal), consequential thinking (the ability to identify potential results of a particular act or solution), causal thinking (the ability to relate one event to another over time and understand why one event led to a particular action by other persons, and sensitivity to interpersonal problems (the ability to detect a problem, identify its interpersonal aspects, and prevent a possible confrontation).

Systematic rational restructuring focuses on the immediate cognitive factors that mediate maladaptive behaviors and emotions. The way children evaluate a situation determines their emotional reaction to the situation. Through imagined scenes or role-playing the child is exposed to an anxiety-producing situation and asked to identify any self-defeating, anxiety-provoking cognitions produced by, or related to, the situation. The therapist helps the child rationally reevaluate these cognitions.

Self-instruction training is a step-by-step approach that includes defining the problem, focusing on the task, and self-evaluation. Therapists perform a task while talking to themselves out loud. The children then perform the same task, first under the therapists' instruction then while instructing themselves aloud. Next the children whisper the instructions to themselves as they perform the task. Finally, the children perform the task while using private, or internalized (and inaudible), speech. The loud dialogue provides a model for the children until they incorporate the process and use private speech.

Other techniques used alone or in variation with others include thought stoppage, which involves stopping irrational beliefs before they begin to cause discomfort and role-playing, in which children are encouraged to see themselves in the perspective of other people and to take the roles of other people.

Indications Cognitive therapy was developed to treat depressive and anxiety disorders in adults. However, the format was adapted to the treatment of children and other problems in addition to depression and anxiety. Because cognitive therapy is time limited, there must be a fit between the child's characteristics and the therapist. The therapist must establish clear goals at the outset, remain focused, and work toward these goals. Parents are also involved in the child's treatment and are trained in problem-solving skills so that they may facilitate and promote the child's skills, enhance communication among family members, and change the child's interpersonal environment.

Cognitive therapy is rarely used today as the sole modality for the treatment of children with mental disorders. Cognitive-behavioral therapy, which combines cognitive and behavioral techniques, is the current treatment of choice for childhood disorders. Therefore, application of cognitive therapy is discussed below in the cognitive-behavioral section.

Research Issues Cognitive therapy has been used successfully in various settings, such as outpatient, inpatient, and school settings, to change maladaptive cognitive processes in children. Outcome studies indicate that variations of cognitive therapy produce greater change than nontreatment or control conditions. The changes are usually demonstrated in measures that reflect behavior in the home, school, or community. There is no information on the effects on long-term

functioning of these children.

COGNITIVE-BEHAVIORAL THERAPY

Definition Cognitive-behavioral therapy resulted from efforts to expand the conceptual base of behavioral techniques by according cognitive processes a more prominent role. Cognitive-behavioral therapy thus has its roots in both behaviorism and cognitive theory. It represents a more comprehensive approach to understanding impairment, etiology, and symptom display and incorporates techniques from both treatment modalities. A combination of treatment techniques has emerged.

Theoretical Issues Cognitive therapy was developed by dynamically trained theorists and tended to emphasize the role of meaning—what a person thinks is not as important as what that person believes. Since behavior therapy could not deal with nonobservable cognitive events, theorists trained as behaviorists developed cognitive-behavioral therapy. In this theoretical concept, thinking tends to be conceptualized in a more concrete fashion and is often regarded as a set of covert self-statements (private behaviors) that can be influenced by the same laws of conditioning that influence other covert behaviors.

The cognitive theorists led the development of strategies for examining the rationality or validity of existing beliefs, whereas the cognitive-behavioral theorists focused on the development of strategies for teaching specific cognitive skills. Both approaches borrowed from each other to the point that today the distinctions between them are blurred. Thus, cognitive-behavioral therapy focuses on the cognitive processes believed to underlie disordered behaviors while simultaneously using specific behavioral techniques such as rehearsal reinforcement to change these processes.

The cognitive-behavioral model includes the role of both affect and social context. Therefore, the cognitive-behavioral analysis of child and adolescent disorders and adjustment problems as well as related analyses of treatment-produced gains includes considerations of the child's internal and external environment and represents a blended perspective. That is, it integrates the cognitive, behavioral, affective, and social strategies to bring about change.

Techniques Selected techniques within behavior modification, particularly those based on operant conditioning (e.g., positive reinforcement, punishment, token economy, response cost), emphasize the role of environmental influences on behavior. On the other hand, social learning theory explains behavior on the basis of an integration of cognitive processes and environmental events. Cognitive processes are believed to be pivotal because they mediate environmental influences and determine what the individual attends to and perceives and how the environment is interpreted.

Indications Cognitive-behavioral therapy is probably the most extensively used therapy today for the treatment of all psychological problems, especially in children ages 9 years and above because of their ability to verbalize their problems. It is used for both group and individual therapy. Following are some examples of the application of cognitive-behavioral therapy to various childhood disorders.

Conduct Disorder Children with conduct disorders may be impulsive, oppositional, defiant, and angry. Assessment sessions delineate the problem to be addressed. The way the child approaches the situation and the thought process is evaluated, and based on this evaluation, therapist and child construct an agenda for systematic therapy. The child is then taught to use a step-by-step approach to solving problems. Problem-solving skills training involves having children make statements about themselves concerning the problem and guiding them to a more appropriate solution. Dysfunctional thought processes are examined, and the therapist helps children generate alternate solutions to problems, focus on goals, see the consequences related to their behavior, and recognize the causes of other people's behavior and become less sensitive to it. This technique may be adapted to include ages 4 to young adults. The treatment uses structured tasks such as games, academic activities, and other age-appropriate tools. The therapist plays an active role by making verbal statements and applying the sequence of statements to a particular problem while encouraging the child to use the skills. Modeling follows with practice and role playing. Punishment or withdrawal of privileges may be applied whenever necessary.

Group Therapy of Adolescent Depression Peter Lewinsohn and his colleagues developed the Adolescents Coping with Depression Course, which consists of 16 2-hour sessions conducted over an 8-week period for groups of up to 10 adolescents. It includes a psychoeducational component that aims to destigmatize the problem, to emphasize skill training to promote control over one's mood, and to enhance the adolescents' ability to cope with problematic situations. The group activities include role playing. Social skills training is distributed throughout the therapy to facilitate and enhance communication by teaching conversational techniques, planning social activities, and developing strategies for making friends. Sessions are designed to increase pleasant activities, based on the assumption that depressed adolescents have little positive reinforcements in their lives. Relaxation training is provided to enhance enjoyability and performance in social situations. Focus on changing depressogenic cognitions is provided by identifying, challenging, and changing negative thoughts and irrational beliefs. Six sessions involve teaching communication skills focusing on the acquisition of positive behaviors such as paraphrasing to verify the message, active responding, and appropriate eye contact. Adolescents are also taught negotiating and problem-solving techniques such as defining the problem without criticism, brainstorming alternative solutions, evaluating and mutually agreeing on a solution, and specifying the agreement with the inclusion of positive and negative consequences.

Obsessive-Compulsive Disorders John March and his colleagues developed the cognitive-behavioral treatment called How I Ran OCD Off My Land. This treatment uses a variety of techniques such as exposure, response prevention, extinction, anxiety-management training, reinforcement, modeling and shaping, habit reversal, individual therapy, group psychotherapy, and family therapy. Following the assessment, the first session is dedicated to educating the child about obsessive-compulsive disorder and categorizing it in the neurobehavioral framework, that is, equating obsessive-compulsive disorder with a medical illness and detailing the treatment. In the second session the aim is to make the disorder the target of treatment. The child is asked to give obsessive-compulsive disorder a disparaging nickname, so it becomes the enemy and allows the child to “boss back” the disorder. In addition, the use of story metaphors allows development of a therapeutic relationship and treatment monitoring through the use of informal symptom diaries. The third session is dedicated to mapping the disorder, that is, describing specific obsessions, compulsions, triggers, avoidance behaviors, and consequences. Sessions 4 to 16 deal with anxiety-management training and exposure and response prevention. Anxiety-management training includes relaxation, diaphragmatic breathing, and constructive self-talk. Exposure involves therapist-assisted imaginal and in vivo exposure. Finally, response prevention consists of exercises coupled to weekly homework. Parents are trained to ally with the child to “boss back” obsessive-compulsive disorder.

Socially Rejected Children Fred Frankel and his colleagues developed the 12-session cognitive-behavioral treatment called Parent Assisted Social Skills Training. First the child's social network is examined taking in consideration the natural environment, family, school, neighborhood to develop an integrated approach to treatment. Children are seen in groups to learn the rules of peer etiquette. They are also offered training skills to expand their peer network, while parents and children are taught how to work together to promote more-successful play dates, improve the child's competence with nonaggressive responses to teasing and conflict with children and adults. Coached play begins in session 2, in which coaches do not participate in the activities but observe the children's play. They only intervene to dispense reinforcements (verbal and token) and if necessary a 2-minute time-out for misbehavior. Child socialization homework begins in session 1, with the aim of setting the mechanics of the telephone call in place. First children call someone from the group, then children outside the group. Also, children may bring a toy from home, so they may engage other children in play. Didactic presentation of parents consists of informing the parents of their part in their child gaining peer acceptance and ensuring that the parents adhere to their assigned roles in the child's socialization homework and provide supportive feedback for the principles being taught.

Patrick, a 15-year-old boy presented with aggressive, violent behavior; used offensive language toward his mother, teachers, and other adults in his environment; and made up stories (my father is the head of the Mafia) to impress his peers, who in turn rejected him. He was under court order to enter psychotherapy because he threw a flower pot from the twenty-fourth floor of the building where he resided and almost injured a pedestrian. Patrick is the only son in a divorced family. His parents divorced when he was 4 years of age. His father then left the country and was never heard from again. His mother was alcoholic but has been sober the last few years. Although highly educated his mother could not hold a job. The communication between mother and son was hostile and charged with threats. Patrick was threatening to physically abuse his mother and she responded by threatening to deprive him outings and television, but she never followed through on her threats. The treatment plan consisted of seeing mother and Patrick separately for 20 sessions plus 6 sessions conjointly at the end. The two first sessions were dedicated to assessment and discussion of the treatment plan. The techniques used for both parties were 6 sessions of *anger management*, that is, to recognize body warnings such as getting flushed and muscle tension; to stop and go away from the distressing situation; to avert their gaze from the other; and to take a few deep breaths and count backward from 15 to 0. Twelve sessions of cognitive restructuring were devoted to reorganizing Patrick's and mother's distorted thinking. Specific self-statements were offered for each of the areas of conflict (e.g., “She or he may have started the tirade but I do not have to answer the same way,” “If she or he asks me to do something she/he may need it or be looking after my interest”). In addition, mother who was more eager to learn was offered psychoeducational training concerning adolescent development, acceptable and unacceptable adolescent behaviors, and ways to respond. At first Patrick resisted this “silly stuff,” but soon he complied because his mother had changed her behavior, which facilitated his acquiescence. Conjoined sessions were used for role playing, practice, and termination. Patrick began to change because he discovered that he was more successful in making his ideas and wishes respected. This change generalized to the peer group.

Research Issues Cognitive-behavioral therapies are the most used and the most manual-driven treatment modalities. Cognitive-behavior therapy has been successful in treating a variety of child and adolescent problems and even more severe conditions than psychodynamic therapy, behavior therapy, or cognitive therapy alone. Some evidence suggests that cognitive-behavior therapy may be useful for the treatment of comorbid conditions; however, it is preliminary and further study is needed. As with the other short-term therapies, there is a dearth of information concerning long-term effectiveness. The existing information on follow-up ranges between 6 to 18 months; thus the long-term effectiveness of cognitive-behavioral therapy is unknown.

INTERPERSONAL PSYCHOTHERAPY

Interpersonal psychotherapy is a developing and promising therapy for adolescents with depression. It has not been tested extensively, so only a summary of its principles is presented. Interpersonal therapy was originally developed by Gerald Klerman and his colleagues for the treatment of depressed adults. It places the depressive episode in the context of interpersonal relationships and focuses on current interpersonal conflicts. It aims at decreasing symptomatology and improving interpersonal functioning.

Laura Mufson and her colleagues have recently adapted this treatment for depressed adolescents. Interpersonal therapy consists of three phases. Phase 1 (sessions 1 to 4) comprises a diagnostic assessment, including evaluating the child's social and familial relationships, identifying the problem areas, and establishing a treatment contract. In phase 2 (sessions 5 to 8) therapist and child begin to work on one or two of the problem areas. The child is encouraged to express feelings and monitors depressive feelings. Techniques used include exploratory questioning, encouragement of affect, linkage of affect with events, clarification of conflicts, communication analysis, and behavior change techniques such as role playing. Parents are also involved in the treatment. Phase 3 (sessions 9 through 12), which is addressed at the beginning of treatment, has as goals giving up the relationship with the therapist and establishing a sense of competence in dealing with future problems. No research results are available at this point, and it has not been tested with younger children.

SUGGESTED CROSS-REFERENCES

Information related to child and adolescent group psychotherapy may be found in Section 48.4 on group psychotherapy, combined individual and group psychotherapy, and psychodrama, in Section 48.5 on family therapy, in other sections of Chapter 49 and in Section 51.6c on ethics in psychiatry. Normal child development is discussed in Section 32.2 and normal adolescent development in Section 32.3.

48.3 COGNITIVE-BEHAVIORAL PSYCHOTHERAPY

JOHN S. MARCH, M.D., M.P.H.

With the emergence of a rich psychopathology literature, child and adolescent psychiatry has moved away from nonspecific interventions toward problem-focused treatments keyed to specific fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) diagnoses. In particular, the past 40 years have seen the emergence of diverse, sophisticated, empirically supported, cognitive-behavioral therapies that cover the range of childhood-onset mental disorders. Hence, many now believe that cognitive-behavioral therapy administered within an evidence-based, disease management model is the psychotherapeutic treatment of choice for many if not all pediatric mental illnesses.

HISTORY AND DEFINITION

Historically, behavior therapy evolved within the theoretical framework of classical and operant conditioning, with cognitive interventions assuming a more prominent role with the increasing recognition that person-environment interactions are powerfully mediated by cognitive processes. Looked at in the context of situational or cognitive processes, behavioral therapy is sometimes referred to as nonmediational (emphasizing the direct influence of situations on behavior) and cognitive therapy as mediational (emphasizing that thoughts and feelings underlie behavior). Behavioral psychotherapists work with patients to change behaviors and thus reduce distressing thoughts and feelings. Cognitive therapists first work to change thoughts and feelings, with improvements in functional behavior following in turn. For the most part these two main conceptual positions and newer contributing theories, such as information processing theory are usually subsumed under the broad umbrella of social learning theory.

For example, two-factor conditioning theory frames posttraumatic stress disorder as a stimulus-driven anxiety disorder in which both classical (factor one) and instrumental, or operant, (factor two) conditioning play important roles. In classical conditioning, the stressor, or traumatic event, acts as an unconditioned stimulus that in turn elicits an unconditioned (reflexive) response in the child, characterized by extreme fear and the cognitive perception of helplessness and terror. Cognitive, affective, physiological, and environmental cues accompanying the traumatic event then constitute conditioned stimuli, often called “traumatic reminders” by pediatric traumatologists. In turn, traumatic reminders become capable of eliciting a conditioned response in the form of posttraumatic stress disorder symptoms, which should decrease (habituate) with prolonged exposure, assuming the absence of real threat. In the second factor (instrumental conditioning), children quickly learn by trial and error how to reduce posttraumatic stress disorder symptoms through cognitive and behavioral avoidance and sometimes anxiety-dampening rituals such as checking or seeking reassurance. These operant anxiety-reducing behaviors preclude the extinction of trauma-based anxiety and foster stimulus generalization, rendering them relatively straightforward as targets for exposure-based interventions.

Like psychoanalytic theories, cognitive-behavioral theories regarding the genesis of psychiatric symptoms also recognize that internal mental phenomena play an important role in mediating behavior. Continuing the posttraumatic stress disorder example, Edna Foa and colleagues note that persons with this disorder develop “fear structures” that are conditioned by both the event and the posttraumatic stress disorder symptom picture. Fear structures (which contain automatic stimulus-response elements such as verbal, somatic, and behavioral cues and information regarding the meaning of the event) are exceptionally sensitive to activation by internal and external cues reminiscent of the initiating trauma, including thoughts and affects incorporated during and after the event. These alterations in meaning determine in part whether the event is traumatic, that is, whether it becomes a stressor. In turn, the cognitively oriented therapist attends closely to the ideational content of the trauma-based fear structure, actively supplying both corrective and behavioral information as required.

Cognitive-behavioral therapy also meshes nicely with developmentally sound neurobehavioral approaches to pediatric mental illness in which psychopathology can be seen as analogous to a learning disability mediated by highly conserved central nervous system (CNS) information processes. As with academic skills, children normally acquire social-emotional (self and interpersonal) competencies over time. The failure to do so, relative to age-, gender-, and culture-matched peers, may reflect capacity limitation, individual difference in the rate of skill acquisition for specific competencies, environmental factors, development of a mental illness, or a combination of these factors. In cognitive-behavioral therapy, the mental health practitioner must understand the presenting symptoms in the context of constraints to normal development and tailor a target-specific cognitive-behavioral treatment program that eliminates those constraints so that the youngster can resume normal developmental trajectory insofar as possible.

Finally, to the extent that symptom relief occurs, it is assumed to reflect concurrent changes (e.g., learning) in the CNS. In this view, the cognitive-behavioral treatment of pediatric mental illness can be thought of as partially analogous to the treatment of juvenille-onset diabetes, with the caveat that the target organ, the brain in the case of major mental illness, requires interventions of much greater complexity. For example, treatment for diabetes and obsessive-compulsive disorder both involve medications, which in diabetes might be insulin and in obsessive-compulsive disorder, a serotonin reuptake inhibitor. Each also involves crucial psychosocial interventions that work in part by biasing the somatic substrate of the disorder toward more normal function. In diabetes, the psychosocial treatment of choice is diet and exercise, and in obsessive-compulsive disorder, cognitive-behavioral therapy. Finally, not everyone recovers completely, so some interventions need to target coping with residual symptoms. Just as diabetic foot care must be targeted in diabetes, patients and their families need help to cope with residual symptoms in obsessive-compulsive disorder.

GENERAL CHARACTERISTICS OF COGNITIVE-BEHAVIORAL THERAPY

Most mental health clinicians are familiar with treatments that assume that psychological distress results from historical and current relationship problems that must be uncovered and addressed in therapy. In contrast to these more “story-oriented” approaches to psychotherapy, cognitive-behavioral therapy uses a problem-solving model in which the clinician acts as a coach to teach the patient a set of adaptive coping skills (and also to unlearn unskillful coping behaviors) for specific symptoms associated with distress and impairment in the present. From the point of view of differential therapeutics—defining different treatment interventions for different treatment targets—this hypothesis-driven process is somewhat analogous to a game of pick-up sticks. Put prosaically, one must correctly identify the targets of treatment at the symptom level (the sticks) before sequencing a set of target-specific interventions (picking up the sticks in the proper order) to help the patient get better. Put experimentally, cognitive-behavioral therapy allows viewing the treatment of each patient through the lens of one of several possible single-case designs.

Behavioral Assessment Vagueness is anathema to expert cognitive-behavioral therapy; that is, the cornerstone of cognitive-behavioral therapy is a careful functional analysis of problem behaviors that is governed by several important assumptions. First, behavior (both normal and problematic) is primarily governed by environmental contingencies (and in cognitive theory, by thoughts and emotions), so the relation of thoughts, feelings, and behaviors is the primary focus of assessment. Second, the antecedents and consequences of target behaviors and the behaviors themselves must be operationally defined and accurately measured. Third, behavior may differ across settings, so multiinformant, multimodal, multidomain assessment is critical. Fourth, treatment planning depends on careful assessment with periodic reassessment of how behaviors have changed and revision of treatment interventions as necessary. Thus, behavioral assessment continues throughout treatment.

In terms of the disease management model, modern cognitive-behavioral therapy requires clear specification of the behavioral/emotional syndrome (e.g., depression); and within the syndrome, the problems (e.g., oppositional behavior); and within the problems, the symptoms (e.g., won't go to bed) targeted for intervention. Consequently, a thorough diagnostic assessment that includes both a clinical interview and a multimethod, multiinformant, multidomain scalar evaluation is needed to design a cognitive-behavioral treatment plan. The overall assessment goal is to move from the presenting complaint through a DSM-IV five-axis diagnosis to a treatment plan tailored to the problems besetting the child or adolescent. This evaluation might begin with review of demographic, developmental, treatment and psychiatric/medical history; review of findings from normed rating scale data; school records and previous mental health treatment records; a clinical (or preferably structured) interview of the child and parents covering Axes I through V of DSM-IV; a formal mental status examination structured interview; and in some cases, a

specialized neuropsychological evaluation.

Of all these assessment tools, gender-, age- and race-normed rating scales are perhaps the most efficient way to collect information about both internalizing and externalizing behavioral disturbances at home and school. Excellent scales with good psychometric properties are now available for self-report of conduct problems, anxiety, and depression. Besides assessing an overall construct (e.g., anxiety), child self-report measures also provide useful information about factors (e.g., physical anxiety symptoms) and items (e.g., suffocation anxiety). This both speeds the interview and begins a dialogue between the doctor and the patient about the patient's most troubling symptoms, which facilitates treatment planning. This procedure is consistent with medical evaluation procedures across other medical specialties and meets goals for guidelines-based practice in managed care.

After the diagnostic evaluation, the clinician inevitably needs detailed data on the patient's specific symptomatology and its impact on the patient's developmental trajectory. These data provide a baseline for evaluating treatment and identifying targets for specific behavioral interventions. To explicate more clearly factors in the family that may be associated with childhood behavioral symptomatology, cognitive-behavioral therapy in pediatric patients depends on a molecular examination of the interactions between children and their parents. Hence, most cognitive-behavioral therapy manuals include detailed mapping of triggers, responses, and problem-maintaining factors (including family, peer, and school problems) as a routine part of treatment planning.

Finally the course and outcome of treatment is monitored with child-specific symptom checklists, standardized rating scales, or scales of global improvement, such as the Clinical Global Impairment and Improvement scales. Why evaluate outcome? First, tracking symptoms requires updating the problem target list periodically, which minimizes the possiblity of missing new or reemerging symptoms. Second, child and parent ratings let the clinician address any discrepant views of the child's progress. Third, rating scales detail how the child is progressing in treatment. In this regard, disorder-specific rating scales, whether standardized or tailored to the patient's problems, provide far more information than global measures, that simply involve therapist ratings of general outcome. With obsessive-compulsive disorder, patient symptomatology can be tracked with the Yale Brown obsessive-compulsive scale (YBOCS) symptoms checklist, obsessive-compulsive disorder symptoms with the YBOCS itself, specific cognitive-behavioral therapy targets with a stimulus hierarchy and anxiety in response to successive exposure to phobic stimuli (e.g., habituation curves), using a fear thermometer.

Cognitive-Behavioral Therapy Is Action-Oriented in the Present Many child and adolescent therapists are used to empathic, nondirective listening and especially to play therapy techniques that focus on uncovering past traumas. While good listening skills and creative play are important to cognitive-behavioral therapy, play by itself works poorly for the cognitive-behavioral psychotherapist who must instead actively focus on action-oriented, present-time change strategies. In other words, cognitive-behavioral therapy is best suited for patients with an identifiable problem and an active desire to change their behavior to reduce their suffering. Because cognitive-behavioral therapy in some ways resembles coaching an athletic team (i.e., the coach instructs, models, insists on practice, and finally stands on the sidelines while the players play the game for keeps), it is not surprising that cognitive-behavioral therapists and their patients do a lot of active communicating, talking as well as listening. In particular, cognitive-behavioral therapists typically use a Socratic dialogue in which they query patients about their experiences (e.g., “Can you be more specific?” “Tell me more about that.” “Can you give me an example of what we're talking about from the last week or so?”) This approach sometimes seems like a videotape replay in which the therapist and patient engage in a playful, two-way, detailed interchange about how the child or parents or both experience being in or successfully resisting the problem. Stylistic considerations, such as greater self-disclosure, therapist modeling, and extensive use of humor, also characterize successful cognitive-behavioral therapies.

Cognitive-Behavioral Therapy Includes Everybody Necessary While most psychiatric disorders tend to run in families, family psychopathology is neither necessary nor sufficient to generate mental illness in youth. Nonetheless, families affect and are affected by a child's symptoms, especially if more than one family member is affected. For example, high expressed emotion exacerbates behavioral problems; a calm, supportive family typically improves outcome. The treatment of choice for children with externalizing disorders is parent training, and for adolescents (especially when substance abuse is an issue), behavioral family therapy. Similarly specific behavioral programs have been developed to handle behavioral and pedagogic problems in the school setting. Cognitive-behavioral treatments for internalizing disorders are more commonly administered in an individual setting; however, a combination of individual and family sessions may be helpful when families are tangled up in anxiety or when treatment must involve transferring control from the therapist to the parent and then to the child. The failure to include parents, teachers, and (if needed) peers is a common source of treatment failure in child-centered therapies. Cognitive-behavioral therapy avoids this trap by including those considered crucial to the intervention. Hence, cognitive-behavioral therapy requires that the therapist include others in treatment as is appropriate at any given stage.

APPLICATION TO CLINICAL SYNDROMES

Although cognitive-behavioral therapy may appear to the casual observer to be a simplistic, unitary treatment, it is actually a diverse collection of complex and subtle interventions that must be mastered and then blended for the patient presenting with more than one mental disorder. Cognitive-behavior interventions for the disruptive behavior disorders concentrate on helping parents issue effective rules and instructions and subsequently manipulate rewards and punishments, with some cognitive training in anger coping for the child. Cognitive-behavioral therapy for depression directly confronts maladaptive depressogenic cognitions (e.g., helplessness, hopelessness, and hostility) and aims behaviorally to reconstitute relationships, whether they are intrapsychic, interpersonal, work, or spiritual. Parenthetically, cognitive-behavioral therapy for depression is the least specific treatment with respect to response; for example supportive, dynamic, and interpersonal psychotherapies also appear effective, and all are associated (not surprisingly) with a large placebo response. With the anxiety disorders, cognitive-behavioral therapy targets cognitions, autonomic arousal, and behaviors in a manner designed to promote habituation or extinction of inappropriate fears. Theoretically, these three treatments involve somewhat different emphases, for example, reward and arousal with the disruptive behavior disorders, interpersonally mediated affects in depression, and habituation theory in anxiety. Few therapists can discuss, much less apply, all the various forms of cognitive-behavioral therapy for pediatric mental disorders.

Despite their seeming differences, virtually all cognitive-behavioral interventions share four qualities: (1) an emphasis on psychoeducation, (2) a detailed behavioral analysis of the problem and the factors that maintain or extinguish it, (3) problem-specific treatment interventions designed to ameliorate the symptoms of concern, and (4) relapse prevention and generalization training at the end of treatment. As evidence-based therapies, each is supported by a more or less robust research literature and manuals are usually available to guide practitioners in using cognitive-behavioral therapy for specific problems. Cognitive-behavioral therapy thus fits nicely into the current medical practice environment that appropriately values empirically supported, brief, problem-focused treatments. Table 48.3-1 illustrates common cognitive-behavioral intervention strategies, most of which are common to a wide range of cognitive-behavioral treatments.

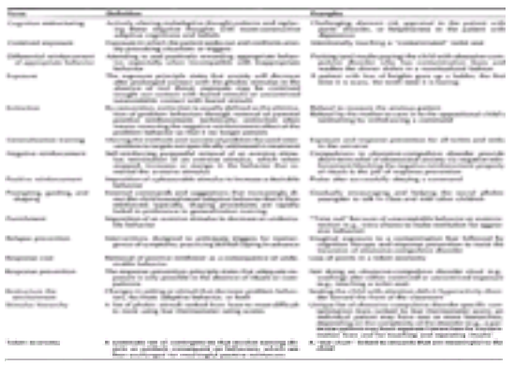

Table 48.3-1 Techniques of Cognitive-Behavioral Therapy

Disruptive Behavior Disorders Cognitive-behavior therapy targeting disruptive behaviors in children with attention-deficit/hyperactivity disorder has wider empirical support than any other area. It also provides a heuristically valuable example of how cognitive-behavioral therapy and medication can and should be combined.

First, exclusive treatment with psychostimulant medication is effective, but may not be maximally effective for attention-deficit/hyperactivity disorder, especially in older children or adolescents. Many children will experience reduced symptoms that nevertheless persist at clinically significant levels. Although many children improve substantially with pharmacotherapy, many do not achieve full normalization with stimulant treatments alone, even at very high dosages. More children may achieve

normalization with combination treatment.

Second, stimulant medication may not affect the full range of symptoms of children with attention-deficit/hyperactivity disorder and other, comorbid conditions. Although the primary symptoms of the syndrome (i.e., attention, impulsivity, and activity level) may be greatly improved, effects on other primary or comorbid characteristics of the syndrome (e.g., oppositional and aggressive behavior, academic underachievement, and poor peer relationships) are often insufficient. Because these conditions (along with family dysfunction) are robust predictors of poor long-term outcome for children with attention-deficit/hyperactivity disorder, treatment with stimulants alone may not significantly improve the outcome for these children. Research suggests the great relevance of the secondary problems of aggressive behavior (and the coercive family process associated with aggression), academic underachievement and associated school behavioral problems, and peer relationships to intervention in attention-deficit/hyperactivity disorder. These arenas are most amenable to psychosocial treatments. Moreover, psychosocial treatments may be the only treatments available for the minority of children with attention-deficit/hyperactivity disorder who do not respond to stimulants, who experience intolerable adverse effects, or whose parents reject the use of medication.

A final limitation of stimulant monotherapy involves its applicability to home behavior problems. Many pharmacotherapists limit the use of stimulants to school hours during the 9 months of the academic year to avoid appetite suppression, sleep disruption, and other adverse effects. This leaves parents to their own devices to manage impulsive, oppositional, and disruptive behavior in the afternoons and evenings, weekends, and summers. When no other treatment is provided, parents frequently become coercive, hostile, and overly punitive, which may exacerbate the child's behavior problems. Child and parent aggression are among the best predictors of poor outcome. For all of these reasons, cognitive-behavioral therapy continues to be used and evaluated, alone and in combination with stimulant medication.

Psychosocial treatment for attention-deficit/hyperactivity disorder optimally involves a clinical, behavioral therapy approach that focuses on the child, the parents, and the school. Intervention with parents typically uses parent training designed to teach parents skills and techniques for managing disruptive, impulsive, and oppositional behaviors in the home and in the community. Intervention in the school involves direct consultation with teachers about establishing behavior management systems in the classroom. In addition, systems that tie the school and home together in a direct, cooperative effort are increasingly being used to improve school behavior and academic performance. Innovative treatment programs can be tailored to the individual child.

In parent training for attention-deficit/hyperactivity disorder parents are taught a comprehensive set of behavior management skills geared toward the behavioral excesses and deficits displayed by these children. Common targets include improving the general family emotional climate, parental skills for positively reinforcing children's prosocial behavior, and parental skills for confronting disruptive child behavior with effective antecedents and consequences. For example, parents are taught how to spend structured, positive time with their children; how to “catch their child being good” and apply reinforcers on these occasions; how to teach their children to engage in independent on-task behavior, give effective instructions, and set appropriate rules and expectations with their children; and how to apply specific consequences to negative child behaviors. Typical child behavior targets are noncompliance with instructions, other oppositional behavior, aggression with sibs and other family members, independent behavior while the parent is busy, and impulsive, disruptive behaviors within the family. Because these youngsters frequently present management problems outside the home, parents are also taught to design mini-behavior-management programs for use on outings outside of home. Finally, more-recent innovative parent training programs for attention-deficit/hyperactivity disorder include stress management for parents as well as training them to become advocates for their child in the school system.

Another major aspect of clinical behavior therapy for attention-deficit/hyperactivity disorder involves the use of behavior management strategies in the classroom. Indeed, there are many more research evaluations of behavioral intervention in the school than in the home. School intervention usually begins with consultation with the teacher about the disorder and social learning and behavior management principles. Explaining the disorder is especially important if the teacher has labeled the child “lazy” or “bad” and has adopted a coercive posture toward the child. Even a teacher knowledgeable about general behavior management may need to learn the special refinements to standard behavior management needed for successful treatment of the child with attention-deficit/hyperactivity disorder.

A cueing system is developed to prompt teachers to increase their monitoring of ongoing child behavior and deliver positive attention at regular, frequent intervals. Teachers also are taught how to use ignoring and effective reprimands for disruptive behavior. A token system may be established with specific academic performance and behavioral targets. The child earns tokens or points at regular intervals (worked out with the teacher) for successfully achieving those targets. For younger children, tokens are usually delivered by the teacher. Self-monitoring and self-reward systems have been used for older children (third grade and above) in which they monitor and reward their own behavior, with occasional reliability checks by the teacher. Token programs for these children also include a response cost component (i.e., points are lost for inappropriate behavior), which research has shown to increase the effectiveness of reward programs with these children. A more-recent innovation in classroom behavior management uses daily report card systems that tie the home and school together in a cooperative effort; teachers monitor behavior at school and deliver points or tokens at regular intervals, and parents deliver backup consequences at home. With guidance from the cognitive-behavior therapist, teacher and parent work together over the course of the school year to refine the system.

While much research supports the efficacy (though not the maximum effectiveness) of clinical behavior therapy including parent and teacher training for children with attention-deficit/hyperactivity disorder (with the exception of anger coping), cognitive therapy with the child, once thought to hold great promise, has proved largely ineffective. Social skills training in the typical outpatient setting has also produced disappointing results. Consequently, innovative clinical researchers have turned to intensive summer day-camp treatment programs to provide academic remediation and address the peer problems and social and athletic skills deficits exhibited by these children. Because these areas of functioning contribute to low self-efficacy and self-esteem and poor long-term outcome and are not amenable to standard treatment, such innovative treatment approaches may be the wave of the future, although firm empirical support is not yet in hand.

William is an 11-year-old white boy from a single-parent, lower-class family, who presented to an attention-deficit/hyperactivity disorder clinic because of mild behavior problems at home and school. Temperamentally, William was high in novelty seeking, low in harm avoidance, and very dependent on high salience rewards. In school, he was generally well liked by his teachers, who noted that he had a great deal of trouble because of poor sustained attention and impulsive behavior, especially when bored. His teacher suspected that he might have a reading disability. William's family history was positive for a past history of depression in his mother and “reading difficulties” in his father, who was in the military and lived overseas. A careful psychoeducational evaluation resulted in a variety of pedagogic (a reading tutor) and behavioral (a classroom points system) interventions. William was then started on psychostimulant therapy, which together with the classroom adaptations normalized his behavior at school. However, he continued to be stubborn and oppositional at home with his mother, who had little patience after being at work and so yelled and nattered, with no follow-through in terms of rewards or consequences. As a result, William's pediatrician recommended that the mother attend an 8-week group parent training course led by the practice psychologist that was to be held on Saturday mornings. Parent training focused on psychoeducation about attention-deficit/hyperactivity disorder and general child management skills, how to issue effective commands, and how to institute a reward schedule for good behavior and time out and other punishment procedures for failing to follow commands. Specific attention was paid to generalizing these procedures from home to other settings, such as shopping and riding in the car. Working with the school guidance counselor, William's mother also worked out a daily report card that specified daily and weekly rewards if William followed the rules at home and at school. One specific problem behavior—provoking his younger sister—required a response-cost procedure in which William lost television minutes for picking fights, but otherwise the program emphasized rewards. With this program in place, William's mother began spending more time with William. Her overall mood improved, as did William's grades at school. When summer vacation came around, William's mother was able to stop his medication entirely, relying solely on the behavioral plan to manage his attention-deficit/hyperactivity disorder.

Anxiety Disorders Recent years have witnessed increased attention to the treatment of anxiety in children and adolescents. Although well-controlled empirical studies for anxiety and depression in youth are just beginning to emerge, the literature validates the effectiveness of specific techniques and a mounting literature supports the use of prescriptive treatment protocols for these disorders. The behavioral treatment of fear and anxiety in children builds on early studies conceptualizing anxiety as a set of classically conditioned responses that can be unlearned or counterconditioned through associative pairing with anxiety-incompatible stimuli and responses. For example, in systematic desensitization, anxiety-arousing stimuli are systematically and gradually paired (imaginally or in vivo) with competing stimuli such as food, praise, imagery, or cues generated from muscular relaxation. Systematic desensitization with children consists of three basic steps: (a) training in progressive muscle relaxation, (b) ordering of fearful situations from lowest to highest, and (c) hierarchically presenting fear stimuli via imagery while the child is relaxed. Systematic desensitization appears to work well with older children and adolescents; however, younger children often have difficulty with both obtaining vivid imagery and acquiring the incompatible muscular relaxation. Strategies such as using developmentally appropriate imagery and adjunctive use of workbooks may boost the effectiveness of these procedures with younger children.

Without encouragement, anxious children and adolescents often find it difficult to remain in the presence of anxiety-arousing stimuli long enough to allow extinction in the natural environment. Following the adult treatment literature, this led to the development of exposure-based interventions for a wide range of pediatric anxiety disorders. Because escape and avoidance behaviors are negatively reinforced by cessation of anxiety, exposure-based procedures require extended presentation of fear stimuli with concurrent prevention of escape and avoidance behaviors to elicit extinction. Unlike systematic desensitization, stimulus presentation is not

accompanied by progressive muscle relaxation. Rather, anxiety to phobic stimuli is attenuated by graduated imaginal or in vivo exposure (or both) to hierarchically presented fear stimuli. Gradual exposure, with the consent of the child, is generally considered to produce less stress for the client (and therapist) and thus is often preferred over more prescriptive techniques, especially flooding.

Cognitive interventions, usually combined with exposure, also have a prominent role in cognitive-behavioral therapy for anxious children and adolescents. Based on the premise that anxious children view the world through a template of threat, automatic questioning (e.g., "What if"), and behavioral avoidance, treatment focuses on providing educational experiences to build a new coping template for the child. Therapists help the children reconceptualize anxietyprovoking situations as problems to be solved, situations to be coped with. A variety of cognitive-behavioral components help the therapist and child build the coping template: relaxation training, imagery, correcting maladaptive self-talk, problem-solving skills, and managing reinforcers. Therapists use coping modeling, role-play rehearsals, in vivo exposure, and a collaborative therapeutic relationship with the child to facilitate treatment. As a rule, parents are active collaborators in all facets of treatment.

For example, when significant others are contributing to the child's anxiety symptoms or maladaptive coping strategies, it is crucial to help the child help the parents to stop this behavior (e.g., participating in avoidance strategies or rituals). To test the hypothesis that adding a family anxiety management component would boost treatment effectiveness, Paula Barrett and her colleagues developed a family program that parallels Kendall's "Coping Cat," based on behavioral family intervention strategies effective for the treatment of externalizing disorders in youth. After each child session with the therapist, the child and parents participate in a family anxiety management session with the therapist. The program aims to empower parents and children by forming an expert team to overcome and master anxiety. Parents are trained in reinforcement strategies, with emphasis on differential reinforcement and systematically ignoring excessive complaining and anxious behavior. Contingency management strategies are the main methods for reducing conflict and increasing cooperation and communication in the family. Parents are also trained in communication and problem-solving skills so that they will function better as a team in solving future problems. Preliminary results suggest that combined treatment is more effective and has lower relapse rates than individual treatment. In much the same vein, tailored family involvement in the treatment of children and adolescents with obsessive-compulsive disorder is the rule rather than the exception. In this regard, unilateral extinction strategies (e.g., a parent returning the school phobic-child to school by force) have significant disadvantages compared with consensual child involvement: (1) parents often have no workable strategy for managing the child's distress; (2) the treatment relationship is disrupted; (3) symptoms out-of-sight for parents and teachers cannot be targeted; and (4) most importantly, these approaches fail to help the child internalize a more-skillful strategy for coping with current and future anxiety symptomatology.

> Sally is a lovely, very shy, 7-year-old white girl from a two-parent upper-middle-class family. Her mother at one time suffered from panic disorder; her father has mild social phobia. About 1 month before coming to the clinic, Sally began to experience stomachaches at school. Many other children were sick with a stomach virus at the time so Sally's symptoms didn't arouse unusual concern. After a visit to the pediatrician, which turned up nothing unusual, Sally soon went back to school. Unfortunately, although the other children were back to normal, Sally continued to have stomachaches; other sick feelings, such as dizziness, began as well. After several more days of this, she began to resist going to school, since she felt better at home. Sally's mother, who was generally sympathetic and protective of Sally, let Sally stay home. Conversely, Sally's father got rather angry when Sally wanted to stay home again and again, and over Mom's objections insisted that Sally go to school, which she did, protesting all the way. Midmorning, Sally experienced her first full panic attack, actually throwing up in class, which caused her mother to come to school to take Sally to the pediatrician, who again found nothing wrong. Sally by this time had become clingy, refused to stray far from home, and repeatedly expressed fears that something might happen to her parents, particularly her mother, who she worried might not be able to help her when she felt sick and scared. By the time she presented to a psychiatrist on the advice of her pediatrician, Sally had been out of school for 2 weeks. By this point, Sally and her family were at war over whether Sally was sick or just being oppositional. On the Multidimensional Anxiety Scale for Children Sally showed markedly elevated *t*-scores for separation anxiety along with anxious coping and somatic-autonomic symptoms. Cognitive-behavioral psychotherapy was started with the possibility of later addition of a medication if she did not respond rapidly. Treatment began with psychoeducation about separation anxiety disorder and a parental intervention to bring both parents into alignment with Sally's gradual reintroduction to school. Individual treatment began with cognitive-restructuring of faulty attributions regarding panic, harm to her parents, and vomiting fears; specific behavioral interventions targeting somatic/autonomic symptoms, including breathing retraining, relaxation training, and exposure to specific interoceptive panic triggers; and gradual reintroduction to the school setting, using a fear hiearchy that the school guidance counselor, Sally, and her mother developed together. While at home, Sally was required to follow the class schedule and to keep pace with her classmates in school work. Within 2 weeks, Sally was back in school for the morning, and full attendance was restored in 6 weeks without pharmacotherapy.

Major Depressive Disorder At any one time, approximately 1 in 20 children and adolescents suffers from major depressive disorder, and rates of depression rise dramatically in adolescents, especially in girls. While the economic burden of depression in youths is uncertain, the human cost is considerable, especially with teenage suicide. The empirical literature shows considerably more support for problem-specific psychotherapies, especially cognitive-behavioral therapy, than for medication management of pediatric depressive disorders. In particular, several controlled trials have now demonstrated that individual or group administered cognitive-behavioral psychotherapy is effective for depressed youth, and some investigators now consider cognitive-behavioral therapy the treatment of choice.

Like other cognitive-behavioral treatment packages, cognitive-behavioral therapy for depression in youth is a skills-based treatment, in this case based on the assumption that depression is either caused or maintained by inadequate social cognitive skills for coping with stress. Personality is an interactive multidirectional system of behaviors, cognitions, and emotions, and depression is manifested in each of these three components of the personality. However, cognitive-behavioral therapy for depression assumes that symptom change is most likely to occur when interventions modify patterns of behavior or cognition, with emotion following in turn. Among the behavioral and cognitive skill deficits that may characterize depressed youths are low involvement in pleasant activities, poor problem-solving and assertion skills, cognitive distortions that negatively bias perceptions, negative automatic thoughts, negative views of self and future, and failure to attribute positive outcomes to internal, stable, or global causes. Thus the therapist must establish a working alliance with adolescents and help them learn new ways of behaving or thinking that will in turn reduce depressive severity and risk of relapse.

Most cognitive-behavioral treatment packages for depressed youths share two salient characteristics: (1) both general, or required, skill-building sessions and optional, or modular, sessions for specific problems and (2) integration of parent and family sessions with individual cognitive-behavioral therapy. Treatment is generally designed to improve the teenager's problem-solving ability when faced with a stressful situation (e.g., parent-child conflict, role transitions, and grief reactions or peer problems). Thus the required aspects of treatment include psychoeducation about depression and its causes, goal setting with the adolescent, and general problem-solving skills. Modules chosen jointly by therapist and adolescent then address the specific skill deficits of the teenager. Parent-child conflict is a risk factor for depression, a poor treatment outcome, and a relapse after treatment, which justifies including a parental component in cognitive-behavioral therapy, and preliminary evidence suggests that parent and child treatment may be somewhat more effective than treatment directed at the teenager alone. Parents are taught contingency management procedures and alternative, effective methods for parenting and creating a more positive family environment. Moreover, family interactions are targeted directly to shape and reinforce effective communication and interactions and increase pleasant activities and positive affect.

Other Applications For heuristic purposes, this chapter focuses on three common applications of cognitive-behavioral techniques to childhood mental disorders. However, as summarized nicely by Euthymia Hibbs, cognitive-behavioral interventions are also effective for impulse-control disorders, such as trichotillomania, tic disorders, autistic disorder and other pervasive developmental disorders, and severe conduct disorders as well as a wide variety of common childhood behavior problems not found in DSM-IV, such as dental and medical fears.

FUTURE DIRECTIONS

Cognitive-behavioral therapy is quintessentially scientific in its theoretical foundations and pragmatic evolution. Thus it fits beautifully in the context of evidence-based medicine, which is a promising paradigm for ensuring competence in clinical practice. Because evidence-based medicine stresses systematic diagnostic assessment technologies and clinical research, it helps the individual clinician incorporate information into everyday clinical work. Compared with other psychotherapeutic approaches, current research in developing and generalizing cognitive-behavioral psychotherapies illustrates the power of using the scientific method in treatment development, namely, using a careful review of the literature to generate a hypothesis regarding a treatment efficacy or mechanism that can be tested experimentally against a control or against other active treatments. Pediatric psychiatry is now moving rapidly toward multimodal treatment research that studies not only the effectiveness of cognitive-behavioral therapy alone, but also the interactions of pharmacological and cognitive-behavioral treatments.

Despite limitations in the research literature with regard to long-term outcome; how best to combine cognitive-behavioral treatments; effectiveness across divergent cultural, age, and ethnic groupings; comparative efficacy with medications; and optimal assessment procedures, the empirical literature generally supports the benefits of short-term cognitive-behavioral psychotherapy for the major neuropsychiatric disorders in children and adolescents. However, the short-term benefits of cognitive-behavioral therapy do not necessarily translate into long-term successful outcome. In some (but not all) cases, psychosocial treatments may substantially improve long-term outcome in the most severely ill young persons when combined with pharmacotherapy. Thus, psychosocial therapies alone, or when combined with

psychotropic medication treatment, is most likely to provide sustained benefit to mentally ill children, adolescents, and adults.

The author wishes to thank John Curry, Ph.D., Karen Wells, Ph.D., and Anne Marie Albano, Ph.D., for their help.

SUGGESTED CROSS-REFERENCES

Cognitive therapy is extensively covered in Section 30.6, and behavior therapy in Section 30.2. Mood disorders are covered in Chapter 14 and Chapter 45, and anxiety disorders in Chapter 15 and Chapter 46. Attention-deficit disorders are presented in Section 39.1, and disrupted behavior disorders are discussed in Chapter 40.

48.4 GROUP PSYCHOTHERAPY

ALBERTO C. SERRANO, M.D.

DEFINITION

During their formative years children and adolescents spend significant amounts of time in groups, beginning as members of the family group, followed by complex group interactions with a growing number of peers and adults. While basic interpersonal skills develop in the context of the family, children learn developmentally appropriate interpersonal skills in a wide range of natural group experiences. This interpersonal learning, essential for successful social functioning, takes place to a large extent in schools and the community. These are natural group settings in which a child acquires basic cultural cues and learns ways of interacting with peers and adults, including skills for negotiating interpersonal relationships and resolving conflicts. Disturbed children and adolescents frequently have a background of faulty early group experiences, typically beginning in the family and extending to school and community. These early deficits often lead to new rejection and failure at the time when the child should be able to develop positive identifications with peers and significant others. In this context maladaptive patterns emerge that may affect all aspects of the child's development and lead to further failure.

Group psychotherapy with children and adolescents is a form of therapy in which typically between three and eight young patients of compatible developmental level meet with one or more therapists to change disturbed behavioral and psychological patterns. Considerable experience has been accumulated over the past decades in applying group psychotherapy techniques to a wide range of psychiatric disorders in this age population. Group modalities have proved efficacious and cost-effective. Unfortunately in the current climate of health care funding their use is often limited to inpatient and residential programs and time-limited groups that focus on such specific clinical conditions as eating disorders, substance abuse, sexual abuse, and children of divorce. Further, training in group psychotherapy for psychiatrists has declined with limited or no support for their being involved as therapists in groups.

This decline is associated with advances in biological psychiatry and at the expense of psychodynamic psychiatry. Fortunately treatment outcome studies are beginning to bring brain and mind back together. Growing evidence indicates that psychopharmacological interventions elicit more compliance and are more effective when used in a well-integrated, psychosocial treatment plan. Group modalities have proved effective alone and in combination with biological therapies.

HISTORY

Several names are associated with pioneering applications of groups in the treatment of children and adolescents. Jacob L. Moreno, a psychiatrist in Vienna, was interested in theater and developed group psychodrama. As early as 1911 Moreno had created a children's theater with children and adolescents. Also in 1911, Sam Slavson in New York had developed the Self-Culture Club which is the precursor of activity group therapy, a technique for which he is best known. By 1918 Alfred Adler was leading groups with children and with parents in child guidance clinics, and August Aichorn reported treating delinquent youths in groups. In the late 1920s Betty Gabriel described her technique of interview group therapy with adolescents, combining activity and group discussion. In the late 1930s Lauretta Bender incorporated the use of puppets and plastic materials in groups with hospitalized children. Also at this time John Levy and Helen Durkin applied relationship therapy principles in preschool and school age groups. In the 1940s Fritz Reidl promoted the use of groups in specialized summer camps for delinquent, early-adolescent youth. In 1961 Haim Ginott published the first textbook on group psychotherapy with children; Slavson, Saul Scheidlinger, and Mortimer Schiffer published several books on this subject during the 1970s. The American Group Psychotherapy Association published two important monographs in the 1980s, *Child Group Psychotherapy—Future Tense*, edited by Albert Reister and Irvin Kraft, and *Adolescent Group Psychotherapy*, with Fern Cramer Azima and Lewis Richmond, editors. By 1991 a specialized journal started to be published quarterly, the *Journal of Child and Adolescent Group Psychotherapy*. Paul Kymissis and David Halperin edited a textbook, *Group Therapy with Children and Adolescents*, published in 1996, that includes some of the most current thinking and applications in this field.

Theoretical Issues Group psychotherapies developed as a way to treat several patients together. Children and adolescents have been involved in therapeutic groups for several decades. Regardless of theoretical orientation, most clinicians would agree that in the hands of trained clinicians, psychotherapy groups are practical and effective agents of behavioral and psychological change. Multiple interactions among group members can be directly observed, including those that involve the therapist. Additional therapeutic factors include the development of group cohesiveness among the members, which leads to mutual support and the modeling of adaptive prosocial behaviors, which have unique value for improving interpersonal skills and reducing symptoms. Irvin Yalom's well-established review of “curative factors” was based on groups of adult patients but is basically applicable to children and youths, with the caveat that some of the factors have different significance because of developmental considerations.

While early contributors distinguished between psychotherapy groups and group applications of psychoeducational or behavioral nature, current practices underline the need for theoretical and technical eclecticism. Psychiatrists should be familiar with the use of a wide range of group approaches, including their indications and limitations in the treatment of specific clinical conditions at specific developmental levels.

Therapist While a comprehensive background in child development and psychopathology is essential, the personal characteristics of the therapist are also of crucial significance. Children and adolescents are very perceptive about adults and often suspicious of their feelings and motivation, particularly those in a clinical population. Children expect the therapist to be able to understand and contain their feelings and behaviors, even when they are not clearly expressed. A detached attitude in a therapist (which might be appropriate with an adult patient population), would typically be interpreted by children and adolescents as a lack of personal interest and evidence of rejection.

Some group therapists become particularly skilled at working with certain age groups, specific patient populations, or special techniques. Supervised training experience is essential, but certain personality characteristics and clinical experiences are needed for a good fit and effective therapeutic group engagement. Capacity for empathy, warmth, high tolerance for frustration, spontaneity, imagination, curiosity, a good sense of humor, and a playful touch are some of the qualities associated with group therapists effective at working with children and adolescents. With the growing ethnic and cultural diversity in the patient population, understanding the significance of cultural factors has become an additional challenge.

Structure The therapist is responsible for maintaining the therapeutic integrity of the group, which is predicated on having the well-defined structure essential for a group to be therapeutic. In this context the therapist has a number of important roles: selecting the membership when possible, setting limits, establishing treatment goals for each group member and changing them as indicated, and modulating the interactions among members to maximize behavioral and emotional learning.

Transferential Issues Transference and countertransference are more complex in groups than in individual therapies. These valuable therapeutic tools can be observed even in groups with a primary psychoeducational or recreational focus. The recent emphasis on short-term groups limits the opportunities to observe and analyze transferential and countertransferential issues. The multiple transferences that emerge in groups are most helpful in understanding and correcting maladaptive patterns of behavior and thinking. Whether the therapist applies a psychodynamic approach, a cognitive-behavioral approach, or psychodrama, to just name a few orientations, transferential issues are always present in patients and therapists and cannot be ignored. A child whose provocative behavior in group seems to be associated with earlier experiences of anticipated rejection is one situation in which a competent clinician, regardless of theoretical orientation, could

make an intervention of therapeutic value for that child and the other group members. The ability of the therapist to contain the anxieties of the group is closely associated with awareness of countertransference, particularly during those periods of emotional and behavioral upheaval in which one notices the difference in how experienced and novice group therapists intervene to set limits and make the experience a therapeutic event.

TECHNIQUES

Being a member of a group is a social phenomenon with roots in the natural world. Groups are essential for the survival of animals and humans alike. Learning to be an accepted member of one's culture starts with the family and continues in the larger social context. Disturbed emotions and behaviors are most often manifested in the interpersonal matrix of family, school, and community. Therapeutic groups used either as a single modality or in combination with other treatment approaches can be effective, but careful selection is needed in matching a child with a group.

Placing children in groups at their developmental levels is a well-established practice, but even more important is the suitability of a specific group for the child. Levels of physical, cognitive, emotional, and social development need to be considered in the selection process to maximize the therapeutic value for both the patient and group members. Will this group be “good” for this patient? And conversely, will this patient be a “good” addition to the group? Finding the proper fit goes beyond matching considerations. In practice and for practical reasons, many of these principles are often overlooked. Most inpatient, partial hospitalization, and residential treatment programs for children and adolescents have a wide range of group applications in their treatment repertoire. Children and adolescents admitted to those institutions are expected to participate in their group programs. Assignment to specific groups may not be preceded by careful selection and preparation in the manner discussed above. Institutions that recognize the value of group therapy have developed well-defined standards for its practice and offer ongoing training and supervision. Unfortunately in too many institutions the clinical staff leading groups has limited training and supervision. The therapeutic value of group therapy is seriously compromised in those programs.

PRESCHOOL AGE GROUPS

Developmental Considerations Children ages 3 to 5 are exposed to an active phase of social exploration. During their early years children observe and experience intimate relationships with mother, father, and siblings as well as extended family and significant others. They now move rapidly into a larger social context in which intense social learning takes place by observing and relating to peers and teachers. From initial imitative behaviors, children soon develop new rules of behavior and new judgment standards. The development of new cognitive and social skills facilitates moving beyond egocentricity. At this time preschool experiences expose children to multiple experiences of competition, jealousy, happiness, sadness, guilt, success, failure, anger, fear, and admiration, to name some of the most common. Growing mastery begins to develop along with better modulation of emotions and behaviors, even when the child's cognitive development has not reached the capacity for organizing and reflecting that will be achieved during the latency years.

Techniques Groups for preschool children are typically heterogeneous and include children with different diagnosis, in contrast to the homogeneous groups in which children with a common problem (e.g., a chronic illness or parental divorce) share a psychoeducational and supportive group experience. Preschool groups are structured around toys, play, artwork and other age-appropriate activities. These groups typically include only three to five same-sex children. Because of the children's short attention span, time and space are important considerations, particularly with hyperactive, overanxious, and aggressive children. Groups should not last more than 45 to 60 minutes, including time for a snack. A medium-sized room with appropriate furniture for the age will help provide good boundaries and a therapeutic climate. It is recommended that play and artwork materials be stored away until group time. The use of multiple therapists, highly recommended for child and adolescent groups, is particularly indicated in the treatment of emotionally disturbed preschoolers. These children have acquired at best a basic repertoire of social skills, while emotional regulation is just beginning. As they do in individual therapy, children in a therapy group reenact their behavioral and emotional conflicts, which can become a challenging management problem. Two therapists are needed to maintain clear and firm limits in a consistent structure and model prosocial behaviors and the development of new masteries. Several authors recommend a male-female cotherapy team as the ideal therapeutic configuration. This is not always possible, and cotherapy teams may be of the same sex, including a senior clinician with a trainee or two trainees, and frequently from different disciplines. Young children's limited verbal and social skills, emotional lability, impulsiveness, and out-of-control behaviors can be most challenging, even to the experienced clinician. Availability of consultation and supervision is essential for a successful group therapy program.

With younger children therapists typically initiate each session's activities around educational and therapeutic themes. Using a warm, supportive approach therapists engage children in play activities with puppets, toys, and art materials. The therapist's knowledge of the patients' individual and family histories permits using the group context for further identification and understanding of children's conflicted behaviors and interactions. Mutual-story-telling techniques can provide the children with corrective models that introduce constructive, prosocial options and new masteries. Emphasis is placed on understanding the children's disturbed behaviors in light of their individual and family histories. Children soon reenact earlier experiences in the group, mostly through play and interpersonal behaviors. Interpretations should be kept at a minimum. Therapist interventions are aimed at providing corrective emotional experiences that help the child reach greater social and emotional mastery. Most frequently these groups are offered in combination with family therapy or parents' groups that tend to be mostly supportive and psychoeducational. Close participation of the family in children's groups greatly facilitates the therapeutic engagement and progress. It also empowers the parents by helping them become more competent in their role.

LATENCY AGE GROUPS

Developmental Issues Latency evolves over several years and can be divided into early (5 to 7); middle (8 to 10) and late childhood (10 to 12). During the early period children demonstrate advances in social skills with improved self-control and better behavioral and emotional modulation. The beginning of a moral conscience can be noticed as the child reaches the stage of concrete operations. Further maturation of the child's nervous system proceeds rapidly in areas of motor, intellectual, emotional, and sensory development. Physical action and competitive games and sports become of growing interest, particularly for boys. Higher mastery of verbal skills, better capacity for concentration, and tolerance for frustration make older children more interested in sports and team activities. Development of friendships and participation in group activities becomes of growing interest in older children and continues into adolescence.

Techniques Latency age groups require a larger room. These groups typically include from six to eight members of the same sex. A larger space is needed to engage them in games and physical activities involving group play and discussion. These groups last from 60 to 90 minutes. The combination of activity with interview techniques, evolved from Slavson's early contributions, incorporates psychodynamic and behavioral concepts and techniques.

Children who have reached latency age are more able to connect with each other, but initially the therapist must actively foster a climate of safety and trust before they can engage effectively as group members. Activities should be introduced by the therapist with the intent of facilitating creative and playful interactions that catch the children's interest. Observation of the children in group also clarifies diagnostic questions. Limit setting is an important consideration, particularly with aggressive children with poor control. Some of the more typical activities include games, storytelling, creating a mural, dramatizations, use of puppets, masks, and physical activities. These activities must be structured to allow enough time for discussing the experiences to connect the group members. As the group becomes more cohesive members can be allowed to initiate games and activities with the therapist intervening to set limits to prevent or to deescalate dangerous situations. Interventions also include interpretations and clarifications that help the group become a therapeutic agent. Going around and group discussions are valuable techniques to further facilitate connecting group issues with individual, school, and family problems. When a group has matured to developing its own culture, limits are set by the group itself. This level is more typical of longer-term inpatient and residential facilities, but it can be achieved in outpatient groups.

> Child psychiatry residents who started a latency-age group with eight boys reported the struggle they had establishing rules for the group, considering the disruptive behaviors of several members. The group met for 20 minutes to discuss and plan the activities of the day followed by 20 minutes of participation in the selected activity. The last 20 minutes were devoted to discussion of the process while they had a snack. The cotherapists reported initially that they complemented each other well. One took a more active direct role and was a limit setter; the other was more passive and willing to trust the group process. After several weeks the more-active therapist discussed in supervision his frustration with his role and a growing resentment toward his cotherapist. His background as a school teacher was compared with his new role as therapist. His cotherapist recognized the need for more active involvement.
> Out-of-control behaviors diminished after the cotherapists became more aware of how their behaviors affected the group process and brought better balance to their leadership styles. The therapeutic value of the group experience emerged even more clearly when parents and school reported significantly improved behaviors in most of the children, even when their level of insight was limited.

EARLY ADOLESCENT GROUPS

Developmental Issues Early adolescence applies to youths between about 13 and 15 years of age who are usually in grades 6 to 8. It is associated with major

physical, psychological, emotional, social, and cultural changes, often taking place unevenly. The onset of puberty, one of its markers, typically occurs 1 to 2 years earlier for girls than for boys. Physical maturation, a second phase of separation and individuation, reaching cognitive capacity for “formal operations,” and developing strong attachments to peers are some of the most striking tasks of this period. Friendships involve mostly children of the same sex. Relationships with parents and adults become strained and distant as the adolescent struggles with dependency issues. While most adolescents do not seem to experience excessive turmoil, the clinical population under consideration usually presents evidence of conflict in more than one area. Early adolescents often behave defensively with their parents and most adults. A therapeutic alliance with them is difficult to achieve and very fragile. Early adolescents are often on an emotional roller coaster, feeling very insecure and vulnerable to criticism. Denial, projection, and intellectualization are the typical defense mechanisms. Early-maturing boys and late-maturing girls seem to have some advantages over their contemporaries in coping with the challenges of going from childhood into adolescence. A loving, intact family and having achieved reasonable levels of competence during previous developmental phases are also considered protective factors.

Techniques Early adolescents are often more willing to participate in a group of same-sex peers than in individual psychotherapy. On the other hand while they may be willing to discuss problems concerning relationships with family and peers, they have only a limited capacity to contain and modulate emotions, both their own and those of others. To maintain an optimal structure, group size should be limited to eight. Early adolescents often become silly and rowdy when anxiety-laden issues come into focus. Therapists need to keep a good structure and firm limits before the group becomes an effective therapeutic tool.

Establishing a well-defined, clear structure is always essential and is even more challenging with early adolescents. They want to retain the advantages of younger children and simultaneously insist on receiving adult privileges. Simple rules must be established from the outset concerning proper behavior, taking turns to listen to each other, and respect for confidentiality. Other issues that frequently need to be addressed are socialization outside the group and the use of food during group meetings. Most experienced clinicians agree that fewer rules with some flexibility for creative options that can be initiated and monitored by the group can have excellent therapeutic value. Considering a visit to a hospitalized member or planning a special celebration are two examples of projects in which group members would participate in all aspects of development and implementation. How much autonomy and responsibility can be delegated to the group is determined by clinical considerations by the therapist who is ultimately in charge.

A valuable tool in working with adolescents is the careful use of humor in a nonthreatening way. At this stage of development their humor is often scatological and crude, but they feel very vulnerable to criticism. It is an art to learn to accept and contain early-adolescent expressions of humor without reciprocating or reinforcing them. Reframing or redirecting with a light touch of humor or an interpretation can focus the group into examining issues they may be avoiding. A valuable use of humor can be illustrated by the therapist sharing an embarrassing experience during adolescence. Verbal games are also valuable tools, as are role playing and psychodramatic techniques. As with younger children, group techniques are only means to help achieve therapeutic goals. Clinical considerations should determine when and how they are prescribed.

Johnny was a high-functioning, 14-year-old boy diagnosed with autistic disorder. He had been in individual and family therapy for several months before he was considered ready for group therapy. Johnny was an awkward-looking adolescent who looked and acted younger than his chronological age. His academic level was above average, but his social development was very limited. A supercilious, hypermoralistic attitude of more recent development contributed considerably to his social isolation, particularly after starting seventh grade. He was assigned to an established group of early adolescents with a mixture of clinical conditions, meeting once weekly for 75 minutes. Initially Johnny limited his participation to monosyllabic answers to direct questions, then he would go back to reading a book on the history of Napoleon, his favorite subject and object of fascination. Group members chose to ignore him after a while. Over a period of several weeks his interest in the book seemed to abate. Johnny brought it, but it remained unopened on his lap. He would make an occasional remark, mostly to criticize another group member for his “vulgarity.” The group laughed at his remarks but scapegoating could be avoided. They seemed to respect his “differentness.” Two months later, Peter, a very shy schizoid 13-year-old boy joined the group. After a few sessions Johnny had developed an unexpected interest in Peter and sat by him and encouraged him to interact with the group. Soon it was noticed that Johnny was not bringing a book any longer and that he was more actively involved with group members. He responded to social cues in a more age-typical and appropriate manner, and though he continued having morbid preoccupations with power and a fascination with Napoleon, the intensity was considerably reduced. Johnny's growing interest in people was clinically evident. Group therapy was used in combination with individual and family therapy and psychotropic medication over 18 months. Although the group experience was only one component of the treatment plan, it became a most significant tool to help Johnny with his interpersonal deficits.

MIDDLE AND LATE ADOLESCENT GROUPS

Developmental Issues Middle adolescents are approximately 15 to 17 years of age, usually in high school in ninth, tenth, and eleventh grades. Late adolescents are ages 17 to 19, typically at the completion of high school and the transition into adulthood. Middle adolescence is punctuated by a more stable involvement with peers and the development of relationships with the opposite sex. Greater autonomy from the parents also emerges, along with a clearer sense of identity and growing vocational interests.

As they move into late adolescence, commitments to further education, training, work and other people become clearer. A more solid sense of self emerges, and the earlier critical attitude about the parents becomes less intense.

Techniques A mixed group of boys and girls with a cotherapy team representing both sexes provides an ideal format. In practice this balance cannot always be achieved. These groups can be larger, 8 to 12, depending on clinical considerations and fit. Older adolescents are capable of higher levels of abstraction, introspection, and emotional and behavioral control. They can typically discuss openly topics of personal and mutual interest. The therapist initially invites each member to express the reasons for being in group and to give a brief background. Going-around, group discussions often facilitate active interaction. In contrast with leading younger age groups, older adolescents typically enjoy the opportunity to discuss feelings, opinions, and concerns that would be harder to elicit in individual therapy. Because of their tendency to intellectualize or avoid dealing with personal issues by focusing on someone else's problems, the therapist should be able to redirect the focus by reflecting, interpreting, and going around, asking each individual's opinions and feelings. Group cohesiveness often develops quickly, and members discover that many concerns that had been a source of worry and shame are not unique. Catharsis is important, particularly in the beginning stages. The therapist's empathetic interventions, support, confrontation, and careful use of interpretations are essential for developing group cohesion. Soon group members can interact with each other more openly and enter a new phase of group work. The therapist's role is maintaining the therapeutic focus with good boundaries. Intense relationships develop in group, and members often want to socialize between sessions or start dating each other. Group members need to be reminded that outside contacts and pairing off affects the integrity of the group, because those members are no longer able to be as honest and open with the rest of the group as in the past. Group members often underestimate the significance of breaking this rule and may blame the therapists, projecting on them the image of overrestrictive parents. Further elaboration in group typically brings new appreciation for the value of this rule and a stronger awareness of how group psychotherapy works. Often the infractors ask the group to allow them to continue as members and promise to stop contact outside the group. Confidentiality is another major issue for careful review. Patients must understand that confidentiality should be respected at all times except when the patient's or someone else's life is at imminent risk. Otherwise, abstinence in discussing any information concerning individual members outside the group is essential for the safety of the group as a therapeutic environment.

PARENT GROUPS

Considerable literature supports the effectiveness of parent groups, particularly those with a psychoeducational supportive orientation with emphasis on learning behavior-management techniques. They are well structured and didactic and are offered in a course format over a limited number of classes which typically include time for questions and less frequently for group discussion.

Psychoeducational formats have become popular in the management of specific conditions such as attention-deficit/hyperactivity and conduct disorders, but are also indicated for parents of children and adolescents with posttraumatic stress disorder, learning disabilities, retardation, schizophrenia, bipolar disorders, Tourette's disorder, autistic and pervasive developmental disorders, eating disorders, substance dependence, and juvenile delinquency, of adolescent sexual offenders; and of children or adolescents with a wide variety of chronic medical conditions such as cystic fibrosis, cancer, diabetes, and various types of transplantation. Hardly a condition exists that lacks an educational/support group. However, self-help groups that are purely educational and led by nonclinicians differ from those whose group leader is a clinician. The latter would be more inclined to use group dynamic principles in their approach. Going beyond the instructional goal allows more-personalized recognition of individual and family issues, particularly those concerning the relevance of expressed emotion in families and its impact on relapse prevention. When the focus shifts from behavioral management of a diagnosed child to exploration of parental emotions and thoughts in response to the child's condition, the intervention becomes more psychotherapeutic. Parent's groups and multifamily groups are valuable tools that have proved effective, but unfortunately they only are widely used in specialized centers.

There are several advantages to conducting parental guidance and support groups. The more-experienced parents can serve as models for resistive parents and those of newly diagnosed children, which benefits both “senior” and “junior” members. An insight-oriented approach is not indicated when the need is providing basic mastery of effective parenting to reduce the sense of guilt or failure that these parents often experience. Parents who are psychotic, paranoid, narcissistic, or extremely rigid and controlling cannot function effectively in a group and should be offered a more traditional individual or family approach. Parallel parents groups have been popular in child guidance centers, particularly with children up to the young adolescent age. Close collaboration between the therapists of the parallel groups often includes a monthly joint session with children and parents, resembling the multiple family groups but not including siblings or other family members.

CLINICAL ISSUES

Indication In the context of a psychiatric evaluation, assessment of the child and family should identify areas of strength and weakness, including protective factors and vulnerabilities. The formulation and treatment plan should be comprehensive enough to include consideration for a group psychotherapy approach in combination with the possible use of psychotropic medication and individual or family techniques or both. Residential care and day program group treatments are often the primary modality for hospitalized children and adolescents, with several different group experiences offered daily. Individual and family interventions, while significant, are offered less frequently. In contrast outpatient groups are more frequently used as adjunctive treatment to deal with specific diagnostic conditions such as attention-deficit/hyperactivity disorder, conduct disorders, victims of abuse, posttraumatic stress disorder, postdivorce adjustment, and adolescent sexual offenders. Groups using cognitive-behavioral therapy have proved effective in the treatment of conduct disorders and depression. The use of cognitive-behavioral therapy is expanding rapidly, and it has become one of the most popular and best-researched psychotherapy approaches.

Deficit or impaired social skills are the most frequent indications for group therapy; they include many clinical conditions (e.g., schizoid personalities, conduct disorders, sexual disorders, social phobias, physical and sexual abuse, and depression).

Limitations As a single treatment modality group psychotherapy is of limited use in children except when combined with other therapeutic interventions. Older adolescents are a possible exception. Late adolescent groups are used effectively as a single treatment modality in counseling centers and colleges for a number of the clinical conditions discussed above.

Complications Problems of breach of confidentiality and of dating or socializing outside the group have been discussed. Additional problems are associated with out-of-control or psychotic behaviors that become too disruptive for adequate group function. Inducing delinquent behaviors or using drugs are reasons for exclusion from the group. With careful assessment these problems are often anticipated before placing a patient in group. Therapeutic termination from the group is at times painful, but needed, when the patient cannot be contained by the group and attempts at corrective intervention prove ineffective. Several authors have discussed strategic exits from group with a more individualized approach as an alternative. Another complication involves a possible cultural mismatch when a member of a cultural or religious minority finds himself or herself isolated and without basic social cues to overcome the barriers. Again, careful diagnostic assessment should anticipate this complication. Adding another member of the same minority as a member or a therapist can turn around this complication. Consultation and supervision are most helpful at preventing these complications and facilitating alternative therapeutic options.

Contraindications Children and adolescents who are extremely anxious, actively psychotic, and disorganized cannot benefit from group therapy before they are stabilized with medication and individual and family techniques. Sociopathic, narcissistic patients with potential for predatory behaviors could make destructive use of a group and should not be included. In juvenile correctional institutions these patients can make good use of group therapy; typically, psychoeducational and behavioral interventions are effective with incarcerated youth.

Goals of Treatment As a single modality or most frequently in combination with other therapeutic interventions, treatment goals should be clearly defined and specifically related to each modality. Typical goals for a group intervention include improved interpersonal and social skills and increased trust in others, empathic sensitivity, and ability to recognize and express feelings in self and others. The case of Johnny (described above) included all of those goals. When combined therapies are used including involvement of two or more clinicians, the treatment plan must include coordination of various modalities, with the treatment team maintaining open lines of communication. Consultation and supervision are particularly valuable in those cases to maximize their therapeutic value and prevent complications. In Johnny's case, the frequency of family sessions was reduced from weekly to twice monthly over a period of several months, followed by once-monthly sessions; weekly group and individual therapies continued and for the final 6 months, group was the primary modality, with the mother in a parallel group. Infrequent family and individual sessions were scheduled periodically to assess and integrate the treatment.

Homogeneous and Heterogenous Groups Early authors recommended that groups include children with mixed clinical conditions. They described the advantage of combining, for example shy, inhibited children with more aggressive or expressive youth. Opportunities for mutual learning can thus be complemented, with a wider range of therapeutic opportunities available for group interaction and for learning. Psychodynamic, activity-discussion groups that include children and youths with mixed clinical conditions follow this orientation.

More recently the use of homogeneous groups has grown in popularity. Patients with diagnoses in a similar category are placed together in homogeneous groups for such conditions as eating disorders, attention-deficit/hyperactivity disorder, posttraumatic stress disorder, and substance dependence. These groups develop strong cohesiveness faster than heterogeneous groups, but they usually do not reach the more intense levels of clinically mixed groups. They have a more psychoeducational design, with a primary focus on behavioral changes. Homogeneous groups have proved effective and are often used on a time-limited basis. Self-help groups are also homogeneous but are led by nonclinicians; they provide excellent support and have an educational focus. They are used less frequently with children and adolescents, with the exception of Alateen groups for children of alcoholics.

SETTING

Outpatient Child and adolescent groups mostly occur in child guidance clinics, community mental health centers, and large clinics. Individual practitioners in private practice find it difficult to gather enough suitable patients with compatible clinical needs to organize groups, particularly because involvement of parents and collateral therapeutic interventions is required. Group practices are more able to organize groups. Space, volume of patients, opportunity for cross referrals, availability of clinicians for cotherapy, consultation, and supervision make it possible. Student health centers frequently use groups for adolescents. Group approaches are also popular in school-based and day programs for emotionally disturbed children and adolescents. Specialized group programs have recent popularity in the outpatient treatment of single clinical conditions.

Inpatient Current practices of inpatient and residential psychiatric care for children and adolescents include a strong group therapy program. Because the length of stay in most institutions has become very short, most payers and institutions emphasize the use of groups 7 days a week, often including several different types of group during the same day, depending on the diagnostic problems and the level of care. Multiple members of the staff or trainees may be involved in one or more group modalities depending on their training and experience. In addition to psychodynamic groups, most inpatient, partial hospitalization, and residential care institutions currently offer a menu of groups to select from. The list includes, but is not limited to, mixed-gender, single-gender, anger management, relaxation and stress management, substance dependence, social skills training, acquired-immune deficiency syndrome (AIDS) education, recreational, art, psychodrama, movement and dance groups, and multiple family groups. Team meetings and a clinician case manager facilitate the integration of these modalities into a treatment plan along with individual, family, and psychopharmacologic interventions.

Schools Counseling groups have been popular in schools. They are typically led by school counselors, with psychiatrists frequently as consultants, coleaders, or supervisors. The groups are held during the school day. The range of options is narrower because of time limitations. More intense, focused group experiences are indicated when a traumatic event affects a school and its community such as a recent suicide of a student, a shooting, or a serious accident on school grounds.

ETHICAL ISSUES

Confidentiality Confidentiality is usually not a significant issue with younger children. Preschoolers and young elementary age children expect parents to have close involvement and to know just about everything about them. A rule of confidentiality concerning group activities could be misinterpreted as a request for secrecy by young children and their parents. Older children should understand the importance of keeping group information in the group, particularly information about members and group material to be kept private. Sharing a personal experience or insight with parents is acceptable, but disclosing someone else's is not. Inevitably children sooner or later run into another group member in school, church, or the neighborhood. They should be cautioned to avoid discussing group experiences, particularly when around other children. Sharing information with parents is another ethical issue, particularly with adolescents. Collaboration with the parents is needed to

maximize the therapeutic benefits. What information should be shared and how is decided on the basis of clinical considerations. Certainly when the child is at risk of harming self or others, the rule of confidentiality does not apply. In all other cases it is best to discuss with the child or adolescent the therapeutic value of bringing a particular piece of information in the open to be shared with their parents. A family session, regularly or specially scheduled, is often the best context for such disclosure which may open or reopen channels of communication between parents and child. Contacts with parents are often regarded with suspicion. Clinical judgment should determine how much of those contacts is discussed in group. Parents are also entitled to confidentiality and should be free to discuss personal issues with the therapist.

A breach of confidentiality by a group member is a serious matter that puts the integrity of the therapist and the group on the line. It must be discussed in group in an open and straightforward way to have trust in the value and safety of the group restored. Risk-taking behaviors including promiscuous sexual activities, use of drugs, abuse of alcohol, and involvement in delinquent behaviors cannot be condoned. Clinical judgment should determine where experimentation ends and self-destruction starts. A mature, caring group often can recognize the problem and put group pressure on that individual to face the problem openly. Disclosure to the parents and the need for additional help are central considerations. Ignoring self-destructive behaviors would be regarded by the group as the therapist condoning and even encouraging them. The group would no longer feel as safe, and the therapist risks losing the trust of its members.

RESEARCH AND EVALUATION

Fewer studies have been conducted on group therapy with children and adolescents than with adult populations. Several explanations for this have been offered, including problems in patient recruitment, ethical issues, funding, family involvement, developmental factors, compliance, and motivation. A suitable pool of patients may be available only in larger institutions. There is a stronger tradition for psychotherapy research with adults, and the number of researchers specialized in the field of child and adolescent group psychotherapy is rather small.

Short-term groups and cognitive behavioral therapies have been better studied than psychodynamic groups Therapists using manualized techniques in university settings have reported better outcomes than therapists in field studies. Despite some of those limitations, outcome studies consistently demonstrate that group psychotherapy with children and adolescents is as effective as individual therapy, and both are significantly more effective than control conditions. Only 20 of approximately 500 studies involved child or adolescent groups, but their effect size was not analyzed separately. Many of the studies examined different areas of outcome, process, and leadership. Unfortunately, standardized research instruments were used in only a few of them, and most groups did not have control or contrast groups. Follow-up studies are limited or absent.

Time-limited group psychotherapy as applied to a number of clinical conditions has received more interest. Eating disorders, including anorexia and bulimia, have responded well to group formats that combine cognitive-behavioral, psychoeducational, and psychodynamic theories and techniques, alone or in combination with psychotropic medication. The use of group therapy modalities in the treatment of chemical-dependent youth has been the subject of several excellent studies.

Unfortunately there has been great diversity in the treatment designs, and comparing studies is problematic. Most treatment approaches for this population predict better outcome when families participate actively in treatment. In general, well-structured, problem-oriented, psychoeducational groups are more effective and have more practical value than psychodynamically oriented, unstructured groups.

Groups for sexually abused children have been an established practice; however, few studies demonstrate their efficacy. Some have victims alone, others have a parallel group for parents, and some combine group with family sessions. Authors conclude that children become less anxious, manifest improved self-esteem, show less suicidal and self-mutilating behavior, are more able to trust and show anger, and present less-sexualized behaviors. Adolescent sexual offenders have also benefited from group therapy approaches. Because treatment takes place most often under court order and conditions of probation, compliance is high. They are problem oriented, including among other goals that the victimizer admit responsibility for the offenses and over time develop empathy for the victim, followed by a formal apology. Social skills training and school and vocational support are also part of the treatment of sexual offenders. Psychodramatic applications and role playing techniques are valuable with this population. The few published studies demonstrate that group techniques are significantly effective, and the “admitters” show a marked reduction in new sexual offenses over a period of 2 years.

TRAINING

While psychiatry and child and adolescence residency programs are required to offer training in group psychotherapy, this training often takes a back seat to other treatment practices. Further, the number of well-trained psychiatric faculty for teaching and supervision of group psychotherapy, particularly child and adolescent psychiatry, is limited. Frequently training is delegated to nonpsychiatrists. Fortunately most training programs expose residents to a variety of group experiences in outpatient, inpatient, and residential settings and schools. Trainees typically participate as coleaders but only rarely over an extended period of time, mostly because of rotation requirements. It is best to have several well-supervised group experiences to become familiar with the power of group dynamics and the value of group psychotherapy in the treatment of children and adolescents, even though opportunities for personal involvement may be limited following residency training.

SUGGESTED CROSS-REFERENCES

Information related to child and adolescent group psychotherapy may be found in Section 48.4 on group psychotherapy, combined individual and group psychotherapy, and psychodrama; in Section 30.5 on family therapy; in Section 30.11 on evaluation of psychotherapy; in other sections of Chapter 48; and in Section 49.13 and Section 54.2 on ethics in psychiatry. Normal child development is discussed in Section 32.2 and normal adolescent development in Section 32.3.

48.5 FAMILY THERAPY

ALLAN M. JOSEPHSON, M.D.

DEFINITION

Family therapy is any intervention that focuses on altering the interactions among family members and attempts to improve the functioning of the family as a unit of individual members of the family. The clinician conducting family therapy attempts to interrupt rigid intergenerational patterns that cause distress within or between individuals. Family therapy can address the concerns of any family member, yet it is most likely to influence children, whose daily reality is directly affected by family context.

The term *family therapy* is typically used in two contexts: to describe an intervention modality, the focus of this chapter, and as a conceptual framework for intervention. To complicate matters, there is no one type of family therapy but numerous schools of family therapy subsumed under the generic term.

As opposed to *family therapy*, the denotation “family treatment,” may more accurately reflect the numerous ways in which clinicians can intervene with families—with the entire system, with dyadic subgroups, and with individual members. For a generation, the systems view (i.e., all family members must be present for treatment) has been synonymous with family therapy. Eclectic family treatment encompasses behavioral, psychological, and educational interventions with families who have a child or adolescent with a psychiatric disorder. *Family therapy* and *family treatment* are used interchangeably in this chapter.

While most child and adolescent psychiatrists believe that families must be involved in clinical interventions with children and adolescents, views on the family's role in the evolution of a child's psychopathology differ. Families can be categorized as promoting individual disorders, as responding to disorders, or as a system in which an individual disorder indicates family dysfunction. In a biopsychosocial, interactionist model, family interventions often involve a combination of these perspectives. The cumulative impact of family interaction can worsen or ameliorate a child's symptoms.

Family therapy can include concepts familiar to individual therapists, such as developing an alliance and working through and dealing with resistance. Family therapy also uses a behavioral emphasis. Clinicians observe specific behaviors and design plans to alter them by intervening in interactional patterns associated with these behaviors. Family therapy shares characteristics of group therapy. Pragmatically, more than one individual is receiving clinical attention. Conceptually, individuals are viewed as performing functions for the group as a whole. In family therapy, however, roles and hierarchies do not solely evolve out of group interactions but are also assigned by biological relationship of parent to child and sibling to sibling. Further, a shared history of participants exists that is more intense and influential than that experienced by group therapy members. Finally, because family interactions observed in therapy reflect enduring patterns outside the therapy experience, they indicate a pervasive effect on the internalized world of its members in contrast to the more limited effects of group therapy interactions on its members.

HISTORY

Most observers agree that the roots of family therapy originated in the early 1900s when child guidance clinics emphasized that the problems of children were embedded in a family context. The orientation of these clinics was characteristic of the time, a depth psychology approach informed by psychoanalysis. While Sigmund Freud had pointed out the importance of family forces on intrapsychic development, the primary clinical intervention typically focused on the mind of the child. The psychiatrist treated the child, and the parents were seen by the social worker. This division of labor reflected the primacy of the individual approach, a situation that continued through the first half of the century. Even as family treatments ascended, most psychiatrists saw family interviews as ancillary to the treatment of the child's internal conflicts.

Pioneers Nathan Ackerman, arguably the father of family therapy, typified the early family therapy leaders. Many of these clinicians had psychoanalytic backgrounds yet were increasingly dissatisfied with individual treatments. They either believed the treatments ineffective or observed effective treatments undermined by families who were having difficulty adjusting to therapeutically induced changes in their children. Many of these individuals worked alone, outside mainstream psychiatry. These clinicians began to experiment by working with families and, while not disbanding psychodynamic notions entirely, began to take a broader view of the psychodynamic process.

Coincident with the appearance of formal family approaches, modifications of psychoanalytic theory began to emphasize social forces: Erik Erikson's epigenetic theory, Heinz Hartmann's adaptive ego psychology, and Harry Stock Sullivan's interpersonal psychiatry. By taking into consideration the interactional forces and relational matrix that give rise to intrapsychic process, these theorists indirectly fostered the development of family therapy. These perspectives helped pave the way for empirical research by Margaret Mahler and colleagues on the separation-individuation process, which furthered the notion that development does not occur apart from social context. Mahler's seminal work is rarely mentioned in family therapy literature, yet it supports family interventions.

Radical Environmentalism and Family System Theory The next era in the development of family treatments was revolutionary; its impact is still being felt. The family was defined as a system, and this notion dominated family therapy for a generation. For many clinicians, the only way to intervene with a family was through systems therapy. The biologist Ludwig von Bertallanfy was perhaps the most influential theoretician of general systems theory. The first wave of family systems thinkers included Carl Whitaker, Donald Jackson, Gregory Bateson, and Salvador Minuchin, originator of structural family therapy, perhaps the most influential school of family therapy.

While systems therapists avoided individual psychodynamic approaches, they remained vigorous environmentalists. In the systems view, they did not focus on an identified patient, individual differences, individual symptoms, diagnostic classification, and therapeutics related to such classification. Early systems proponents believed all mental illness would be cured through this new approach. Along with this radical view came a rigid adherence to the systemic view. It was not uncommon for a family to come for a session without a family member, have their session canceled and be asked to return with the member at another time. By such actions, systems therapists were making their point: the family is a system, and an absent member crucially alters what happens in a session.

The here-and-now focus of family systems treatment was often demonstrated through live interviews in educational and clinical settings. One-way mirrors and the advent of video technology allowed practitioners to demonstrate their work, which was an enormous educational advantage over the challenge of verbally describing complex family interactions to a supervisor. On the other hand, direct observation appeared to foster an emphasis on techniques and a dramatization of the change process. For example, it was not uncommon for a clinician to teach that a strategic intervention in a stuck system could produce results immediately. Some specificity of family type related to disorder was sought with little success.

Child psychiatry and family systems therapists interacted minimally, in part because of the antimedical and antiindividual stances prominent in the work of family systems therapists. Child psychiatrists experienced cognitive and affective challenges related to the shift in clinical focus from the dyadic patient-therapist relationship to complex group interactive processes. These challenges precluded an easy transition to systems thinking for many psychiatrists.

Rapprochement and Integration The perspective of the system offered a new vantage point yet also possessed limitations as the sole conceptual basis for family therapy. The exclusive emphasis on the system led some therapists to believe that relevant perspectives on individual functioning had been lost in the systemic schools of family therapy. The current status of family treatment (and the orientation of this chapter) is that an approach integrating systems and individual

psychodynamic and behavioral concepts is necessary to treat the psychiatric disorders of children and adolescents. Family treatments now include parent training and education, and individual work with parents and children, as the clinical needs of a family dictate. Integrated family treatments often include aspects of different schools of family therapy.

Two common clinical problems illustrate the need for integrating systems and individual perspectives. When an adolescent with anorexia nervosa restricts food intake and loses weight, she experiences success and self-efficacy. The young girl's success in weight loss is not present in more typical adolescent pursuits and this seems to feed her compulsion to succeed at being thin. The disorder is often accompanied by familial interactions that are characterized by intense family involvement in the child's eating behaviors. Eating, an autonomous event, becomes inextricably involved with interactional processes. The adolescent's symptoms allow the family to maintain a set pattern of interaction, while the experience of weight loss is associated with her struggle for identity. Alternatively, the symptoms can be viewed as performing a defensive function for her and for other family members.

Similarly, individuals who exhibit self-harming behavior draw others toward themselves. Any assessment of self-harm must consider the family system as a potential etiologic factor, while simultaneously appreciating the effect of such behavior on a family. This interactional assessment must be balanced by an assessment of the affective and perceptive state of individuals who harm themselves. Self-harming behavior is often associated with disturbing affects and inadequate individual coping skills.

Several areas of clinical activity, research, and theory building support the integration of family treatments with other interventions, particularly interactions with individuals.

1. Family theorists such as David Reiss have emphasized factors that reside within the individual as well as factors that reside within the system.
2. Child development studies, such as the work of Daniel Stern and Robert Emde, have described the development of mental representations, or the inner world of the child, as generated from a relational context.
3. Clinical child psychiatry research emphasizes that biological vulnerability interacts with environmental demands to determine clinical outcome (“goodness of fit”).
4. Biopsychosocial psychiatry is a useful model for many clinicians because it considers the individual's biological and psychological endowments interacting with the individual's social context.
5. Psychodynamic psychiatry includes interactive concepts in its theoretical base, if not in actual practice. Self psychology uses the concept of parents as self-objects who must provide mirroring and idealizing functions for healthy child development, while object relations theory is based on the internalized object relations derived from life experience.

THEORETICAL ISSUES

Most practitioners of family therapy over the last generation have maintained that family therapy is both a theory of understanding human behavior and a set of strategies to intervene in problematic patterns of family interaction. Three core issues illustrate the current integrative approach to working with families. The effective practitioner understands the biopsychosocial approach to the relationship of family interaction to individual psychopathology, the importance of integrating systems and individual psychodynamic concepts and the need to appreciate the individual narrative, or personal experience, of each family member.

Biopsychosocial Approach Most contemporary approaches to family therapy emphasize that the family never causes psychopathology. This is accurate but also misleading in that biological, psychological, and social contributions to disorders (e.g., genetic vulnerability, inability to trust others, unemployment) do not solely cause disorders but predispose individuals to such disorders. The effective family therapist is open to two possibilities—that a family's interactive problems may primarily be a response to disorder or a cause of disorder. Past inaccurate attribution of familial responsibility for disorders such as autistic disorder appears to have given way to a reluctance to address parental and familial deficiencies. Effective family therapy supports a family that is responding to a disorder within a child and empathically explores family interactions that seem more etiologically important in the onset and maintenance of a child's disorder.

Integration of Individual and Systems Perspectives In family therapy influenced by systems perspectives, pathology results from structural or functional imbalances in the system rather than from individual difficulties. What happens to an individual's development, especially the development of a child, when such familial structural imbalances are persistent and pervasive? The answer to this question brings the focus back to the individual. Persistent, repetitive life experiences shape individual cognitive and emotional development to the point where these external experiences become internalized. This dynamic, developmental perspective is at the core of the contempor ary shift to integrated psychosocial treatments for children and adolescents.

The *systems approach*, a departure from so-called linear theories, uses cybernetics and general systems theory. Cybernetics denotes that systems maintain an equilibrium whereas in general systems theory, all living systems are characterized by tension between homeostasis and change. All things are interdependent, and nothing changes without everything else changing accordingly. In this view, symptoms are not seen as residing within the child but as serving a purpose for the whole family system. These symptoms provide systemic survival, or continuity, and maintain homeostasis. Each family member is presumed to act in a way that opposes symptomatic improvement in the presenting patient. Most family systems theorists hold this view, and therapeutic interventions attempt to counteract this hypothetical process. For example, in this view, one must destabilize the family system to promote change. The formulation for a systems-oriented clinician has less to do with the symptoms residing within a child than with the meaning such symptoms have for the family. Problem-maintaining sequences are observed, and these processes are interrupted. Schools of family therapy seen as systems therapy include strategic and structural schools (Table 48.5-1).

Table 48.5-1 Varieties of Family Therapy

The *dynamic, developmental approach* emphasizes that life experience becomes internalized within the individual, and the internalizations are derived from a relational (typically family) matrix. These internalizations prepare the way for choice of partner and new family formation. When parents' family-of-origin life experiences are negative (e.g., abuse, parental intrusiveness or overprotectiveness), they predispose to pathological family interaction. In some measure, they predict how parents will negotiate the transitions of the family life cycle in the next generation. The family's negotiation of life cycle tasks and the interactions that accompany it give rise to the inner world of the developing child.

In this cumulative view of development, the internalization of interactions over time constrains the way future interactions may develop. The term “dynamic” is used because each relationship can potentially alter inner models of self and others. This approach and its variations have been termed psychodynamic, and intergenerational (Table 48.5-1). Object relations family therapy and contextual family therapy heavily rely on these developmental and dynamic concepts. Experiential and cognitive-behavioral therapies, while not dynamic and developmental, also focus on the individual perspective.

Effective family therapy of child and adolescent psychiatric disorders is not predicated upon a choice between systems and dynamic, developmental views. It does involve a choice in the sequencing of interventions, which over time often involves both perspectives. Effective family therapists consider how these two approaches can be used in the choice of treatment modality and sequencing of treatments.

Narrative Therapy More recently, a dissatisfaction in pure systems approaches has been associated with the development of narrative therapy as an organizing

construct for clinical work with families. At first examination, this approach appears to be a return to the developmental perspective—life is lived in stages, and in each stage one's life story is developed. While there are similarities, there are also distinct differences. This school of therapy is heavily influenced by social constructivism, the idea that there are no essential truths except the ones individuals construct for themselves. In this view, the therapist enters the therapy session without a priori assumptions regarding healthy family life and normal child development but rather joins the family through interpreting their experience.

This approach is similar to the dynamic, developmental approach to family therapy in that the patient and family's descriptions of their lives—their narrative—are key elements to clinical formulation. The clinical data are interpreted quite differently however. Whereas a clinician from a dynamic, developmental perspective seeks to identify generalizable, if not universal, principles of families and child development, the narrative therapist brings no such structures to the interview. A therapist using this perspective helps the family to construct a new, current reality from the spontaneous conversation of the session. Since the systems therapist brings systemic principles to the clinical encounter and attempts to make clinical observations congruent with guiding systemic principles, the unstructured narrative approach departs from the systems perspective as well.

This new theoretical approach will be difficult to research in that, by definition, it rejects generalizable principles and primarily emphasizes the diversity of human functioning.

TECHNIQUES AND THERAPEUTIC PROCESS

Conjoint family therapy refers to sessions in which all family members are treated by a single therapist or cotherapists. *Concurrent family therapy* refers to family therapy and individual therapy conducted concurrently, usually with different clinicians. Finally, *a multiple family group* denotes meetings of several families, all of whom have an individual member with a specific problem. In each of these varieties, family therapy sessions are held regularly, with wide variation in frequency, and can last as long as 2 hours.

The clinician conducting family treatment must consider how therapy differs according to the constellation of ages presented by the family in treatment. The younger the child, the more likely it is that the nature of the dyadic parent-child relationship will determine the clinical presentation. Excluding instances of organic disease, caregiving practices are seen as the prime determinants of a clinical presentation in infants and toddlers. Families of school-age children are dealing with issues of success and competence. Mastery of this stage requires the availability of parents to foster the success of their children. Adolescent children question parental values and test the strength of the parents' marriage and parental self. The adolescent's emotional and geographical moving away from family taxes the resources of both parent and adolescent. The potential serious consequences of high-risk behaviors involving sexuality, drugs, and motor vehicles, brings an urgency to many family treatments of adolescent patients.

Overarching all these specific age issues are the tasks and stages of the family life cycle, which should be an orienting principle for family therapists. The concerns of families with children not yet in school and of families with children on the verge of becoming young adults are almost discontinuous. Consideration of the family life cycle, indeed almost any issue implying normal development, is complicated by the dramatic alterations in family structure influenced by divorce, single parenting, remarriage, and stepfamily formation. Attempts to structure and define the life cycle of stepfamilies are but one example of the complexity of considering the contemporary family life cycle.

Assessment and Formulation A family usually becomes involved in family treatment through the presentation of a symptomatic child or adolescent. There are two basic approaches to assessing the family. Some clinicians request that the entire family be present for the first session and focus this session on interactional factors, the meaning of the symptoms for the family system, and how the symptoms are maintained by the family system. Other clinicians do not request that the entire family be present but use separate interviews with child and parents to gather extensive history before observing the family as a unit.

Once the assessment is complete, a formulation is developed, and a recommendation for treatment offered. Patterns of family interaction arise for systemic and dynamic, developmental reasons. Repeated experience of these interactions makes them habitual for family members. The original motivation for initiating the interactions gradually becomes less influential in maintaining of the interaction. For example, an overprotective parent may initially behave that way to shore up a low sense of self, but the behavior eventually becomes somewhat independent of this underlying factor. This evolution suggests an initial behavioral approach to family treatment that interrupts the interactions that have become independent of motivational factors. Subsequently, the clinician explores more-complex, intrapsychic issues that underlie the presenting problems. The formulation serves as the basis for a primary therapeutic emphasis: supporting and educating a family about the consequences of a child's disorder or empathically exploring and ameliorating the family's contribution to a child's disorder.

These systemic and dynamic, developmental formulations lead to a sequential, integrated approach to family treatment. In the following description of clinical process, family treatments may not use all phases, and each phase (when experienced) may not occur in the order given. The process is presented as an attempt to address comprehensively the complex phenomena of family treatments.

Stabilize the Crisis Clinical disorders may have a sudden onset as a crisis or a less dramatic onset as the culmination of pervasive, ongoing problems. To stabilize a crisis, family and other systems interventions are needed, which may include removing a child from the home for a psychiatric hospitalization for emergency evaluation and treatment of life-threatening conditions. Clinicians may also need to use community resources, such as shelters for runaway children or emergency foster care. Short-term pharmacological interventions may accompany these systems interventions.

Parent Education After stabilization, or in the management of chronic problems, education is the initial family intervention. The clinician offers directives about child management that are easily understood and implemented by many parents. Parent training and education may suffice to interrupt behavioral problems, particularly when the problems are mild or parents are merely inexperienced. Problems related to limit setting, fostering a child's independence, and understanding a child's developmental needs often respond to didactic interventions and the development of behavioral plans. When education is partially effective or completely ineffective, the clinician likely has observed parental psychopathology or marital conflict underlying the inability of parents to respond to education. This information prepares for intervention in family interaction.

Intervention in Family Process At this point (the point of traditional family therapy), the clinician sees the entire family and notes patterns of interaction that are maintaining the clinical problem. The clinician challenges patterns of family interaction, using techniques such as those developed by the various schools of family therapy (Table 48.5-1). A few of the more common interventions follow.

In a *paradoxical intervention*, the clinician makes an unusual or contrary demand of a family, such as a request to exaggerate a symptomatic family pattern. If a family refuses or is unable to meet this demand, new potentials for change are experienced. By asking an overprotective mother to go everywhere with her son, a clinician opens up the topic of individuation in a new way, and healthier adaptations can be considered. Antecedents to the overprotectiveness can be explored, and a desire for liberation from this behavioral pattern is verbalized. If complied with, the paradoxical directive facilitates a family's alliance with the therapist. This technique is likely to be unsuccessful in the therapy of individuals who are cognitively and emotionally unable to process nuance and may be less useful in treating families with young children.

Reframing is a verbal intervention, analogous to *clarification* in individual psychotherapy, in which the therapist provides an alternative way to perceive a behavior. It is often used in taking problematic behaviors and giving an adaptive, positive connotation to them. For example, a therapist could hear of a child's distracting, demanding behavior while his father watches television and say to the father, “Your son sure has an interesting way of saying ‘I want to spend time with you, Dad.' ”

In *family enactment*, the therapist promotes an enactment of a family problem to understand its interactional and structural aspects. By directing an anorexic patient to eat in front of her family and thus enact a family meal, the therapist can observe pathological responses and offer alternatives. In less dramatic fashion, the clinician can direct family members to resolve communication conflicts evident in the consulting room.

The clinician who *prescribes tasks* gives instructions to the family on how to handle a specific conflict area and thus encourages their attempt to solve such conflicts away from the session. The results of the prescribed task, or homework, are brought back to the next family session and reviewed by the therapist. As families review their successes and failures with the therapist, areas for change are further clarified.

By *circular questioning* the therapist does not directly confront the symptomatic individual but explores patterns of communication within the family as various problems are discussed with family members. The therapist does not, for example, challenge a young boy about his aggressive, noncompliant behavior but understands the symptom through interaction with the boy's mother who describes its effects on her, her fears of its consequences on her other children, and her concerns regarding

possible future legal difficulty.

Through *mimesis* the therapist adopts the cultural style and understanding of the family in an effort to gain their acceptance. The therapist makes every attempt to adopt family rules and perspectives as a way of gaining their trust and minimizing resistance to treatment.

Altering interaction may eliminate the problem and provide opportunities for improved adaptation by all family members, yet these interventions are often resisted. Individual family members may have their own reasons for resisting change.

Considering the Individual Perspective Unsuccessful interventions in family interaction are often the result of the motivations of a family member or members. In trying to interrupt a symbiotic mother-child dyad, for example, the mother's attribution of meaning to her child's independence and the affects attendant to separation manifest. The preexisting factors that placed her at risk to overprotect her child begin to be exposed, and she resists this exposure. Concomitantly, the effects of symbiosis on the developing adolescent (e.g., dependency and selflessness) manifest. This conflict, conferred by developmental processes and promoted through therapeutic intervention in family process, is distressing, often to the point of inducing a return to dysfunctional interactions. By considering the internalized world of family members and using individual interviews to explore this world, a clinician can understand resistances and plan effectively for them. At this stage, family treatment may include individual interventions with the symptomatic child, either parent, or the marital unit. In this stage, the clinician must not be drawn in to pathological family processes, such as scapegoating an individual member.

Marital Therapy Parents may consider their marital relationship after, and sometimes alongside, the previous sequences of family intervention. Developmental histories prior to marriage, issues surrounding choice of partner, and the nature of the family life cycle come into new perspective for individuals who are considering the difficulties of their child. Parents more easily reflect on their possible contributions to the clinical problems when their child's disorder is stable. This stage usually occurs later in family treatment and indicates the deepening of family therapy.

Interventions With Siblings From a systems viewpoint, change in family interaction may be accompanied by the onset of symptoms in other members. If a family interactive process has been toxic to the development of one child, this toxicity will have affected other children as well. Individual factors such as a child's temperament, intelligence, and birth order also determine whether siblings develop clinical problems. For example, an overbearing intrusive father may have one son who is dependent and submissive and another son who actively rejects his authority. It is important to determine whether the onset of symptoms in another child is a diverting mechanism away from another problem, such as marital pathology (systems view), or a statement of individual vulnerability (dynamic/developmental view).

Other Interventions The clinical processes just described illustrate an integrated approach to family treatment conducted over a period of time. The chronological sequence is offered as a guide; the actual sequence varies according to clinical need. Some lower-functioning families will at some point in treatment require interventions at all levels, while higher-functioning families may require only a few components of this sequence (e.g., parent training or family process intervention). A coordinated family treatment may involve an intervention with the entire system or work with parts of the system. The duration of family treatment varies from brief interventions for a specific problem to longer-term treatment with intermittent clinical contacts around different problems, often posed by different family members.

Families in treatment often require other supports and interact with other systems of care and other interventions. Group therapy is helpful for children with socialization difficulties and becomes increasingly important with older children. Parents who work collaboratively with schools maximize educational success for children with academic difficulties. Conduct-disordered children frequently are involved with the courts. This involvement can be therapeutic in that it reinforces families in their limit-setting efforts. Families who have difficulty setting limits can benefit from collaboration with probation officers and court workers. Family therapy interventions with such children are strengthened when behavioral consequences for breaking the law are applied by an agency outside the family.

CLINICAL ISSUES

Indications *Family therapy*, broadly defined as working with the family, is always indicated in treating children, because the family is so critically a part of each child's life, whether it is causing problems or responding to problems. The sequencing of family interventions and whether those interventions should involve an individual child or parent, a subsystem such as the marital unit, or the whole group are important considerations. With some children, the family is viewed as etiologically important in the onset and evolution of the disorder. Here the clinician empathically explores and elucidates the role of family conflict in a child's disorder. With other children, family interactions are seen as a response to illness within the child. In this instance, the clinician educates and empathically supports the family. Complex family situations may involve both approaches.

Empathic exploration of family issues is indicated when (1) the clinical problem presents as an interactional problem (e.g., child abuse, a child running away from home), (2) parental psychopathology (e.g., substance abuse) complicates parenting efforts, (3) a child fails to respond to repeated medication trials, and (4) there is empirical and clinical support for the efficacy of specific family approaches with specific disorders (Table 48.5-2).

Table 48.5-2 Family-Oriented Treatment Approaches for Specific Clinical Problems

The empathic support of families is indicated in neurological disorders such as mental retardation and autistic disorder, medical disorders such as cystic fibrosis and diabetes, and psychiatric disorders with strong biological components such as schizophrenia. The stresses faced by the families of such ill children are unique and often overwhelming. Education, family support groups, respite care for children, and linkage with relevant agencies are all important adjuncts to supportive family treatment.

Limitations The limitations of family therapy are related not so much to the techniques and interventions associated with the modality but rather with developments in psychiatry that have impeded family therapy's full acceptance. Four of the most prominent limitations are (1) the reluctance of systems-oriented clinicians to accept current diagnostic nomenclature, (2) the absence of a generally acceptable classification relational disorders, (3) the preeminence of biological approaches to psychiatric disorders, and (4) a health care system that impedes the full utilization of family treatments.

The fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) includes an axis delineating psychosocial problems in any diagnostic assessment. This has not satisfied many family therapists because the diagnostic system still mandates that an individual must be diagnosed with a disorder. Systems family therapists resist this notion because it is contrary to the basic systems postulate that symptoms do not reside within an individual but result from a particular family context. Family therapists of this orientation would rather have a relational disorders classification replace or at least supplement the individual-based DSM-IV. Such a classification has yet to be fully developed. This limitation should recede as integrated approaches to treatment emphasize both individual and systems variables.

The rapid development of the neurosciences has improved the diagnostic and treatment capability of the contemporary child and adolescent psychiatrist. At the same time, its emphasis has obscured the clinical reality that most disorders result from a mosaic of biological, psychological, and social variables. Psychosocial strengths can protect children from expressing disorders with biological contributions, while psychosocial stresses can foster clinical expression of a biological vulnerability. Many psychiatric training programs are having difficulty conveying this perspective, which supports the relevance of child and adolescent psychiatrists incorporating

family assessment and treatment in their clinical work.

For family therapists, health care delivery has primarily focused on the needs of the individual. From record keeping to individual diagnoses, the delivery system has tended to deemphasize systemic factors in favor of individual ones. This has been reinforced by many third-party payers who do not reimburse for family therapy. This has intensified recently as rapid changes in the economics of health care delivery have dictated the characteristics of psychiatric treatment and the roles of respective disciplines. These shifts have increasingly fragmented psychiatric treatments, exemplified by the psychiatrist providing biological treatments and the nonmedical professional providing psychosocial treatments, such as family therapy.

Complications and Difficulties Mobilizing the power and influence of the family in the life of a child can be dramatic. When progress does not occur, one or more common impediments to successful family treatment may exist.

1. Lack of appreciation of the cultural context of the family. Norms of expected family development and child development vary according to culture and, within cultures, socioeconomic level. The treating clinician must understand a family's cultural background and adjust treatment approaches accordingly.
2. Minimal father involvement. Mothers may bring children for intervention with fathers either resisting the process of intervention or physically unavailable, the case in many single-parent families. When fathers do get involved in treatment, progress is not ensured, but a major roadblock to success is removed.
3. A poorly defined role for siblings. Many siblings do not understand why they need to come to therapy, and their lack of involvement promotes the idea that there is only one identified problem child in the family.
4. Lack of clinician objectivity. Family problems have a high potential to mobilize countertransference responses. Gender roles, child-rearing practices, divorce, and human sexuality are emotionally laden areas that clinicians may be dealing with in their own lives. These are also common foci of family treatment and, correspondingly, may mobilize clinician attitudes that negatively affect treatment.
5. An inaccurate formulation of the family's role in the child's disorder. Progress is delayed when a family receives a supportive therapy approach when its conflicts should be explored and change expected in them. Similarly, progress is frustrated when families are inappropriately held accountable for a child's biologically based disorder.
6. Inattention to influential nonnuclear family relationships. Relationships that have the potential to be a resource for the child (e.g., an estranged biological father, a mother's boyfriend) and those that may be negatively affecting the child (e.g., an intrusive grandparent) must be included in planning family treatment.

Contraindications Like other psychotherapeutic interventions, family therapy is generally contraindicated for those who are not motivated to change. A therapeutic trial may be necessary to determine the appropriateness of family therapy. The main areas of contraindication are those that involve ethical and legal issues. In family treatment, it is contraindicated to

1. Repeatedly involve individuals who are not regularly involved in a child's life. Some family therapists recommend interviews with extended family members and using the material gathered from them to assist in the assessment and formulation of problems. Regularly involving individuals who do not have generational authority to make caregiving decisions for children is contraindicated.
2. Conduct family therapy that escalates the potential for harm to family members. Some family interactional pathology predisposes to violence. Some parents have so many deficits they can never safely and effectively set limits on their child's behavior. The family therapist must avoid exploring family conflicts with potential to lead to postsession violence.
3. Continue to work jointly with parents who are divorced. A session to clarify both parents' relationship to the clinician may be necessary, including such things as how information about a child's disorder is to be communicated. Ongoing work with each parent and new family unit should be conducted separately to reflect the new legal definition of family and to minimize confusion for the child.

Merrilee, a 15-year-old female, was referred by her maternal grandmother, with whom she was living. She had been expelled from school, been increasingly oppositional, and experienced depressive symptoms with vague suicidal ideation. Merrilee would return to her mother's home for periods of time only to get into conflicts with Mandy (her mother) and Bob, her mother's live-in boyfriend of 8 years' duration. Merrilee's father and Mandy had divorced when Merrilee was 3 years of age.

The initial formulation of family problems included a mother dependent on her daughter for affection, an immature “stepfather” with limited vocational skills and low self-esteem, and a maternal grandmother viewed by the mother as intrusive. Merrilee's adolescent behavior disturbance seemed the culmination of persistent developmental problems. Her two younger half siblings, Bob's sons, aged 6 and 4, were also suspected of having difficulties.

Merrilee was hospitalized to ensure safety, complete a diagnostic evaluation, and initiate pharmacotherapy. This stabilized the crisis, and resulted in a thorough assessment of familial strengths and liabilities. Contacts with community resources—mental health agency, court and school—helped prepare for outpatient treatment. Merrilee was noncommunicative in individual and group therapies but did comply with the behavioral expectations of the unit. She was discharged with noticeably improved affect, although she remained defiant.

Parent education in behavioral management techniques was an early focus in the outpatient course of treatment that followed hospitalization. Bob and Mandy were taught how to provide Merrilee with consistent discipline, and the family therapist discussed how a nurturant, nonpunitive stance can facilitate a child's acceptance of limits. Mandy related to her daughter as a sister would, indulging her when consistent discipline was indicated. Efforts to get Mandy and Bob to work together to set limits on Merrilee were unsuccessful, as she accurately perceived that Bob had no sanctioned role in the family. Merrilee's tyrannical, aggressive behavior toward her 6-year-old half brother necessitated an intervention in family process.

Merrilee's rejection of Bob's authority revealed problems in family structure. Bob was not supported by Mandy, and Merrilee took advantage of this fact, often commenting, “You are not my father.” Mandy frequently joined her daughter in berating Bob, exacerbating family tension. This structural problem made effective behavioral control of Mandy impossible. It appeared that commitment in the couples' relationship was tenuous and that perhaps Mandy was only continuing the relationship because of the income she received from Bob's Social Security disability benefits.

A family intervention attempted to strengthen the parents' relationship and decrease the control of the grandmother, who not only allowed Merrilee to stay in her home but also was caring for Jacob, the 4-year-old brother. Efforts were made to have both Jacob and Merrilee return home, with their parents working together to provide nurture and discipline. Parent education and intervention in family process were frustrated by the significant individual needs of parents.

Mandy was a self-preoccupied woman who had experienced a severe burn when she was a young child. Some facial disfigurement and a father who spent all of her developmental years incarcerated seemed important factors in her low self-esteem. Mandy's choice of husbands further reflected a low self-concept. Merrilee's father, Mandy's first husband, abandoned the family, and Bob, eight years her junior, was often unemployed and had cognitive impairments. Individual sessions with each parent revealed their feelings of being overwhelmed with raising three children. The role of grandmother took on a new perspective. Individual contacts with the grandmother revealed her to be less intrusive and more the family safety net, providing support and structure for a couple that desperately needed it. Merrilee refused individual therapy but received some support from a group intervention. Merrilee became increasingly aggressive toward John, the 6-year-old. It became apparent that the reunification of the family, with all three children in the home, taxed the parents as individuals and their relationship.

Bob fled from the responsibilities of parenting while Mandy undermined Bob, refusing to marry him. This inadequate parental coalition precluded effective parenting. Family process interventions, thus, became secondary to an evaluation of Bob and Mandy's relationship and its future. Little hope was offered for the children's stability without clarification of their relationship. Several episodes occurred in which Bob impulsively left the home or was asked by Mandy to leave. Couples (marital) therapy reviewed these conflicts and their antecedents, with the goal of enhancing Bob and Mandy's skills in resolving conflict.

School personnel initiated contacts with the family therapists (a cotherapy team) to identify problems with siblings, John and Jacob. John was seen as an aggressive, noncompliant boy while Jacob was seen as distractable, preoccupied, and impulsive. They appeared to be in competition with each other for the affections of teachers. Individual assessments, therapy, and parent training were offered for the boys.

The treatment of this disorganized family was fraught with difficulty, and the process described had several recursive loops. Well into treatment, Merrilee required rehospitalization for aggressive behavior and experienced legal detention for destruction of property. The family received in-home, behavioral parent training for several months. Ultimately, Merrilee could not be integrated into her mother's home, and when residential placement was unavailable, she was permanently placed with her grandmother. This boundary clarification seemed to help Mandy and Bob to focus on the needs of John and Jacob, who remained with them. John and Jacob's behavior improved in the school setting, although in individual sessions they both manifested indications of insecurity

The treatment of this disorganized family was fraught with difficulty, and the process described had several recursive loops. Well into treatment, Merrilee required rehospitalization for aggressive behavior and experienced legal detention for destruction of property. The family received in-home, behavioral parent training for several months. Ultimately, Merrilee could not be integrated into her mother's home, and when residential placement was unavailable, she was permanently placed with her grandmother. This boundary clarification seemed to help Mandy and Bob to focus on the needs of John and Jacob, who remained with them. John and Jacob's behavior improved in the school setting, although in individual sessions they both manifested indications of insecurity related to their father's impermanence in the family. The parents made some progress with their individual conflicts but continued to have difficulty with a long-term commitment in their relationship and experienced another physical separation.

The continuing availability of the family therapists, who identified the needs of individual family members and the need for family system alterations, served an organizing function for this multiproblem family. When the therapists identified the need for adjunctive supports outside clinical sessions, they coordinated family therapy with the activities of other agencies.

Goals of Treatment The immediate goal of family therapy is the relief of presenting symptoms of the child or adolescent. Family treatment involves other goals, but all are an outgrowth of the attempt to address the presenting symptom, usually described by the parent or child as residing within the identified patient. The practicality of this approach fosters a treatment alliance with the family and patient and becomes a marker of therapeutic progress. The systems and dynamic, developmental approaches differ in how they approach the goal of symptom removal and in addressing other, secondary goals.

Systems approaches address abnormalities in family structure, communication, and belief. Symptoms are used as markers of abnormalities in these areas, not as residing within a patient, and they have a meaning for the system. Goals of this approach are related to altering these underlying processes and thus ameliorating presenting symptoms.

The dynamic, developmental approach assesses how individual motivations and unfinished developmental tasks engender problematic family interactions. Symptoms are seen as residing within a patient and having been induced by family interactions that have meaning for each family member. Goals of this approach include understanding how internal mental representations of self and others have given rise to family interactions.

A key principle of family therapy is that any intervention in the family can potentially benefit other family members. As therapy proceeds, its scope naturally broadens to where the individual needs of all family members, including asymptomatic members, are understood and addressed. This outcome is an implicit goal in all family treatments, one with prevention implications.

ETHICAL ISSUES

The most important ethical considerations in family treatment are related to issues of therapist-patient relationship and confidentiality. When a family is seen, the simplest of questions—Who is the patient?—becomes problematic. Therapy may initially focus on an identified patient, but as therapy continues, the concerns and, at times, disorders of other members of the family become a focus for treatment. By empathically exploring the concerns of one family member, the therapist is at risk of coming into conflict with the needs of other family members. Healthier families can tolerate the therapist's apparent unfairness and lack of responsiveness to their concerns. Families whose members have not met each other's needs are less likely to be patient when one member appears to be benefiting most directly from the clinician's intervention. The therapist must be aware of this common ethical dilemma and make a deliberate attempt to relate to all family members. Drawing upon a therapeutic alliance with the whole family, the clinician specifies that, over time, each family member will be heard, and each perspective will be taken into account.

The concept of confidentiality changes in family therapy because the therapist is relating simultaneously to other members of the family. The family therapist can comfortably discuss with any family member any material that previously emerged in a family session and is known to other members. It is more problematic when information shared with a therapist in the absence of other family members has relevance to all family members. In this instance, the therapist must encourage the individual to bring up the issue in a future family session or (in rarer instances) initiate sharing the information with the family. In this latter case, discerning clinical judgment is essential.

RESEARCH AND EVALUATION

In the era of rapid growth of family therapy, the development of systems thinking was not accompanied by a parallel research tradition. Family therapy was developing outside the psychiatric community and, for many systems practitioners, the cause-and-effect logic of science was epistemologically inconsistent with the systems approach. Further, lack of agreement on a classification system for families and a wide variation in treatment methods also hampered research into the outcome of family treatments.

In the last several decades, however, as family treatments have become more accepted, empirical approaches have been developed and applied to family treatment outcome and family process evaluation. While many studies have included heterogenous patient samples with respect to diagnosis and severity of clinical disorder, the positive outcomes of family treatment are impressive. Meta-analysis studies also support family treatment efficacy by combining results from numerous studies and weighing methodological variations. These studies have shown family treatments to be better than no treatment, more effective than some alternative treatments, and comparable to behavioral and cognitive-behavioral treatments in a variety of disorders. Outcome research on family treatments for specific disorders provides further perspective on the direction of family treatments.

Schizophrenia For the last two decades, research on the impact of a negative emotional environment, termed “expressed emotion,” on the course of schizophrenia has led to family-based treatments. While controversy remains about whether high expressed emotion in families (e.g., critical, hostile responses) causes relapse or is a response to it, family treatments are now core components of schizophrenia treatment. These treatments provide family education to reduce guilt and blame, assist in communication skills, and help family members detect decompensation.

Mood Disorders Relatively few studies have used family treatments for mood disorders, although there is clear evidence of family characteristics that serve as risk factors for depression. These include weak parent-child attachment, hostility between parent and adolescent, parental depression, and ineffective parenting behaviors. These factors suggest that family treatment studies are indicated and that a family intervention has potential for success.

Eating Disorders A family treatment intervention appears helpful for patients with anorexia nervosa and bulimia nervosa, compared with individual supportive therapy, particularly for adolescent patients (compared with adults with the disorder), and when the disorder is of less than 3 years' duration. Uncontrolled trials have demonstrated such impressive results with anorexia nervosa that family treatment is now routinely part of most treatment programs. Clinical experience and uncontrolled trials suggest that family treatments aid the adjustment of children and adolescents with psychosomatic disorders such as chronic asthma and diabetes.

Anxiety Disorders Little work has been done on family factors associated with anxiety, let alone intervention studies. Studies of adult patients suggest that family processes such as lack of conflict resolution and triangulation are more common in panic disordered patients than in depressed patients and a nonclinical control sample. Studies of childhood anxiety are beginning to identify family factors associated with anxiety to complement a rich clinical literature on separation anxiety. Family treatment in combination with a cognitive-behavioral approach appears promising in the treatment of childhood anxiety disorders.

Conduct and Oppositional Defiant Disorders There is abundant evidence that family factors such as harsh and inconsistent discipline and poor parental supervision are relevant to conduct disorder and oppositional defiant disorders. Further, several treatment programs based on parent management models, behaviorally oriented family treatment, home-based models of intervention, and integrative treatments have all been shown to be successful. Regardless of the model used, working with families is a core component of any treatment of youths with conduct disorder and oppositional defiant disorder.

Substance Abuse Family risk factors for substance abuse mirror those for conduct disorders. Similarly, there is impressive evidence that family treatments have positive outcomes with substance-abusing adolescents.

Status of Research In several areas, there is consensus regarding outcome research on family therapy for children and adolescents:

1. No one method or school has established overall superiority in effectiveness.
2. Treatment groups are categorized by individual diagnosis or clinical problem as there is no universally accepted method of family diagnosis.
3. The epidemiology of family risk factors associated with developmental psychopathology suggests areas in which family interventions are clinically justifiable (e.g., anxiety disorders, mood disorders) even though effectiveness may not yet be empirically verified.
4. Significant limitations remain in the ability of current research efforts to measure the complex components of family treatments.
5. General dysfunctional family processes and characteristics are easier to demonstrate than their diagnostic specificity.

6. Whether it is better to measure a positive outcome in family treatment by change in an individual or change in the family as a unit remains unclear.

Outcome research in family treatments is developing sophistication and breadth. It is supplemented by family treatment process research, which does not examine the results of treatment models but rather assesses how the processes of treatment determine outcome. Linking process measures to outcome studies will encourage the development of specific, effective family treatments.

SUGGESTED CROSS-REFERENCES

Individual psychotherapy is discussed in Section 48.1 and group psychotherapy in Section 48.4. Family, couples, and marital therapy are also covered in Section 30.5.

48.6 PEDIATRIC PSYCHOPHARMACOLOGY

BARBARA J. COFFEY, M.D.

Contemporary pediatric psychopharmacology has been driven by an exponential growth in the clinical investigation and use of psychotropic agents to treat childhood- and adolescent-onset psychiatric disorders. This development makes it essential for today's practitioner to learn the basic principles and indications for use of medications and become up-to-date on results of the growing body of clinical trials in youths. This chapter reviews and summarizes pertinent information about current use of psychopharmacological agents in children and adolescents.

Indications for the use of psychopharmacological agents in childhood and adolescence have increased in the past decade as developments in neuroscience and clinical research have broadened the knowledge base. Psychopharmacological agents are used to treat symptoms of juvenile-onset psychiatric disorders that cause significant distress and impairment, and they can facilitate optimal development and adaptation. From the biopsychosocial perspective, pharmacotherapy represents one component of a comprehensive treatment plan.

Established indications are discussed in the sections on specific agents. General indications for pharmacotherapy in child and adolescent psychiatry include the following disorders:

- Childhood- and adolescent-onset schizophrenia
- Autistic disorder and pervasive developmental disorder
- Tourette's disorder
- Enuresis
- Attention-deficit skill/hyperactivity disorder
- Obsessive-compulsive disorder
- Major depressive disorder
- Bipolar disorder
- Separation anxiety disorder
- Panic disorder
- Sleep disorder

GENERAL GUIDELINES

Comprehensive diagnostic evaluation is the foundation of treatment planning in child and adolescent psychiatry. Use of the biopsychosocial model as a guiding principle for case formulation remains relevant and sound. The fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) has contributed to improved reliability and validity in childhood and adolescent psychiatric diagnostic evaluation. The multiaxial system has been particularly useful in child and adolescent settings, as children often have multiple, coexisting problems and need to be evaluated in the context of both developmental stage and family situation.

The multiaxial diagnostic system lends itself to a diagnosis-specific treatment approach, a general guideline in child and adolescent pharmacotherapy. Diagnosis is a foundation for indications for pharmacotherapy and for medication selection, and individual target symptoms determine specific medication choice.

Developmental issues must be considered in the pharmacological treatment of children and adolescents. Growth and development are associated with changes in organ size and proportion and in tissue mass, particularly water and adipose tissue. Children differ significantly from adults in their pharmacokinetic capacities. Children have relatively large livers in proportion to body weight compared with adults and after about 1 year of age reach adult glomerular filtration rates. Thus, because children may metabolize medications more efficiently, higher doses relative to body weights (compared with adults) are often necessary. In addition, children tend to have less adipose tissue and less protein-binding than adults and may have more drug available for bioactivity and potentially adverse effects.

In addition, juveniles likely differ significantly from adults in their central nervous system (CNS) capacities. Neurotransmitter development takes place sequentially and at differential rates during childhood; for example, dopamine and norepinephrine pathways and functions probably develop earlier in life than do serotonin capacities. Hormonal changes during adolescence are also likely to affect CNS responsivity to pharmacological agents.

The children's place in their family context is an essential component of treatment planning. Typically, the child's behavior or emotional state disturbs someone else in the environment, usually an adult, and the child is not always a willing participant in treatment. Parents are a necessary source of information about the child's functioning and response to medication and need to be considered treatment allies. Parental attitudes of anxiety, doubt, or antagonism can significantly affect compliance. The child's views are also crucial in the decision to use pharmacotherapy. All children have fantasies and beliefs about their problems; the use of “pills” or “drugs” to modify behavior or alleviate mental states is likely to be emotionally charged for the child.

Issues of informed consent are another guiding principle. Since many pharmacotherapeutic agents used in child and adolescent psychiatry are not formally approved for pediatric use by the Food and Drug Administration (FDA), a detailed discussion between physician and parents or legal guardians is needed when the decision to use pharmacotherapy is made. Benefits and risks of pharmacotherapy must be weighed and discussed with the parent or legal guardian. Clinically accepted but off-label medications may be used with detailed discussion. Informed consent can be obtained when the patient (if adolescent) or parent or guardian is mentally competent and understands the nature of the condition being treated, the proposed treatment, and its potential risks and consequences. Natural history of the condition if untreated and alternatives should be discussed. The discussion should be noted in the record. Records should also indicate that the patient and parent or guardian had an opportunity to ask questions during the discussion.

Baseline Assessment and Premedication Workup All children and adolescents who are candidates for psychopharmacological agents should undergo a thorough medical and psychiatric evaluation. The clinical workup should include a comprehensive psychiatric evaluation with particular emphasis on previous psychopharmacological treatment including response to medications, dosages, and duration of trials. A family history is necessary, including medication history for family members with psychiatric illness, with responses to medication noted.

A complete physical examination prior to starting medication is important for differential diagnostics and for monitoring physiological effects such as alterations in blood pressure, pulse, or weight. A screening neurological examination should be performed on all patients who are candidates for psychotropic agents, noting overall developmental level, gross and fine motor coordination, cranial nerve functions, sensory-perceptual apparatus, and gait. Before medication is given, abnormal movements, tics, or stereotypic behaviors (Abnormal Involuntary Movement Scale [AIMS]) should be carefully observed as abnormal movements are not uncommon in children with attention-deficit/hyperactivity disorder, tic disorders, and psychotic disorders. Preexisting movements need to be distinguished from medication-related dyskinesias or tics. Basic laboratory workup for most should include screening of hematological, metabolic, hepatic, and renal function and for some medications, cardiovascular function.

Rating Instruments Systematic baseline evaluation is necessary for all child and adolescent candidates for medication. The use of structured diagnostic interviews and rating instruments can help achieve this goal. Structured or semistructured diagnostic interviews such as the Schedule for Affective Disorders and Schizophrenia–Parent Epidemiological version (K-SADS) or Diagnostic Interview for Children (DISC) obtain systematic history of lifetime or current psychopathology or both in juveniles. They function as a systematic anamnesis, reducing errors of omission in psychiatric evaluation of children and adolescents. Severity-rating scales such as the Conners Parent and Teacher Rating Scales, the Achenbach Child Behavior Checklist, and the Kovacs Children's Depression Inventory have an established place in research studies and can be applied in the clinical setting to add quantitative measures to the child's evaluation. These can be particularly useful

when multiple informants' assessments of the child are used.

Careful record keeping is a must. Documentation should include all relevant diagnoses and disorder-specific symptoms that are targets for medication intervention, rationale for medication selection, initial dosage and treatment plan, increases of dosages and response, documentation of discussion with parents and child regarding informed consent issues, any adverse reactions including expected adverse effects or any unexpected allergic or idiosyncratic reactions, and rationale for changing or discontinuing medications.

Appropriate medication selection requires comprehensive information about the child's history and current functioning. Medications available for use in children and adolescents have increased considerably in the past decade, and the clinician has many choices. Medication selection should always be based on efficacy and safety; in general, the best-established and least toxic agent should be tried first. If after an adequate trial the medication has not ameliorated the symptomatology, another medication or category of medications can be tried. An adequate trial is defined as a high enough dosage for a long enough duration, taking into account the child's age and size.

Pharmacotherapeutic Maintenance and Monitoring Dosage regulation requires time and experience. Plasma concentrations of some drugs are readily determined, and therapeutic ranges similar to those of adults have been found for some drugs such as the tricyclic drugs and lithium (Eskalith, Lithobid). In general, except in emergencies, it is best to start with a low dosage and raise it by small increments at regular intervals until therapeutic effect or range is reached or adverse effects appear. Once the child has been stabilized, usually after several weeks on a maintenance dosage, the maintenance phase begins. Information from teachers and other clinicians involved in the child's care must be regularly communicated to the prescribing physician. Periodic monitoring of laboratory and growth parameters is recommended.

Duration of treatment depends on the diagnosis, the child's age, the specific medication, and the clinical situation. Few fixed guidelines exist for long-term treatment, medication-free periods, and indications for discontinuation. In general, children do not respond to an agent within the expected time frame while in the therapeutic range, they are unlikely to respond at a later date. A rational approach to this situation is to switch to another drug in the same category or to another category altogether if indicated.

Most children who respond positively to a medication need a 6- to 12-month trial of the agent, depending on the clinical situation. The academic year is often used as a framework for medication treatment; if the child has improved and a trial off the agent is indicated, summertime is relatively less risky for a medication-free period. However, the child's clinical situation should be carefully reviewed before a decision is made to discontinue a particular trial; many of the disorders that respond pharmacologically in youths persist over time and may only become more symptomatic during the school year. Consideration of treatment discontinuation should weigh the risks of untreated illness.

Adverse Effects Despite their medication-handling efficiency, children and adolescents are no less at risk than adults and perhaps are more at risk in some cases for development of adverse effects (Table 48.6-1). This has both physiological and practical significance: the clinician must know the adverse effect profiles of all medications being prescribed and must know how to manage adverse effects if they arise. In addition, children and adolescents can be particularly sensitive about their bodies and how they work and often get quite frightened or suspicious if a sudden change or dysfunction occurs during pharmacotherapy. Such feelings can interfere with compliance and optimal outcome.

Table 48.6-1 Adverse Effects and Their Management in Children and Adolescents

Many of the adverse effects of antipsychotic drugs, antidepressant agents, and lithium seen in adult patients can be observed in children and adolescents. Of particular concern are the anticholinergic and cardiovascular effects of the tricyclic drugs and the extrapyramidal adverse effects of the neuroleptics, including dyskinesias. Withdrawal dyskinesias seem more frequent than tardive dyskinesia in young children, but tardive dyskinesia has been observed in this age group.

In general, the best therapy for adverse effects is preventive. It is generally best to start with a low dosage and titrate upward in a stepwise fashion as the child can tolerate. Use of the lowest possible maintenance dosages in the therapeutic range can minimize adverse effects. Monotherapy with a broad-spectrum agent is generally preferable. However, targeted combined pharmacotherapy is often necessary in children with multiple comorbid disorders. Judicious use of two or more agents in combination should not precede careful, systematic trials of single agents from two or more classes of medication as indicated by the clinical situation.

SPECIFIC AGENTS

Sympathomimetics The sympathomimetics are the most widely prescribed and best-studied psychopharmacological agents in juveniles. Methylphenidate (Ritalin), dextroamphetamine (Dexedrine), pemoline (Cylert), and a combination of dextroamphetamine and amphetamine (Adderall) are currently available for use in the United States (Table 48.6-2). Sympathomimetics are formally indicated in the treatment of attention-deficit/hyperactivity disorder, including all subtypes. Core symptoms of attention-deficit/hyperactivity disorder occur in two clusters: hyperactivity-impulsivity and inattention. Psychostimulants achieve their therapeutic effect by reducing these core symptoms including motoric hyperactivity, distractibility, inattention, and impulsivity. Stimulants also reduce aggressive behavior and impulses and improve social skills.

Drug*	Oral Dosage Range (mg/day)
Methylphenidate (Ritalin)	2.5–60
Dextroamphetamine (Dexedrine)	2.5–30
Dextroamphetamine-amphetamine (Adderall)	2.5–40
Pemoline (Cylert)	18.75–112.5

* All cause weight loss with extended use.

Table 48.6-2 Sympathomimetics Used for Attention-Deficit/Hyperactivity Disorder in Children and Adolescents

Mechanism of action involves stimulation of catecholamine activity in the CNS and peripheral nervous system; stimulants prevent catecholamine reuptake at the synaptic cleft and inhibit metabolism and breakdown. More than 160 controlled trials of stimulants have demonstrated their efficacy in reducing symptoms in most

school-age children, as well as adolescents and adults with attention-deficit/hyperactivity disorder. Highly effective, they are easy to administer and generally safe. Their effect actually is not paradoxical in that adult men and normal boys also display increased concentration and focus when given a single dose of dextroamphetamine. Stimulants appear to achieve their effects by short-term improvement of attentional difficulties and concentration; they have been reported to improve performance efficiency, work output, and peer interactions.

Because dextroamphetamine and methylphenidate have a relatively short duration of action, with peak effects between 1 and 3 hours, they must be administered in divided doses two or three times a day. They are typically given at breakfast and at noontime (or early afternoon). Pemoline and combination dextroamphetamine-amphetamine have a longer duration of action and thus can be given once a day, before school. Slow-release forms of dextroamphetamine and methylphenidate are available. Shorter-acting forms can be added to slow-release preparations in the afternoon after school to facilitate the completion of homework.

Dosage titration should be individualized. Historically, dosing was adjusted according to body weight, but more-recent research suggests an absence of correlation between weight and methylphenidate dose. Current recommendations are to use fixed-dose stepwise titration starting with low dosages (5 to 10 mg of methylphenidate or equivalent). Maximum dosages for school-age children are typically around 40 to 60 mg of methylphenidate (or equivalent); individual children may require more or less. Adolescents and adults may require higher maximal dosages. Sustained-release preparations are available for methylphenidate and dextroamphetamine.

Common adverse effects include nausea, abdominal discomfort, anorexia, and insomnia. Some have reported adverse effects on growth parameters that are reversible with discontinuation of the medication, but other evidence is contradictory. Several studies have noted decreased height and weight percentiles with long-term treatment and reduced growth velocity; however, growth tends to rebound after stimulants are discontinued. More-recent research suggests that children with attention-deficit/hyperactivity disorder may already be at risk for growth delay. Common short-term adverse effects include reduced appetite, insomnia, dysphoria, and (possibly) tics.

Some reports have documented the development of tics in children on stimulants. However, some of these youths may have had preexisting risk factors for the development of tics with or without the use of stimulants. The use of stimulants in children with Tourette's disorder is controversial. The most recent research suggests that the ameliorative effects of stimulants on the coexisting attention-deficit/hyperactivity disorder may outweigh any theoretical risk of increased tics.

Stimulants may precipitate dysphoria and mood lability in certain vulnerable children. Psychotic symptoms (including hallucinations) are rare.

Antipsychotic Agents

Dopamine Receptor Antagonists Formal indications for use of antipsychotic agents include childhood- and adolescent-onset psychoses and pervasive developmental disorders, Tourette's disorder and severe self-injurious behavior, uncontrollable agitation, or assaultive behavior (Table 48.6-3). Dopamine receptor antagonists include the phenothiazines, butyrophenones, thioxanthenes, dibenzoxazepines, dihydroindolones, diphenylbutylpiperidines, and dibenzodiazepines. These drugs function as dopamine, a-adrenergic, and cholinergic receptor antagonists in the CNS and peripheral nervous system. They have antipsychotic actions in adults and children with psychotic symptoms such as auditory hallucinations and delusions. They reduce agitation, severe aggression, and movements including motor tics and stereotypic movements.

Table 48.6-3 Antipsychotics for Use in Children and Adolescents

Overall, comparable doses of dopamine-receptor antagonists are approximately equally efficacious for psychoses. The low-potency aliphatic and piperidine phenothiazines such as chlorpromazine (Thorazine) and thioridazine (Mellaril), respectively, tend to be sedating and more anticholinergic, whereas the high-potency butyrophenones and piperazine phenothiazines such as haloperidol (Haldol) and trifluoperazine (Stelazine) tend to be less sedating but more likely to induce extrapyramidal effects such as akathisia, acute dystonic reactions, and parkinsonism.

PSYCHOSES Childhood-onset schizophrenia is rare but probably has continuity with later-onset schizophrenia. Children with psychotic disorders not otherwise specified include a more recently described subgroup with complex developmental disorders and fluctuating psychotic symptoms known as multidimensionally impaired (or multiplex developmental) disorder.

There are few controlled studies of antipsychotics in youth. T. Spencer and coworkers found haloperidol (0.5 to 3.5 mg daily) to be superior to placebo in a 10-week double-blind study in children ages 5 to 11. In a controlled study of 75 youths ages 13 to 18, B. Pool and coworkers found no difference between haloperidol (2 to 16 mg; mean, 9.8) and loxapine (Loxitane) (10 to 200 mg; mean 87.5). Those more severely ill showed somewhat greater improvement on active drugs than on placebo.

TOURETTE'S DISORDER Currently the only formally approved treatments for Tourette's disorder are haloperidol and pimozide (Orap). Several controlled studies have demonstrated that these drugs have greater efficacy than placebo. A 6-week controlled trial of haloperidol and pimozide in adults with Tourette's disorder showed equal efficacy but slightly more adverse effects with haloperidol. Since most patients with Tourette's disorder have mild-to-moderate symptoms and antipsychotic agents are associated with a relatively high risk of adverse effects, treatment alternatives should be considered, such as the a-adrenergic receptor agonists. Additionally, most Tourette's disorder patients treated in clinical settings have significant comorbidity that antipsychotic agents do not address adequately.

Common adverse effects of typical neuroleptics include sedation, weight gain, and cognitive blunting, particularly at higher doses. Extrapyramidal effects associated with typical neuroleptics include acute dystonic reactions, parkinsonism, akathisia (motor restlessness), neuroleptic malignant syndrome, rabbit syndrome, and tardive dyskinesia.

There is growing evidence that adolescents and even young children can develop antipsychotic agent–related dyskinesias. Some studies indicate that children are more likely to develop withdrawal-emergent dyskinesias that are reversible on discontinuation of the medication than tardive dyskinesia or late-appearing dyskinesias; nevertheless, tardive dyskinesia has been reported in both young children and adolescents. Recently, in a study of 34 children with childhood-onset schizophrenia who were not responsive to antipsychotic medication, 17 (50 percent) had neuroleptic-related dyskinesias, including 9 withdrawal and 8 tardive. Abnormal movements present in these children before pharmacotherapy must be differentiated from any that develop after medication treatment, with baseline and periodic AIMS examinations.

Serotonin-Dopamine Antagonists Serotonin-dopamine antagonists are indicated for the treatment of childhood and adolescent-onset psychoses. Those currently available for pediatric use include clozapine (Clozaril), risperidone (Risperdal), and olanzapine (Zyprexa). Both risperidone and olanzapine may be used as first-line treatments; clozapine should be used only as third-line treatment following failure of two adequate trials of other antipsychotic agents.

Mechanism of action includes both dopamine- and serotonin-blocking effects. Serotonin-dopamine antagonists are thought to have reduced risk for extrapyramidal effects, particularly tardive dyskinesia.

Clozapine, historically the first available serotonin-dopamine antagonist, was found effective in about 30 percent of patients with childhood-onset psychoses who had not benefited from multiple previous trials of dopamine-receptor antagonists. A double-blind controlled comparison of clozapine and haloperidol in 27 treatment-refractory childhood-onset schizophrenia patients (mean age, 14) demonstrated clozapine's (mean daily dosage 176 mg) superiority for both positive and negative symptoms. Potentially serious adverse effects included neutropenia and seizures.

Risperidone was found effective in 10 adolescents with childhood-onset schizophrenia (ages 11 to 18) at mean daily dosages of 6.6 mg for positive and negative symptoms and in 16 youths ages 9 to 20 at mean dosages of 5.9 mg a day. It was also studied openly in Tourette's disorder and was found effective in a small group of children ages 8 to 16 at mean dosages of 2 mg a day and in 31 children and adults at mean dosages of 9 mg a day. Adverse effects included fatigue and weight gain.

To date few published controlled data exist on olanzapine in psychotic youths, although studies are in progress. Olanzapine's mechanism of action is similar to that of clozapine. Daily dosages up to 20 mg may be helpful. Adverse effects include headache, fatigue, and gastrointestinal symptoms.

Antiparkinsonian Agents In general, except for the acute dystonic reactions, reduction of antipsychotic dosage is recommended before addition of an antiparkinsonian agent. If decreasing antipsychotic dosage is impossible or ineffective, then antiparkinsonian treatment is indicated (Table 48.6-4). With the high-potency antipsychotic agents, since some investigators found that the greatest risks for acute dystonic reactions occur with males under age 30 during the first few weeks of treatment, prophylactic use of antiparkinsonian agents for the first few weeks of treatment may be indicated. Acute dystonic reactions are treated with intramuscular diphenhydramine (Benadryl) or benztropine (Cogentin), followed by a switch to the oral form for 2 to 4 weeks. Any recurrence of extrapyramidal effects is an indication for further treatment.

Generic Name	Trade Name	Indications	Dosage Range (mg)
Diphenhydramine	Benadryl	Acute dystonia	25–50 i.m.
Benztropine mesylate	Cogentin	Extrapyramidol effects: parkinsonism, akathisia	1–2 i.m. 1–6 p.o. daily
Trihexyphenidyl	Artane	Extrapyramidal adverse effects	2–6 p.o. daily

EPS, extrapyramidal adverse effects.

Table 48.6-4 Antiparkinsonian Medications for Use in Children and Adolescents

Antidepressant and Antiobsessional Agents

Tricyclic Drugs Tricyclic drugs are formally established for use in children and adolescents with enuresis, attention-deficit/hyperactivity disorder, and major depressive disorder (Table 48.6-5). Additional indications for use include school refusal based on separation anxiety and sleep arousal. Imipramine (Tofranil), desipramine (Norpramin), and nortriptyline (Aventyl) have been most frequently studied in youths.

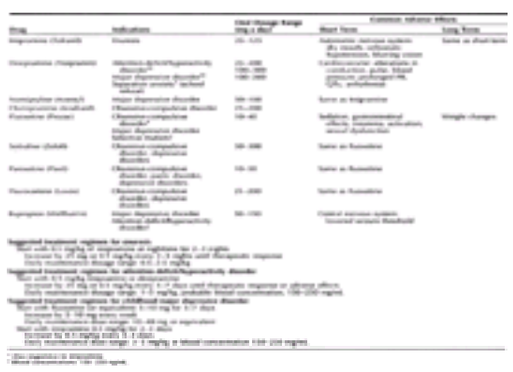

Table 48.6-5 Antidepressants for Use in Children and Adolescents

Tricyclic drugs may have several different mechanisms of action including inhibition of catecholamine or indoleamine reuptake at the receptor level in the CNS and both adrenergic and anticholinergic activity in the CNS and peripheral nervous system. Studies indicate that imipramine's effectiveness in enuresis is related to neither its anticholinergic properties nor its effects on sleep architecture but perhaps some direct effects on bladder muscles. Desipramine has been found more effective than placebo in the treatment of attention-deficit/hyperactivity disorder.

Controlled studies have failed to demonstrate efficacy of tricyclic drugs over placebo in the treatment of major depressive disorder in both children and adolescents. Diagnostic heterogeneity, small sample sizes, hormonal influences, high levels of comorbidity, neurotransmitter immaturity, and pharmacokinetic factors are among the factors proposed to account for this lack of treatment response. Open studies have shown that some children with major depression respond to tricyclic drugs in dosages that achieve concentrations of 150 to 250 ng/mL of blood.

Anticholinergic adverse effects of tricyclic drugs are common but transient and include dry mouth, blurred vision, and constipation. Antihistaminic adverse effects include weight gain and fatigue. In vulnerable individuals with a previous history of seizures, family history of seizures, or history of electroencephalographic (EEG) abnormalities the seizure threshold may be lowered.

Cardiovascular adverse effects are not infrequent, but most are not clinically significant. Small but clinically significant elevations in heart rate and blood pressure occur with tricyclic drugs. However, electrocardiographic (ECG) effects with more serious implications are possible, since tricyclic drugs have a quinidine-like effect and prolong the PR interval and can widen the QTc interval. There have been several case reports of sudden death of school-age and early adolescent children on desipramine, apparently with therapeutic dosages for treatment of attention-deficit/hyperactivity disorder or depression. Unfortunately, no data are available regarding medical, cardiovascular, and family history in these cases so these catastrophic events cannot be informatively interpreted. Nevertheless, until further data are available, it is recommended that children and adolescents who are candidates for tricyclic drugs receive careful cardiovascular evaluation and monitoring. Given the safety concerns with desipramine and the lack of demonstrated efficacy of the tricyclic drugs in general, their use as first-line treatment of major depressive disorder is not supported.

Recommendations for ECG monitoring include the following:

- Careful individual and family history of cardiovascular, neuromuscular, neurological, or other medical problems
- Baseline ECG prior to medication trial
- ECG repeated at 2 mg/kg and with dosage increments up to 5 mg/kg or therapeutic range
- Blood concentration monitoring with serum concentrations not to exceed 150 to 250 ng/mL (depending on the laboratory) ECG parameters: pulse < 120; blood

pressure < 130/90; QTc increased £ 25 percent above baseline; PR < 0.20.

Serotonin Reuptake Inhibitors SSRIs are used in the treatment of depressive disorders, obsessive-compulsive disorder, panic disorder and selective mutism. Fluoxetine, the oldest of the SSRIs, has a long half-life in adults and takes several weeks to reach clinical efficacy. A recent double-blind placebo-controlled study of 96 subjects with major depressive disorder showed significant superiority of fluoxetine over placebo.

SELECTIVE SEROTONIN REUPTAKE INHIBITORS (SSRIs) SSRIs available in the United States include fluoxetine (Prozac), sertraline (Zoloft), paroxetine (Paxil), fluvoxamine (Luvox), and citalopram (Celexa). Open studies have suggested that more than two-thirds of patients treated for major depressive disorder with SSRIs have benefited. The SSRIs act by blocking reuptake of serotonin.

In general, SSRIs are better tolerated than tricyclic drugs and have a significantly reduced risk of cardiovascular toxicity. Common adverse effects include insomnia, gastrointestinal symptoms, and behavioral activation. This class of medications has significant effects upon the hepatic cytochrome P450 oxidase system; thus when SSRIs are used in combination with other agents, a potential for adverse effects through pharmacokinetic interactions exists.

Open trials have supported the efficacy of fluoxetine and fluvoxamine in juvenile-onset obsessive-compulsive disorder. Fluvoxamine was recently found to be more effective than placebo in a multicenter study of 120 children and adolescents with obsessive-compulsive disorder.

NONSELECTIVE SEROTONIN REUPTAKE INHIBITORS Clomipramine (Anafranil) is a nonselective serotonin reuptake inhibitor and tricyclic drug with antiobsessional properties. It has been studied in children and adolescents with obsessive-compulsive disorder and has been found to be more efficacious than placebo. Because of its tricyclic structure, it has the same potential adverse effects as the other tricyclic drugs; cardiovascular monitoring is necessary.

Other Antidepressants Bupropion (Wellbutrin), an aminoketone unrelated to the tricylic drugs, has antidepressant properties. Not formally approved for patients under 18, it has been studied in the treatment of attention-deficit/hyperactivity disorder. Nefazodone (Serzone) was reported to be beneficial in a small open study of depressed children.

Experience in the United States with monoamine oxidase inhibitors in children and adolescents is extremely limited, particularly in the prepubertal child. Due to their potential for toxicity, these medications are difficult to prescribe for most youngsters. Some adolescents with atypical depressive features or phobias may be candidates.

Anxiolytics and Sedative-Hypnotics Historically, anxiolytics and sedative-hypnotics have been used for a number of childhood and adolescent neuropsychiatric disorders such as night terrors, insomnia, and anxiety (Table 48.6-6). Unfortunately, to date, there have been few controlled studies of anxiolytic drugs, despite the prevalence of sleep and anxiety disorders in juveniles. Concerns about the diagnostic validity of pediatric anxiety disorders and adverse effects of benzodiazepines have contributed to the lack of studies of these agents.

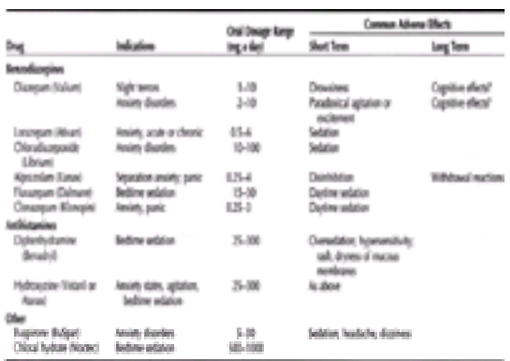

Table 48.6-6 Anxiolytics and Sedative-Hypnotics Drugs for Use in Children and Adolescents

Indications for use of benzodiazepines include sleep disorders, anxiety symptoms or disorders causing significant distress or impairment, and augmentation for other medication used in the treatment of mood and anxiety disorders, such as SSRIs. Night terrors (pavor nocturnus), a sleep disorder in young children during non–rapid eye movement sleep, frequently on arousal from stage 3 or 4 to lighter sleep stages is characterized by awakening in terror with physiological arousal. Although no controlled studies have been conducted, open reports have suggested beneficial response to low-dose diazepam (Valium).

In the nonpsychotic, non–substance-using adolescent population, benzodiazepines can be useful in short-term treatment of anxiety disorders that cause significant distress or impairment. Jovan Simeon and coworkers reported that alprazolam (Xanax) was superior to placebo in a double-blind study of 30 youths with overanxious and avoidant disorders. Though the results did not reach statistical significance, global clinical improvements were observed. K. Graae and coworkers in 1994 treated 12 youths (mean age 9.8 years) with mixed anxiety disorders with clonazepam (Klonopin) or placebo in an 8-week double-blind crossover study. Most children were rated as improved on clonazepam compared with placebo, but the results did not reach statistical significance.

Adverse effects of benzodiazepines include fatigue, dysphoria, and disinhibition. Cognitive effects have not been systematically assessed but are potentially problematic in use of the benzodiazepines.

Buspirone (BuSpar), a nonbenzodiazepine anxiolytic agent, is a partial serotonin (5-hydroxytryptamine [5-HT]) type 1a (5-HT $_{1A}$) agonist. It does not have muscle relaxant or anticonvulsant properties, nor is it likely to cause dependence. It has been used adjunctively with SSRIs in the treatment of obsessive-compulsive disorder and mixed depression-anxiety states. No controlled studies of buspirone in youths have been done, but a few open reports exist of use in separation anxiety disorder and mixed anxiety disorders. Adverse effects include headaches, tiredness, and gastrointestinal symptoms. Cognitive effects and abuse potential are minimal, especially compared with the benzodiazepines.

Mood Stabilizers

Lithium Mood stabilizers are indicated in children and adolescents with bipolar disorders. Lithium, historically the first studied for bipolar I disorder in adults, has been studied far less extensively for bipolar I disorder in youths (Table 48.6-7). Lithium is effective for both treatment of acute mania and for prophylaxis or augmentation in youths at serum concentrations of 0.6 to 1.4 mEq/L. Children with periodic or cyclic disturbances of behavior and mood, children with such disturbances who have relatives who were lithium responsive, and children with severely aggressive behavior disorders may also be lithium responsive. Plasma concentrations should be monitored regularly. Concentrations of 0.6 to 1.2 mEq/L are in the therapeutic range, but some patients may require higher levels for therapeutic efficacy. Kidney, endocrine (thyroid, calcium), and cardiac function must be monitored regularly.

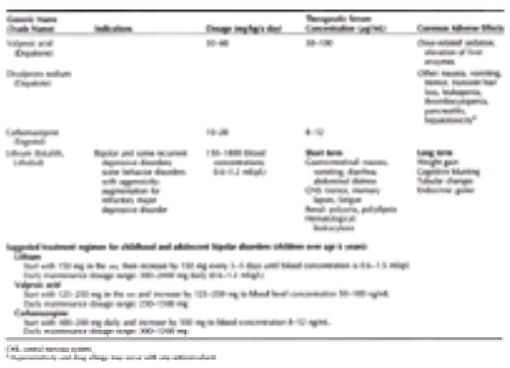

Table 48.6-7 Mood Stabilizers for Use in Children and Adolescents

Anticonvulsants In recent years, valproic acid (Depakene) or divalproex (Depakote) and carbamazepine (Tegretol) have been used to treat bipolar disorders in adults, and divalproex was recently approved by the FDA for bipolar I disorder in adults. As adult data and usage have accumulated, experience with these agents in children and adolescents has also grown. Open studies of valproic acid have shown beneficial effects in youths at dosages that give a serum concentration of 50 to 100 mg/mL. Valproic acid is being used as a first-line treatment for childhood and adolescent bipolar I disorder in clinical practice. Adverse effects include gastrointestinal symptoms and particularly hepatotoxicity, fatigue, tremor, and blood dyscrasias.

Carbamazepine, used for acute mania and rapid-cycling bipolar I disorder in adults, is a third-line option for youths. There are no controlled studies of carbamazepine for bipolar disorder, but it has been used openly in diagnostically heterogeneous children with behavior disorders. Adverse effects include blood dyscrasias, gastrointestinal symptoms, and neurotoxicity.

a-Adrenergic Receptor Agonists and b-Adrenergic Receptor Antagonists In recent years, other drugs available to the adult practitioner have been investigated in the pediatric and adolescent population. The b-adrenergic receptor antagonist propranolol (Inderal) has been found useful in some young patients with uncontrollable aggressive behavior, those with lithium-induced tremors, and those with certain anxiety states that have physiological symptoms such as posttraumatic stress disorder. b-Adrenergic receptor antagonists are contraindicated in diabetic patients, asthmatic patients, and patients with cardiac disease.

The a-adrenergic receptor agonist clonidine (Catapres) has been found useful in some studies in the treatment of Tourette's disorder and attention-deficit/hyperactivity disorder. Some evidence indicates that it is useful in decreasing the motor and verbal tics and associated attentional problems, hyperactivity, and lability of mood. Children who appear to be good candidates for the use of clonidine for attention-deficit/hyperactivity disorder are those with highly aroused impulsive characteristics; clonidine ameliorates these symptoms but may not be quite as efficacious for the cognitive effects of the disorder such as inattention and distractibility. An alternative is guanfacine (Tenex), a longer-acting a-adrenergic agonist that may be less sedating.

SUGGESTED CROSS-REFERENCES

Mental retardation is discussed in Chapter 34, pervasive developmental disorders in Chapter 38, disruptive behavior disorders in Chapter 40, tic disorders in Chapter 42, elimination disorders in Chapter 43, selective mutism in Section 46.4, and stereotypic movement disorder in Section 44.2. Psychiatric treatment of children is covered in Chapter 48. Personality assessment of adults and children is discussed in Section 7.5 and the neuropsychological and intellectual assessment of children in Section 7.4. Schizophrenia is discussed in Chapter 12, mood disorders in Chapter 14, anxiety disorders in Chapter 15, sleep disorders in Chapter 21, and biological therapies in Chapter 31.

48.7 PARTIAL HOSPITAL AND AMBULATORY BEHAVIORAL HEALTH SERVICES

LAUREL J. KISER, PH.D., M.B.A., JERRY D. HESTON, M.D. AND DAVID B. PRUITT, M.D.

Partial hospitalization has been used historically as an umbrella term describing many varieties of alternative care. With the advent of managed care and health care reform, less costly and less restrictive treatment modalities are in increasing demand. To define these alternatives, which stretch along the continuum of psychiatric care between inpatient and outpatient office visits, three levels of ambulatory behavioral health care have been outlined. In this new environment, partial hospital programs (PHPs) are providing short-term, crisis-stabilization services as an alternative to inpatient care. Day treatment programs (DTPs) are serving the needs of children and adolescents with moderate-to-severe disorders who require interventions focused on improved level of functioning, skill-building, and disease management. Intensive outpatient programs (IOPs) function as intermediate or step-up programs from outpatient psychotherapy.

In the behavioral health delivery system, ambulatory behavioral health care (partial hospital, intensive outpatient services, etc.) is analogous to outpatient surgery. These services represent a specific segment along the continuum of care and are more intensive than outpatient services without the iatrogenic effects of hospitalization. Ambulatory behavioral health care services strive to provide intense, highly structured treatment. They do so by utilizing a variety of therapeutic modalities: individual, group, and family therapy; educational or vocational therapy; recreation and activity therapy; as well as medical and nursing services. This multimodal treatment requires an interdisciplinary staff typically drawn from psychiatry, psychology, social work, educational or vocational therapy, occupational or recreational therapy, and nursing. A working definition of ambulatory behavioral health care follows:

> Ambulatory behavioral health care is a time-limited, active treatment offering therapeutically intensive, coordinated, and structured clinical services that incorporate the benefits of a therapeutic milieu within a program and/or within the home/community.

HISTORY

The history of ambulatory behavioral health care for children and adolescents is brief. The first partial hospital programs were for adults in Russia in the late 1930s, Canada in the late 1940s, and England in the early 1950s. The Menninger Clinic introduced the concept to the United States when it opened its unit in the mid-1950s. In 1963 the Community Mental Health Center Act mandated comprehensive services including partial hospital care for children and adolescents. This movement had three main origins: deinstitutionalization, interest in the role of family and community, and movement to cost-effective treatment alternatives

Throughout the 1970s and 1980s and into the present, the modality has been severely underutilized. With only 2 percent of those in need of treatment receiving services in PHPs and the majority of programs operating below 75 percent capacity, underutilization is a major problem for the survival of many programs.

Three clinical issues contribute to underutilization of partial hospitalization. Firstly, providers find it difficult to serve moderately to severely disturbed children and adolescents in an open system with less restrictiveness and a less structured environment. Secondly, families need to make major commitments to family therapy, transportation, and to keeping a difficult child at home. Thirdly, for referral sources who are more accustomed to and better trained to treat severely dysfunctional patients in inpatient programs, a shift in the style and conceptualization of clinical practice is required.

Historically, other factors related to low utilization of partial programs include a lack of definition, criteria, and outcome data with consequent funding limitations. Reimbursement policies serve as a major impediment to wider use of partial hospital services. Traditionally, the vast majority of policies with mental health care benefits had better coverage for inpatient than outpatient services, and no coverage for partial hospitalization services. Therefore, instead of treating the child in the least restrictive, least expensive environment, the clinician and family were forced to utilize more restrictive, more expensive programs. Finally, the nature of the health care industry during the 1980s favored the creation of new hospital beds rather than partial hospital programs. Current industry trends, however, promise major changes in the service delivery system.

In the 1990s the emphasis of health care delivery returned to cost containment with increased interest in community, family-based alternatives, managed care, systems of care, and accountability. Managed care focuses on eliminating unnecessary inpatient services with the efforts directed toward development of systems favoring outpatient practices. Although early indications from managed care pointed to their desire to ensure quality and efficiency, fiscal management frequently translates into either rationing care or providing the cheapest services for the shortest length of time possible regardless of clinical decision-making and effectiveness data.

These trends have created major shifts in the delivery and funding of behavioral health care, including growth in the use of ambulatory behavioral health care, increased utilization of immediate, short-term partial hospital care for patient stabilization, and rapid development of a variety of intensive outpatient treatment options. New funding opportunities for ambulatory services include passage of federal regulations offering partial hospital services to Civilian Health and Medical Program of the Uniformed Services (CHAMPUS) enrollees, and the development of more inclusive and flexible benefit and payment plans.

However, severe pressures for cost containment are pushing some managed care organizations toward viewing partial hospital care in a similar light as inpatient care. These companies have begun applying medical necessity criteria to PHPs that are similar to those used for inpatient and approving only brief lengths of stay (3 to 7 days). Cost containment pressures are also driving the development and utilization of less intensive options, such as IOPs or multi-modal outpatient treatment. Approvals for care at this level are sometimes based on cost without adequate consideration of the treatment needs of the adolescent or child.

THEORETICAL ISSUES

There are six essential principles of care upon which the continuum of ambulatory mental health services derives its foundation:

1. Services are designed for children and adolescents who present with a psychiatric or substance dependence diagnosis and the need for treatment more intensive than outpatient office visits and less restrictive than 24-hour care.
2. Services provide a coordinated array of active therapies determined by an individualized treatment plan and based upon a comprehensive evaluation of patient needs.
3. Patients are treated in a manner that simulates real-life experience with the least amount of disruption to normal daily functioning (allowing for optimal transfer of therapeutic benefits to the natural environment).
4. Services require active involvement of the child or adolescent and the family.
5. Services are available on a consistent basis, augmented with 24-hour crisis back-up.
6. Services are cost-efficient.

From these six essential principles, two basic philosophies of care provide the core for child and adolescent ambulatory behavioral health services. Firstly, these services provide treatment to patients requiring intensive therapeutic intervention with the least amount of disruption to their normal daily functioning. This requires ambulatory services to define the limits between when patients can be treated safely in an outpatient setting and when they require the restrictiveness of hospitalization. Thus, ambulatory behavioral health services are designed to maintain a balance between treatment in the least restrictive environment and risk management.

Secondly, ambulatory behavioral health care encourages providers to take advantage of the open system inherent in the modality. This philosophy emphasizes the use of family supports and strengths and community agencies and programs. This philosophy of care has two major sequelae. Ambulatory services invite the patient and the patient's family to maintain a higher level of functioning than treatment settings that remove the patient from the home. Philosophically, this translates into a program of therapeutic interventions designed to maintain power within the parental or familial subsystem and to view that subsystem as competent in providing care for the child. Interventions are structured to alter dysfunctional patterns of interaction rather than to remove the child from these interactions. Translated into program policy, ambulatory behavioral health programs only use techniques and treatment strategies that a family can also implement at home.

Additionally, ambulatory programs promote reliance on community support systems and programs whenever possible. Benefits of this approach include limiting the development of dependence on the treatment team, expansion of and appropriate use of resources, decreased lengths of stay, and improved adjustment following discharge. This unique combination of providing “security and structure while simultaneously promoting patient responsibility and autonomy” may be the particular advantage of this modality.

The goals underlying ambulatory behavioral health care can be met in programs with a variety of theoretical orientations. Behaviorally oriented programs utilize principles of learning theory. Consequently, the goals of a behavioral program are to teach desirable behaviors and to extinguish undesirable ones. For example, the majority of partial hospital programs, although not operating from a behavioral orientation, use some form of level system for consequent patient behavior. Psychoanalytic programs focus on structuring a therapeutic environment in which behaviors and other symptoms are analyzed and interpreted. Another approach uses a psychoeducational orientation with the classroom as the basic structure for program design. “Students,” rather than “patients,” usually receive psychotherapy in conjunction with classroom instruction. Programs using systems theory emphasize the theoretical proposition that many different areas of a child's life influence functioning: biological, intrapsychic, family, peers, school, work, neighbors, religious affiliation, and others. Within a systems orientation, programs are challenged to assess problems and intervene on a multilevel basis. Some programs are based on a medical model in which all patients receive psychiatric diagnoses and treatment is prescribed by a child and adolescent psychiatrist.

These orientations differ in the manner in which they view the child, the child's problems, and the treatment program. Although many theoretical orientations are possible, within an organization the model used should be consistent across the continuum of care. Conflicting models established between components of care may cause confusion for the staff as well as the patient and family.

GOALS OF TREATMENT

The clinical functions of ambulatory behavioral health care differ according to the level of care offered. Partial hospitalization, and other intensive nonresidential treatment options function to provide short-term crisis intervention as an alternative treatment to hospitalization or an intensive transition setting to shorten a hospital stay. Less intensive ambulatory modalities provide support, maintenance, symptom reduction, and skill-building to prevent relapse, longer-term hospitalization, or residential care. Finally, multimodal outpatient services provide a step up for patients for whom one or two office visits per week are insufficient. Another goal or function of ambulatory behavioral health services can be extensive evaluation involving observation, identification of problem areas, diagnosis, and formulation of treatment plans.

CLINICAL ISSUES

Indications The need for ambulatory behavioral health services to define target populations is essential for continued viability of the modality. The continuum of ambulatory behavioral health care represents three levels of care, each of which targets populations with differing needs. Admission decisions are based on matching interventions and services with the needs of the patient in terms of intensity, structure, and accessibility.

Treatment organizations define their target population by establishing admission criteria. From this programmatic standpoint, evaluation to determine appropriateness for ambulatory behavioral levels of care involves the following five factors: (1) psychiatric signs and symptoms, (2) level of impulse control, (3) level of functional impairment, (4) parental support, (5) physical health, and (6) ability to pay. Specific criteria for the three levels of ambulatory behavioral health care are presented in Table 48.7-1.

Criteria	Level 1	Level 2	Level 3
Psychiatric signs and symptoms	Current diagnosis; severe to disabling symptoms related to acute or chronic condition.	Current diagnosis; moderate to severe symptoms related to acute or chronic condition.	Current diagnosis; moderate symptoms related to acute or chronic condition.
Level of impulse control	Limited control of suicidal, homicidal, runaway ideation, and abuse of drugs or alcohol with high risk for confinement.	Moderate control of suicidal, homicidal, runaway ideation, and abuse of drugs or alcohol with some risk of confinement.	Good control of suicidal, homicidal, runaway ideation, and abuse of drugs or alcohol with low risk for confinement.
Level of functional impairment	Severe difficulty functioning in multiple areas including school, social activities, community, and home.	Marked difficulty functioning in one or more areas including school, social activities, community, and home.	Moderate difficulty functioning in at least one area including school, social activities, community, and home.
Parental support	Able to provide adequate control and support at home during evenings/weekends with close monitoring and frequent assistance from staff.	Able to provide adequate control and support at home during evenings/weekends with monitoring and assistance from staff.	Able to provide adequate control and support at home during evenings/weekends with intermittent monitoring and assistance from staff.
Physical health	No requirement for 24-hour medical care.	No requirement for 24-hour medical care.	No requirement for 24-hour medical care.
Ability to pay	Economic resources available to support care at this level.	Economic resources available to support care at this level.	Economic resources available to support care at this level.

Table 48.7-1 Admission Criteria for Child and Adolescent Ambulatory Behavioral Health Care

As pressures increase to manage children and adolescents with unstable, crisis presentations in less restrictive settings, it is critical for providers to develop decision-making tools for patient placement that take risk management into account. For child and adolescent providers, family or community support and structure become a major factor in the decision-making process. A decision matrix, assessing level of impulse control and parental support and structure, is a valuable tool for assessing appropriateness for admission (Fig. 48.7-1). Level of impulse control can be viewed along a continuum with some patients demonstrating no problems and other patients requiring a structured, locked treatment environment due to severe problems with behavior control. On the other axis, the continuum of family functioning (support and commitment to treatment) is evaluated. It is expected that families will work with the treatment team to encourage their child to comply with program limits. Families who are unable or unwilling to participate in this manner are less likely to provide the daily support and structure needed by the patient, who is therefore unlikely to derive significant benefit from treatment in an ambulatory behavioral health care setting.

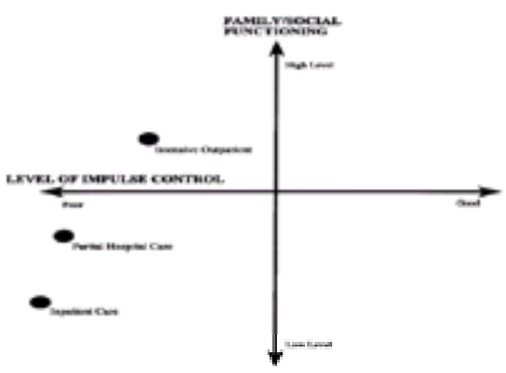

FIGURE 48.7-1 Decision matrix: risk management assessment. (Adapted from Kiser LJ, Heston JD, Millsap PA, Pruitt DB: Testing the limits: Special treatment procedures for child and adolescent partial hospitalization. Int J Partial Hosp *7:*39, 1991.)

Program of Therapeutic Activities The clinical components, that is, each patient's daily activities, are based upon an individual treatment plan developed by the treatment team. Continuous monitoring of the patient's response to treatment dictates alterations in this plan. Therapeutic progress is monitored frequently by the multidisciplinary staff and periodically a treatment update is prepared and the patient's case is reviewed by the entire treatment team. Progress to date on problems is reviewed, new problems are discussed, and progress towards transition to a less intensive level of care or discharge is monitored. A distinguishing characteristic of ambulatory behavioral health care is the intensity of diverse clinical components. These components most often include individual, group, family, medical management, activities, and education.

Individual Individual therapy is offered by most ambulatory behavioral health providers in the United States, usually on a weekly or semiweekly basis with a mean of 1.60 hours per week. Like individual therapy in other settings, it provides the patient with an opportunity to develop a close, interpersonal relationship with an adult other than a parent and an opportunity to work on intrapsychic problems.

Individual therapy in ambulatory behavioral settings differs from outpatient individual psychotherapy because of the wealth of information available to the therapist through contacts with or observations of the patient in other parts of treatment. An example of this occurs in a partial hospital setting when a depressed child denies withdrawal from peers but is frequently observed sitting alone during milieu periods. Differences between individual psychotherapy in ambulatory and inpatient settings are also significant and mainly result from the openness of the ambulatory system. Individual therapy in ambulatory behavioral health care can utilize material from daily encounters with parents, siblings, and peers to address dysfunction in these areas.

Group Group psychotherapy plays an important role in ambulatory behavioral health settings by allowing peers to develop the ability to deal with problems through the expression of feelings and experiences in a safe environment. This therapy also provides an opportunity for work on group dynamics, including cohesion, roles, and norms. As with all group work, it is important that the structure and content of the group be appropriate for the developmental levels of the patients involved. As with individual therapy, therapists in ambulatory behavioral health care have direct knowledge about patient functioning in multiple areas, thus allowing immediate and specific feedback to the group members.

Family The use of family therapies by many programs is consistent with the research demonstrating that family structure is predictive of successful completion of treatment and follow-up. Family involvement in treatment may take a variety of forms, including traditional family therapy, multifamily groups, parent education classes, parent support groups, marital therapy, and in-home services.

Family therapy provides an opportunity to focus on family dynamics in order to facilitate change in the home environment. Within ambulatory behavioral health care this therapy allows intensive work on family conflict and family structure on a day-to-day basis. Because patients remain part of the family while participating in treatment, new skills can be practiced and evaluated continuously. Another important benefit of family therapy in ambulatory behavioral health care is the ability to establish consistent rules and limits for the child both at home and in treatment. Work with the family and community helps to extend the therapeutic benefits of treatment into the patient's overall familial and social milieu. Finally, one powerful difference between family treatment in this modality and that of an inpatient unit is the emphasis on maintaining parental authority. For example, in partial hospitalization parents are involved in every level of decision-making and problem-solving; parents are in effect viewed as co-therapists.

Therapeutic Activities The extent of therapeutic activities, such as recreation and leisure skill-building, and also the availability of a programmatic therapeutic milieu is dependent on the structure and intensity of the services offered. However, at all levels of ambulatory behavioral health care, providers emphasize the development of an active, therapeutic milieu. In ambulatory behavioral health services that do not incorporate a programmatic milieu, the treatment plan prescribes active interventions to extend milieu-based therapeutic benefits to the home, workplace or school, and community, as needed. Recreation, movement, art, occupational, and milieu therapies, as well as community-based activities, provide staff and peer support for appropriate behavior in social settings. Patients learn constructive ways to use leisure time in activities that foster team work, cooperation, and task commitment. Frequent involvement in community events is consistent with the ambulatory behavioral health care belief that children and adolescents should remain active members of the community.

Education Just as much of a child's life revolves around school and related activities, much of the intensive treatment for children and adolescents revolves around school issues and educational therapy. Different ambulatory services meet the needs for educational services in very different ways. Intensive, full-day programs offering a school component provide a minimum of 3 hours of education daily. Short-term programs with lengths of stays under 2 weeks may provide educational experiences based upon a homebound model. Finally, less intensive ambulatory services, such as after-school programs or IOPs, may simply focus on enhancing school performance by offering tutoring or study skills. Regardless of the level of care offered, ambulatory behavioral health care providers utilize the treatment environment to help children to deal appropriately with the frustrations encountered in the school setting, including dealing with authority and assuming responsibility for work. They also understand the importance of schooling in the lives of children and adolescents and thus view active school liaison as a major component of treatment. Obtaining fiscal support for the educational portion of treatment is an area of concern, with piecemeal funding often necessary and with programs thus required to meet several sets of standards and answer to several local and state agencies.

Medical Management The extent of medical involvement in the management of patients in ambulatory behavioral health care varies depending upon the intensity and theoretical background of the program. Medical involvement within ambulatory behavioral health care ranges from medical supervision for patients with unstable, crisis needs to medical consultation for patients with low levels of risk and only moderate symptoms.

Recent trends are toward emphasizing aspects of the medical model in the most intensive ambulatory services such as partial hospital programs. As various forces work toward decreasing rates of hospitalization for children and adolescents, more severely disturbed patients and those with combined medical and psychiatric disorders will be referred to partial hospital programs. In such programs psychiatrists function as attending physicians and members of the treatment team. Under this model the physician can be seen as the team leader, orchestrating the treatment provided. The use of George Engel's biopsychosocial model of medical practice is particularly congruent with the philosophy of ambulatory behavioral health care. Physician involvement is not limited to the specifics of medical management, but includes substantial input into program administration and direction. The cost disadvantage may be counteracted by the preference of insurance companies and Medicaid to reimburse for medically directed services.

Thus, within programs offering short-term symptom reduction and crisis stabilization, medical management includes an assessment of the patient's general medical condition and behavioral health status. Both medical and psychiatric diagnoses are assigned. This may require direct physical examinations done by a physician associated with the program or, in programs that are more community-based, consultation and liaison with the patient's primary care physician or pediatrician. It is the responsibility of nurses and physicians to identify specific health problems that may be important factors in the overall functioning of the patient. These problems may be treated directly or referred to a community physician. Referrals often serve to educate and guide families on accessing needed health care services and on how to use these resources effectively.

Pharmacotherapy, another aspect of medical management, may be practiced within the structure of ambulatory behavioral health care with advantages over other therapeutic settings. As on an inpatient unit, observations from multiple viewpoints are available to determine specific indications for medications. The ability to monitor new medications or changes in regimens is augmented by daily contact with the patient and information about the patient's status in many different activities. This use of medication within a structured environment is frequently seen as an advantage over medication management developed on an outpatient basis. Also, in distinction to an inpatient hospitalization, the family is able to provide or learn to provide ongoing feedback about medication response, adverse effects, compliance, or other concerns about medication.

In programs that are designed as intensive outpatient services, psychiatrists may be contracted to function as consultants to provide specific, limited services. These services typically include initial psychiatric evaluation and diagnosis as well as the monitoring of pharmacotherapy. The psychiatrist is not a part of the treatment team and is usually not involved in the day-to-day care of the patients or administration of the program. Although the advantages of this model are financial and logistical, saving the program the cost of a full-time specialist in a profession that is relatively undersupplied, the main disadvantage is the lack of physician input into the overall treatment of patients.

Finally, as managed care grows and continues to influence psychiatric care, physicians may be expected to help programs, patients, and their families negotiate appropriate financial coverage for treatment. This assistance may come in clarifying diagnoses and outlining treatment options. Frequently physicians in ambulatory behavioral health care are called upon to participate in physician-to-physician reviews of cases that have been tagged as questionable by the managed care company. The psychiatrist will be called upon to document rationale for treatment in ambulatory behavioral health care and should be familiar with medical necessity

criteria and effective arguments for obtaining treatment appropriate to the specific needs of each patient.

Special Populations Proponents of ambulatory behavioral health care suggest that it is a viable treatment mode for many special populations (e.g., juvenile offenders, patients with eating disorders, and abusers of alcohol and drugs) as well as for nonpsychiatric populations (e.g., those with head trauma, epilepsy). Several reports of PHPs designed for adolescent offenders or adolescent antisocial behavior have appeared in the literature. Treatment emphasis for offenders appears to be intensive group therapy and social, recreational, and special educational services with generally positive outcomes noted for these teens who are known to be very difficult to treat.

Another special population described in the literature is preschoolers. Preschool PHPs and therapeutic nurseries for young children place special emphasis upon play, communication and language, socialization, skill-development, and parent-child interaction. Young children benefiting from treatment in a therapeutic preschool include those with developmental delays, victims of physical and sexual abuse, as well as other severe emotional/behavioral disturbances.

Health care reform and the interest in development of cost-effective treatments has resulted in programs that address the psychosocial as well as physical needs of chronically ill pediatric patients. Certain patients with eating disorders, sickle cell disease, asthma, diabetes, and other disorders may benefit from specialized treatment in ambulatory settings that incorporates health care professionals from appropriate pediatric specialties.

Limitations and Complications As various theoretical, ethical, economic, and other factors continue to discourage the use of hospitalization, ambulatory providers will be challenged to manage patients whose behavioral symptoms and impulsivity have escalated to the point that special treatment procedures are indicated. Policies and procedures for dealing with patients displaying aggressive, acting-out behaviors, noncompliance with program rules, and suicidal or runaway ideation are a necessary part of programming. Special treatment procedures designed for use in child and adolescent ambulatory settings must adequately address the issue of safety and involve the family and the community while maintaining the patient in the least restrictive environment.

Management of acutely and severely disturbed patients necessitates policies that address seclusion, physical holding, and restraints. Often PHPs simply do not offer these services on the basis that they are appropriately utilized only on inpatient units. Other child and adolescent PHPs use quiet room and physical holding policies that do not violate the mandate of the program, that is, procedures that can also be used by parents or guardians in the home environment. The quiet room and physical holding are used sparingly with adolescents; immediate transfer to a secure facility may be indicated for an aggressive or acutely psychotic, disruptive adolescent. Manual and chemical restraints are typically not used in PHPs or other ambulatory settings.

Just as programs must develop policies that are compatible with the program's theoretical basis and intensity of treatment to help patients control their behavior, they must address similar issues with other problems both within the treatment setting and at home. For example, PHPs may be able to treat patients with significant suicidal ideation if they are able to maintain appropriate levels of observation and plan for continued supervision after program hours using family therapy, telephone contact, beeper services, or other interventions. Runaway patients may similarly be placed in ambulatory treatment with policies for structure after hours and the ability to liaison with community resources such as runaway homes or other community emergency shelters. Thus, intensive programs that are designed to serve as alternatives to inpatient treatment are able to treat severely disturbed patients using policies that address program structure, family resources, and community involvement.

Because of the intensity of programming, the developmental level and the severity of illness of patients treated, and the lack of restrictiveness, most ambulatory behavioral health care services operate with very low staff-to-patient ratios. Obviously the level of staffing required is dependent on the intensity of care offered and the degree of disturbance within the target population. Within PHPs, a typical ratio is one staff person to fewer than four patients, with a recommended range from 1:3 through 1:6. For afterschool programs or IÒPs, a staff-to-patient ratio of 1:8 to 1:10 is probably sufficient.

Even with small staff-to-patient ratios, the high intensity of the programs results in staff stress and burnout. A fuller explanation lies in the philosophy of the approach: maintaining severely affected patients in the least restrictive environment.

Crisis Management and Hospital Liaison Ambulatory behavioral health care services that attempt to shorten or eliminate hospitalization must have adequate policies and procedures to handle the emergencies that prompt immediate admission to treatment and the inevitable crises that develop during treatment. Specific details of crisis management should be identified by each ambulatory behavioral health service depending upon the level of care offered. At the most intensive level, ambulatory providers should have an integrated emergency system that allows immediate access to current clinical and treatment information. The following recommendations meet these crisis management needs: (1) an on-call child and adolescent psychiatrist available 24 hours per day, 365 days a year; (2) additional on-call services to help families resolve conflicts that do not require hospitalization or major changes in treatment plans, staffed primarily by partial hospital professionals; and (3) an established affiliation with both pediatric and psychiatric inpatient units. In the case of hospital-based programs this should be addressed in policies regarding transfer between PHPs and inpatient units. In free-standing PHPs formal affiliations with hospitals must be made so that admissions can occur quickly and safely for patients with acute emergencies.

Less intense ambulatory programs must also develop emergency plans. These might include policies to admit patients to the PHP within a number of days and consultation with a psychiatrist to assist with decisions regarding emergency management and possible hospitalization. Coverage of crisis situations while a child or adolescent is in care can be handled by a 24-hour crisis call service.

DISCHARGE AND AFTERCARE SERVICES

As integrated systems of care for child and adolescent become more prevalent, planning transitions between levels of care often replaces discharge planning for ambulatory services. Transition or discharge planning remains an integral part of treatment planning, beginning during the initial intake and continuing throughout the treatment process as transition or discharge goals are formulated and clarified. During the course of treatment, progress toward transition or discharge is continually monitored by the treatment team with input from the patient's family.

The following principles govern the planning process: (1) patients receive treatment in the least restrictive environment that provides the structure and intensity necessary; (2) patients receive treatment for the shortest time possible in order to reach maximum treatment benefit; and (3) planning is done in a fashion that maximizes a successful transition to the patient's new setting (either more or less structured). Thus transition or discharge planning involves attention to issues of termination, liaison with community resources (inpatient settings, school settings, etc.), and follow up to encourage compliance with transition recommendations. The case of Tammy, a 16-year-old, African-American girl admitted to a PHP following a suicide attempt, is presented to illustrate the use of partial hospitalization in emergency care.

Tammy was first seen in a pediatric emergency room on a Saturday morning by a psychiatry resident who determined that, although she had continued suicide ideation, she did not have a specific plan and could be treated without hospitalization. Over the weekend the resident contacted Tammy and her family twice by phone and arranged for her to be admitted to a partial hospital program on Monday morning. During her first few days in the program she was monitored closely by the staff and her suicide potential was evaluated at the end of each day by the medical director. During the first week her suicide ideation resolved in response to the support and structure of the program. At the end of her second week in the partial hospital program she was stabilized, started on antidepressant medication, and transitioned to outpatient family and group therapy following stated commitments to follow up by the patient and her parents. The use of partial hospitalization prevented a psychiatric inpatient admission for this acutely symptomatic adolescent.

Other aspects of ambulatory behavioral health care are highlighted in the case of Jamie, a 15-year-old boy who was transitioned to a medium-intensity day treatment program. During a hospitalization for a life-threatening suicide attempt, his family's managed care company decertified his admission saying he was no longer at acute risk for suicide. Due to continued serious depressive symptoms and chronic family dysfunction, he was determined to be inappropriate for routine outpatient management. He was admitted to a day program with a strong family systems orientation. Over the course of his 8-week treatment he was able to develop a therapeutic alliance with his individual therapist, and significant family restructuring was accomplished. The consulting child and adolescent psychiatrist managed Jamie's medication and regularly monitored his suicide potential. At the end of 8 weeks, his depressive symptoms were decreased to the extent that he could transition to outpatient therapy and return to school successfully. This use of the ambulatory behavioral continuum allowed for prompt discharge from the hospital with continued consolidation of progress in a highly structured system.

RESEARCH AND EVALUATION

As partial hospital and intensive outpatient services play a more central role in behavioral health care delivery, it is critical to establish quality standards and to differentiate these services offered from other services currently on the market. In order to provide a summary of ambulatory behavioral health care's indications and limitations, the advantages and disadvantages of the modality are presented in Table 48.7-2.

Table 48.7-2 Advantages and Disadvantages of Ambulatory Behavioral Health Care for Children and Adolescents

Quality of Care Partial hospital and other nonresidential hospital alternatives share many common treatment goals and techniques and differ in important ways from both inpatient treatment and outpatient office visits. Accordingly, the measurement of quality in this modality presents some unique challenges. Using the underlying philosophies, the unique therapeutic aspects, the distinctive treatment procedures as well as the historical problems and promises of the field, specific quality indicators can be formulated.

Several specific quality indicators of effectiveness for partial hospital and intensive outpatient services include valid and accurate admission criteria, standards of care, and low negative, critical treatment incidents. As an alternative treatment modality, it is incumbent upon partial hospital and other ambulatory behavioral health services to establish admission criteria that reliably and validly discriminate between patients who need intervention at a more intensive level than outpatient visits yet at a less restrictive level than 24-hour care. Having targeted an appropriate patient population, the standardization of services rendered as well as special treatment procedures needs to ensure that the care offered provides the safety and security necessary to provide intensive treatment in a nonresidential setting.

Additional unique quality indicators include specific aspects of cost efficiency and patient satisfaction. Providing intensive treatment within a nonresidential environment mandates the use of outside resources and the reliance on strengths within the family and community for augmenting treatment, both of which translate into cost-efficient care. For ambulatory behavioral services, two specific areas of patient satisfaction become applicable: the patient's feelings regarding receiving treatment as an outpatient and the family's sense of contentment with their role in the treatment process.

Finally, for all ambulatory providers viability is a critical factor, both at the level of the individual program and industry wide. Increased utilization, cost containment, and internalization of quality are integral to survival of the modality. It is incumbent upon leaders in the field as well as managed care to improve patterns of utilization if alternative, intermediate forms of behavioral health care are to fulfill a role in the overall continuum of mental health services.

Treatment Outcome Research on treatment effectiveness and outcome in psychiatry involves a complex constellation of factors. Major problems are encountered, including providing an objective, standardized definition of effectiveness and solving methodological constraints such as difficulties of selection procedures and randomization. The scope of the research literature on the effectiveness of child and adolescent partial ambulatory behavioral health care is not yet broad enough to provide definitive information. A growing body of research is available on treatment effectiveness or outcome with child and adolescent samples. A summary of the studies conducted to date on adolescents in partial hospital programs indicates generally positive outcomes with gains in relationships and school performance. Decreased symptoms have been found following treatment in PHPs with effects evident for up to 5 years following discharge. Review of studies on treatment outcome with children suggests that 66 to 90 percent of patients demonstrated improvement and successful return to community-based schools. Some studies suggest that family functioning (structure and stability) are major factors in improvement while others conclude that the younger children showed greater benefits from treatment in partial hospital settings than did older patients. Following a review of outcome studies, improvements were reported in behavioral, academic, and family role functioning following partial hospitalization with a variety of aftercare services needed. In a 5-year follow-up of severely disturbed children treated in a multimodal day program, improvements in global functioning, behavior, self-esteem, peer relations, and academic performance were maintained with parental cooperation of primary importance to positive outcomes.

Movement to partial hospitalization away from traditional treatment modes would be alarming and irresponsible without treatment comparisons. It is essential to look at the treatment effectiveness of partial hospital settings in comparison to the effectiveness of other modalities. Again, published research has not been as extensive as desirable. The literature on child and adolescent populations contains three studies that compare treatment outcomes in partial hospitalization and residential settings and one study comparing partial hospital with inpatient care for substance abusing adolescents. Overall, the findings suggest that partial hospitalization is equally effective with some patients on some variables, is more effective with some patients on some variables, and is less effective with some patients on some variables. Clearly, advocates of partial hospitalization must continue to compare outcomes from different treatment modalities, from various partial program models, as well as compare treatment outcomes of specific populations.

One of the major difficulties encountered in the area of outcome measurement is the lack of standardization of outcome variables and instruments. Six areas of outcome measurement are recommended for ambulatory behavioral health care, including cost of services, utilization of services postdischarge, severity of symptoms, level of functioning, patient ecology (family-community support network), and satisfaction. Standardized assessment of these variables is a goal with the objective of providing industry-wide information regarding expected outcomes.

Ambulatory behavioral health care represents an important segment of the continuum of psychiatric care available to children and adolescents with a wide array of disorders and allows these patients treatment in less restrictive settings than hospitals. In the current era of health care reform, this and other ambulatory mental health services are likely to face increased demand. As policies encourage such options it is necessary to be aware of differences between PHPs, DTPs, and IOPs so that patient needs can be matched with service variables such as theoretical orientation, targeted populations, types of treatments offered within the program, staffing patterns, and the degree of structure provided. Issues related to quality of care, therapeutic outcome, and cost-effectiveness must also be considered. With careful review it is possible to identify intensive PHPs that serve as alternatives to inpatient hospitalization, DTPs or IOPs that function as transitions between highly restrictive treatments and outpatient services, and programs that serve as outpatient alternatives.

Although partial hospitalization is an established concept and has a significant history, the field is in transition as is health care in general. In the years to come several questions will arise as ambulatory behavioral health care providers face the broad challenges brought by health care reform. How will partial hospital programs integrate with other children's services such as special education systems, juvenile courts, and state departments of child protection and human services? How will they fit into large health care organizations to provide prevention and related services? It is hoped that the closing of the twentieth century will provide answers to these important questions and the further development of this exciting mode of treatment.

48.8 RESIDENTIAL AND INPATIENT TREATMENT

MARK DEANTONIO, M.D.

The use of residential and inpatient treatment facilities for children and adolescents has changed significantly since the mid-1980s. There has been a dramatic increase in use of both facilities, including a tripling of admissions of adolescents to inpatient units. This change has challenged the child and adolescent psychiatrist to rethink the appropriate use of these interventions. The advent of managed care and tighter control of dispersement of mental health resources has further modified inpatient and residential placement utilization. The decision to use these interventions, however, remains powerful and dramatic, for it makes the judgment that a child or adolescent must be separated from parents or caregivers to be given appropriate treatment.

A child and adolescent inpatient psychiatric unit may be located in a general hospital or in a free-standing psychiatric hospital. It must meet the same credential and licensing requirements as other hospital settings. It usually has stricter requirements in terms of patient rights. The unit may be either locked or unlocked. A locked unit can restrain and seclude patients. Due to the higher acuity of involuntary patients, it has psychiatric nursing staffing equivalent to an intensive care unit. While an unlocked unit has less nursing staff, usually it has the same complement of the rest of the interdisciplinary team, which includes psychiatry, psychology, social work, nutrition, occupational therapy, recreational therapy, and school staff. Pediatric and neurological consultations are available. The task of inpatient hospitalization has changed over the years with refined diagnostic and treatment formulation and increasing financial constraints. Currently the goals of inpatient psychiatric hospitalization for children and adolescents are to safely contain patients while intensively evaluating them and implementing treatment that will bring them to a less restrictive setting as quickly as possible.

Residential treatment is less clearly defined. In the literature the terms *residential treatment* and *inpatient psychiatric units* have been used interchangeably, but residential treatment centers should be defined as a separate entity. Such a center is a facility that houses children and adolescents 24 hours a day but is not licensed as a psychiatric hospital. It is not necessarily directed by a physician and does not have the full complement of staff that an inpatient psychiatric unit must have for licensure. A psychiatrist is part of the staff but usually more in a consultative role than as a leader of the treatment team. There are also significantly fewer psychiatric nursing staff. Often social workers and other licensed mental health professionals are the primary staff. Because of the prominence of nonmedical staff, children and adolescents in such facilities are not as acutely disturbed, because interventions such as one-to-one staffing, seclusion, and restraints are not available. Additionally, aggressive medication cannot be managed in such settings. The goals of residential placement are also different. While children and adolescents are often evaluated, the primary focus is to develop better interpersonal group and social skills so that patients can either return to their parents or live independently as adults. The length of stay is in the range of 6 months to years.

HISTORY

By the late 1800s children with severe psychiatric disorders were being described in the literature. However, the concept of hospitalizing children for psychiatric disorders began in the early 1920s in the United States. After World War I, a worldwide influenza epidemic caused a large number of postencephalitic children. These children exhibited emotional lability, agitation, and cognitive deficits requiring containment in a hospital setting. Therefore, pediatric behavioral units were established. These units were run by pediatricians and pediatric neurologists and served a primarily custodial function. The 1950s saw an increased understanding of child psychopathology as well as individual, group, milieu, and family psychotherapeutic interventions. With this new understanding, child psychiatrists became involved in the inpatient units, and their emphasis changed from custodial care to diagnostic evaluations and individually focused treatment interventions.

The development of residential treatment facilities evolved along different lines. In the early 1700s orphanages were organized to attend to orphans and abandoned children. In the mid-1800s, two orientations for residential treatment developed: residential schools for the education and rehabilitation of the cognitively impaired and reform or training schools. With the industrial revolution came urbanization of families and the subsequent need for multiple family members to work, often resulting in fragmentation of families and lack of supervision of children. Issues of abuse and delinquency among children were identified. The field of social work was developed to address chaotic families and abused and delinquent children. It was felt that society and the children would be best served if reform schools were focused on rehabilitation. However, by the 1930s, these institutions changed their focus to detention with a punitive orientation. In the 1950s, the orientation of residential programs was revised to multimodality therapeutic treatment because of new understanding of the psychopathology and psychotherapy of children, paralleling the changes in the inpatient psychiatric settings. Additionally, the psychological and social work literature indicated that custodial care of children without attention to individual issues and needs actually impaired social, emotional, and cognitive development. Orphanages were closed, and a model of foster and group home care was used. By the 1960s the actual treatment in inpatient psychiatric units and residential treatment centers was similar, except for the medical and nursing orientation of the former and the educational and social work orientation of the latter. Analyses of treatment programs in the two settings did not differentiate different diagnostic groups, treatment interventions, or goals, except for a slightly shorter length of stay in the inpatient settings.

In the 1970s another major change occurred, with a shift away from treatment in residential settings to treatment in inpatient psychiatric units in response to societal questioning of putting children and adolescents in long-term residential care. The priority changed to the goal of reintegration into families and communities. Additionally, an understanding of the biological nature of many disorders of childhood developed in child psychiatry. Autistic disorder, attention-deficit disorders, mood disorders, psychotic disorders, and anxiety disorders were being shown to have a biological component with specific medical treatments. As specific medical treatments were articulated for these disorders, both private insurance and federal programs were willing to pay for hospital treatment of them. This change in orientation led to the dramatic increase in inpatient hospitalization of children and adolescents in the 1980s and a decrease in use of residential treatment centers.

In the late 1980s a serious reevaluation of the use of inpatient psychiatric services for children and adolescents began. The cost of inpatient child and adolescent treatment consumed most of the money spent on mental health in the United States. Third-party payors, including the federal government, implemented managed care review to decrease the frequency of hospitalization and length of stay. Capitated contracts with psychiatric institutions were also implemented, which also reduced the use of inpatient hospitalization and length of stay. In the early 1990s it was revealed that some psychiatric hospitals used unethical and even criminal practices in the hospitalization of children and adolescents. Financial and ethical concerns forced a rethinking of the use of inpatient and residential hospitalizations. Critical reviews of uses and goals of inpatient hospitalization began to be published in the child psychiatry literature. The American Academy of Child and Adolescent Psychiatry published a policy statement for inpatient hospitalization. Parental and patient advocacy groups demanded deemphasis of inpatient hospitalization.

Currently the focus in treatment of children and adolescents is to implement the least restrictive intervention for evaluation and treatment. Instead of inpatient treatment being the first intervention, it is now used only as the most restrictive component in an integrated system of care that includes outpatient, partial hospitalization, and residential treatment.

PHILOSOPHY

Inpatient and residential treatment of children and adolescents is now seen as a component of an integrated system of care for psychiatrically disturbed minors. They must interact dynamically with outpatient and partial hospital treatments rather than be exclusive from them or compete with them. Treatment interventions must be individualized to the specific needs of the disturbed child or adolescent and the family. The ultimate goal of both residential and inpatient settings must be to stabilize patients so that they can move to the least restrictive treatment setting in an accountable, timely fashion, with both patient and family engaged in this treatment plan.

ADMISSION CRITERIA

As part of the reevaluation of inpatient hospitalization, specific admission criteria have been developed to ensure appropriate use. The following criteria are derived from recommendations of the American Academy of Child and Adolescent Psychiatry and individual psychiatric facilities. First, the patient must be assessed by a psychiatrist, who must be a child and adolescent psychiatrist for patients 13 years of age or younger. For patients 14 years of age and older, a psychiatrist with documented adolescent training and demonstrated competence in work with adolescents is required. The assessment can also be based on an evaluation by the admitting psychiatrist at the time of admission of the findings of an appropriate clinician. If a psychiatrist does not perform the initial evaluation, such an evaluation must be done within 24 hours of admission. Second, there must be a diagnosis of a psychiatric disorder as defined by the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders*, (DSM-IV). Because of this disorder, the patient must be an imminent risk to self or to others, be gravely disabled, or be experiencing medical complications arising from a psychiatric illness. Imminent risk to self is evidenced by a suicide attempt that presents a severe medical threat; a clear, lethal suicide plan that presents a serious threat to the patient's life; or significant changes in behavior that indicate hopelessness or helplessness (e.g., increased withdrawal, social isolation, decline in school performance accompanied by serious family conflict disruption, or loss of a significant other). Imminent risk to others is evidenced by homicidal or assaultive behaviors that present a serious risk to others; homicidal ideation with a specific, clear, and realistic plan; or significant changes in behavior, loss of judgment, and impulse control accompanied by threatening behavior that cannot be safely contained. Grave disability is evidenced by an impairment in judgment, orientation, memory, and affective functioning. An acute psychotic state, major depressive episode with significant vegetative signs, severely debilitating panic or anxiety, and inability to maintain adequate nutrition because of a mental disorder are clinical conditions that can cause such disability. Medical complications arising from a psychiatric illness are unstable, life-threatening conditions complicating the management, evaluation, or treatment of a psychiatric illness. This may be manifested by one of the following clinical signs and symptoms: serious adverse side effects from psychotropic medications, failure to maintain adequate nutrition, uncontrolled seizure disorder, diabetes mellitus uncontrolled because of the patient's mental disorder, or the use of psychotropic medication requiring constant skilled observation because of a coexisting medical condition. Third, the failure of appropriately intensive treatment in a less restrictive setting must be clearly documented. If a less restrictive setting has not been attempted, it must be documented that either such a setting would put the patient or others at significant risk or the patient's family is severely disrupted and unstable.

The child or adolescent and the family must be informed of the reasons for inpatient admission and why such an admission is the least restrictive intervention. Effort should be made to have the patient and the family voluntarily agree to hospitalization. When hospitalization is involuntary, the patient and family should be so informed.

Admission criteria for residential treatment programs have been less well defined, and there are no consistent standards to date. Prior to admission the child or adolescent must be evaluated by a licensed mental health professional who must diagnose a psychiatric disorder as defined by DSM-IV. The psychiatric disorder must be severe enough to significantly impair daily functioning in interpersonal relations, social interactions, family relations, or school performance. The disorder must be treated in the residential setting because the home environment failed to contain the patient safely and to allow successful outpatient treatment. As in the inpatient admission, the child or adolescent and family must be informed of the indication for admission and why it is the least restrictive option.

GOALS

The primary goal of inpatient hospitalization is to stabilize the issues that formed the basis for admission, so that the patient can be moved to a less restrictive setting. To this end, the hospital uses therapeutic interventions to keep the patient from harming self or others or causing severe milieu disruption. Second, a comprehensive, timely, multidisciplinary diagnostic evaluation must be conducted. This evaluation must address physical, neurological, psychiatric, cognitive, academic, social, interpersonal, and family issues. Third, the family, posthospital caretakers, or both must be actively engaged in understanding how to manage the patient out of the hospital safely. Finally, there must be active networking between the hospital and the outpatient treatment setting to ensure continuity in treatment. For these goals to be achieved in the shortest time, they must be addressed at admission and reviewed on a daily basis throughout hospitalization.

The primary goal of residential treatment is to create a therapeutic living environment that safely contains the patient while allowing for multidisciplinary interventions so that the patient can return to the home or function independently as an adult. While the focus of inpatient care is on containment and stabilization, in residential care the focus is on immersing the patient in an environment that addresses interpersonal, social, educational, and familial deficits. A comprehensive, multidisciplinary diagnostic evaluation must be conducted. This evaluation must also address physical, neurological, psychiatric, cognitive, academic, social, and interpersonal and family issues. Since children and adolescents who enter residential placements have a much higher incidence of psychiatric hospitalizations, school failure, and past out-of-home placements, past records and evaluations must be obtained so that evaluations are neither needlessly repeated nor critical information lost. From the evaluation, specific multidisciplinary treatment goals must be developed so the patient can function successfully in a less restrictive setting. The time frame for meeting these goals can be months to years, though they must be reviewed weekly. It is expected that upon discharge from a residential treatment center, the child or adolescent's issues will be ameliorated but not resolved. Therefore, there must be continuity of care with an outpatient program, family, or other care providers.

ASSESSMENT

A complete multidisciplinary assessment must be done on inpatient and residential treatment patients. A common reason for treatment failure or lack of treatment progress is the lack of a clear diagnostic formulation along biopsychosocial lines. Most children and adolescents have noncontributory physical, neurological, and laboratory findings related to inpatient hospitalization; however, a significant minority have physical issues that need to be addressed. A complete physical and neurological examination is needed during an inpatient stay, and relevant findings must be followed up. There has been discussion in the literature about the necessity of screening laboratory tests and neurological evaluations. With the better understanding of psychopharmacological interventions in inpatient settings, and the resultant more aggressive use of medications, assessment of blood indexes, liver function, renal function, thyroid functions, and cardiac conduction is more relevant. Pregnancy status must be determined when considering medication in adolescent females. Performance of pelvic and rectal examinations must be considered carefully; these examinations should not be routine in children and adolescents. When sexual abuse is of concern, the examination should be done by a physician, nurse practitioner, or physician assistant specifically trained in sexual abuse examinations of children and adolescents. Examinations should be done at other times when specific complaints or behaviors necessitate them. With the continued pressure on decreasing cost and shortening length of stay, comprehensive neurological evaluations come into question. As with laboratory tests, most children and adolescents do not show clinically significant abnormalities on electroencephalogram (EEG) or brain imaging studies. These studies should not be done just to be complete but should be done to resolve a specific clinical concern that would change the treatment.

The human immunodeficiency virus (HIV) epidemic adds to the challenges of psychiatric treatment of children and adolescents in inpatient and residential settings. Because of confusion and controversy around HIV antibody testing in the inpatient setting, the American Academy of Child and Adolescent Psychiatry has made the following recommendations concerning HIV and inpatient psychiatric treatment:

1. HIV infection or risk of HIV infection is not a reason to deny a child or adolescent admission to a psychiatric hospital.
2. All patients admitted to a psychiatric hospital should be treated as if they were HIV infected; even if all patients were tested on admission for antibodies to HIV, one is still not sure of their infection status because of the latency period in antibody response.
3. Because of the convergence of the tuberculosis and HIV epidemics, inpatient staff should be knowledgeable about tuberculosis exposure and infection control procedures.
4. Children and adolescents should *not* be routinely tested for HIV infection; testing should be considered for children and adolescents at risk for infection including, but not limited to, homosexual and bisexual males, those who have taken drugs intravenously, those with HIV-infected mothers, those with histories of sexual abuse, those with multiple sexual partners, and those with sexually transmitted diseases.
5. HIV-positive or potentially positive patients do not require individual rooms or toilet facilities or isolation from the milieu or peer groups; they should participate in all aspects of the inpatient treatment program.
6. All HIV testing requires informed consent. It is not enough just to have a consent form signed; it must be documented that both the patient and the person authorizing testing are fully informed of the consequences of both a positive and a negative result. Specific state laws exist regarding confidentiality of HIV antibody testing results and who authorizes consent for minors. Regardless of legal issues, it is strongly recommended that children and adolescents be actively involved in this consent process.
7. Results of patients' HIV antibody tests must be kept confidential; information about HIV status should be available only to staff who need to know the status to ensure appropriate care of the child or adolescent while an inpatient. These recommendations also apply to residential settings.

The psychiatric assessment combines information from the patient, parents or caregivers, past records, and outpatient clinician and pediatrician with observation and

evaluations of the patient in the inpatient setting. This data collection should focus on delineating the issues leading to the necessity for inpatient hospitalization and making a diagnostic formulation. It is necessary to inquire about frequency, intensity, duration, and circumstances of symptoms and problematic behaviors. To assess the functional impairment caused by the patient's symptoms and difficulties one must inquire about the patient's internal distress, interference with social and academic activities, impact on ongoing development, and impact of the behavior on others. Data collection should concern both the patient's difficulties and symptoms and the patient's strengths, talents, areas of positive adjustment, and support systems. If such strengths are known, they can be integrated into the treatment plan to facilitate stabilization and growth.

The interview with the child or adolescent inpatient provides information about the patient's own perception of the issues leading to hospitalization and an assessment of the patient's overall developmental and mental status. This information is critical because the crisis precipitated by inpatient hospitalization often results from a disparity in the understanding of the relevant issues between the child and adolescent and the parent or caregiver. For example, an adolescent may be admitted to a hospital because of a serious suicide attempt. In interviewing the parents, they may explain that the attempt was due to perceived increasing social withdrawal and school failure. In interviewing the adolescent, he or she may admit for the first time that auditory hallucinations commanded the suicide attempt. For the mental status examination, the clinician observes and assesses the physical appearance; manner of relating; orientation to time, place, person; mood; affect; motor behavior; content and form of thought, including hallucinations and delusions, speech and language; intelligence; attention; memory; neurological functioning; and judgment and insight.

Standardized interviews and rating scales have become powerful tools for consistent assessment of psychiatric disorders and symptoms in clinical research settings. However, it is not known how useful they are in inpatient treatment settings. Symptom rating scales focusing on depressive, psychotic, attentional, anxiety, or obsessive-compulsive symptoms may have utility in quantifying the severity of a symptom and serving as a baseline against which response to a therapeutic intervention can be established. Standardized assessments and rating scales should never be a substitute for face-to-face clinical interviews. They cannot prioritize the significance of symptoms or diagnoses in the context of a child or adolescent's personality style and interpersonal and family relational style, and hence the treatment will not be individualized and focused. Psychological testing, both cognitive and projective, should not be done routinely. It should be performed when it can provide specific answers that cannot be elicited through interview and observation. However used appropriately, such testing can be instrumental in refining treatment strategies. For example, a patient who has a history of failing school and oppositional behavior with new onset of depression and suicidal ideation should be treated with different multimodal strategies depending whether the cognitive level of functioning is in the normal or the borderline range. Projective testing of patients who cannot articulate thoughts and feelings or refuse to do so may add important data to clarify the diagnosis. Speech and language testing can also be used when suspected receptive and expressive language deficits are not documented. Educational assessment is needed if academic failure or disruptive behavior in the school setting is part of the issues around hospitalization. A comprehensive evaluation of the family is also critical. Each family member's strengths and weaknesses in interaction with the patient and whether they add or detract to family stability must be documented. Assessment of family members' communication, ability to resolve conflict, and ability to solve problems is important. Issues of neglect and abuse need to be clarified as well as the family's attitude and response to having their child hospitalized and the degree to which they support this decision.

After the interdisciplinary team has made their assessments, a diagnostic conference should be held. This should take place 5 to 7 days after admission. A diagnostic formulation should use a biopsychosocial model, which entails documenting a psychiatric diagnosis or diagnoses per DSM-IV. Then the biological, psychological, social, and interpersonal issues and patterns that caused the crisis leading to hospitalization must be identified. The patient's physical and psychosocial strengths and resources must be documented for use in promoting stabilization.

This assessment process should be similar in a residential placement. However, more time should be taken in coming to the diagnostic formulation, as the goal of treatment is focused on more complex interpersonal social, educational, and familial deficits, which take more time to clarify. Because of this, a diagnostic conference should take place after 30 days.

TREATMENT PLAN

After the diagnostic formulation is made, the multidisciplinary team documents a treatment plan. Hospital accreditation organizations now require documented problem-oriented treatment plans, which are updated weekly. Essential problems need to be abstracted from the formulation. The problems should not be a diagnosis such as “depression” or a category such as “family,” but specific symptoms, behaviors, emotions, or dysfunctions that must change for the patient to be treated in a less restrictive level of care. These specific problems should address issues from different areas of the biopsychosocial formulation but should be kept to a limited number that can be effectively addressed and ameliorated. For example, a 13-year-old adolescent who is hospitalized after a severe suicide attempt with a 2-week history of increasing depression in the context of parental divorce and conflict, academic failure, and increasing social isolation could have the following essential problems: (1) suicidal ideation with impulse to kill self, (2) feelings of hopelessness and helplessness, (3) conflicted family dynamics, (4) recent academic failure, and (5) increasing social withdrawal. Under each essential problem one notes the treatment intervention, its frequency, and the member of the interdisciplinary team responsible for it. The purpose of the treatment should be briefly stated. Next, a treatment goal for the essential problem is specified that can be achieved in 1 week. An example, for the essential problem of suicidal ideation with impulse to kill self; would be one-to-one observation, 24 hours a day, by nursing staff (identified by name). The purpose would be to keep patient from harming self. The treatment goal for the week would be no self-injurious acts. A second treatment or intervention would be psychotherapy five times a week with the child psychiatrist (by name) responsible for this intervention. The purpose of the treatment would be to have the patient understand why he or she feels like killing self. A treatment goal for the week would be for the patient to develop a written plan to safely manage feelings of wanting to hurt self, with assistance of the child psychiatrist. The same process is completed for each essential problem. Patient and family awareness of, and participation in, the treatment plan must be documented. Formally involving the patient and family in developing the plan increases their participation and motivation to be part of the treatment process.

Every week the multidisciplinary team meets to review the treatment plan. In that meeting they review each essential problem and the progress of the weekly treatment goal. If the problem has not been resolved, a new treatment goal must be formulated for the next week. If new essential problems arise, they can be documented with the proposed intervention and goal as described above. Additionally, the diagnosis, estimated length of stay, discharge plan, and plan for outpatient follow up should be reviewed weekly. Twenty-four hours prior to discharge, a final discharge plan must be documented by the multidisciplinary team, with specific recommendations from each member of the interdisciplinary team. The outpatient follow-up, living arrangement, and discharge medications should be listed. It should also be documented that the parents or other responsible party understood the discharge instructions and recommendations.

In a residential treatment center the treatment planning process functions the same way. The treatment plan should be reviewed weekly, but the weekly goals may reflect more-incremental change.

TREATMENT MODALITIES

For an inpatient hospital or residential treatment center to be effective in treating children and adolescents, it must use the full range of therapeutic modalities. Milieu therapy, psychopharmacotherapy, individual therapy, group therapy, family therapy, recreational therapy, occupational therapy, and a school program must be present. Use of these therapies is individualized by the interdisciplinary treatment plan.

The concept that the actual hospital or residential environment can be seen as a therapeutic instrument has been acknowledged since the 1950s. In the inpatient setting, the milieu primarily needs to be safe and containing. It is the primary responsibility of the nursing staff to manage the milieu. In the past, milieu had specific orientation, often behavioral or psychodynamic, to which the patient had to adapt. Interacting with the ward structure the patient's maladaptive coping strategies would be elicited and therefore be a focus of intervention. While this kind of identified milieu orientation continues to be seen in residential treatment centers, it has been largely revised in the inpatient setting because of the changed goals of hospitalization. The milieu must now be more flexible so that each patient's individualized treatment program can be implemented. The nursing staff develops an individualized treatment plan that addresses the specific treatment interventions articulated in the multidisciplinary treatment plan. Thus, some patients may have a more behavioral treatment program in which they are earning points or stars for specific behaviors while others may discuss feelings with staff for 30 minutes three times a day with no reinforcement beyond the patient-staff interaction. Safety and containment are critical to inpatient units; therefore the use of seclusion and restraints is necessary. When used appropriately and safely, these interventions promote impulse control in the patient and reduce behavior that could be severely dangerous to the patient and others. Research has shown that appropriate use of seclusion and restraints can decrease the length of hospital stay and help engage the patient in the treatment process.

Because the goals of residential treatment address long-term change in interpersonal, social, and family interactions, there is a more specifically defined milieu. It is usually designed to re-create a maturing, consistent environment that contains firm limits and boundaries but tolerates expression of feelings and promotes competency in problem solving. The milieu philosophy can range from behavioral to psychodynamic. Often part of the treatment is seen in the conflict created in

patients as they struggle with the structure of the environment and the specific issues it evokes from their past living situations.

Psychopharmacological interventions have been in use since the beginning of child and adolescent inpatient units in the 1920s. Initially, barbiturates were used to sedate agitated patients. Psychostimulants were used in the 1930s to address symptoms of hyperactivity. Until the 1970s, medication intervention for children and adolescents tended to focus on sedating agitation and improving impulsivity and inattention. Anxiety, mood, and even psychotic symptoms were treated with other psychotherapeutic modalities. Since the 1980s there has been a revolution in the understanding of the use of psychotropic medications for specific disorders in children and adolescents. Protocols have been developed to use medications in children and adolescents effectively. Medication intervention is implemented after the evaluation and recommendation of the treating psychiatrist and written informed consent by the parents. The medication should address specific target symptoms of a diagnosed disorder and should be documented in the interdisciplinary treatment plan. The hospital progress notes should give the indication for the medication and note that the parents and patient have been told the indication and the risk and benefits of the psychopharmacological intervention. Positive effects and adverse effects need to be documented as well as the rationale for dosage changes. Children and adolescents are often resistant to medication interventions. Repeated explanation and using the parents to reinforce compliance may be necessary. In both the weekly interdisciplinary meetings and daily rounds the psychiatrist should get input from all members of the interdisciplinary team about the effects of psychopharmacological interventions.

In residential treatment centers, every resident needs psychopharmacological evaluation. Because in many residential settings, psychiatrists only have a consultative role, some patients may be overlooked unless they exhibit agitated, disruptive, or self-injurious behaviors. A psychiatrist must be part of the regular treatment planning meetings so all cases can be reviewed for medications.

Individual psychotherapy remains an important treatment in inpatient and residential settings. In the inpatient setting the type of psychotherapeutic intervention should be directed by the multidisciplinary treatment plan. Supportive, cognitive, behavioral, insight-oriented, and psychodynamic approaches can all be used to address essential problems. The psychotherapeutic modality should be individualized to the patient's needs at the time. An adolescent who is hospitalized for severe agitation after a rape may initially require a supportive and cognitive behavioral orientation. As the patient is stabilized and moves to an outpatient setting, a psychodynamic orientation may be used if the trauma brings up more dynamic issues. In the residential setting, again the orientation of the individual psychotherapy should reflect the needs and abilities of the child or adolescent. Because of the long-term nature of residential treatment, the therapy may change orientation over time. Initially it may be more supportive and cognitive-behavioral. As time progresses and the child or adolescent matures or develops greater insight, a shift can be made to an insight-oriented or psychodynamic approach.

Family therapy is a powerful and essential part of both inpatient and residential treatment. Active involvement of the family in the therapeutic process decreases both length of stay and frequency of rehospitalization. Often some failure in family interactional dynamics precipitated hospitalization or residential treatment. Because of this, staff tends to view the family in adversarial terms, as family failure is seen as the cause of the hospitalization or residential placement. The challenge is to make the family feel an active part of the treatment team. While familial dysfunctional dynamics must be addressed, equal effort must be made to see the strengths in the family. Intervening in the dysfunctional dynamics and supporting and developing the family strengths further motivates patients in their other modalities of treatment. Seeing that one's family can change instills hope in the child or adolescent and confidence in the therapeutic process. All dysfunctional family issues do not need to be resolved in the inpatient setting. The issues need to be identified and therapeutic interventions initiated. The importance of clear communication of the family assessment and treatment strategies to the outpatient therapist must be stressed.

Residential treatment contains the same issues and goals as the inpatient setting. The treatment with the family must be more intensive and longer term if the goal is having the child or adolescent return to the family, because the need to place an adolescent or child in a residential treatment setting reflects more profound chaotic or dysfunctional family interactions.

Group therapy in an inpatient and residential setting is another powerful tool for addressing social and interpersonal issues in children and adolescents. It also becomes a place where the patient can process issues brought up in the milieu with peers and staff and can mirror appropriate family interaction. Therapy groups can also have specific foci so that patients learn to use peer feedback and support in managing and understanding their issues. Occupational therapy programs are critical in demonstrating and evaluating adaptive functioning of the patients. Recreational therapy demonstrates social interactive skills and deficits and promotes the ability to work together to solve tasks. Both occupational and recreational therapy contribute substantially to the treatment program by being less confrontational and focusing on the patient's strengths.

Educational evaluation is necessary in the inpatient setting, and an educational program during the inpatient stay is ideal. Children requiring inpatient hospitalization have a significant incidence of learning disabilities and school failure. For the patient to progress, reasons for school failure, clarification of learning disabilities, or both must be elucidated. Initiation of an Individual Education Plan, which must be developed by the local school board for severely emotionally disturbed children and adolescents under federal mandate, can be initiated in the inpatient setting. In the residential setting, the educational program is as significant a part of the patient's experience as it would be if the patient were at home. Whether the school setting is part of the residential center or separate, the teaching staff must be part of the multidisciplinary treatment team so they can follow through with treatment interventions and goals.

OUTCOME OF HOSPITALIZATION

Past studies of the effectiveness of inpatient hospitalization may no longer be relevant because of the stricter admission requirements, shorter length of stay, and reevaluation of goals of hospitalization. However, inpatient hospitalization should not be seen as an endpoint of treatment. It should be considered the most restrictive and intense intervention in the context of a comprehensive mental health care continuum that includes outpatient, intensive outpatient, partial hospitalization, inpatient hospitalization, and residential interventions. Patients now move more fluidly between the different treatment settings, so the efficacy of hospitalization must be seen in the context of the entire treatment program. The changes of the late 1980s, while painful and chaotic to clinicians, have had a positive effect in better defining the purpose, goals, and treatment of inpatient and residential treatment centers for children and adolescents.

SUGGESTED CROSS-REFERENCES

Normal child development is discussed in Section 32.2. Normal adolescent development is discussed in Section 32.3. Disruptive behavior disorders are discussed in Chapter 45. Schizophrenia with childhood onset is discussed in Chapter 47. Other aspects of psychiatric treatment of children and adolescents are discussed in the other sections of Chapter 48.

48.9 COMMUNITY-BASED TREATMENT

ANDRES J. PUMARIEGA, M.D.

The field of child and adolescent community-based treatment has received increasing attention and significance over the last decade during which time it has gone beyond the traditional community mental health consultation model that was prevalent from the 1950s to the mid-1980s. Community-based treatment now involves the study and implementation of approaches to improve access, utilization, financing, and clinical and cost-effectiveness of mental health services provided to children and adolescents within the context of their home communities, as well as the functioning and effectiveness of systems of care for child mental health.

RECENT TRENDS

A number of recent trends have led to the increasing importance of this field. First, the increasing utilization and demonstrated need for child mental health services in the United States has spurred the rapid growth of such services. Although child and adolescent mental illness and emotional disturbance were once thought to be relatively rare, recent studies suggest overall prevalence rates of 15 to 19 percent, with 3 to 8 percent for serious mental illness and emotional disturbance. A number of morbidities associated with emotional disturbance and mental illness are increasing at alarming rates among children and youth; these include suicide, homicide, substance abuse, child abuse, teenage pregnancy, school drop-out, youth crime, and associated institutionalization and incarceration. A number of health and human service agencies (schools, social welfare agencies, child protective agencies, juvenile justice agencies, public health agencies) have experienced the increasing impact of psychosocial morbidity in children and youth. These agencies typically address pieces of the service system puzzle, with little or no coordination with other agencies that may serve the same youth. However, less than 1 percent of children in the United States receive mental health treatment in hospital or residential settings and another 5 percent in outpatient or community-based settings; the majority of children in need receive either insufficient mental health services or none whatsoever. In contrast, the budgets dedicated to financing public and private mental health services for children have grown exponentially since the 1970s, with total expenditures growing to 4.8 billion by 1990, which is approximately 7 percent of the total national mental health budget. The majority of these expenditures have been dedicated to inpatient and residential treatment, and treatment in such restrictive care settings is viewed with increasing skepticism because of its high cost as well as the limited documentation on its results.

At the same time as these needs are recognized, the resources available to fund child mental health and human services are increasingly limited. Medicaid, the public insurance program for the poor and disabled, funds a significant proportion of child mental health services in the United States through the coverage of Aid to Families with Dependent Children (AFDC) recipients and children with disabilities. Approximately 14 percent of children and adolescents 18 and under are enrolled in the Medicaid program, at least 450,000 of whom have severe emotional disturbances. The great majority of these are poor, underserved children of ethnic minority backgrounds. Children from these populations experience higher levels of stressors, such as poverty, discrimination, immigration, acculturation stress, and exposure to violence and trauma. However, minority populations have been traditionally underserved by mental health, health, and human services, both in terms of overall access to services as well as the cultural competence of the services available to them. The cost of serving these populations of children and adolescents is in contrast to the high cost of the psychosocial morbidity they contend with, including lost productivity and the costs of welfare dependency and institutionalization.

As a result of these trends public child mental health and social service agencies are increasingly pressured to demonstrate improved clinical and cost-effectiveness, and they increasingly turn to managed-care approaches to finance and organize mental health and social services. However, managed-care approaches are relatively new in the field of mental health, and those that have existed were developed with adult and private sector populations in mind. These approaches have relied on *a priori* benefit restrictions based on actuarial formulas that exclude poorer populations, which are high utilizers of services, while including large pools of relatively healthy, minimally impaired populations from higher socioeconomic backgrounds, who are lower utilizers of services. If applied to child mental health services, the usual benefits restriction approach in traditional behavioral managed care has the potential of depriving poor, underserved, and more impaired children of timely and effective intervention and preventive services. Thus, care is fragmented and the burden of services and costs shifts to the other child-serving agencies and systems and potentially increases morbidity significantly. Managed-care models for children's mental health need to emphasize community-based treatment and prevention of such morbidity by enhancing family and community resources and reducing psychosocial stressors for the child as they provide clinical services.

HISTORY

From their earliest origins, mental health services for children have emphasized a community orientation. These services began in the United States in response to the perceived need to counsel juvenile offenders rather than incarcerating them with adult offenders. This was the case in the 1890s when America, much like today, was undergoing rapid cultural changes because of immigration, rapid industrialization, and urbanization. These social strains led to marked increases in juvenile crime. Enlightened reformers saw the need to detain young offenders separately from adult prisoners, adjudicating them in a separate court system—this was the beginning of the juvenile court system—and to provide rehabilitative services to them. The juvenile court clinics in Chicago and Boston gave rise to the first child mental health services in the nation. The success of these clinics led the Commonwealth Foundation to commission a study that recommended the development of child guidance clinics throughout the United States staffed with interdisciplinary teams of professionals to serve the child and the family. At first these clinics were primarily staffed by social workers, but later attracted pediatricians, psychologists, psychoanalysts, and psychiatrists, and subsequently served as the bases of the first child psychiatry programs in the nation. The clinics were quite removed from the specialty-driven medical system that was evolving in tertiary medical centers, and particularly distinct from the practice of hospital-bound care. They provided low-cost services oriented to the needs of the child and the family, with treatment modalities evolving to include individual psychodynamic psychotherapy, family therapy, crisis intervention, and even day treatment programs. Many clinics that have survived to this day have served as the core for the child mental health services in many community mental health centers.

The move towards the medicalization of psychiatry served to move child and adolescent mental health services towards a more hospital-based, tertiary-care model. This left the child guidance clinics and the community mental health centers that followed them without significant psychiatric input as well as generally understaffed and underfunded. In the meantime the United States experienced a rapid increase in the population of poor and minority children, and a greater need for mental health services. Many of these children were placed in the custody of child welfare agencies or placed in residential and detention facilities.

The modern era of community-based systems of care for children was ushered in by the publication of Jane Knitzer's groundbreaking book *Unclaimed Children*, which exposed the aforementioned consequences of neglecting the provision of community-based mental health services for children and their families. Her advocacy and that of others led to the development of the Child and Adolescent Service System Program (CASSP), which assisted all 50 states in the development of an infrastructure for publicly funded community-based services. The CASSP initiative was supported by the conceptual work of Beth Stroul and Robert Friedman, who coined the term *community-based system of care for seriously emotionally disturbed children* and advocated interagency coordination among all the child service agencies in providing mental health services for children and related family support services. They proposed that such services be delivered as close to the child's home and community as possible to avoid more restrictive levels of care that often separated children from natural family and community supports, and that families be involved as partners in the effective treatment of the child. Stroul and Friedman's work spurred the development of various innovative community-based treatment modalities as well as several model demonstration programs that implement these modalities within the context of an organized interagency system of care.

THEORETICAL ISSUES

The CASSP initiative set forth the initial principles inherent in community-based systems of care. The key aspects of these systems include: access to a

comprehensive array of services, treatment individualized to the child's needs, treatment in the least restrictive environment possible (with full utilization of the resources of the family and the community), full participation of families as partners in services planning and delivery, interagency coordination, the use of case management for services coordination, no ejection or rejection from services because of lack of “treatability” or “cooperation” with interventions, early identification and intervention, smooth transition of youth into the adult service system, effective advocacy efforts, and nondiscriminatory, culturally sensitive services.

The principle of cultural competence is an integral aspect of the philosophy of community-based systems of care. It requires that systems of care include practitioner guidelines for a necessary attitudes, skill, and knowledge base to serve minority children and families in their communities, as well as policies and procedures to remove barriers for access to services. Community-based systems of care approaches were found to be consonant with the cultural values of ethnic minority populations, which emphasize strong extended-family involvement in the raising of children and the use of natural community resources first in dealing with the emotional and physical problems of family members. These factors have been shown to be protective against some of the morbidities associated with emotional disturbance, such as substance abuse and suicidality.

Another important principle inherent in this approach is that of the targeting of services to “seriously emotionally disturbed children.” This designation includes the presence of an Axis I diagnosis as specified by the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV), but equally emphasizes the child's inability to function in at least one life domain (school, home, socially with peers). This reflects the difficulty that many children and their families have had in accessing necessary services when their diagnosis was not “severe enough,” particularly when the child was diagnosed with a disruptive behavioral disorder. Some studies indicate lack of clarity and validity in clinical child diagnosis, especially in relation to the prognosis of the child, with many children with disruptive behavioral disorders having comorbid serious mental illness when evaluated systematically. These problems are more pronounced in the diagnostic assessment of ethnic minority youth with serious emotional disturbance, with serious underestimation of comorbid mood and substance-related disorders and overestimation of psychotic and cognitive disorders by clinicians. Other studies indicate that the level of care received by children is only partially accounted for by their clinical diagnosis, with much of it accounted for by their level of function and psychosocial stressors.

The movement to managed behavioral health necessitated the application of principles of community-based systems of care to these approaches. These principles actually embody a true managed-care philosophy whereby care management becomes the primary modality for services utilization management rather than arbitrary, *a priori* benefits management. Combined with the principles of least restrictive levels of care, this approach results in higher-quality services and less disruption of children's lives and development, all at a lower cost than when more restrictive, higher levels of care are utilized. Pumariega and colleagues outline guidelines for states developing managed behavioral services for children funded by Medicaid to integrate principles of community-based systems of care into their contracts with managed-care providers, or into their policies and procedures for public managed services.

THERAPEUTIC PROCESS

A community-based treatment approach to services begins with access to services facilitated through multiple portals of entry, including direct referral or referral through child service agencies (such as schools and juvenile justice, child welfare, or public health facilities). A triage system should direct children and families to services and providers appropriate to their special needs. A full interdisciplinary team, including a child and adolescent psychiatrist, should be involved in the development of triage procedures and protocols. Comprehensive mental health assessments should be made by licensed providers who are credentialed and trained to evaluate children and families, in consultation with a child and adolescent psychiatrist. Such assessments should include diagnostic, functional, developmental, family, and cultural or community evaluations of the needs and strengths of the child and family. Standardized measures should be used whenever possible that are reliable, valid, clinically useful, culturally targeted to the population being served, and useful for programmatic evaluation.

Children and families who require time-limited, less intensive services should have an initial care plan developed by a licensed mental health professional in consultation with a child and adolescent psychiatrist. The initial care plan on children who require more extensive treatment should be developed by an interdisciplinary team, including all relevant child mental health and child service professionals. The parents, other relevant family members, and the child, if appropriate, should be members of this team. The care plan should identify problem areas and strengths that are relevant to the functioning of the child and family, as well as community-based interventions to address these needs. Patients and their families should be equal participants with the clinical team in the development and implementation of the plan of care. Plans of care should be individualized to the needs of the child and family, including attention to cultural issues, and should follow the child continuously through all levels of care, being amended as needed. The plan of care should promote continuous coordination and integration of all applicable services and agencies that are responsible for providing services to the child and family (such as primary health care, juvenile justice, schools, and social services).

Treatment and other services should be specific to the unique needs of the child and family and should use approaches that maintain or reintegrate the child into the family and community. Child and adolescent psychiatrists, psychologists, social workers, psychiatric nurses, and other members of the team should participate in the development of service protocols to ensure that the special developmental, physical, mental, and emotional needs of the child are addressed. The system should use as many diverse therapeutic modalities as possible, particularly those that have demonstrated effectiveness with seriously emotionally disturbed children. These include traditional and intensive outpatient services, nonresidential community-based interventions (including family preservation, wrap-around services, day treatment, and school-based services), community-based residential services (such as therapeutic foster homes and group homes), and brief, acute inpatient services. These interventions are aided by the increasing effectiveness of cognitive, behavioral, family-based, and psychopharmacological therapies, which should be integrated into all community-based interventions and levels of care.

Case management services are essential in community-based treatment, including assessment of problem areas, measurement of functioning level, determination of needs, linkage with necessary resources, care coordination, advocacy, and monitoring of services provided and their outcomes. The child and family should be assigned a case manager who has the necessary skills to ensure seamless coordination of care across all levels, different providers, and the full time course of illness or disturbance. The frequency and intensity of case management services is proportional to the clinical and psychosocial needs of the child and family. Patients and their families should be participants in the case management process, sharing responsibility with case managers for using and coordinating services. Case management protocols should facilitate the coordination of multiagency, multisystem interventions, integrating services from the various providers and agencies responsible for serving the child, and ensure coordination of services with primary care physicians and health providers.

ROLES AND FUNCTIONS OF PSYCHIATRISTS

Given the complexity of these new systems of care, the skills that psychiatrists must bring and the roles that they must play go far beyond the circumscribed professional roles of their disciplines. These roles include front-line clinician, clinical consultant to other professionals, clinical team leader, administrative leader in delivery organization of system, quality assurance and improvement consultant, consultant to interagency teams, and outcome evaluator or researcher in systems of care. Given their broad biopsychosocial perspective, child and adolescent psychiatrists are often the professionals who have the broad expertise to integrate and coordinate community-based treatment delivered by multiple professionals with diverse skills. However, given the emphasis on tertiary-care models of care in the training of many child and adolescent mental health professionals, they often lack the skills necessary to function as effective members and leaders of these new systems. A publication from the American Academy of Child and Adolescent Psychiatry, *Guidelines for Training Child and Adolescent Psychiatrists in Community-Based Systems of Care*, provides guidance on the array of skills, knowledge base, attitudes, and training experiences that psychiatrists will need to function effectively within community-based systems of care for children.

CLINICAL ISSUES

Indications Community-based treatment is indicated for the treatment of the majority of children with moderate to serious emotional disturbance or mental illness. It is most indicated for the prevention of out-of-home placement of such children, and for the treatment of multiproblem, multiagency children with limited family resources. It has some limitations in dealing with situations involving extreme danger (to self and others), serious abuse, or neglect, which necessitates removal of children from their environment. Community-based treatment can be contraindicated when the child's family is too fragmented or dysfunctional, as well as when there is imminent danger (suicide, homicide), dangerous symptomatology (e.g., acute psychotic symptoms), or decrease in function that prevents the child from being cared for in the home or community. However, community-based treatment can be resumed when such symptoms or conditions are resolved (usually after brief stabilization), or the family is able to function again such that it can safely participate in the care of the child.

Goals of Treatment The goals of community-based treatment usually include the following: (1) to restore the child's functioning in school, at home, and in the community; (2) to reintegrate the child within the family and community and avert further separation or disruption of community tenure; (3) to individualize interventions to the need of the child and family; and (4) to maximize the strengths and resources of the family and the surrounding community on behalf of the child.

Libby and Shawna were African-American girls aged 13 and 14 when they came to the attention of the interagency community-based team in their rural community. They had been removed from their home at ages 6 and 7 because of their mother's substance abuse, mental illness (bipolar disorder), and resulting neglect, as well as physical abuse by their stepfather. They lived in a succession of foster homes in the region for 2 years, until they were placed in the home of the Browns, an older retired couple. The girls seemed to do well in this setting until Mrs. Brown died from multiple health complications. This left Mr. Brown, a highly religious and rigid man, caring alone for the girls. The girls and Mr. Brown engaged in pitched power-control struggles as they became older, with the girls running away and often ending up in their mother's home. The girls also had difficulties at school with disruptive behavior, especially Shawna, who was quite irritable and agitated and suspected of using drugs; Libby also had significant academic difficulties. Mr. Brown felt that he could no longer handle the girls in his home, and the girls both expressed the desire to be reunited with their mother.

The case of the sisters was referred to the interagency team for consultation and development of a comprehensive care plan. The team first recommended evaluation of the mother's home environment because she had faithfully attended treatment in the mental health center for her substance abuse and bipolar disorder over the past 4 years, and had maintained sobriety for 3 of those years. The family preservation therapist found a stable relationship between the mother and her new husband; the mother was eager to provide for the girls' needs. The consulting psychiatrist was asked to evaluate Shawna, and his impression was that she suffered from major depression, which was successfully treated with a serotonin agent and brief psychotherapy. A therapist in the mental health center and a diagnostician at the school concluded that Libby had a significant learning disorder that required remedial tutoring in a resource class. The team then agreed to stage a gradual plan of reunification, starting with weekend visits with the mother, and later having Libby, then Shawna, rejoin their mother and her husband over a 2-month period. The family preservation therapist, with consultation from the child psychiatrist and assistance from the child welfare case worker, worked with the mother and her husband on behavioral and parenting techniques to address the girls' occasional oppositional and impulsive behaviors, as well as to access support resources from their local African-American congregation. After 6 months of follow-up, the girls were successfully reunited with their mother, with no recurrence of mood or disruptive symptoms or runaway behavior.

ETHICAL ISSUES

Ethical issues can arise in community-based treatment when extremes are pursued, such as when a child is placed in an environment that is too restrictive or insufficiently restrictive. A home with a high level of conflict or abuse can be more restrictive for a child than many residential programs because of the degree to which activities are constrained for the child and family. On the other hand, the child may require a more structured or restrictive environment than the family can provide, such as when the child is exhibiting suicidal, violent, or severe runaway behaviors. Pursuing community-based treatment in such situations can create an ethical dilemma that needs to be addressed by the mental health professionals involved.

The utilization of community-based treatments exclusively to reduce costs without taking the needs of the child and family into account is another serious breach of ethics. Unfortunately, the financial incentives to provide less care inherent in most managed-care approaches often lead to such situations, which can potentially endanger the child. Community-based approaches need to be pursued within organizational and financial structures that do not have arbitrary benefit limits and that rely on on-site case management for the management of care.

RESEARCH EVALUATION

The field of child mental health services research has particularly focused on the effectiveness of community-based treatment. Research in this area has included the evaluation of community-based residential interventions, intensive nonresidential community-based interventions, and the clinical, functional, and cost outcomes of community-based systems of care, as well as factors affecting the need and utilization of mental health services in different populations of children.

Community-Based Interventions A number of innovative techniques that go beyond traditional outpatient services and provide more intensive and individualized services have been developed recently and are undergoing initial evaluation studies. These include different types of day treatment programs, school-based interventions, wilderness programs, crisis mobile outreach teams, therapeutic in-home emergency services, time-limited hospitalization with coordinated community services, intensive case management, and family support services. Studies involving these modalities have demonstrated significantly better outcomes than traditional outpatient or residential services. These include lower levels of externalizing and internalizing symptoms, improved family functioning, and reduced utilization of more restrictive services.

The wrap-around model of care embodies this approach towards multimodal community-based interventions. This model emphasizes aggressive outreach, use of least restrictive treatment options, and individualized, flexible, and unconditional child- and family-centered services for children imminently at risk or already in out-of-home placements. A number of studies of wrap-around programs in different communities across the nation with diverse populations of at-risk children and families have reported positive outcomes in terms of reduction of externalizing behavioral problems, level of function, reduction in out-of-home placement, improved family management skills and function, and consumer/family satisfaction. *Multisystemic therapy*, a therapeutic approach that combines home-based and wrap-around interventions within a systemic context, has been tested with youth at risk of detention and incarceration, with significant results in reducing out-of-home placement, externalizing criminal problem behaviors, rates of arrest and incarceration, and costs.

Community Systems Evaluations Initial outcome data on overall service system function in Vermont, New York, and Ventura County, California have demonstrated reduced hospitalization rates and days, decreased out-of-home placement and less restrictive placements, significantly lower incidence of negative behaviors vulnerable to out-of-home placement, and significantly lower rates of overall problem behaviors. The emerging model of community-based systems of care is being tested in a number of pilot demonstration sites, including 30 pilot community programs funded by the Center for Mental Health Services in different communities with a strong child mental health services' infrastructure and eight community-based systems pilot sites funded by the Robert Woods Johnson Foundation. The Fort Bragg Demonstration Project has been the largest systems of care demonstration project attempted so far. The project developed a comprehensive continuum of care for the children of military dependents at Fort Bragg, North Carolina, with ready access to outpatient and intermediate levels of care and relatively restricted utilization of residential and inpatient services. The outcomes from this system were compared to the usual CHAMPUS-funded services accessed by military dependents at various military installations nationally. Multiple process, quality, and outcome indicators (including clinical indicators, level of function, and cost of care) were evaluated and compared across the experimental site and the usual service sites. The initial results suggest that the program did achieve significantly lower restrictiveness of care, higher consumer satisfaction, greatly increased access to services, and greater funding spent on less restrictive services. However, clinical and functional outcomes were not significantly different overall, with split differences across diagnostic subgroups while overall outcomes were no different. Additionally, costs were not significantly different and possibly even somewhat higher in the demonstration site.

Services for Minority Youth Research on services for underserved minority youth has been sparse, and had initially focused on documenting racial differences in services provided. African-American children tend to remain in foster care longer and to have more foster-care placements than European-American children. Studies have shown that culturally diverse children are underrepresented in mental health institutions and overrepresented in child welfare and juvenile justice settings and placements as compared to nonminority youth, even when they are equally psychiatrically impaired. Ethnic and racial differences in the diagnoses of culturally diverse adolescents have been identified by some investigators, including overdiagnosis of conduct disorder and psychotic disorders and underdiagnosis of mood personality, and substance-related disorders. Significantly lower rates for overall utilization of services and specifically for the treatment of depression in culturally diverse groups have been documented; some studies have found a significant relationship between race and the service needs of racial ethnic minorities.

FUTURE RESEARCH NEEDS

The National Evaluation of the Center for Mental Health Services children's systems of care pilot demonstration sites should provide information on the effectiveness and cost efficiency of community-based systems of care and the effectiveness of our evaluation and research methods. In spite of current research activity, there are still significant deficits in our knowledge of children's mental health services and systems of care. Further research is needed on consumer satisfaction with services, the effectiveness of culturally competent services, the school-mental health interface, the interface with juvenile justice and child welfare, the impact of different cost-containment and reimbursement mechanisms, the effectiveness of interagency collaboration and coordination, and the integration of child mental health and primary care services. The application of mental health services' research findings in service system policy and planning is the ultimate objective and value of such research.

SUGGESTED CROSS-REFERENCES

Section 30.2, Section 30.5, and Section 30.6 contain important background information on behavior, family, and cognitive therapies. Chapter 40 and Section 49.7 contain important information on disruptive behavior disorders and child or adolescent antisocial behavior, including information on comorbidity with other psychiatric

disorders and the relevance of community-based interventions in their treatment. Section 48.7 and Section 48.8 have further details on partial hospitalization and residential and inpatient treatment as they relate to community-based treatment and systems of care. Section 48.9 has relevant information on community psychiatry.

48.10 PSYCHIATRIC TREATMENT OF ADOLESCENTS

CYNTHIA R. PFEFFER, M.D.

The onset of adolescence marks a major transition in life and encompasses developmental changes in cognitive, affective, neurobiological and social features of an individual's profile. Since the 1980s, significant advances in characterizing these features have been associated with the development of new techniques to define and measure them. Consequently, advances in techniques for characterizing normal and pathological features of adolescence have led to innovative strategies for psychotherapeutic and psychopharmacological treatment of adolescents.

Treatment schemas have become more specific to coincide with normal developmental parameters and indicators of developmental psychopathology. Framing treatment needs of adolescents requires understanding the developmental concepts because a particular type of treatment may not be appropriate or applicable for individuals across the life span. Thus, application of treatment for adolescents should be guided, in large measure, by empirical research that identifies the complexities of developmental psychopathological deviation and the efficacy of specified psychotherapeutic and psychopharmacological treatments. Thus the treatment of adolescents presupposes knowledge about the characteristics and timing of onset of psychopathology, its course, rates of recovery, risks for relapse or recurrence, and comorbid states.

DEVELOPMENTAL CHARACTERISTICS OF ADOLESCENTS

Adolescence is a period of life that readies an individual to leave the family of origin and prepare for future adult roles encompassing independent support of self, family, and others. Developmental accomplishments of adolescence involve maturation of cognition, profound physical changes in hormonal balances that eventuate in growth in stature and sexual capacities, and more-complex interpersonal interactions with attendant increases in social roles and identity consolidation. Numerous sociocultural rituals are used to designate the onset of adolescence.

Although the onset of adolescence is marked by enormous states of transition in biological and psychosocial dimensions, the termination of adolescence is less apparent and is associated with significant psychological and social adjustments. In this regard, psychotherapy applied to adolescents who suffer from psychopathological states presents an important opportunity to facilitate intense reorganization in psychological and social functioning that highlights adolescence. Because of the many changes during adolescence, psychotherapy with adolescents must target multiple domains of psychosocial functioning.

According to theoretical concepts of cognitive development, adolescents achieve levels of abstract reasoning that enables them to conceptualize events in terms of causality. These changes suggest that intervention can emphasize cognitive skills designed for independent problem solving.

Although pubertal changes begin at approximately age 9 to 10 years, pubescence is the hallmark of adolescence. Emotional, hormonal, and behavioral changes evident at pubescence are characterized by intense urges for independence and a simultaneous heightened dependency. Rates of pubertal changes are individually determined and differ for boys and girls.

Physical, emotional, and cognitive maturation in adolescence involving advanced levels of spatial, linguistic, and executive functions that control and regulate the integration of information and resultant behavioral responses is instrumental in the progression of the more complex interpersonal relationships formulated in adolescence. Conflicts with parents are juxtaposed with intense needs for guidance from parents and peers. Intensification of peer relationships points the way for future independent living and significant conceptualization of identity. Concerns about autonomy and decreased dependency on parents are major issues in the middle and late phases of adolescence, which are characterized by the slowing of major biological changes, heightened peer relations, increased capacity for abstract and formal operational thinking, identity resolution and consolidation, and preoccupations with future plans. Although emotional and behavioral turmoil is considered a component of adolescence, significant turmoil is not usual and should be considered an indication of psychopathology.

The choice of psychiatric treatment for adolescents is largely determined by the cognitive, emotional, physical, and interpersonal characteristics of individual adolescent patients. Treatment plans must also consider the nature of adolescent psychopathology.

PSYCHOPATHOLOGICAL CHARACTERISTICS OF ADOLESCENTS

Since the 1970s, rates of psychopathology have increased for adolescents. Suicide is the third leading cause of death in those 15 to 24 years of age, and the rate of suicide for children and young adolescents has more than doubled. Adolescents have significantly higher rates of depression, substance abuse, eating disorders, and posttraumatic stress disorders than those born before World War II. Heightened aggression, homicide, and psychotic states have been documented. Comorbidity of these psychopathological states is highly prevalent and challenges any treatment paradigm. Diagnostic formulation of adolescents involves an emphasis on their social context. Development of treatment strategies involves consideration of current psychopathology, features of continuity and discontinuity in psychiatric symptoms, prior psychiatric disorders, physical illness, social stresses, and general adaptive functioning. These issues are classified in the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV).

Great advances in understanding the etiology of adolescent psychopathology have been achieved since the late 1970s. For example, etiological parameters are related to acquired and constitutional neurobiological lesions and deficits, psychiatric disorders in the family, family discord, institutional rearing, and unique genetic factors. Given current knowledge about the epidemiology and clinical characteristics of adolescent psychopathology and psychosocial functioning, the most effective treatments for the prevalent psychopathologies of adolescents must be identified.

HISTORY OF PSYCHOTHERAPEUTIC TECHNIQUES FOR ADOLESCENTS

Distinct treatment strategies for adolescents were used before and after the 1970s. Before the 1970s, psychodynamic psychotherapy modeled after the principles of psychoanalysis was the main treatment for adolescents. Among the first instances of psychoanalytic treatment of adolescents was Sigmund Freud's treatment of his patient Dora, who entered psychoanalysis at the age of 16 years. Many pioneers in treating adolescents, such as August Aichorn, Anna Freud, Erik Erikson, and Peter Blos, described interventions based on psychoanalytic-developmental issues. The work of these pioneers centered on characterizing treatments for deviant youth such as delinquents (Aichorn), describing developmental lines for affective and behavioral achievements (Freud), schematizing critical life phases involving psychological achievements and deficits (Erikson), and defining a theory of adolescent development (Blos). These contributions continue to guide clinicians and researchers in developing treatments for adolescents.

Since the 1970s, combinations of psychotherapy and psychopharmacology have been used to treat adolescent psychopathological symptoms and disorders. Pressure to determine the outcomes and cost-effectiveness of psychiatric treatments for adolescents have made certain treatment approaches more common. Currently, health care reform demands methods of cost containment and documentation of the benefit gained by patients who undergo specific treatments. Pretreatment and posttreatment measurement of parameters expected to change as a result of undergoing treatment is advocated. The time needed to achieve clinically significant change in these parameters is considered in treatment planning. Partition of administration of specific types of treatment has become commonplace, so adolescent patients may be treated by multiple providers. This approach makes it necessary to clarify who has oversight for treatment planning.

TYPES OF PSYCHOTHERAPEUTIC TREATMENTS

Psychotherapeutic treatments can be divided into those that focus on the individual and those that involve multiple individuals. Within these classifications, specific types of treatments are offered.

Individual Psychotherapies A therapy that focuses on the individual adolescent intensively evaluates and aims to change patterns of thinking, affect expression, and behavior. Different types of individual psychotherapy emphasize different features of an adolescent's psychosocial functioning and are based on different theoretical paradigms and intervention techniques. Application of such therapies is assumed to have long-term effects that can be generalized to various circumstances encountered by an adolescent. Therefore, multiple interventions administered at varied points in time may be necessary, especially in treatment of adolescents with chronic psychopathology. In general, these therapies do not focus on effecting specific changes in the adolescent's environment. It is assumed that the therapeutic response will foster adaptive means of coping with environmental situations.

Psychoanalytic Treatment and Psychodynamic Psychotherapy Historically, the most widely used individual treatment involves psychodynamic psychotherapy whose theoretical basis is the resolution of unconscious conflict through expression of ideas and emotions and the development of specific insights about the causes of such conflict. The treatment aims to have the adolescent gain insight about problems and acquire skills for more effective coping. This type of treatment is usually not time limited and it requires highly skilled therapists with an active, verbal manner that enables the adolescent to form a real relationship with the therapist. This type of treatment assumes that the adolescent patient has a capacity for self-reflection and can establish a relationship, and it is applied to various types of psychopathology. A spectrum of such therapies exists ranging from psychoanalytic treatment and insight-oriented psychotherapy to supportive psychotherapy.

Psychoanalytic treatment requires multiple sessions each week and uses free association to elicit the material used to identify etiological conflicts and maladaptive coping styles. Various interpretations are offered by the psychoanalyst about the conflicts and their sequelae. Within the psychoanalytic process the patient forms a relationship to the therapist that reflects the unconscious conflicts and their emotional and behavioral sequelae. This transference is used by the analyst to interpret the patient's conflicts.

Psychodynamic psychotherapy uses psychoanalytic principles and is a variant of the psychoanalytic process. It also aims to identify and reduce unconscious conflicts, but it does not require such frequent therapeutic sessions and the therapist offers supportive comments about how the patient can respond to situations and how responses reflect unconscious conflicts.

Psychoanalytic and psychodynamic treatments have not been subjected to extensive systematic research to evaluate the resolution of patient's conflicts and changes in cognitive, emotional, and behavioral profiles. Nevertheless, the principles of such treatments are based on developmental principles that can be readily adapted to the distinct features of unconscious conflict in the adolescent patient. Thus such treatment does not emphasize psychiatric disorder. It has been used to treat adolescents with varied psychiatric disorders.

Cognitive-Behavioral Treatment Recently, cognitive-behavioral treatment has gained popularity and has been a focus of systematic outcome research for a variety of adolescent psychopathologies. This treatment uses cognitive and behaviorally based interventions to effect change in emotional, cognitive, and behavioral profiles of adolescents. It focuses on both the external environment and the adolescent's internal processing of environmental situations. The therapist offers suggestions about coping with the environment and improving problem-solving techniques. This treatment aims to strengthen an adolescent's cognitive skills and behavioral control. A central issue for cognitive-behavioral treatment is how patients respond to their cognitive interpretation of experiences and to a lesser extent the actual environment or experience. It aims to change distorted information processing by changing cognition and methods of behavioral contingency management.

In this treatment cognitive skills are taught and practiced initially within an affectively neutral environment. Once sufficient proficiency has been achieved in neutral settings, cognitive skills are practiced in situations of affective arousal. Thus, cognitive-behavioral therapy aims to develop and strengthen adaptive coping templates. It is not aimed at decreasing unconscious conflicts. Controlled studies have shown cognitive-behavioral treatment to be effective in a time-limited number of sessions to treat adolescents with anxiety, mood, eating, and specific developmental disorders.

Anxious adolescents misperceive environmental demands, which increases situational stress. Cognitive-behavioral therapy aims to identify anxiety-provoking situations, characterize the ideas and emotions associated with such situations, and alter these perceptions and enhance adaptive stress-relieving responses by the use of modeling procedures. Other techniques used include role playing, relaxation, and contigent reinforcement. When skills are learned, they are practiced in a real situation and encouraged by social reinforcement.

> A 13-year-old boy with a recent onset of obsessions about locking the front door of his home and the compulsion to keep his room excessively clean was treated as an outpatient with cognitive behavior therapy. In addition, he complained of worries about getting dirty when he played soccer. Despite this adolescent's talent in athletics, he became very anxious when he attended soccer practice for his school team. Cognitive behavior therapy began with providing a detailed account of his obsessions and compulsions. Desensitization techniques were utilized to reduce these unwanted symptoms. Cognitive paradigms were utilized to reduce his obsessive thinking and to prevent acting out his compulsions. Within 2 months of therapy, he was able to play soccer without interference from the obsessions and compulsions.

Depressed adolescents have cognitive distortions involving global, stable, internal attributions of negative events that lead to low self-esteem, decreased motivation, helplessness, and hopelessness. Cognitive-behavioral treatment aims to restructure thinking and promote adaptive perceptions of self, others, and circumstances as well as strengthen problem-solving skills.

Perceptions of aggressive adolescents are so distorted that they do not use all available information to make decisions. Instead they use biased recall of hostile cues and so, in ambiguous situations they attribute hostile motives to others' behavior. This produces an aggressive, action-oriented behavioral pattern in such adolescents, and they have difficulty planning alternative solutions to problems and selecting appropriate responses. Cognitive-behavioral therapy aims to reorganize concepts and develop less impulsive behaviors.

Behavior Therapy Behavior therapy has a distinct role in effective management of adolescent psychopathology, although research is needed to determine its efficacy for specific disorders or psychiatric symptoms, its comparative efficacy and its use in combination with other interventions for adolescents. When applied to humans, behavior therapy combines approaches of respondent and operant conditioning and reinforcement methods with features that address the complex mental processes, especially the cognitive processes, of humans. Behavior therapy is based on the principles of learning theory. It uses a problem-oriented approach and targets specific symptoms or behavior rather than focusing on a psychiatric disorder.

An important feature of behavior therapy is systematic desensitization, in which an adolescent is exposed to the specific anxiety-provoking stimulus, either in fact or in imagination. This is done gradually and only after the adolescent is taught relaxation as a counterphobic technique. Behavior therapy also involves operant techniques, in which events immediately prior to a behavior (eliciting stimuli) or subsequent to a behavior (reinforcing or punishing contingencies) are systematically manipulated in an effort to change the target behavior. Shaping involves applying positive reinforcement to a behavior targeted for enhancement. Such techniques are used for skill acquisition.

Contingency management involves systematically controlling the consequences of a behavior targeted for change (e.g., by using contracts, token economy, or points). Frequently these techniques are used in conjunction with cognitive techniques and social skills training.

Behavior therapy has been used widely and effectively to treat symptoms prevalent among mentally and developmentally delayed adolescents. Behavior therapy involving contingency management has been widely and effectively used to treat symptoms of attention-deficit disorder. In the case of oppositional defiant and conduct disorders, behavior therapy has shown beneficial long-term effects when applied with behavioral contracting, conflict-resolution skills training, token economies used in the home, and training the parents to restructure the home environment. Methods that incorporate systematic desensitization, social learning, and cognitive methods have been shown effective in treating anxiety disorders, including simple phobias, school refusal, and obsessive-compulsive disorder. Operant conditioning techniques have been helpful in treating eating disorders such as anorexia nervosa and obesity. Behavioral therapy techniques for adolescent substance abuse involve decreasing immediate reinforcing properties of the substance, reinforcing abstinence, teaching alternative successful social behavior, and cognitive approaches that enhance self-help.

Interpersonal Psychotherapy In 1984 interpersonal psychotherapy was developed by Gerald Klerman and colleagues as a time-limited, brief, psychotherapeutic treatment for depressed adults, and subsequently it was applied and studied with depressed adolescents. Its main concept is that depression occurs in the context of

interpersonal relationships that involve discrete problem areas of grief, interpersonal role disputes, role transitions, and interpersonal deficits. One or two of these issues become the main focus of treatment. Treatment is based on the assumption that the onset and continuation of symptoms of depression are associated with these interpersonal situations. This treatment has been studied extensively in controlled clinical trials and shown to be effective with depressed adults alone and in combination with antidepressant medication. It has been adapted and studied in adults for long-term maintenance treatment of recurrent depression, opioid dependence, cocaine abuse, bulimia nervosa, bipolar disorders, and depression due to human immunodeficiency (HIV) disease.

An essential feature of this treatment is a focus on the present and future, rather than the past. Interpersonal treatment has been modified for treatment of nonpsychotic, nonsuicidal, depressed adolescents. In addition to the four issues of focus for treatment of adults, interpersonal treatment for adolescents also focuses on issues relevant to adolescents who live in single-parent families. Specifically, the treatment for adolescents addresses perceptions of authority conflicts with parents and other adults, reactions to separation or divorce of parents, development of interpersonal relationships with adolescents of the opposite sex, peer pressure, and reactions to the death of a relative or friend. An open treatment trial with a relatively small sample of depressed adolescents suggested significant reduction of symptoms of depression at termination of treatment, and 1 year of posttreatment, recovery was generally maintained. Controlled treatment trials are necessary to determine the efficacy of this treatment for depressed adolescents.

A 15-year-old girl complained of intensifying symptoms of sadness, crying, problems falling asleep, difficulty concentrating on academic tasks and thoughts of committing suicide since she broke up with her boyfriend 4 months previously. She was treated as a psychiatric outpatient with time-limited interpersonal psychotherapy that focused on her grief over losing her boyfriend. Treatment educated her about the nature of grief and depression, assisted her to consider her feelings of guilt in causing the loss of her boyfriend, and strengthened skills in adapting to this loss and to develop new satisfying relationships. Follow-up 3 months after treatment indicated that she had maintained improvement in academic work and social relationships with peers and that she reported no symptoms of depression.

Family Treatment The family is the actual and perceived essential interpersonal structure for children and adolescents. It provides the basis for satisfying the dependency needs of the young, protecting against adverse environmental situations and providing models for socialization that significantly determine characteristics for future independent living. Family psychotherapy amplifies these basic constellations and enhances the intrafamilial communication, behavior, and routines to ensure that adolescents' sense of identity, social values, and future goals are identified and discussed.

During early adolescence, a strong antagonistic equilibrium is apparent, as the adolescent begins to move out of the family but remains dependent on parental influences. At this time pubertal changes are most marked and rapid, which heightens the adolescent's wish for privacy and intolerance of parental scrutiny. Often conflicts arise around these developmental events. Family therapy offers a way to guide the parents in planning their responses to their adolescent child.

Midadolescence is significant for its intense peer relationships and identity formation and heightened independence. Family therapy may need to focus on the adolescent and parents to assist the development of these important features. Often parents feel excluded by the adolescent or they feel less empowered to control the behavior of the adolescent. Adolescent problematic behaviors are perceived as insurmountable by the parents, who are often rendered helpless and feel anxious about the adolescent's striving for independence. Family treatment must help parents learn to assess the circumstances of the adolescent and to set appropriate limits while letting adolescents feel that moving toward autonomy and choice is within their domain of responsibility.

In late adolescence important transitions to adult life become evident. Consolidation of identity promotes new choices about school, work, and interpersonal relations, with a view toward family planning. Major biological development has been completed and psychosocial transition is paramount. Family therapy facilitates these advances by helping parents loosen their parental oversight and guide the adolescent out of adolescence and into adult behavior, responsibility, and insights about future life expectations. The availability of parental support is essential, but at lower intensity and less frequently.

Family therapy techniques focus on the family's expression of emotions; the communication styles of individual family members; conflicts; cohesiveness (i.e., the degree to which family members perceive and behave as an emotionally adherent unit), sharing of values, goals, and behavior; the satisfaction of individual family members with family functioning; adaptability; and problem-solving skills. Family treatment also addresses the developmental phase of adolescence, the family developmental status, and the specific psychopathology of individual family members, while maintaining a focus on the interpersonal structure of family functioning. An overview of the family as a unit is essential in conducting family psychotherapy. Thus, the individual is considered within the context of the larger family unit. Specific needs are addressed with regard to the cohesive needs of the family unit, and the individual family members must contribute to satisfying family needs.

Group Treatment Adolescent development involves gaining psychosocial independence from the nuclear family and acquiring the skills to assume adult responsibility. During this process, peer relations let adolescents practice their skills and get feedback in the form of friendships. Developing competence in peer relationships heavily depends on the quality of parent-child relationships. Group treatment provides peer discussion to exchange perceptions, guide problem-solving, and promote a more solid sense of identify. Group intervention is often preferred by adolescents because of the opportunity to be with peers. The guidance offered within the context of the group can be extensive and specific and may be integrated by the adolescent. As in family treatment, focus is maintained on the group as a unit, and progress is estimated by the development of a group cohesion that facilitates active interchange of ideas among its members.

As with treatment of prepubertal children, group psychotherapy of young adolescents (12 to 14 years) often involves a combination of discussion and other activities such as drawing, reviewing pictures, and storytelling. In contrast, group psychotherapy for midadolescents (15 to 18 years) and late adolescents (19 to 21 years) primarily involves discussion, with some dependence on other approaches (e.g., roleplaying, storytelling). Psychoanalytic, psychodynamic, behavioral, cognitive, transactional, and systemic approaches have been used.

Psychopharmacotherapy and Combined Therapy Major advances have occurred in the use of medications. However, few systematic studies of the safety and efficacy of psychotropic medications for adolescents exist, and they are greatly needed. Nevertheless, as with psychiatric treatment of adult patients, treatment of adolescents may be most effective when combined with psychopharmacology, especially for severe symptoms of psychiatric disorders. Studies of adult patients, such as those with major depressive disorder, obsessive-compulsive disorder, and schizophrenia suggest that psychotherapy plus medication is most effective in reducing symptoms. Studies of the combinations of treatment for attention-deficit/hyperactivity disorder, depressive disorders, obsessive-compulsive disorder, and school phobia in children and adolescents offer clues about the most effective clinical management of these disorders in adolescents.

A 17-year-old girl complained of episodes of rapid heartbeat, sweating, trembling, and fears of going out alone to the shopping mall. She had entered her senior year in high school and was considering her choices of colleges and was planning to take her college entrance examination. Her parents wanted her to go to the college from which her mother graduated to maintain the family tradition. Psychoanalytically oriented outpatient treatment and a selective serotonin reuptake inhibitor (SSRI) treatment were instituted to alleviate the panic disorder symptoms. The psychotherapy focused on the patient's conflicts with her parents; highlighted were chronic concerns that she could not maintain parental expectations and fears of her independence. Medication appeared to reduce symptoms of tachycardia, tremulousness, and preoccupations of lack of competence. Psychotherapy was maintained for 8 months during her last year in high school.

Attention-deficit/hyperactivity disorder has been studied most systematically with regard to combinations of psychotherapy and medications. Psychostimulants such as methylphenidate (Ritalin) and dextroamphetamine (Dexedrine) when combined with behavior therapy or cognitive behavioral therapy are most effective in improving social behavior and academic performance. Advances in drug development has widened the choice of medications to treat mood disorders (e.g., SSRIs) and schizophrenia (e.g., serotonin-dopamine antagonists including risperidone [Risperdal], olanzepine [Zyprexa], and clozapine [Clozaril]). These medications have been applied to adolescent disorders. Systematic research is required to determine the efficacy and safety profiles of these medications for treatment of adolescent psychopathology. No empirical studies of combined psychotherapeutic and medication treatment of mood disorders, anxiety disorders, or schizophrenia in adolescents have been published.

Before starting psychopharmacotherapy with adolescents a comprehensive workup is needed, including a physical examination; blood tests to evaluate hematological, kidney, liver, thyroid and other physiological functions; and an electrocardiogram (ECG) to measure cardiac function. Neurological assessment with an electroencephalogram (EEG) is necessary if seizure disorder is suspected or if the medication is likely to lower the seizure threshold.

Treatment Settings Although most of the treatments described are applicable to outpatient settings, treatments may be modified for a variety of treatment settings such as day hospital, partial hospital, and inpatient services. Treatment within these settings implies a disturbance greater than that in adolescents in outpatient services. The expected degree of change when such treatments are applied requires systematic study. Treatments in inpatient, day hospital, and partial hospital services are currently being systematized in terms of indications, type of treatments offered, length of treatment, and assessment of outcome. Much of this is related to

health care reforms with emphasis on cost containment. However, research is needed to determine the most effective treatment approaches in such settings.

Indications for admission of adolescents to inpatient settings are acute danger to self or others, acute psychotic behavior that cannot be modified in less-restrictive treatment settings, and significant inability to function autonomously. A psychiatric inpatient setting offers multidisciplinary and multimodal treatment approaches. An important element is the milieu in which an adolescent inpatient can practice newly developed social and problem-solving skills. Psychiatric inpatient treatment programs usually combine psychotherapeutic and psychopharmacological treatment.

Partial and day hospital treatment of adolescents has received recent increased attention as a cost-limiting and efficacious treatment for severely disturbed adolescents with more-chronic psychiatric problems. Such treatments augment the psychiatric care in psychiatric hospitalization and often are recommended for continuation of the psychiatric treatment received in a psychiatric hospital. Multimodal treatments that combine individual and group psychotherapy with psychopharmacological treatments are applied. Stays in such treatment settings often are longer than those offered in psychiatric hospitalization. The goal of such treatment is to promote significant improvement that will enable the adolescent patient to live in the general community.

CHAPTER 49. CHILD PSYCHIATRY: SPECIAL AREAS OF INTEREST

49.1 PSYCHIATRIC ASPECTS OF DAY CARE

KLAUS MINDE, M.D., F.R.C.P.(C)

Women with small children represent the fastest growing sector of employed mothers in the labor market. In 1991 about 35 percent of all women in the United States and Canada with children aged 0 to 5 years and 45 percent with those aged 6 to 14 worked full time. An additional 37 percent of mothers with infants and toddlers and 34 percent of those with school-aged children worked part time, bringing the total of working mothers to more than 70 percent, almost double the rate seen 20 years ago. Since mothers want to ensure that their children are well cared for during their absence from home, they have triggered a number of studies that examine the effects of maternal employment on children.

Maternal employment does not only affect children because their mothers spend less time at home. In many dual-worker families both parents and children experience increased stress because women generally have continued their traditional role in child rearing and family life. This has led to role conflicts and guilt in more than 40 percent of both employed men and women. Hence children often do not only have less time with their parents, but they may also be affected by the stress their parents experience from trying to do too much.

EFFECTS OF NONPARENTAL CHILD CARE ON CHILD DEVELOPMENT

Child-Adult Relationships Some highly publicized studies in the late 1980s indicated that early initiated nonparental care (i.e., before 12 months of age) affects the security of infant-parent attachment. Specifically, these authors reported that in five homogeneous samples of 491 maritally intact middle- and working-class families, 43 percent of the infants were classified as insecurely attached if they experienced 20 or more hours a week of routine child care during the first year of life. Infants with less-extensive routine child care showed an insecure attachment rate of only 26 percent. This pattern was confirmed by Michael Lamb and Kathleen Sternberg. However, more-recent work suggests that a number of family and maternal personality characteristics affect both the timing and the extent of maternal employment and consequently the duration and type of nonparental care of children. For example, Edward Melhuish and colleagues showed that of 18-month-old children who had either stayed home with their mothers or were cared for by relatives, by caregivers, or in a nursery, only those in the last two categories showed a diminished number of affectionate acts toward the caregiving adult, less overall responsiveness, and less-engaged activities. However, the characteristics of the mothers who chose each nonparental setting also varied and explained much of the overall variability in their children's behavior. This points out the need to assess children both before and after they enter day care to control for these factors. In just such a study, Jaipaul Roopnarine and Michael Lamb found that 3-year-old children whose parents had decided to enroll them in day care were initially more anxious about, and distressed by, a brief separation than those in a control group who would remain at home. After 3 months of day care, however, group differences had disappeared, suggesting that differences observed between home and day-care children cannot automatically be interpreted as effects of nonparental care. Other, more-recent investigations found no significant relationship between child care experience and attachment security.

One possible explanation of the differences between studies from the 1980s and 1990s could be that today's mothers who place their infants in child care are more informed about the possible effects this may have on attachment patterns. This in turn may make them more sensitive and responsive toward their babies when they are with them after work, which compensates for possible deleterious child-care effects. Or perhaps employed mothers receive more social support today than in the past, which allows them to spend more quality time with their infants when they are with them.

To clarify some of these important questions, the National Institute of Child Health and Human Development (NICHD) funded a major 10-site study of early child care, involving 1153 infants and their mothers. This study had various advantages. It was prospective (i.e., infants were identified at birth and followed through their first 3 years). The authors were able to examine the effects of child care in context, (i.e., as it relates to the age at entry and the quality, amount, and stability over time). Early results of this study showed no significant difference in attachment security related to child-care participation. Even enrollment in extensive, unstable, poor-quality day care was not associated with a higher rate of insecure attachment. However, childhood attachment was affected by a combination of child-care and maternal factors. For example, children who received less sensitive care both at home and from their child care providers (i.e., were at dual risk) showed the highest rate of insecure attachment (up to 56 percent). This confirms work by Albert Hausfather and coworkers. The attachment ratings of less-sensitively mothered children were also affected by more-extensive or unstable care arrangements. Furthermore, high-quality, brief day care served a compensatory function for children with unresponsive and insensitive mothers. This suggests that extensive day care, regardless of its quality, did not help compensate for insensitive mothering. The authors suggest that this is due to a dosage effect for maternal sensitivity and involvement. Children with a less-involved mother may need more time with her to develop a sense of her being available, hence they show the highest rate of secure attachment if they are exposed to brief, high-quality day care.

Relationships With Peers Authors who have investigated relationships with peers have reported results similar to those examining the child-adult relationship following nonparental care experiences. Thus, papers published in the 1980s report that infant day care was associated with later aggression toward peers or other problematic behaviors. However, more-recent work emphasizes the relation between the quality of nonparental care and later behaviors with peers. For example, Carrollee Howes found that children who had experienced low-quality care in infancy displayed poor peer relations in kindergarten. In contrast, the more secure the teacher-child relationship had been in day care, the more gregarious, complex, and empathic the play was between these children at age 4.

Long-term follow-up studies confirm this benefit of high-quality care. For example, Tiffany Field and her colleagues found that 7-year-olds with a long day-care history were more popular, more mature, and less aggressive than children who had entered day care only after the age of 2. Benet-Evis Anderson, in a longitudinal study of Swedish children, confirmed the superior social competence of 13-year-old youngsters who had received other than home care since infancy. This supports the notion that the quality of early nonparental care is associated with later relationship skills toward both adult and peers.

Behavior Problems According to attachment theory, children who are insecurely attached to their parents are less compliant as toddlers than those who have established a secure relationship. Since an increased rate of insecure attachment has often been reported in children who have experienced early nonmaternal care, it is not unexpected to find studies that suggest an association between day care in infancy and later inappropriate noncompliance with parental requests. Carrollee Howes and Michael Olenick studied toddlers at home, in their day-care centers, and in a laboratory situation and found that compliance with adult requests at home and in a laboratory were not correlated. This suggests that compliance or noncompliance is not a trait related to child-care history.

Nevertheless, some reports indicate that children in day care show high levels of externalizing problems and overall poor behavior right after school age; others disagree. Overall then, the literature suggests that nonparental care is sometimes associated with behavioral problems. These difficulties tend to involve externalizing symptoms such as aggression and assertiveness and may be similar to the behaviors these children show toward their peers. However, since there are no good studies that use the quality of day care as a possible defining variable, the available data must be interpreted cautiously. The multisite NICHD study may provide more-contemporary data.

COGNITIVE COMPETENCE

The literature dealing with cognitive competence can be divided into studies that describe infants who were enrolled in intervention programs because of specific biological (e.g., prematurity) or social risk factors (e.g., poverty) and reports that explore the overall effects of infant day care on cognitive development. Specific intervention programs are invariably associated with increased cognitive competence, although very small, premature infants benefit less from enrichment than heavier ones, possibly because of neurological constraints. Furthermore, evidence suggests that the effects of cognitive stimulation, even in the bigger premature infants, do not persist after the enrichment program terminates. For example, in the multisite cohort of 986 premature infants studied by Jeanne Brooks-Gunn and colleagues, the special programs for the treatment group continued for 3 years. The cognitive advantages of the children who had attended the child-care program

were highly significant at 3 years of age (14 intelligence quotient [I.Q.] points) but far less so at age 5, and 3 years later all treatment effects had disappeared. Findings are also variable in non-high-risk populations, although children from disadvantaged families seem to benefit most, especially those in high-quality programs. Cognitive gains are usually assessed as school achievement or verbal abilities. In some Scandinavian prospective long-term studies, 8-year-old children with more center-based care before age 3.5 years scored higher than those with less care, irrespective of family background. This may reflect the uniformly high quality of group care in these countries.

QUALITY OF CARE

Quality has been defined and measured by structural and dynamic measures. Structural measures are aspects of the care setting that allow sensitive adult-child interaction. They include staff-to-child ratios (i.e., there should be no more than three infants under age 2 per caregiver in a good-quality day-care situation), quality of physical settings (e.g., furnishings and toys, physical safety features), experience and training of staff and management, group size, and the type of nutrition the children receive. Dynamic measures are designed to assess the quality of the experience provided to the children. They include the developmental appropriateness of the children's experiences and stimulation (e.g. fine and gross motor activities, language and reasoning experiences, creative experiences), the sensitivity of the caregivers' responses to the children, staff-parent interactions, and staff supervision and evaluation. There are also established instruments that assess the overall environment and the actual adult-child interactions.

Unfortunately, only a minority of children receive high-quality child care services in North America at present. For example, only about 2 percent (1800 of 80,000) of eligible child-care facilities in the United States and 10 percent in Canada had achieved accreditation by their respective national organizations in 1990.

ROLE OF THE PSYCHIATRIC CONSULTANT

Psychiatrists can be helpful in various ways. They can help staff understand especially challenging youngsters and provide direct case consultations. They can also be used on a more systemic level. For example, they may provide regular in-service training for staff and administrators, speak at parent meetings on specific developmental topics, or be available in times of crisis (e.g., documented child abuse). Some child psychiatrists may engage in a mix of these activities.

As with any consultative role, the psychiatrist and the child-care agency must clearly state their respective obligations and roles toward the children, their families, and each other. This engenders mutual respect and trust and makes the work of the psychiatrist more effective. Children in nonparental care situations need multifaceted care, and the psychiatrist can have a well-defined role within this multidisciplinary orchestra of caregivers.

Peter was 11 months old when he was referred to a child psychiatrist by his pediatrician and the director of his day-care program because he did not want to go to sleep at night unless his mother laid down with him and entertained him for up to 1 hour. He would wake up at least twice at night and cry until his mother picked him up. He usually fell asleep again in her arms after 30 minutes. At day care, he was unhappy and did not mix with the other children.

Peter's mother was 38 years old and worked as a fashion designer from 9:00 am to 6:00 pm. His father was an accountant. The couple had been married for 8 years and had tried to have children for 3 years prior to Peter's birth. Both had been delighted when Peter was born and Mrs. A. had taken 6 months off work to be with Peter at home. One week before her return to work, she had enrolled him in a day nursery to ease the transition. She had spent some time in the nursery during his first week there but now only delivered him to the nursery every morning. The staff claimed that Peter slept well in the nursery but did not readily mix with the other children and seemed visibly relieved when he was picked up by his father around 5:30 pm. This had not changed since he had entered the nursery 5 months ago.

Mrs. A. had also weaned Peter during the month preceding her return to work. This had been quite difficult, Peter initially refused to take the bottle for 3 days and had cried for many hours. In fact, his sleep had become problematic at this time, and his mother felt that he “may have missed his midnight breastfeed.” However, she had not dared to continue breast-feeding him in the evening and at night, as she feared he would then refuse the bottle during the day.

Mr. A. was 43 years old and felt that Peter was spoiled and needed more discipline. He did not get up at night to care for Peter but did enjoy playing some special “boys' games” with him after he had brought him home from the nursery. Mr. A. also thought Peter should be allowed to take a bottle into bed at night and was convinced that Peter could and would take the bottle on his own and, as a consequence, sleep much better. Mrs. A. was the oldest of three children. Her parents had emigrated from northern Africa, and she had grown up in a family in which her mother's traditional family values had clashed with her father's demands on his children to meet North American expectations of high professional achievements. Mrs. A. saw her “artistic” profession as a compromise between these two cultures, but she had welcomed the opportunity to join her husband in a city far away from her hometown. The only direct family in town was Mr. A.'s 75-year-old father, who had lost his wife 12 years earlier and lived with another woman in a residence for seniors. He visited the A. family three to four times a year.

Mrs. A. brought Peter to the initial interview and cried a great deal, expressing both exasperation and anger with Peter because he kept her up every night and seemed to be so needy. She discussed her work and the pressure she was under with respect to the upcoming season. She discussed her mother, whom she remembered as aloof and lacking understanding when she was a youngster. She frequently mentioned how much she wanted to be a good mother to Peter. The therapist mentioned how much Peter loved and missed her when she went back to work and how hard it was for him to understand the sudden changes in his life. They discussed Peter's inability to judge time and how that might make his days in the nursery seem indeterminably long. After a play session with Peter and his parents during which he was keen to set up games that involved both his father and mother, the following treatment plan was developed.

1. Mother would accept the offer of her trusted cleaning woman to have her sister look after Peter during the afternoon in his own home.
2. Mother would continue to bring Peter to his day care at 9:00 am but alternate with her husband in picking Peter up at noon and bringing him back home to his new baby sitter.
3. Mother would put Peter to bed each night and develop a specific ritual to facilitate his falling asleep (e.g., two songs and one story before leaving the room).
4. Father would attend to Peter at night, if Peter woke up, by simply putting him down when he cried and remaining in his room without engaging in elaborate conversations or games until Peter had calmed down.

This new plan was discussed with Peter and his parents in the therapist's office. Peter obviously did not understand the details of the discussion but he clearly knew that something important was taking place. The therapist promised to call the family every second evening during the following week and arranged another interview about 2 weeks later.

Follow-up Peter accepted his new babysitter readily, especially since she initially came with her sister, the cleaning woman, and enjoyed taking him out for a walk and let him sit on her shoulder while she prepared his supper. While Peter initially seemed unhappy that his father came to his room at night, he ceased to wake up within a week, improving the level of contentment of all family members. He also seemed delighted to welcome his mother home in the evening and show her what he had done with the babysitter during the day. The nursery also reported improvement, and the staff commented on the sensitivity Peter showed toward other children's feelings.

Discussion This case shows that the sudden transition from being a single child at home to being one of 20 children in a nursery can be extremely stressful for a toddler. The associated sudden weaning obviously added to the sense of loss Peter felt and made his poor sleep and behavior at night quite understandable. While his father seemed to be somewhat aloof and distant, he did respond to his new role as the night caregiver and quickly managed to reassure Peter of his parents' faithfulness. In return, Peter could sleep better and enjoy his mother in a less controlling and anxious way.

Research has shown that regular exposure to nonparental caregivers need not have harmful effects on children's development and their relationships with others. The relationships children develop with their caregivers influence their later behavior and may compensate for, or magnify, the effects of the original parent-child attachment. While previous researchers focused on between-group differences, current interest is focused on preexisting differences among children and within-group effects of the day-care experience. Research also shows that the quality of children's interaction with their family members and the quality of care they receive at home exert the most influence on their later development and behavior. Nonparental care, therefore, is most beneficial if it complements the quality of family care. Psychiatrists can play an important role in sensitizing staff and families to the developmental and emotional needs of groups or individual children. They can also use

their knowledge about child development to influence lawmakers to provide high-quality nonparental care to all those who need it.

SUGGESTED CROSS-REFERENCES

Normal child development is described in Section 32.2. Section 25.12 provides an overview of consultation-liaison psychiatry. Public community psychiatry is discussed in Section 52.1.

CHAPTER 49. CHILD PSYCHIATRY: SPECIAL AREAS OF INTEREST

49.2 ADOPTION

STEVEN L. NICKMAN, M.D.

Adoption, the custom whereby children become the legally recognized sons or daughters of adults who are not their biological parents, has existed in human societies throughout recorded history. It has taken various forms in different cultures; in ancient Babylonia its primary purpose was to provide continuity for the transmission of property or skills, while in the Roman Empire it was often used to elevate the status of an individual who was already an adult. In some areas of the Pacific, adoption of young children formed part of an exchange system between related clans. In some traditional adoption systems the care and upbringing of a child was only one part of a complex system of expectations and obligations, and the adults' agendas were seen as more pressing than those of the children.

HISTORY

Other institutions have provided care and nurturance for children. Child abandonment in classical, medieval, and Renaissance times often led to the child's being taken in by a family. Orphanages arose in Europe during the Renaissance; many boys and girls were “oblated” and taken in by monastic institutions that then raised them with the expectation that they would live a life in the Church. Many apprentices to trades or professions were raised primarily as members of their masters' families.

The concerns expressed by adopted persons about not knowing their roots are as ancient as they are contemporary. Euripides' *Ion* contains a touching dialogue between a woman in search of the child she gave up years before and a young priest of Apollo, who does not know he is the woman's son and who says the only mother he knows is Apollo's priestess.

When the social work profession became established in the third quarter of the nineteenth century, one of its tasks was placing children in adoptive homes. This development was made possible by the enactment of laws about the same time that established adoption as the means whereby a child could be made a legal member of a family (though for some time adoptees did not automatically inherit from their adoptive parents). Because of the fear of “hereditary taint,” infants were commonly kept in hospitals or temporary placements for a number of months, sometimes until 1 year of age, to make certain that the child was healthy in all respects and developing normally. These procedures deviate from contemporary practice in two respects: the lack of awareness that children should be placed as early as possible because of concerns about attachment, and the emphasis on the need of adoptive parents to be certain of getting a normal child (as opposed to the current view of adoption as an institution that exists primarily for the child's benefit).

In the second quarter of this century, as research on child development demonstrated the need for early attachment, adoption practice shifted, and infant placements began to occur in the earliest weeks of life. *Closed adoptions* were the rule (i.e., the identities of the birth parents and the adoptive parents were kept secret). This was thought to facilitate the birth mother's ability to get on with her life, to protect her from later intrusion when the child grew up, and to help the adoptive parents feel unencumbered and fully authoritative in the child's upbringing. From the child's standpoint, information about birth parents was not considered essential for healthy development, and adoptive parents were encouraged to give formulaic responses to a child's questions (e.g., “your birth parents had you placed for adoption because they loved you and couldn't care for you”).

After World War II numerous European children were placed in the United States, and domestic transracial adoptions were tried by some agencies about midcentury. After the Korean War needy Korean children were placed in U.S. homes. These trends arose at the time when traditional infant adoption became more difficult because of the availability of abortion and contraceptive pills and increased social acceptability of single parents raising their children developed. Another growing trend by the early 1970s was the adoptive placement of children formerly considered unadoptable: those past infancy who had survived abuse and neglect and been placed in foster homes, and children with physical, mental, and emotional handicaps.

Beginning at midcentury but increasingly forcefully in the last 25 years, a number of adult adoptees, some professionals, birth parents, and a smaller number of adoptive parents have joined to change the laws and customs surrounding adoption—specifically the secrecy involved in traditional, confidential adoption. State legislatures periodically increased the availability of both nonidentifying and identifying information to adoptees at maturity; however, in only two states can adoptees or birth parents now obtain identifying information. In many states, the placing agency serves as an intermediary, and if mutual permission is extended by both adoptee and birth parent, the agency provides each with the other's name and address. This development is seen as part of a general trend toward openness in adoption, which has several facets: actual *open adoption* in which birth parents and adoptive parents (and in some instances the child) have various degrees of contact with each other and a tendency to encourage adoptive parents to value the birth parents, to raise the child with some knowledge of them, and to accept the child's curiosity about them and support a search if such is the child's desire in late adolescence. It has been argued that traditional closed adoption is flawed and that the institution of adoption should be restructured to allow most adoptees to grow up knowing their birth parents, making allowance for the fact that some birth parents are unavailable, uninterested, or too disturbed to participate usefully in an open adoption. This recommendation is controversial but is attracting considerable attention.

In the case of children adopted from abroad, such matters are more complicated, but there is considerable agency support for adoptive families' attempts to search in Korea and Latin American countries. With children adopted from the foster care system, matters are complicated in a different way, but clearly such children (especially if placed after the toddler years) often maintain some attachment to birth parents and need help, especially during adolescence, to solidify their ties with their adoptive families. Occasionally this involves renewed contact with birth families, to aid the adolescent's identity formation. The open adoption movement is currently influencing these placements as well as infant adoption, and causing agencies and courts to reexamine the old policy of total cutoff. Open arrangements in postinfancy adoption require sensitive and creative management by the placing agency as well as good will and mutual respect on the part of all the parents involved; commonly not all of these requirements are met. The obvious concern of those who question open adoption is that the child will be confused and suffer divided loyalties, but a closed adoption in these circumstances may lead to divided loyalties in any case. Later difficulty frequently arises from the agency's failure or inability to facilitate one or more termination meetings between the child and the birth parent, at which the child can receive the parent's permission to be parented by the adopting parents. The usefulness of therapeutic reunions for disturbed adopted adolescents suggests that having some continued contact with the birth parent stipulated in the adoption arrangement might help to avoid or mitigate a troublesome form of attachment disturbance (multiple emotional attachments).

EPIDEMIOLOGY

From 1.5 to 2 percent of children grow up in adoptive placements with parents who are not blood relatives; approximately another 1.5 percent are adopted by relatives or by stepparents married to one of their biological parents. Figures from the National Adoption Information Clearinghouse indicate that in 1992, there were 127,441 adoptions in the United States. Of these, 42 percent (53,525) were by stepparents or relatives and 58 percent (73,916) were unrelated adoptions. Of the unrelated adoptions, 27 percent (19,753) were conducted by public agencies (i.e., adoptions of children from the foster care system); 8 percent (6536) were from other countries, with largest numbers from Korea (1787), Colombia (403), and Chile (403); and 64 percent (47,627) were either arranged by a private agency or were independent adoptions, in approximately equal numbers.

The number of international adoptions varies with world events. In 1995 there were 9384 such adoptions, the increase being brought about by political changes in Russia, Romania, and other former Communist areas of Europe and by the Chinese government's new policy of allowing infants to be adopted in North America and Europe.

The number of completed adoptions from the U.S. foster care system does not give a full picture of the numbers of waiting children. The National Adoption Information Clearinghouse estimates that as of March 1998 there were approximately 500,000 children currently in foster care in the United States. Of these, 110,000 (just over

20 percent) are eligible for adoption. Figures from 1993, when the corresponding number was 86,000 were broken down as follows: 17,000 children were legally free for adoption and waiting in not yet legalized adoptive homes; 21,000 children were legally free but still waiting to be placed in adoptive families; and 48,000 children were not yet legally free for adoption, some living in preadoptive foster placements, but most in ordinary foster homes or residential facilities. Between 1983 and 1993 the number of children in foster care increased 154 percent in California, 158 percent in Illinois, 123 percent in Texas, 120 percent in New York, and 67 percent in Michigan.

PSYCHOLOGICAL ASPECTS OF ADOPTION

Clinical and Research Findings Since the 1940s the literature of child psychiatry has described various problems in adopted children and adolescents, and debate continues about whether they have more difficulty than their nonadopted peers. In 1960 Marshall Schechter found that adoptees were highly overrepresented in his private psychotherapy practice. He and other psychoanalytically oriented observers described difficulties in resolving oedipal conflicts and in formation of the superego, as well as low self-esteem. These adopted children commonly saw themselves as unwanted, and devalued their birth parents, whom they viewed at times as lower-class or debased individuals. Some authors recommended delaying the disclosure of adoption until midlatency to minimize the confusion that might arise from children having to define their psychological place in the family while simultaneously coming to terms with not having originated there.

Several studies found more adoptees referred for externalizing behaviors than for internalizing problems. More-recent studies continue to find adopted children and adolescents overrepresented in outpatient settings. One study found adoptees overrepresented among their hospitalized children but underrepresented among children referred to the juvenile court. They postulated that the relatively high socioeconomic status of adoptive parents led to their children being referred to the psychiatric network rather than the criminal justice system. Another study of adopted adolescents before the juvenile court found that judges were harsher and parents were more rejecting with them than with a group of neglected adolescents also referred to the court. The authors ascribed the difference in the court's disposition to the fact that the parents of neglected children defended them while the parents of adopted children failed to defend them or even requested placement in correctional facilities.

A weakness of many studies is that insufficient distinction is drawn between groups of adoptees that would be expected to differ in the extent of their disturbance (e.g., those adopted in infancy and those adopted at school age following neglect and abuse). The concept of multiple types of adoption has not been well enough recognized. Thus, some of the figures cited above might be taken as reflecting pathogenicity of infant adoptions to an extent that is not warranted.

Adoption Triad With adoption increasingly considered an institution that exists primarily to benefit the child rather than the adopters, activists and child welfare experts have come to speak of the triad, or triangle, that includes birth parents, adopted person, and adoptive parents.

Adoptees' Losses It has been proposed that adoptees experience three general categories of loss and that different types of placement tend to predispose toward certain types of loss. Most adoptees appear to suffer from all three types at certain times during their development. *Overt losses* are those that would be visible to an observer as they happened: changes of caretaker, loss of familiar surroundings, loss of siblings or foster siblings, pets, and belongings; these losses predominate in children adopted from the foster care system and are prominent in children adopted from abroad after the toddler years. *Covert losses* are experienced intrapsychically and are the inner representations of the adoptee's life situation (e.g., “Why wasn't I kept by my birth parents?” “Was there something wrong with me?” “How can I determine whether and when I want to get more information or search for them?”) In addition, some young adoptees have a propensity to fantasize or to engage in activities that represent symbolically the wish to search or the feeling of being devalued. Time spent engaging in fantasy may affect grades in school, and these symbolic activities may be regarded as acting out and lead to consequences for the child or adolescent. Covert losses are the most prominent form of loss in children adopted in infancy by parents of the same ethnic group as themselves, but they are also common in other infant adoptees as well as later-adopted children. *Status losses* are experienced by adoptees who feel stigmatized or singled out in unwanted ways by virtue of some aspect of their adoptive status—most often, appearing different from their adoptive parents or siblings. This type of loss is seen in its clearest form in transracial and international adoptees, but it occurs generally.

Disclosure and Dialogue In the 1960s, child psychiatrists debated the proper age at which to disclose adoption to children. Early disclosure (in the first 3 years), which had been recommended in the 1940s to prevent later traumatic discoveries, was questioned on the ground that children's ability to negotiate oedipal concerns was interfered with and they were confused about family membership and suffered problems identifying with their adoptive parents. Such concerns would probably be viewed somewhat differently now, and in North America and Western Europe there is general belief that children, as well as people in general, deserve the truth about matters of importance concerning themselves. Adoptive parents are still encouraged to tell children quite early about adoption. An important concept in helping them to do so and to carry out a subsequent dialogue about this with the child as needed is *affect tolerance* in the parent (i.e., the ability to bear a degree of anxiety and sadness within themselves and the child, with the confidence that their relationship with the child will survive and that the child will not ultimately be harmed significantly).

Age of Understanding Research has shown that prelatency children, adopted or not, have a fragmentary or distorted understanding of adoption no matter how much information they have been given. As children move into Jean Piaget's stage of concrete operations they begin to understand complex ideas, and for adoptees this includes the fact that being adopted also means being relinquished. From this one can deduce a clinical principle and a caution. The clinical principle is that children of 7, 8, and 9 years of age might be expected to exhibit sad affect and self-doubt as they begin to grasp the sadness implied by relinquishment—and this in fact occurs frequently. The caution is that this research finding should not be used as a reason for not telling the child earlier (“because he wouldn't understand”); later disclosure has its own complications; school-age children who feel that their parents have not been open with them can have consequent difficulties of trust.

> Amy A. was placed with her adoptive parents at age 20 days. She was now 6 and entering first grade, but after a week refused to go. She said, “I miss my old teacher, Miss Z. I don't like going all day. I miss my mommy.” At moments of friction she would say, “I wish I had stayed with my real mother.” Her first-grade teacher, Mrs. Y, was middle-aged and brisk, unlike last year's young teacher Miss Z, whose gentle manner had made school a wonderful experience for Amy. Mrs. A. was taken aback when Amy confided, “I'm afraid Mrs. Y. will steal me from you the way you stole me from my real mother.” In treatment, Amy demonstrated via puppet play her preoccupation with mother-child relationships, specifically her concern with abandonment. Eventually she made it clear that her fantasy went a step further: the kind, gentle Miss Z. was her original mother, and Amy had experienced the changeover to the more work-oriented, demanding first-grade teacher as a reliving of her fantasy of the transition from biological to adoptive family—a version that could be called “paradise lost.” Both Amy and her parents were pleased with the new light that was shed on her school difficulty, and after a few months of weekly psychotherapy, she was attending school happily and successfully.

Adolescence With the onset of adolescence, adopted young people develop a renewed interest in their origins, often specifically in the behavior patterns of their unknown birth parents with respect to sexuality and other aspects of parental behavior (e.g., drugs, alcohol, or illegal activities) that the adoptee believes may have contributed to the birth parent's “badness” or inadequacy and thus to the adoption itself. When embroiled in negative interactions or power struggles with their adoptive parents, adopted adolescents may test illicit behaviors, both as a trial identification with birth parents and as a test of the adoptive parents' loyalty and support. Both teenage pregnancy and alcohol and other substance abuse can be seen in these circumstances.

Another common theme in adolescence is the adopted son or daughter declaring independence from parents with respect to certain types of schooling; athletic, religious, or musical activities or life goals. This can occur without rancor or strife and can represent the adoptee's true or false belief, that his or her abilities and talents differ from those of the adoptive family—perhaps differences that the parents have not sufficiently taken into account. Parents are well advised not to leap to the conclusion that this merely represents rebellion and should be dealt with as a disciplinary matter. In fact, it may be highly adaptive and may give adolescents a solution to the dilemma of defining themselves as a member of their family, but who in some ways differs from them.

Some adopted adolescents are involved for a time in fairly dramatic conflict with their parents. This is almost the rule for later-adopted children from the foster-care system, and it is fairly common in adolescents adopted as infants. When these families—particularly families of later-adopted children—seek help, it is common for professionals to fail to recognize the permanent commitment of adoptive families and to assume that the adoption did not work out or that the child never formed a solid attachment to his or her parents, even though the adoption may have occurred in infancy and vast amounts of love and nurturance may have gone into making a later adoption work. Psychiatrists, psychologists, social workers, and juvenile court judges need to regard the family as a whole as their client and do whatever they can to keep the family intact. Out-of-home placements may be necessary as a temporary measure (e.g., residential treatment, respite care, or placement with other family members), but the adoptee should only reenter the foster-care system as a last resort, because this implies a failure on the part of the family that may not be accurate and may lead to permanent dissolution of the adoption.

Scott, age 14, was referred by his boarding school for cutting his arms and abrading his knuckles with sandpaper, behavior he had engaged in with another adopted student named Kevin. Scott was adopted in infancy but his parents divorced when he was 7. He had average intelligence but also had a reading disorder and other learning difficulties. He saw his parents rarely; his mother was self-absorbed, and his father lived in Europe. “Life's been pretty hard for me,” Scott said. “I wonder if I belong anywhere. I'm worried about who my (birth) mother and father were. I went to the adoption agency on my last vacation, but they wouldn't give me the address.” With feeling he recited the few factual details the worker had been willing to give him. “I wonder why they gave me up for adoption. I was told she had brown hair and brown eyes. I wonder what she looks like now. Whenever I see someone who looks like that I start to wonder. I want to ask if she had a kid and had it adopted. I wonder if my father is mean, or nice, or strict. I lie in my room and get this weird dreamy feeling; then I get mad and start hurting myself. I found out Kevin was adopted too. He refused to follow the rules. He went to a psychologist and found out he was a battered child. He tried to hang himself once. Right after we found out we both were adopted we figured we might be real brothers, so we cut each other to mix the blood. We think about evil sometimes. If you see it from an adopted kid's view, you're trying to find your parents. Evil is what keeps you from finding them. Once you find your parents and the battle's over, you settle down and live a quiet life.” Asked about his goals, he said, “I don't think about that much. I want to stay young.”

Scott was seen 13 times over a 10-month period. He showed his drawings as well as a story he was writing with themes of good, evil, and secret knowledge. Three themes that preoccupied him were his adoption, his learning disabilities, and his parents' divorce. He was encouraged to think of himself as the hero of his own life story and to see himself as having specific gifts and abilities that would serve him well in life. It was clear that his use of fantasy served at least two purposes—to connect him with his birth family and to protect him from the anxiety-provoking task of thinking about how to move forward in his life. He was given support for his feelings of sorrow about the divorce, for how burdened he felt by the learning disability, and for his worries about having a good future; he was also encouraged to view the cutoff from his birth parents as a sad event that was legitimately worthy of being mourned.

Scott was seen again some months after his sessions had ended. His school had written to say that his attitude about school and work had improved, that he was a happier, more active participant in school, and that he had been elected to student council. Scott reported, “Things are better. My old friends left and I have new friends. I'm on the wrestling team. I've seen too many bad things. I'm trying to get my life started good now, to get on the right track.” He indicated that adoption was no longer as great a preoccupation for him. “Before, people would ask, ‘What religion are you?' or ‘What nationality?' and I'd say ‘I don't know', or ‘I was raised as a Protestant,' or I'm adopted.' Now I figure I don't have to bring adoption into it, I can just tell them about what kind of person I am.”

Adoptive Parents and Grandparents Professionals dealing with adoptive families should recognize that it is difficult for parents to impart knowledge of adoption to children and that this process often evokes feelings about parental infertility, if present, and also evokes empathy for the children, whose picture of the world and their place in it now has the added complications implied by this new knowledge.

Adoptive parenthood is stressful for other reasons as well. As the adopted child grows up, the topic must be dealt with repeatedly, and parents must be able to respond to the child or adolescent's distress, which may at times be manifested by externalizing behaviors. In open adoptions, contact with birth parents must be arranged and managed in a way suitable to the child's interest. In addition, adoptive families are perceived by some members of society as different from other families. This is most true for internationally adopting or transracially adopting families and those who adopt older children, but even parents who adopt same-race infants at times feel stigmatized, sometimes in subtle ways.

For these reasons, adoptive parents' relationship with their own parents becomes very important. Grandparents cannot fully support adoptions if they resent the fact that the adopted child is not biologically related to them. Earlier in this century grandparents commonly left adopted grandchildren out of their wills or showed greater affection to biological grandchildren than to adopted ones, and in some families these still occur. Astute clinicians may help grandparents who are exclusively interested in the perpetuation of their biological line to readjust their values on behalf of themselves, their adult children, and their adopted grandchildren.

A couple in their 60s learned of the engagement of their son, in training for what promised to be a prestigious professional career. He shared with them his mixed feelings about telling his fiance that he had been adopted. They advised him strongly to overcome his hesitation, stressing that there was nothing shameful about being adopted and that if the young woman had negative feelings about it, it would be best to find out now. Though aware of these things intellectually, the son needed his parents' guidance under stress. The couple were married and have a charming 12-year-old daughter.

Psychopathology in Adoptees Most adoptions and most adoptees turn out well. The various outcome statistics indicating that child and adolescent adoptees are more vulnerable to developing problems are best understood with reference to the factors outlined above, also bearing in mind that biological factors (e.g., attention-deficit/hyperactivity disorder, bipolar I disorder) may play a part. Overt, covert, and status losses, combined with any problems within the adoptive family that interfere with empathic disclosure or helpful dialogue, contribute to the formation of internalizing or externalizing problems and disorders of personality. In addition, some observers would consider the way adoption is structured in society, with the attendant secrecy, to be a pathogenic factor.

Adopted Adults On reaching adulthood most adoptees are indistinguishable from their nonadopted peers in terms of behavior and achievement; those who showed externalizing symptoms as children and adolescents have largely discarded them. A small number qualify for an Axis II diagnosis and most of these probably fall into two groups: those who were adopted after infancy following abuse and neglect in their biological families and those whose adoptive parents had some psychopathology and did not help the child deal with feelings about adoption. Many adopted adults do have substantial concerns related to their adoption, however.

Difficulty with relationships is common, particularly vulnerability to loss and reluctance to make permanent commitments. Another frequent problem is low self-esteem. Many articulate adoptees express the belief that society treats them as children by not allowing them full access to their original birth records. Occasionally they encounter prejudice (e.g., a potential spouse who is reluctant to marry a person whose family background is not completely known). Adopted adults often long to have a child of their own; this developmental stage has special meaning for them because it will be the first time they will see an individual who is related to them by blood.

Search The *search* is commonly understood to mean that the adoptee wants to meet and get to know the birth parent, but many who search have more-limited goals, such as learning what the birth parent looks like, obtaining a family medical history, or learning about the birth parents' abilities and interests. Under the closed adoption system, most adoptees reach adult life having had no contact with birth parents and little or no knowledge of them. Society does not provide normative standards for whether or not to search, or when or how to do so, because the prevailing attitude is that adoptions are closed and remain so. Adult adoptees have to decide whether they accept this societal standard or reject it as inconsistent with their way of constructing their lives. Some are deterred by the fear of hurting or alienating their adoptive parents, and in fact many parents of adult adoptees are not sympathetic to the search and view it as a negative judgment about themselves or as a threat to their relationship with the adoptee. It is common for adoptees to begin a search following the death of an adoptive parent or other close relative; in some cases because they felt inhibited from doing so before and in others because an old curiosity reasserts itself in the context of loss.

Adoptees who choose to search can obtain support from the adoptee movement (which also includes many birth parents and some adoptive parents), which contains search and support groups that offer moral support and technical assistance to adopted persons who search. Such groups also promote legislation that facilitates contact between adult adoptees and their birth parents.

The closed adoption system is such an accepted part of society that it is difficult for many people to appreciate the losses involved for individuals. Mental health professionals are aware of the widespread family disruptions during World War II and more recently the theft and subsequent placement for adoption of many infants in Argentina. Similarly, earlier in this century many Native-American and Australian-Aborigine children were moved far from their families to large residential schools with the goal of teaching them the culture and values of the majority. The individual tragedies caused by these events are easy to grasp in a context of oppression visited on a group of people: attenuation or loss of personal relationships as well as alienation from one's cultural heritage. Some advocates of adoptees' rights maintain that closed adoption has elements in common with these large-scale social events because it views infants as tabulae rasae with no right to their pasts and views birth parents as without rights to knowledge of, or contact with, their infants. Advocates of the traditional system argue that most adoptees do well and that the risks of openness might offset any advantages it would provide.

Birth Parents Adults in psychotherapy often fail to mention that they have had a child who was placed for adoption. This important fact should be sought specifically, particularly with depressed women of childbearing age and older, because the resulting losses are commonly unresolved and incompletely mourned. Many birth mothers have kept their experience secret because of shame, and this in itself impairs their ability to grieve the loss because they cannot share it with anyone. Birth parents vary in their attitude about being found by a child they had relinquished. Some birth parents, particularly birth mothers, initiate searches themselves, usually after the child is 18 or older. Concerned United Birthparents (CUB) is an activist organization dedicated to improving the way adoption is structured and to increasing openness in adoption; they are also concerned with decreasing the stigma associated with having relinquished a child and encourage individuals to “come out” as

birth parents.

Reunions and Subsequent Relationships There is no formal etiquette in the search and reunion process, though magazine articles, meetings of adoption organizations, and the Internet provide a great deal of relatively recent material that individuals can use as a guide. Some seekers want information and a brief contact rather than a continuing relationship; others wish to convert the cutoff of closed adoption into an ongoing relationship. Uncertainty and anxiety are unavoidable under these circumstances, especially since the two members of the pair may not be seeking the same level of involvement, and in fact one may be reluctant at best. One recently described phenomenon is so-called genetic attraction, in which newly reunited relatives find themselves interested in each other physically. Such interest needs to be understood primarily as nonsexual curiosity, and adoptee organizations caution successful searchers to use restraint when experiencing such curiosity because the normal incest taboo that arises within families over many years does not exist in these dramatic and often emotional reunion situations. Most adoptees and birth parents appear to feel quite positively about their reunion experiences, whether or not they lead to ongoing relationships, and some adoptive parents and adoptees report that their relationships improve after reunion.

Legal Issues Adopted children and adoptive families continue to be vulnerable in a number of ways and this vulnerability motivates the effort to enact legislation. A currently circulated American Bar Association Model State Adoption Act promotes adoptions but focuses largely on independent adoptions and provides few safeguards for children, adoptive parents, or birth parents. The interests of all these parties are better protected by traditional agency adoptions than by the increasingly common independent adoptions. Foci of proposed legislation include:

1. The right of a birth mother to revoke her consent, and after how long a time a consent to adoption is revocable
2. Federal and state subsidy to special-needs adoption and whether subsidies are permitted when adoptions take place across ethnic or racial lines
3. Rights of Native American tribes to reclaim children who were adopted by non-Indian parents and now have existing emotional attachments to those parents
4. Rights of adopted persons 18 years of age or over to have access to nonidentifying or identifying information about their birth parents or to their original birth certificates

The struggle over specific pieces of adoption legislation reflects the fact that the world of adoption contains several constituencies whose interests do not always coincide. The above discussion contains historical background to illustrate this statement. Contemporary child welfare thinking as well as reasoned statements from adult adoptee and birth parent organizations do largely coincide, however, in the belief that the rights of all concerned (child, birth parent, adoptive parent) must be respected to the greatest extent possible in crafting individual adoption arrangements.

SUGGESTED CROSS-REFERENCES

Foster care is the subject of Section 49.3 Mental retardation is discussed in Chapter 34. Attention-deficit disorders are presented in Chapter 39.1, disruptive behavior disorders in Chapter 40, and mood disorders and suicide in Chapter 45. Psychiatric treatment is the focus of Chapter 48 and childhood and adolescent antisocial behavior is the focus of Section 49.7.

49.3 FOSTER CARE

MARILYN B. BENOIT, M.D.

It is estimated that foster care costs $10 billion a year with a per capita cost of approximately $17,500, not including the cost of treatment that the foster child may need. Foster care is defined as temporary out-of-home care that some minor children and adolescents need when their families of origin are unable to care for them and the child welfare system intervenes to provide care. As medical and social problems have evolved, so too have the reasons for children's eligibility for foster care placement. Serious and protracted parental illness, parental death, and financial hardship used to be some of the earlier reasons for foster placement. However, since the 1960s child abuse and neglect, and abandonment secondary to parental substance and alcohol abuse have emerged as major reasons for out-of-home placement. Foster care is primarily utilized by the lower socioeconomic stratum, and is linked to issues of teenage pregnancy, substance abuse, family fragmentation, minority status, poverty, and urban residence. Children in the welfare system, Temporary Assistance for Needy Families (TANF)—previously called Aid to Families with Dependent Children (AFDC)—are overrepresented. Although parental abuse is a significant reason for placement, there has been a shift to abandonment and neglect as the predominant reasons for placement in the 1980s and 1990s. This correlates with the epidemic use of drugs since the mid-1980s. Although most foster children return to their families of origin, an increasing number of children are raised in foster care. These vulnerable children are overrepresented in the population that seeks mental health services and are at high risk for development of psychiatric disorders and substance abuse problems as adults. They are also overrepresented in the criminal justice system where the cost to the public is significant. Unfortunately, little research exists in foster care, and much of what is known is descriptive. The field of psychiatry has not traditionally focused on this population as a target of research.

HISTORY

In his book, *Kindness of Strangers*, John Boswell reveals some disturbing information about the abandonment of children. Children were abandoned or “exposed” and sometimes even killed by their parents because the parents felt unable or unwilling to care for them. Illegitimately conceived children also ran the risk of being “exposed.” This was more common in cities than in the rural areas where illegitimacy was less stigmatized. Such was the case in sixteenth-century Basque country in northern Spain where the illegitimacy rate was high, but abandonment of children was low. Abandoned children were at the mercy of strangers. For example,

> The slave places the baby (an illegitimate child), with pork in mouth, in a small covered shelter at the base of a tree in the woods. He is retrieved four days later and reared by a neighbor well aware of his origins, who nonetheless specifically pretends that the child is his own.

Even the wealthy would abandon children because they wanted to preserve their estates. The monasteries and churches played a major role in the care of abandoned children who were often taken into the monastery either as oblates or as servants to the monks. It is believed that many children who were placed in fosterage, as the term was used, ended up being used as child labor. Boswell reported that of the slaves sold in Sicily, Naples, and Venice in the fourteenth century, about one third were under 15. Many abandoned children were housed in congregate care settings, called foundling homes. In France, the practice of fostering came into the mainstream as a way of caring for abandoned children because it proved to be less expensive for the state. Even in the thirteenth century, foster parents could be of either gender and did not have to be married. The term *fostering* was more liberally applied and could actually refer to apprenticeship and godparent relationships. Because the prevailing sentiment was that the abandoned children were the offspring of “debauchery and crime,” there was concern that they could “inherit” such characteristics. Girls seemed to be at particularly high risk for prostitution. Fostering was extended into late adolescence with the expectation that the children would be apprenticed and educated and would become self-supporting. This is not unlike the current practice in the United States where the state will extend support until age 21 to assist foster children with transition into adulthood. In the early 1800s the concept of family reunification was exemplified by the mothers being given the option of presenting themselves to reclaim their children after paying a fine and reimbursing the state for the costs of having raised their abandoned children.

As early as 1853 Charles Loring Brace had implemented a “placing out” system, the New York Children's Aid Society, to rescue children who had been neglected, maltreated, or abandoned by their families and had consequently become a threat to their communities. These children were sent to distant institutional locations without any connections to families. In 1886 Charles Birtwell of the Boston Children's Aid Society attempted to improve upon this approach by establishing foster care in families. His focus was on prevention of long-term out-of-home placement. The first White House conference on children was held in 1909 and led to a national shift from placing children in institutions to family support for child rearing, that is, foster care. Later, a landmark exposure of “foster care drift” in 1959 revealed that many children were not receiving any permanency planning and that the goals of the 1909 White House conference were being neglected, because few efforts were focused on family reunification. In 1961 Title IVA (Aid to Dependent Children) was adopted under the rubric of the Social Security Act, and its intent was to facilitate family preservation. In 1966 the Casey Family Program (long-term out-of-home placement) was initiated in response to the finding that for some children neither adoption nor family reunification was a viable alternative. Although Title IVB (1993, family preservation PL 103-66) supported this placement option, Title IVB-2 encouraged family rehabilitation to improve the chances that children would return home successfully. Reviews of outcomes of foster care children are mixed. Proponents of the system claim that most children have satisfactory outcomes. Critics have declared that foster care is in crisis, citing that it has come under receivership of the courts in several states for failure to provide adequate care, timely placement, and monitoring of the children in care. In 1980 the federal government acted to promote adoption rather than long-term foster care. Congress passed the Adoption Assistance and Child Welfare Act (PL-96-262), which includes foster care but was expanded in 1985 (PL-99-514) to special-needs children who would have additional funding (for provision of services) when adopted (Title IVE of the Social Security Act). In 1997 President Clinton signed into law a new Adoption and Safe Families Act (PL 105-89). This law is designed to improve provisions for child safety and decrease the length of time a child remains in foster care without permanency planning. It also effectively limits the length of time (12 months) parents must undergo rehabilitation before they can resume parenting of children who have been removed from their homes by the child welfare system. Foster care children generally receive medical services by qualifying for Medicaid under Title XIX of the Social Security Act. Another amendment (PL-99-272) made to the Foster Care and Adoption Assistance Bill authorized use of federal funds for Independent Living Assistance to assist foster care “graduates” ages 16 and above (currently up to age 21) with a smoother transition into independent adulthood. These funds were permanently authorized in 1993 with a 75 percent matching rate for state training.

EPIDEMIOLOGY AND DEMOGRAPHICS

Health and Human Services (HHS) numbers for 1994 indicate that 6.5 of every 1000 children are in foster care versus 3.9 of every 1000 in 1982. This represents a 61 percent increase in foster care during that decade. There are more girls than boys; 55 to 69 percent of the clients are girls. Children placed in care as infants are more likely to stay in care. Whites represent 48 percent of children in care and their numbers have been declining since 1982 while the numbers for African-Americans and Hispanics have been increasing. African-Americans represent 40 percent of the approximately half-million children in placement, with 83.4 percent entering foster care at a mean age of 3 years. This finding is compatible with the trend that since the mid-1980s the age of new entrants into foster care has been decreasing. The under-5 age group currently accounts for the fastest-growing segment of the foster care population. Studies reveal that as many as 62 percent of foster children had prenatal drug exposure. A 1989 HHS study revealed that 30 to 50 percent of all drug-exposed children entered foster care, and among African-Americans, parental drug use precipitated almost 80 percent of foster care placements. Parental drug use is positively correlated with maltreatment, with approximately 89 percent of maltreatment cases involving drug abuse. In one California study, 89 percent of infants tested positive for drugs at birth—cocaine being the identified drug in 85 percent of those who tested positive.

Orpheus is an African-American teenager who has been in out-of-home placement for 6 years. Orpheus' mother is a chronic substance abuser who has made multiple unsuccessful attempts (inpatient and outpatient) to become drug free. His father has been incarcerated for most of Orpheus' life. Orpheus has a history of physical abuse and sexual victimization. He has a history of violent episodes during which he is a significant danger to himself and to others. Psychotherapeutic and psychopharmacological interventions have not been successful in stabilizing him. He started out in foster care but was sent to group homes where his out-of-control behavior precipitated admission to a residential treatment center. He was discharged to therapeutic foster care. Since discharge, he has failed two foster care placements and has now returned to a group home. He has also entered the juvenile justice system because of drug involvement. His mother's substance abuse and the unpredictability of her involvement in his life appear to be the most consistent variables that account for his lack of stabilization. Father absence is also contributory.

Mike is a 16-year-old African-American male who was born to an alcohol- and drug-addicted mother. Father was absent from any involvement in Mike's life. Mike was removed from the home because of neglect. He was diagnosed with fetal alcohol syndrome and attention-deficit/hyperactivity disorder. He has been treated with psychostimulants only. He had borderline intellectual functioning and significant mixed learning problems. After repeated, unsuccessful foster care placements because of his highly aggressive behavior, he was referred to residential treatment at age 11. Mike adjusted well to the demands of the program, engaged positively with the staff, and allowed himself to accept the nurturing provided. He had a court-appointed special advocate who was very predictable and consistent in his involvement with Mike throughout Mike's residential stay. This youngster thrived in residential care. His mother was an infrequent visitor. Mike was discharged at age 13 to therapeutic foster care with a single mother. Continued visits with his biological mother and siblings were part of the discharge planning. At yearly follow-up Mike had maintained his foster care placement, was involved with his mother and siblings, had maintained his discharge school placement, and continued involvement with psychotherapeutic and psychiatric services. He was a nonreader when he came into residential placement, and at the most recent follow-up, his foster mother was delighted to report that he had passed the state literacy test.

NEEDS OF CHILDREN IN FOSTER CARE

The late 1980s and 1990s have registered an increase in the complexity of the cases referred to foster care. There has been an increase in the number of children with emotional and developmental disorders. In several studies, mental health services were repeatedly identified as the number one health care need. Studies show that more than 80 percent of foster care children had developmental, emotional, or behavioral problems. Growth abnormalities (including failure to thrive), neurological abnormalities, neuromuscular disorders, language disorders, cognitive delays, and asthma are significant. It is estimated that those AFDC children who are served in the foster care system have health care needs that are six times as costly as matched peers who do not enter foster care. Approximately 28 percent of foster care children need special education services. Children 0 to 5 years of age are eligible for services under PL101-119, which addresses the educational needs of persons with handicapping conditions. About 25 percent are so emotionally damaged that their mental health treatment needs are high. They use the full range of services: outpatient, acute inpatient, day treatment and partial hospitalization, and residential treatment. In recognizing the needs of foster care children, Title IVE Mandatory Protection of Foster Care Children included (under PL-101-239) a statute that mandates reviews of health and education records. Adolescents in foster care are at increased risk for substance abuse, teenage pregnancies, and sexually transmitted diseases, including human immunodeficiency virus (HIV) disease. With public health care moving in the direction of adopting a managed health care system, particular attention has to be paid to the delivery of services to this medically and psychiatrically vulnerable population.

KINSHIP CARE

Although no good data are available on just how much kinship care is used, its use is definitely increasing. Currently, approximately 23 percent of African-Americans are in kinship care nationwide. In New York City it is estimated that as many as 50 percent of African-American children are in kinship care. Kinship caregivers are generally female (mostly maternal grandmothers) with low income, low education, and minority status. The few studies available indicate that outcomes are more positive than those for children in nonkinship care. Children reportedly receive more positive regard from caregivers in kinship care, which consistently results in more stability than nonrelative foster care. As best as can be determined, there is no demonstrable difference in the need for mental health, medical, and educational services. More states are recognizing kinship care as a reasonable placement option and are authorizing licensing and reimbursement to kinship caregivers.

THERAPEUTIC FOSTER CARE

Therapeutic foster care is a treatment placement that has emerged as an alternative to the more expensive and more restrictive traditional residential treatment center. Beth Stroul states:

> Therapeutic foster care is considered the least restrictive option among the range of residential services for severely emotionally disturbed children and adolescents. Therapeutic foster care can be defined as a service that provides treatment for troubled children within the private homes of trained families. The approach combines the normalizing influence of family-based care with specialized treatment interventions, thereby creating a therapeutic environment in the context of a nurturant family home.

Therapeutic foster parents are the agents of therapeutic change, functioning as “extenders” of the clinical treatment team. They are required to have more extensive training than regular foster parents, receive a higher reimbursement because of the special-needs status of the children, are subjected to more intensive monitoring and supervision, and receive more ongoing support from the foster care agency. Although the concept of therapeutic foster care is a promising one, no reliable outcome data are available to determine just how successful it is as an intervention with emotionally troubled foster care youth.

CULTURAL COMPETENCE

According to Anna McPhatter, “Cultural competence denotes the ability to transform knowledge and cultural awareness into health and/or psychosocial interventions that support and sustain healthy client-system functioning within the appropriate cultural context.” The Multiethnic Placement Act of 1994 urged authorities to “consider child's cultural, ethnic and racial background” when making placement decisions. Of approximately 460,000 children in care in 1994 approximately 14 percent were Hispanic, 48 percent white, and almost 38 percent were African-Americans, about three times their representation in the general population. Societal racism has resulted in some children being denied placement with families of a different race, and they ended up in long-term foster care rather than in a permanent adoption placement. Minorities are twice as likely to remain in long-term foster placement, so this has been an issue primarily for African-Americans and Native Americans. As the Hispanic foster care population increases, it can be anticipated that similar issues will emerge for this ethnic group. In 1978 the Indian Child Welfare Act (PL-95-608) transferred to Tribal Courts the power to make placement decisions about Native-American children to reverse the practice of placement in non–Native-American homes. The Association of Black Social Workers went on record as opposing transracial placement of African-American children. Adoption studies have shown that it is not inherently harmful for children to be cross-racially adopted. Congress has passed legislation facilitating transracial adoptions while maintaining the language of cultural awareness in placement decisions. Shawan Gregory and Frederick Phillips of a foster care placement agency in Washington, D.C., Progressive Life Center (PLC), have an Afrocentric approach, “Ntu,” to therapeutic foster care. They describe the “Ntu” perspective as an “Afrocentric, spiritually based, therapeutic framework,” that harnesses “the positive force that is universal to all people.” Their process of admission to therapeutic foster care is carefully orchestrated to include African rituals–a libation and “crossing over.” The principles of Kwanzaa are incorporated into the practices. No research data are yet available from this organization, but a descriptive report states that 74 percent of their clients “improved significantly emotionally” and thus “PLC's faith was justified.” The need for cultural sensitivity, respect, and a capacity to facilitate a foster child's cultural development and identity are well acknowledged. These issues must be addressed in the training of all who provide services to the children in the foster care system. However, no rigorous research has yet identified the essential variables that ensure “success” in cultural competency.

PSYCHOLOGICAL ISSUES IN FOSTER CARE PATIENTS

Foster care children are overrepresented in psychiatric populations. Among those who return home, 40 percent reenter the foster care system. Given the reasons why children enter foster care, the major issues with which they struggle involve abandonment, neglect, rejection, and physical, emotional, and sexual maltreatment. The age of entry into the foster care system and the specific reason for placement affect the emotional issues that any specific child must handle. Early abandonment and neglect of infants and young children can lead to anaclitic depression. Attachment issues are prevalent in this younger population because they have not had an early opportunity to form a secure attachment with a consistent nurturing figure. They are often unprepared for separations, which may be abrupt and repeated. Because of financial constraints, the foster care system simply does not allow time for good relationships to form with foster parents prior to placement.

Joseph is a 13-year-old boy who has been in residential treatment for the past 15 months. He has done extremely well in residential care after five foster care placement failures and psychiatric hospitalizations. He was removed from the parental home because of neglect. He has demonstrated a remarkable capacity for appropriate attachment. He is being discharged to foster care because his mother cannot care for him. A request was made to the department of child welfare that his discharge planning should include a 3-month period of preplacement and graduated home visits with the identified foster mother to promote trust and bonding. This request was denied by the agency and the court. Joseph's emotional and behavioral condition so deteriorated prior to discharge that he required one-to-one suicidal observation, and discharge had to be postponed.

If the child-serving agencies focused on the psychological needs of the child, rather than on the bottom line, thoughtful decision-making about placement of children would lead to better outcomes and ultimately improve the bottom line they so arduously protect. Children who experience foster care drift or foster care bouncing have their capacity to form enduring emotional attachments further compromised and the issue of trust becomes a lifelong challenge. Defense mechanisms tend to be primitive, that is, denial, splitting, projection, and introjection. Characterological problems are not uncommon in adulthood. It is not at all surprising that children who have never had their narcissistic needs appropriately met grow up to become unempathetic adults with pathological narcissism. Children who have experienced traumatic physical and sexual abuse develop behaviors evidenced by dissociation, mistrust, hypervigilance, aggressivity, impulsivity, oppositionality, and avoidance as they attempt to negotiate a world they experience as threatening, hostile, and uncaring. Unmet narcissistic needs render them demanding and unempathetic. When children are raised in a psychosocial environment of trauma, aggression, and lack of empathy from adults, the psychological seeds are sown for later violence against the self and others.

FAMILY PRESERVATION

Much hope was invested in the thrust toward family reunification and family preservation. Estimates on the percentage of children who are reportedly reunited vary from 66 to 90 percent. However, the finding that about 40 percent of reunified children reenter out-of-home care is disappointing. Philosophically, family reunification appears to be the right thing to do, but too little attention has been given to developing discriminating criteria to identify psychosocial profiles of families that would benefit most from family preservation services. In 1996 the Child Welfare League of America acknowledged the failure of family preservation efforts and requested that the child welfare policy makers rethink the current use of intensive family preservation. Unfortunately, no research exists to guide thinking and implementation of sound policy to improve outcomes. One hopes that the relatively new Adoption and Safe Families Act of 1997 (PL-105-89) will permit child welfare agencies to step back from the rather myopic view of family preservation and seriously consider the needs of the child before making subjective decisions.

FOSTER CARE OUTCOMES

The overall quality of available outcome studies is poor; however, some patterns recur across studies. One disturbing finding is that studies reveal that 15 to 39 percent of the homeless are foster care graduates. They are also overrepresented among adult substance abusers and clients in the criminal justice system. It is impossible to conclude that foster care is the single major contributor to such negative outcomes. What is more likely is that the reasons that initially precipitated foster care placement remained over time as etiological factors in the negative adult outcomes. Studies indicate that children entering care who have been victimized, who have substance-abusing parents or parents with major mental illness or high criminality, and who come from homes with a high degree of domestic violence are at greater risk of having poor outcomes. As regards a dose-response model, studies indicate quite consistently that longer time spent in care leads to a more successful outcome. Children returned to their families of origin typically have fared worse than those who have remained in long-term placement. Several studies report findings indicating that poor parental involvement consistently leads to negative outcomes. Multiple placements have also been shown to lead to less successful outcomes.

Federal mandate (PL96-272) requires states to maintain a tracking system for children in foster care. New reporting systems due to be adopted are AFCARS (Adoption and Foster Care Analysis and Reporting System) and SACWIS (Statewide Automated Child Welfare Information System). States are being monitored for compliance, and continued federal funds are contingent upon the implementation of these information systems. With improved data collection, the child welfare system should be better informed about the management of the children in foster care, the needs of the children and their families, and how best to address those needs with the limited resources that can be allocated. Because foster care placement is itself the result of psychosocial environmental failure, fixing the existing system will require more than good information systems. Integration of sound, theory-driven, child-focused services provided by multiple governmental agencies will be essential. Three states—Alabama, Ohio, and North Carolina—have disseminated some early performance outcomes. Through the use of longitudinal, research-based performance measures, reliable data are emerging. The complexity of the impact of ever-changing psychosocial variables makes this type of research challenging, but it is necessary if our welfare dollars are to be spent doing the right thing for needy children and families.

SUGGESTED CROSS-REFERENCES

Sociology and psychiatry are covered in Section 4.2 and adult antisocial behavior and criminality are addressed in Section 27.3. Child psychiatry is addressed in Section 32, Section 33, Section 34, Section 35, Section 36, Section 37, Section 38, Section 39, Section 40, Section 41, Section 42, Section 43, Section 44, Section 45, Section 46, Section 47, Section 48 and Section 49. Specifically, residential and in-patient treatment are addressed in Section 48.8 and adoption is addressed in Section 49.2.

49.4 CHILD MALTREATMENT

WILLIAM BERNET, M.D.

Child maltreatment is a terrible misfortune for millions of children and families, for communities, and for society. It affects children of all colors, social classes, ethnic groups, and religions. It damages young people of all ages—prior to birth, infants, children, and adolescents. Recognition and diagnosis of child abuse is compromised by the denial that pervades all aspects of the phenomenon: perpetrators routinely deny they did it; abused children sometimes deny that anything bad happened to them; otherwise concerned adults, such as neighbors and teachers and emergency room physicians, may overlook and underreport abuse for any number of personal reasons; complex legal requirements may make it hard to convict abusive parents; and generalized societal denial protects us from awareness of a very unpleasant side of life.

The evaluation, management, and treatment of child abuse requires the cooperation of diverse professional groups, including pediatricians and other primary care physicians, emergency room staff, radiologists, pathologists, attorneys, social service personnel, and a variety of mental health professionals. Psychiatrists and other mental health professionals participate in child abuse cases in several ways. Psychiatrists may evaluate children for a forensic or legal purpose, either in private practice or as part of an interdisciplinary team. They may assist the court in determining what happened to the child and make recommendations regarding placement or treatment. In particular, child psychiatrists may be asked to evaluate the credibility of children who may have been sexually abused. Psychiatrists may provide individual or family therapy for a child who has emotional or behavioral problems caused by abuse and may treat child and adolescent perpetrators of abuse, many of whom were previous victims of abuse. Psychiatrists may evaluate perpetrators of abuse to clarify the psychiatric diagnosis and assess the person's competency to go to trial, the possibility of an insanity defense, the person's potential for treatment, and the appropriateness of termination of parental rights. In civil law suits, psychiatrists may testify about the cause, nature, and extent of the child's psychological injuries. In some forms of abuse, such as factitious disorder by proxy, psychiatric evaluation may be particularly important in devising treatment approaches for both victim and perpetrator. Mental health professionals may deal with these issues on the level of public policy by sharing information and educating attorneys, judges, and legislators about the psychiatric aspects of abuse and the developmental needs of children.

DEFINITIONS

DSM-IV The somewhat terse classification system provided by the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) lists physical abuse of child, sexual abuse of child, and neglect of child. The three classifications appear under and in the section problems related to abuse or neglect, which is grouped with other conditions that may be a focus of clinical attention. These categories should be used when the focus of clinical attention is severe maltreatment of one individual by another. These conditions and problems are coded on Axis I.

DSM-IV does not include detailed definitions or criteria for diagnosis. Circumstances in which the focus of attention is on the perpetrator of child abuse or neglect or on the relational unit in which it occurs have one code. Three different codes cover situations in which the focus of attention is on the victim (for neglect of child, for physical abuse of child, or for sexual abuse of child).

Federal Law The Child Abuse Prevention and Treatment Act was passed in 1974 and has been amended several times. In the federal law “child abuse and neglect” means “the physical or mental injury, sexual abuse or exploitation, negligent treatment, or maltreatment of a child by a person who is responsible for the child's health or welfare, under circumstances which indicate that the child's health or welfare is harmed or threatened thereby.” “Sexual abuse” includes “the rape, molestation, prostitution, or other form of sexual exploitation of children, or incest with children” and the creation of child pornography.

State Law A large mass of legal definitions and guidelines exists at the state level. The legal definitions of terms related to the maltreatment of children vary from state to state, so clinicians should be aware of the definitions used in their own locale.

Neglect The most prevalent form of child maltreatment, *neglect* is the failure to provide adequate care and protection for children. Children can be harmed by malicious or ignorant withholding of physical, emotional, and educational necessities. Neglect includes failure to feed children adequately and protect them from danger. Physical neglect includes abandonment, expulsion from home, disruptive custodial care, inadequate supervision, and reckless disregard for a child's safety and welfare. Medical neglect includes refusal, delay, or failure to provide medical care. Educational neglect includes failure to enroll a child in school and allowing chronic truancy.

Physical Abuse *Physical abuse* may be defined as any act that results in a nonaccidental physical injury, such as beating, punching, kicking, biting, burning, and poisoning. Some physical abuse is the result of unreasonably severe corporal punishment or unjustifiable punishment. Physical abuse may be organized by the site of injury: damage to skin and surface tissue, damage to the head, damage to internal organs, and skeletal damage.

Psychological Abuse *Psychological abuse* occurs when a person conveys to children that they are worthless, flawed, unloved, unwanted, or endangered. The perpetrator may spurn, terrorize, isolate, or berate the child. Emotional abuse includes verbal assaults (e.g., belittling, screaming, threats, blaming, or sarcasm), unpredictable responses, persistent negative moods, constant family discord, and double-message communications. Some authors feel that the terms “psychological” or “emotional abuse” should not be used and that “verbal abuse” more accurately describes the pathological behavior of the caregiver.

Sexual Abuse *Sexual abuse of children* refers to sexual behavior between a child and an adult or between two children when one of them is significantly older or uses coercion. The perpetrator and the victim may be of the same sex or the opposite sex. The sexual behaviors include touching breasts, buttocks, and genitals, whether the victim is dressed or undressed; exhibitionism; fellatio; cunnilingus; and penetration of the vagina or anus with sexual organs or objects. Sexual abuse may involve behavior over an extended time or a single incident. Developmental factors must be considered in assessing whether sexual activities between two children are abusive or normative. In addition to the forms of inappropriate sexual touching, sexual abuse also refers to sexual exploitation of children, for instance, conduct or activities related to pornography depicting minors and promoting or trafficking in prostitution of minors.

Ritual Abuse Cult-based *ritual abuse,* which includes satanic ritual abuse, is physical, sexual, or psychological abuse that involves bizarre or ceremonial activity that is religiously or spiritually motivated. Typically, multiple perpetrators abuse multiple victims over an extended period of time. Ritual abuse is a controversial concept; some professionals believe that ritual abuse is a common, horrible phenomenon in our society, while others are deeply skeptical about most allegations and descriptions of ritual abuse.

Perpetrators of Abuse There is some lack of consistency in who may be defined as an abuse perpetrator. Usually a person must be a parent or designated caregiver to be charged with neglect, physical abuse, or emotional abuse. Another adult (e.g., a stranger) who injures a child would be charged with battery, not with child abuse. On the other hand, a caregiver or any other person could be charged with child sexual abuse. The state laws vary in this regard.

HISTORY Historical and literary sources have documented child maltreatment for thousands of years in cultures from all parts of the earth. Although some forms of

abuse were considered deviant or prohibited in particular cultures, most often the abusive practices were accepted or even encouraged by the societies in which they occurred. The long-term trend in European and American history has been to move from blatant, socially acceptable child abuse to strong societal disapproval. At least four historical periods can be identified.

Ancient Period In the ancient period adults seduced, violated, and murdered their children in an unashamed and socially acceptable manner. Human sacrifice, including of children, was practiced by Greeks, Romans, Celts, Phoenicians, and others. The Old Testament criticizes human sacrifice several times, so it apparently was practiced during that era. Greeks, Romans, and Egyptians commonly practiced both heterosexual and homosexual pedophilia. The most notorious sadistic child abusers were the emperors Tiberius, Caligula, Claudius, and Nero.

Medieval Period Christianity induced guilt, and parents could no longer abuse their children with impunity. When they did, they asserted that they were following God's will. The notion of an incest taboo—a universal prohibition against incest that presumably transcends cultures—is an ironic manifestation of societal denial. Some authors think that the opposite is true, that incest has been universal for most people in most places at most times.

Early Modern Period In the eighteenth, nineteenth, and early twentieth centuries, the sense of guilt and shame increased to such a degree that incest and child abuse could no longer be considered acceptable. However, abusive practices continued in the underworld, out of sight of polite society. (Infanticide through exposure or poisoning was a long-accepted way to dispose of an unwanted or defective child.) Foundling hospitals were established to care for thousands of abandoned babies, but few children survived the dismal routine of institutions. Charles Dickens (*Oliver Twist*, 1837–1839) and Victor Hugo (*Les Miserables,* 1862) laced their story lines with social criticism and graphically portrayed man's inhumanity. Dickens, for instance, recorded the inhuman aspect of industrial society, including child battery, debasement of children for sensual or recreational purposes, and starvation and deprivation of the laboring child.

Toward the end of this period societal awareness of child maltreatment increased. In the 1860s a French forensic pathologist, Ambroise Tardieu, described severe child abuse after performing autopsies on children who had been beaten to death. Child abuse came to public attention in the United States through the case of Mary Ellen, an 8-year-old girl who was severely maltreated. She was discovered by church workers in New York City in 1874, but they found that the only agency available to help was the Society for the Prevention of Cruelty to Animals. Thus, they founded the Society for the Prevention of Cruelty to Children. In 1875 New York became the first state to adopt a child protection law, which became the model for other states.

Late Modern Period In the latter half of the twentieth century child abuse has become the subject of widespread clinical and governmental concern. Abusive practices are actively identified, rather than ignored and denied. Modern recognition of child abuse was signaled in 1946 by a pediatrician and radiologist, John Caffey, who noticed a syndrome of children with multiple skeletal injuries and chronic subdural hematomas. Up until the 1960s physical abuse of children was considered rare, partly because physical discipline of children was generally more acceptable and partly because of societal denial concerning violence toward children. In 1962 Henry Kempe and his colleagues brought child maltreatment to the attention of physicians in a historic article, “The Battered-Child Syndrome.” Within 5 years child abuse reporting laws were adopted by every state.

It took separate societal realization during the 1970s to acknowledge the extent of sexual abuse. Incest was known to occur, but most people thought that it was very unusual and that it happened primarily among very deviant families. It is now known that incest and other forms of sexual abuse are not rare.

In 1974 the federal government passed the Child Abuse Prevention and Treatment Act, which established uniform national standards for identification and management of child abuse cases. Child abuse legislation, originally directed toward case discovery and perpetrator punishment, now focuses on prevention, rehabilitation, and family reunification. Individual states independently define maltreatment, formulate investigative procedures, collect data, and organize service delivery systems.

COMPARATIVE NOSOLOGY

The first and second editions of DSM, (DSM-I and DSM-II) made no mention of child maltreatment. The Group for the Advancement of Psychiatry mentioned child maltreatment among the pathogenic factors of childhood mental disorders: “The deleterious effects ... of open rejection or neglect, occasionally involving willful injury or inadequate feeding, are well documented.” However, the Group for the Advancement of Psychiatry did not include child maltreatment in their proposed system of classification.

When the third edition of DSM (DSM-III) was published, the American Psychiatric Association (APA) Task Force on Nomenclature and Statistics introduced a chapter called “V Codes for Conditions Not Attributable to a Mental Disorder That Are a Focus of Attention or Treatment.” The V Codes, which were modeled on the practice in *International Classification of Disease, 9th Revision, Clinical Modification* (ICD-9-CM), did not include specific categories for child maltreatment. However, it was intended that child abuse would be coded as a “parent-child problem,” the category used “when a focus of attention or treatment is a parent-child problem that is apparently not due to a mental disorder of the individual (parent or child) who is being evaluated.” DSM-III specifically stated that “an example [of parent-child problem] is child abuse not attributable to a mental disorder of the parent. The emphasis of parent-child problem” was apparently on identifying perpetrators of abuse, not the child victims of abuse.

The revised third edition of DSM (DSM-III-R) provided a similar definition for parent-child problem: “This category can be used for either a parent or a child when the focus of attention or treatment is a parent-child problem that is apparently not due to a mental disorder of the person who is being evaluated.” However, the example involving child abuse was replaced by “conflict between a mentally healthy adolescent and her parents about her choice of friends.”

In DSM-IV the name of the chapter changed to “Other Conditions That May Be a Focus of Clinical Attention.” Also, a specific section was introduced, “Problems Related to Abuse or Neglect,” which included terms related to child maltreatment. For the first time it was possible to diagnose clearly “physical abuse of child,” “sexual abuse of child,” and “neglect of child.” Furthermore, DSM-IV made it possible to distinguish whether the person being evaluated is the perpetrator of abuse or the victim of abuse.

DSM-IV terminology is the same as that in the 10th revision of *International Statistical Classification of Diseases and Mental Health Problems* (ICD-10); only the codes are different.

EPIDEMIOLOGY

The National Committee to Prevent Child Abuse collects data each year on the incidence of child maltreatment. The committee estimated that in 1997 almost 3.2 million alleged victims were reported to child protective services. Of those reports about 1 million were substantiated; this represents about 15 of every 1000 children. The substantiated cases were distributed as follows: neglect, 54 percent; physical abuse, 22 percent; sexual abuse, 8 percent; emotional abuse, 4 percent; and other or unspecified cases, 12 percent.

The committee reported that in 1996 over 1000 children died as the result of maltreatment. About 38 percent of these deaths were children under age 1. Many fatalities were linked to parental substance abuse. A large number (41 percent) of the deaths were children who were current, open cases or previous clients of a child protection service agency.

The National Center on Child Abuse and Neglect also collects data each year on child maltreatment. The center estimated that in 1995 the median age of victims of child maltreatment was 7 years. Of the victims, about 53 percent were girls and 47 percent were boys. It was reported that 79 percent of the victims were abused by parents; 10 percent by other relatives; 5 percent by noncaregivers; and 2 percent by foster parents, facility staff, or child-care providers.

These figures are approximations because the actual amount of abuse is unclear. The reporting of abuse has increased in recent years. This increase resulted in large part from greater public awareness and willingness to report child abuse, improved data collection techniques in individual states, and local economic conditions that place a larger number of families under stress.

ETIOLOGY

Physical Abuse Although child abuse occurs at all socioeconomic levels, it is highly associated with poverty and psychosocial stress, especially financial stress.

Child maltreatment is strongly correlated with less parental education, underemployment, poor housing, welfare reliance, and single parenting. Child abuse tends to occur in multiproblem families, that is, families characterized by domestic violence, social isolation, parental mental illness, and parental substance abuse, especially alcoholism. The probability of maltreatment may be increased by risk factors such as prematurity, mental retardation, and physical handicap.

Sexual Abuse Social, cultural, physiological, and psychological factors all contribute to the breakdown of the incest taboo. Incestuous behavior has been associated with alcohol abuse, overcrowding, increased physical proximity, and rural isolation that prevents adequate extrafamilial contacts. Some communities may be more tolerant of incestuous behavior. Major mental disorders and intellectual deficiency have been described in some perpetrators of incest and sexual abuse generally. Depending on one's perspective, incest may be considered a form of child abuse, pedophilia, or a variant of rape.

DIAGNOSIS AND CLINICAL FEATURES

Abused children manifest a variety of emotional, behavioral, and somatic reactions. These psychological symptoms are neither specific nor pathognomonic; the same symptoms may occur without any history of abuse. The psychological symptoms manifested by abused children and the behaviors of abusive parents can be organized into clinical patterns. Although it may be helpful to note whether a particular case falls into one of these patterns, that in itself is not diagnostic of child abuse.

Physically Abused Children In many cases, the physical examination and radiological evaluation shows evidence of repeated suspicious injuries. Abused children display behaviors that should arouse the suspicions of the health professional. For example, these children may be unusually fearful, docile, distrustful, and guarded. They may be wary of physical contact and show no expectation of being comforted by adults. They may be on the alert for danger and continually size up the environment; they may be afraid to go home.

The literature regarding the psychological consequences of physical abuse and neglect indicates a wide range of effects: affect dysregulation, disruptive and aggressive behaviors, insecure and atypical attachment patterns, impaired peer relationships involving either increased aggression or social withdrawal, and academic underachievement. Physically abused children exhibit a range of psychopathology including depression, conduct disorder, attention-deficit/hyperactivity disorder, oppositional defiant disorder, dissociation, and posttraumatic stress disorder.

Physically Abusive Parents Abusive parents typically delay seeking help for the injuries. The history given by the parents is implausible or incompatible with the physical findings. The parents blame a sibling or claim that the children injured themselves. The characteristics of abusive parents include a history of abuse in their own early lives; a lack of empathy for the child; unrealistic expectations of the child; and an impaired parent-child attachment, especially to babies that are defective in some way.

Sexually Abused Children A variety of symptoms, behavioral changes, and diagnoses sometimes occur in sexually abused children:

1. Anxiety symptoms such as fearfulness, phobias, insomnia, nightmares that directly portray the abuse, somatic complaints, and posttraumatic stress disorder
2. Dissociative reactions and hysterical symptoms such as periods of amnesia, daydreaming, trancelike states, hysterical seizures, and symptoms of dissociative identity disorder
3. Depression manifested by low self-esteem and suicidal and self-mutilative behaviors.
4. Disturbances in sexual behaviors, including sexual hyperarousal. Some sexual behaviors are particularly suggestive of abuse such as masturbating with an object, imitating intercourse, and inserting objects into the vagina or anus; other sexual behaviors are less specific, such as showing genitals to other children and touching the genitals of others; a younger child may manifest age-inappropriate sexual knowledge; sexually abused children may display sexually aggressive behavior toward others; in contrast to these overly sexualized behaviors, the child may avoid sexual stimuli through phobias and inhibitions
5. Somatic complaints, such as enuresis, encopresis, anal and vaginal itching, anorexia, obesity, headache, and stomachache

These symptoms are not pathognomonic. Nonabused children may exhibit any of these symptoms and behaviors. For example, normal, nonabused children commonly exhibit sexual behaviors such as masturbating, displaying their genitals, and trying to look at people who are undressing. Approximately one third of sexually abused children have no symptoms. On the other hand, the following factors have been associated with more severe symptoms in the victims of sexual abuse: greater frequency and duration of abuse, sexual abuse that involved force or penetration, and sexual abuse perpetrated by the child's father or stepfather.

Intrafamilial sexual abuse and other sexual abuse that occurs over a period of time is characterized by a particular pattern or sequence of steps. The process evolves through five phases:

1. *Engagement phase,* when the perpetrator induces the child into a special relationship
2. *Sexual interaction phase*, in which the sexual behaviors progress from less to more intimate forms of abuse
3. *Secrecy phase,* during which the perpetrator threatens the victim not to tell
4. *Disclosure phase,* when the abuse is discovered
5. *Suppression phase,* when the family pressures the child to retract his or her statements

Victims of sexual abuse recount a gradual progression of boundary violations by the perpetrator, starting with tiny invasions and escalating to serious, overwhelming intrusions. Healthy, self-confident children rebuff the intrusions either directly (via temper tantrums and verbal disagreements) or indirectly (through silence and distancing maneuvers) or by adopting any strategy that causes the offender to refrain. If a child's personal space is invaded, whether by emotional threats or physical force, the child perceives that violent or intrusive attention is synonymous with interest or affection. Many incest survivors rally around their perpetrators, seeking to capture any modicum of tenderness or interest. At times affection for the perpetrator outweighs the facts of abuse and children recant their statements about sexual assault, regardless of substantiated evidence of molestation.

Incest may be defined strictly as sexual relations between close blood relatives, that is, between a child and the father, uncle, or sibling. In its broader sense, incest includes sexual intercourse between a child and a stepparent or stepsibling. Although father-daughter incest is the most common form, incest can also involve father and son, mother and daughter, and mother and son.

The daughter in father-daughter incest has frequently had a close relationship with her father throughout her childhood and may be pleased at first when he approaches her sexually. As the behavior continues, the abused daughter becomes confused and frightened because she never knows whether her father will be parental or sexual. If the victim tells her mother about the abuse, the mother may or may not be supportive. The mother often refuses to believe her daughter's reports or refuses to confront her husband with her suspicions. Since the father provides special attention to a particular daughter, her brothers and sisters may distance themselves from her. The father, fearful that his daughter may expose their relationship, and often jealously possessive of her, interferes with the girl's development of normal peer relationships.

EVALUATION PROCESS

The evaluation of a child or adolescent who may have been physically or sexually abused depends on its circumstances and context. Practitioners must consider whether they are conducting a forensic evaluation (which has legal implications and may ultimately be used in court) or a clinical evaluation for a therapeutic purpose. A forensic evaluation emphasizes collecting accurate and complete data to determine—as objectively as possible—what happened to the child. Was the injury an accident, self-inflicted, or a result of parental abuse? Was the child actually sexually abused or was she indoctrinated to believe she was abused? The data collected in a forensic evaluation must be preserved in a reliable manner, through audiotape, videotape, or detailed notes. The results of the forensic evaluation are organized into a report that will be read by attorneys, a judge, and others. On the other hand, the emphasis in a therapeutic evaluation is to assess psychological strengths and weaknesses, make a clinical diagnosis, develop a treatment plan, and lay the foundation for continuing psychotherapy. The clinician may also be interested in determining what happened to the child, but it is not so essential to distinguish facts from fantasies. Compared with the forensic evaluation, the psychotherapist does not need to keep such detailed records and ordinarily does not prepare a report for court.

In addition to distinguishing a forensic examination from a therapy meeting, a number of factors may affect the evaluation of a child who was abused or may have been abused: whether one is a pediatrician in an emergency department or a child psychiatrist in an office; whether a parent or another person is suspected of the abuse; the severity of the abuse and the victim's relationship to the perpetrator; whether physical signs of abuse are obvious or absent; the age and sex of the child;

and the degree of anxiety, defensiveness, anger, or mental disorganization that the child exhibits. Often the examiner must be creative and persistent.

From the psychiatric perspective, the interview is usually the primary source of information and the physical examination is secondary. In practice, children who may have been neglected or sexually abused are interviewed first and later given a physical examination and other tests. A child who has been physically abused is more likely to have a physical examination that may be followed by a psychiatric interview.

Parent Interviews The evaluator obtains a history from the parents (separately, in most cases) and other pertinent informants, as well as from the child. The emphasis of the interview depends on the circumstances.

Suspected Physical Abuse The examiner should consider the possibility that the parents are not telling the truth. The physician becomes a detective because the parents who bring the injured child to the emergency room may also be perpetrators of the abuse. To obtain treatment, the caregivers lie about how the injury occurred.

When the child is brought to the emergency room a detailed and spontaneous account of the injury should be obtained promptly from parents or other caregivers before secondary details and rationalizations cloud the information provided. The interviewer should allow the caregiver to explain, expound, derail, or detour the story line. An abuser or codependent parent may claim to have happened on the injured child in a coma or bleeding from some unknown trauma or to have noticed significant bruising, burns, or a crooked extremity while bathing the child. Comparing the parents' histories can provide valuable insight into how power is wielded in the family unit.

> A 30-day-old female was transferred from a rural hospital to a university medical center because of “near SIDS” (sudden infant death syndrome). The child was unresponsive and required mechanical ventilation. A brain scan revealed bilateral subdural hematomas, subarachnoid hemorrhage, and hemorrhage in the parenchyma of the brain. An ophthalmologist observed extensive retinal hemorrhages. After the child was admitted to the Pediatric Intensive Care Unit, the child abuse consultant interviewed the parents separately. The mother, age 28, said that she had recently started a new job. The baby was perfectly fine when she left her in the care of her live-in boy friend, the child's biological father. The father, age 24, said that when he checked on the baby, he found her to be not breathing, blue, and unresponsive. He ran to report this to a neighbor and then called 911. The child abuse consultant told the father that the child must have been injured in some way and asked whether the father had any explanation for this injury. The father said, “I did shake the baby after I found her not breathing.” The consultant concluded that severe child abuse had occurred in the form of shaken baby syndrome. The consultant notified child protective services and the local police department, so that they could initiate and coordinate their investigation.

Suspected Sexual Abuse The examiner should consider the possibility that the parents are not telling the truth. However, this situation is more complex than suspected physical abuse. For example, the mother may wish to avoid the discovery of father-daughter incest by blaming the child's genital injury on another child or a stranger. In another scenario the mother may concoct an allegation of incest when the child had never been abused at all. The first version protects a father who is guilty; the second version implicates a father who is innocent.

The examiner should determine how the allegation originally arose and what subsequent statements were made. Determine the emotional tone of the first disclosure (e.g., whether the disclosure arose in the context of a high level of suspicion of abuse). Determine the sequence of previous examinations, the techniques used, and what was reported. Try to determine whether the previous interviews were likely to have distorted the child's recollections. If possible, review transcripts, audiotapes, and videotapes of earlier interviews. Seek a history of overstimulation, prior abuse, or other traumas. Consider other stressors that could account for the child's symptoms. The examiner should ask about exposure to other possible male and female perpetrators.

In Either Case Whether physical or sexual abuse is involved, a pertinent psychosocial history should be collected and organized including:

1. Symptoms and behavioral changes that sometimes occur in abused children
2. Confounding variables such as psychiatric disorder or cognitive impairment that may need to be considered
3. Family's attitude toward discipline, sex, and modesty
4. Developmental history from birth through periods of possible trauma to the present
5. Family history, such as earlier abuse of the parents, substance abuse by the parents, spouse abuse, psychiatric disorder in the parents
6. Underlying motivation and possible psychopathology of adults involved

Collateral Information The evaluator should consider requesting collateral information from the following, after obtaining authorizations: protective services, school personnel, other caregivers (e.g., babysitters), other family members (e.g., siblings), the pediatrician, and police reports.

Child Interview No hard and fast rules exist for conducting a competent evaluation of a child or adolescent victim. Experience generally supports flexibility and consistent good-hearted behavior by the interviewer. As when seeing any patient, the evaluator must size up the situation and use techniques that are likely to help the youngster become comfortable and communicative. One victim might need a favorite object (e.g., a teddy bear, a toy truck); another might need to have a particular person included in the interview. Some children are comfortable talking; others prefer to draw pictures. An unrelated joke, a shared cookie, or the picture on the evaluator's wall may lead to a disclosure of abuse. Important comments might be made while chatting during the break time, instead of during the structured interviews.

Interview Process The interviewer of the child who may have been abused should remember the following principles:

1. Audiotape or videotape the interview, if possible
2. Use a minimum number of interviews (perhaps two or three), as multiple interviews may encourage confabulation.
3. Avoid repetitive questions, either/or questions, and multiple questions and try to avoid leading and suggestive questions
4. Use restatement, that is, repeat the child's account back to the child (this allows the interviewer to see if the child is consistent and ensures that the interviewer understands the child's report)
5. Conduct the examination without the parent present (if the child is very young, consider having a family member in the room)
6. Use an examination technique that is appropriate to the child's age and developmental level
7. Determine the child's terms for body parts and sexual acts; do not educate or provide new terms

Interview Content The interview should not take the form of an interrogation. Note the child's affect while discussing these topics and be tactful in helping the child manage anxiety. Young children may not be able to report all of the relevant information. The examiner should explore the following 10 items:

1. Whethher the child was told to report or not report anything
2. Who the alleged perpetrator was
3. What the alleged perpetrator did
4. Where it happened
5. When it started and when it ended
6. Number of times the abuse occurred
7. How the child was initially engaging and how the abuse progressed over time
8. How the alleged perpetrator induced the child to maintain secrecy
9. Whether the child is aware of specific injuries or physical symptoms associated with the abuse
10. Whether any photography or videotaping took place

Step-Wise Interview The usual clinical interview may need some modification for evaluating a child who may have been abused. The step-wise interview, which is primarily intended for forensic evaluations, consists of the following components.

BUILD RAPPORT Build rapport and informally observe the child's behavior, social skills, and cognitive abilities.

ASK THE CHILD TO DESCRIBE TWO SPECIFIC PAST EVENTS Asking the child to describe two specific past events assesses the child's memory and models the

form of the interview for the child. Asking nonleading, open-ended questions is the pattern that will follow through the rest of the interview.

ESTABLISH THE NEED TO TELL THE TRUTH Reach an agreement with the child that in this interview only the truth will be discussed, not “pretend” or imagination. Explain that if the child does not know the answer to a question, it is fine to say, “I don't know.” If the child doesn't remember something, it is fine to say so.

INTRODUCE THE TOPIC OF CONCERN Start with general questions such as “Do you know why you are talking with me today?” Proceed, if necessary, to more specific questions such as “Has anything happened to you?” or “Has anyone done something to you?” Drawings may help initiate disclosure; either the child or the interviewer draws an outline of a person and the child is then asked to add and name each body part and describe its function. If sexual abuse is suspected, the interviewer could ask if the child has seen that part on another person and who has seen or touched that part on the child. If physical abuse is suspected, the interviewer could ask if particular parts have been hurt in some way.

ELICIT A FREE NARRATIVE Once the topic of abuse has been introduced, the interviewer encourages the child to describe each event from the beginning without leaving out any details. Children are allowed to proceed at their pace, without correction or interruption. If abuse has occurred over a period of time, the interviewer may ask for a description of the general pattern and then for an account of particular episodes.

POSE GENERAL QUESTIONS The interviewer may ask general questions to elicit further details. These questions should not be leading and should be phrased in such a way that the child realizes that an inability to recall or lack of knowledge is acceptable.

POSE SPECIFIC QUESTIONS If necessary, asking specific questions may yield helpful clarification. For example, the interviewer may follow up on inconsistencies in a gentle, nonthreatening manner. Avoid repetitive questions or appearing to reward particular answers in any way.

USE INTERVIEW AIDS IF NECESSARY Anatomical dolls may be useful in understanding exactly what sort of abusive activity occurred. The dolls are not used to diagnose child abuse, only to clarify what happened.

CONCLUDE THE INTERVIEW Toward the end of the interview, the interviewer may ask a few leading questions about irrelevant issues (e.g., “You came here by taxi, didn't you?”). If the child demonstrates susceptibility to the suggestions, the interviewer must verify that the information obtained earlier was not contaminated. Finally, the child is thanked for participating, regardless of the outcome of the interview. The interviewer should not make promises that cannot be kept.

PHYSICAL EXAMINATION

A forensic medical examination is usually performed by a pediatrician, preferably one with special expertise in child abuse. No part of the human anatomy is unrelated to the question of possible child maltreatment. Fingernails, hair, oral cavity, eardrums, skin surfaces, clothing, and genitals must be assessed, and the results recorded. A comprehensive examination must direct attention to all aspects of the victim's health status including maturity and developmental assessments, dental care, immunizations, and the review of systems.

Damage to the Skin and Surface Tissues Bruises, burns, bite marks, abrasions, and lacerations should be noted. Harsh punishment of the child may produce bruised lower back and buttocks, slapped cheeks, pinched earlobes, and choke marks about the neck. Injuries resulting from abusive toilet training may include pinch bruises on the penis or scrotum and perineal burns. Feeding-related injuries generate lacerations to the oral cavity and labial frenulum tears. Choke marks may be attributed to attempts at cardiopulmonary resuscitation. Sharp-bordered, rectilinear bruises may reflect strap marks; these markings can cover an entire body surface and leave buckle or eyelet impressions.

The human hand leaves various impression patterns. Grab and pinch marks are diagnosed by bruise-colored fingerprints. Negative imprints of fingers are slapping injuries, whereas oval-shaped bruises may result from grabbing during violent shaking. Human bites cause distinctive, paired, crescent-shaped bruises. The age of the biter can be determined by measuring the point-to-point distance between the center of the third tooth on each side (the canines). A distance of more than 3 cm suggests permanent teeth and hence an adult or a child older than 8 years of age.

Dating the onset and duration of bruises is problematic. As bruises age and resolve, the skin coloration passes through several hues, including red, blue, purple, green, yellow, and brown. The timing and coloration may be affected by variables such as the depth of the bruise and the amount of bleeding into the bruise.

Immersion burns generate a saved and scorched pattern, typically designated as stocking/glove or donut distribution burns. The skin pressed against a tub filled with scalding water is protected from the heat and remains unburned. Skin in direct contact with the water is scalded.

> A 16-month-old boy was brought to the hospital emergency room because of burns from scalding water. The child had patches of erythema on his abdomen, down the sides of his legs, and on the medial aspect of his upper arms. The diapered area had been protected from the heat. While the emergency room staff proceeded with their assessment and treatment, the child abuse consultant interviewed the parents separately. The father reported that he had been trying to heat a baby bottle by placing it in the bathtub and running hot water on it. The father returned in a few minutes and found the toddler, who apparently had climbed into the tub, in about two inches of hot water. The mother confirmed that she had been busy and had asked the father to heat the bottle in the bathtub. The consultant thought that the pattern of the burns was consistent with the story; the pattern did not look like that seen in forcible submersion. Although the parents' accounts were unusual, they corroborated each other and were consistent with the injuries. The consultant concluded that this was not likely to be child abuse but might constitute negligence. The consultant notified child protective services.

Damage to the Head Damage to the head includes scalp hematomas, lacerations, brain injuries, whiplash, or shaken baby syndrome. Head trauma is a worrisome injury. Even minor insults to the head prompt most caregivers to seek immediate medical attention. More than 95 percent of serious intracranial injuries sustained in the first year of life result from physical abuse. The cause of injury, typically, is violent shaking, to-and-fro whiplash, or slamming. Subdural bleeding ranks among the most dangerous inflicted injuries, often resulting in death or serious crippling sequelae. Retinal tearing and hemorrhage may be caused by shaking injuries. Falls are often blamed for injuries, and a fall from 1 to 3 feet can result in linear skull fracture and epidural hematoma. Such falls rarely result in subdural hematomas or clavicle or humerus fractures.

Inflicted black eyes are more common than serious eye injuries. Victims smacked about the eyes with an open or closed hand have both eyelids swollen, with massive bruising. Generally, black eyes sustained from accidents involve trauma to one eye. Although other scenarios are possible, the onset of bilateral black eyes immediately following facial trauma, generally indicates intentional injury.

Traumatic alopecia and subgaleal hematomas are caused by pulling the hair. Alopecia areata (noninflammatory hair loss) is characterized by loose hairs at the periphery of the bald area and is easily distinguished from inflammation or boggy swelling of the scalp caused by violent lifting of the child by the hair. Subgaleal hematomas may result when the aponeurosis connection between the occipital and frontalis muscles is wrenched off the calvarium, permitting rapid filling of the remaining space with blood.

Damage to Internal Organs Damage to internal organs includes blunt trauma to the chest; bruised abdominal organs; occult liver lacerations; duodenal hematoma; pancreatic contusion or laceration; superior mesenteric artery laceration; and spleen, kidney, and bladder rupture.

Skeletal Damage Skeletal damage is usually documented with X-rays taken immediately and, if necessary for better definition, repeated about 2 weeks after the injury. The most distinctive radiological features of infant abuse are metaphyseal lesions, called *corner fractures* or *bucket-handle fractures,* depending on the perspective of the X-ray. In addition to metaphyseal lesions, the following are highly specific for child abuse because they are unlikely to occur accidentally: posterior rib fractures, scapular fractures, spinous process fractures, and sternal fractures. The following are considered moderately specific for child abuse: multiple fractures, especially when they are bilateral; fractures of different ages; epiphyseal separations; vertebral body fractures and subluxations; fractures of the fingers; and complex skull fractures. Radiologists are astute about locating evidence of trauma and can provide insight into causality and patterns of old, healing, or new fractures. A child may not report a fracture if more injuries are likely to result after disclosure.

Intoxication and Poisoning Psychotropic and analgesic medication, alcohol, and illicit drugs have all been used by adult abusers to render a child or adolescent more susceptible to assault and less capable of offering accurate witness. There have also been reports of administration of salt, caustic cleaners, laxatives, animal

tranquilizers, blood, or excrement.

Physical Findings of Sexual Abuse Labial and perineal tissues that are susceptible to friction-induced traumas manifest abrasions, contusions, lacerations, petechiae, and edema. Examination may reveal bloodied tissue, genitorectal tears, and infected secretions. Scarring may be minimal or not evident if vaginal penetration has been gentle, consensual, or gradual. Vaginal and rectal tissues heal rapidly after injury and abrasions can be repaired within several days. Thus the lack of physical findings may indicate either a return to normalcy after rapid healing of minor lesions or trauma perpetrated in a manner that left no material evidence.

Major insults to the penile head (tattoos, scaldings, amputation) produce noticeable scars. The more common traumas (e.g., hematomas, abrasions, and lacerations) are superficial injuries and heal rapidly without scarring.

Anal findings include dilation with loss of anal-rectal tone, flattened rectal rugae, lacerations, and wedge-shaped and linear scars. Acute trauma may result in swelling and spasm secondary to submucosal hemorrhage. Most rectal injuries, massive or minor, heal quickly and nearly completely, leaving little evidence of abuse. Minor but persistent irritants, such as pinworms, lichen sclerosis, atopic dermatitis, and rare hematological disorders, can be longer-standing rectal irritants and may confound examination outcomes.

When sexual abuse is suspected, the victim requires evaluation for sexually transmitted diseases. Children may silently carry *Chlamydia trachomatis* infections, gonorrhea, syphilis, the human immunodeficiency virus (HIV), human herpesvirus 1 (HSV-1) or HSV-2, or other infections. The human papillomavirus, which causes condylomata acuminata, is known to be transmitted by direct sexual contact, but infants and young children may acquire anal and genital warts perinatally.

SPECIAL TESTS AND LABORATORY EXAMINATION

Computed tomography scans are invaluable in assessing an unconscious child with head trauma or abdominal injury. Rarely does a child sustain both cranial and abdominal traumas from a single innocent fall. Significant abdominal blunt trauma should be suspected in an atypically still child, because intraabdominal injuries are the second most common cause of death in battered children. A punch or direct kick can compress the organs against the spinal column, rupturing the liver or spleen and rapidly inducing shock from sudden, massive blood loss.

DIFFERENTIAL DIAGNOSIS

Physical Findings Pediatricians who examine children who may have been abused must consider a wide range of congenital, infectious, toxic, and traumatic conditions in their differential diagnoses (Fig. 49.4-1 and Fig. 49.4-2). The following examples are not meant to be exhaustive:

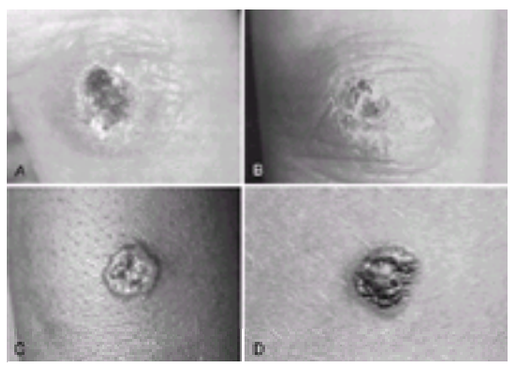

FIGURE 49.4-1 Child maltreatment is frequently manifested by bruises, burns, and other skin lesions. The diagnostic problem is that abusive injuries may be mistaken for medical conditions and vice versa. **A**, Physical abuse, a cigarette burn on the sole of the foot of a 5-month-old infant. **B**, A swimming pool granuloma overlying an interphalangeal joint. **C**, Tinea corporis. **D**, Clark's nevus, a benign, common acquired nevus. [Reprinted with permission from Reece RM: *Child Abuse: Medical Diagnosis and Management*. Lea & Febiger, Philadelphia, 1994 **(A);** Caputo R: *Pediatric Dermatology and Dermatopathology,* vol 4. Williams & Wilkins, Baltimore, 1996 **(B);** Caputo R: *Pediatric Dermatology and Dermatopathology,* vol 2. Lea & Febiger, Philadelphia, 1993 **(C);** Caputo R: *Pediatric Dermatology and Dermatopathology,* Lea & Febiger, Philadelphia, 1990 **(D)**.] (See Color Plate 9.)

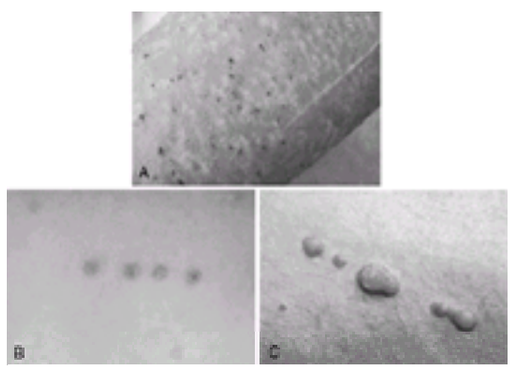

FIGURE 49.4-2 These linear skin lesions illustrate both child maltreatment and other conditions not related to abuse. **A**, Physical abuse, superficial ulcers caused by applying sandpaper to a child's skin. **B**, A series of insect bites distributed in a linear fashion, indicating that a single insect took bites in sequence. **C**, Common warts that are linear because lesions are induced when old lesions are scratched. [Reprinted with permission from Caputo R: *Pediatric Dermatology and Dermatopathology*, vol 2. Lea & Febiger, Philadelphia, 1993 **(A);** Caputo R: *Pediatric Dermatology and Dermatopathology,* vol 4. Williams & Wilkins, Baltimore, 1996 (**B** and **C**).] (See Color Plate 9.)

Conditions manifested by skin lesions: A Mongolian spot, a birthmark, may look like a bruise. Lichen sclerosis may look like sexual abuse. Chicken pox and impetigo may look like cigarette burns.

Conditions manifested by bone abnormalities: Congenital syphilis, cardiopulmonary resuscitation, copper deficiency, and rickets must be considered.

Conditions manifested by bruises: Vitamin K deficiency from liver disease, salicylate toxicity, osteogenesis imperfecta, bleeding disorders, and erythema multiforme must be considered.

Conditions manifested by eye hemorrhages: Valsalva effect and increased intracranial pressure and hypertension must be considered.

Self-inflicted injuries: Scratches from itchy irritations, factitious illness, head-bangers, and Lesch-Nyhan syndrome must be considered.

Psychiatric Considerations The psychiatric evaluation of youngsters who may have been abused may involve assessing the patient's credibility. Although generally children tell the truth when they talk about abuse, sometimes children make false denials (saying they were not abused, when actually they were) or false allegations (saying they were abused, when actually they were not).

Possible Explanations of Denials of Abuse A false denial or retraction may occur for several reasons. The child may have been pressured by the perpetrator or by

family members to recant the allegation. The pressure may consist of bribery, mockery, or threats of injury. The child may be protecting a parent or other family member, even without external coercion (i.e., the child takes on this responsibility through role reversal). A child might be frightened or distressed by the investigation and decide to withdraw participation. For instance, an interviewer could induce a false denial by asking overly challenging questions. A child may be inhibited by shame or guilt; some children mistakenly assume that they were responsible for what happened, and some children accommodate to the abuse, consciously or unconsciously, instead of objecting to it.

Possible Explanations of Allegations of Abuse A false allegation of abuse may occur for several reasons.

ALLEGATIONS ORIGINATING WITH ADULTS Sometimes a false allegation arises in the mind of a parent or other adults and is imposed on the child. The parent may have misinterpreted an innocent remark, a neutral piece of behavior, or a benign physical condition as evidence of abuse and induced the child to endorse this interpretation. This happens in child custody disputes as well as other settings. Sometimes the parent and child share a *folie à deux* or the child may simply give in and agree with a delusional parent. A parent may have fabricated the story and induced the child to collude in presenting it to the authorities.

A false allegation may result from an interviewer's suggestion. Previous interviewers may have asked leading or suggestive questions. An interviewer who believes abuse occurred may unwittingly shape a child's responses until the child validates the interviewer's assumptions.

Group contagion may lead to false allegations. In epidemic hysteria people modify what they have heard to meet their own emotional needs. Thus, rumors may become more convincing as they are retold.

UNCONSCIOUS OR NONPURPOSEFUL MENTAL MECHANISMS IN THE CHILD A younger child may confuse fantasy with reality, and although rare, older children and adolescents may experience delusions about sexual activities in the context of a psychotic illness. Sometimes children misunderstand what happened and later report it inaccurately or they may misunderstand an adult's question and the adult may later misinterpret or take the child's statement out of context. In confabulation, children fill gaps in their memory with whatever information makes sense to them and others at the time.

CONSCIOUS OR PURPOSEFUL MENTAL MECHANISMS IN THE CHILD

Fantasy Lying Children who understand the significance of lying may nonetheless fabricate because of frustration, disappointment, or wishful thinking.

Innocent Lying Children may make false statements because that seems to be the best way to handle the situation they are in. Developmentally, this is more likely to happen with younger children.

Deliberate Lying Children may choose to avoid or distort the truth for some personal advantage. This happens more with older children and adolescents.

PERPETRATOR SUBSTITUTION The child may have actually been sexually abused and exhibits symptoms consistent with abuse but identifies the wrong person as the perpetrator, resulting in a false allegation. The child may do this to protect the actual offender or the child may displace the memories and accompanying affects onto another individual.

Possible Explanations of Allegations of Ritual Abuse Other phenomena may be mistaken for cult-based ritual abuse, including pseudoritualistic abuse, psychopathological repetitive abuse, sexual abuse by pedophilic sex rings, false memories of abuse, and hoaxes.

The parents of a 9-year-old boy were divorced, and he spent the summers visiting his father. When he returned from visitation the mother noticed injuries: a healing cut on the boy's right ear and a collection of superficial, vertical scratches from his umbilicus to his pubis. She had the boy disrobe and took Polaroid photographs of his abdomen. Several days later the mother took the boy and the photographs to the boy's regular psychotherapy appointment. She told the therapist that she was concerned that the boy had been physically and sexually abused. The therapist interviewed the boy individually, who explained in a matter-of-fact manner that his ear was cut accidentally when he had his hair cut and his abdomen was scratched when he went bodysurfing at a North Carolina beach. The therapist concluded the boy had not been abused and reassured the mother. The therapist did not notify child protective services.

SPECIAL ISSUES

Fetal Abuse Fetal abuse can be direct or indirect. Either a mother or a father may directly attack their fetus through the abdominal wall or via the vagina. The risk is greatest during late pregnancy when one of the parents becomes disenchanted with the prospect of a new baby. Indirect fetal abuse by failing to protect the fetus from alcohol, nicotine, or drugs is more common. Fetal alcohol syndrome is an important cause of mental retardation in the United States.

Factitious Disorder by Proxy In factitious disorder by proxy, also called Munchausen syndrome by proxy, a parent, usually a mother, provides a history that fascinates and beguiles family physicians and expert consultants. The mother gives enough data to suggest a serious but poorly understood condition that requires extensive, painful testing. The child is often drawn into the improbable tale out of fear of contradicting the history given by the mother. Professionals become enmeshed in the apparent validity of the history, but no one can verify or witness the extraordinary symptoms that support the pathology of the child's alleged illness. Parents involved in the deception often have narcissistic, histrionic, or borderline personality disorder and thrive on the center-stage position they assume. In families where factitious disorder by proxy is found, more than one child may be involved consecutively, though rarely simultaneously. In extreme cases children can be killed, seriously injured, terrorized, and suffer severe adverse effects from medications or other treatments.

Cultural Variations Parenting practices in American society vary widely. They are partly determined by the cultural heritage of the family, and the cultural context of the alleged act should be considered in evaluating suspected neglect and abuse, including assessing whether the discipline of a child is abusive. Some unusual bruises result from cultural healing practices. Coining or cupping—techniques used in many European and Asian countries—are used to draw toxins from the skin surface and remove feverish mucus from the system. In coining, a coin is heated in hot oil and massaged against the skin. In cupping, a heated glass cup is used to create suction against the skin. Skin scraping and moxibustion may also mimic physical abuse.

Female Genital Mutilation Commonly called “female circumcision,” female genital mutilation is performed on an estimated two million girls worldwide each year. It is practiced across diverse socioeconomic classes and different ethnic, cultural, and religious groups. Commonly, girls are circumcised between 4 and 10 years of age, but the procedure may be performed on infants, postponed until just before marriage, or done after the birth of the first child. In some cultures it is considered part of a ceremonial induction into adult society. Female circumcision, in the mildest form, consists of clitoridectomy, the anatomical equivalent of penile amputation. In its most severe form, total infibulation involves removal of the clitoris and labia minora plus incision of the labia major to create raw surfaces that are then stitched together. This practice has been widely criticized, including opposition by the World Health Organization and other major health care groups. In the United States female circumcision is generally considered child abuse. Efforts have been made to educate immigrant communities on the health risks and legal liabilities of the practice. Compromise may be possible by finding a way to satisfy the cultural requirements without using mutilation such as adopting a nonmutilative ritual incision that results in only small scars on the labia.

Male genital mutilation (circumcision) is not usually considered child abuse, but it does have its critics. Although this simple procedure is one of the most common operations performed worldwide, serious complications may result. These complications include hemorrhage, infection, and penile amputation. In 1999 The American Academy of Pediatrics recommended it not be done as a routine procedure on newborns.

Religious Practices Certain religious practices may be construed as forms of abuse if they are likely to harm children. For example, adherents of Christian Science believe that illness should be treated with prayer instead of medical care. As a result, children may sustain chronic illness, disability, or death. This is an area of flux; some state laws and some courts have allowed parental discretion to withhold conventional medical treatment for legitimate religious reasons, while others have not.

Corporal Punishment Within families, corporal punishment occurs often enough in the United States that it cannot easily be labeled deviant. Most child and adolescent psychiatrists discourage physical discipline but realize that many capable and apparently nurturing parents spank their children. If physical discipline is used as a last resort, parental anger and frustration may exceed acceptable limits. In its most extreme form, a spanking turns into a beating. After 10 to 20 minutes of such abuse, a child will bleed into the muscles and other tissues of the back, buttocks, and legs and may lose enough blood to die from hypovolemic shock.

While sincere professionals may disagree about the propriety of parental spanking of children, there is a consensus against the paddling of children by teachers. Professional organizations (e.g., the American Medical Association, the American Academy of Pediatrics, and the American Academy of Child and Adolescent Psychiatry) have gone on record favoring banning of corporal punishment as a disciplinary measure in schools. Although almost every developed country has banned corporal punishment in schools, it is still allowed in more than 20 states, especially in the South.

Team Work It is draining to establish rapport, delve into hidden agendas, uncover covertly presented data, address multiple human needs, and meet the legal obligations associated with child abuse cases. Clinicians are thus encouraged to participate in a multidisciplinary team. Team participation provides the expert consultation and professional support essential for continued health, hope, and positive social interactions within the grim realities of case discovery.

In cases of suspected child abuse and neglect, the physician should make an assessment based on a history, a physical examination, a skeletal survey (when indicated), and photographs; request appropriate surgical, medical, and psychiatric consultations; diagnose the suspected maltreatment; and perhaps secure the child's safety by admitting the child to a hospital. Usually other members of the multidisciplinary team report the case to the appropriate child protection agency, provide skilled nursing, maintain security, arrange out-of-home placement, arrange a program of care for the child and the parents, and arrange for social service follow-up. These activities, taken together, should be a coordinated team effort. One feature of the team activity is regular meetings of the child abuse committee.

REPORTING LAWS AND PRACTICES

In every state, the District of Columbia, and all areas controlled by the federal government (e.g., military bases), physicians are required to report child abuse to the police or the appropriate child protection agency. The typical statute says that a physician who has “reason to believe” or “reason to suspect” child abuse is required to report it. In most states, other designated individuals, such as nurses, psychologists, school officials, police officers, district attorneys, and providers of child day care and foster care, are also required to report child abuse.

Underreporting A significant factor in reporting errors is the failure of clinicians and other mandated reporters to consider child maltreatment in the differential diagnosis of child injuries. Frequently, mandated reporters fail to pursue the diagnosis of child maltreatment because of diverse cultural and socioeconomic factors. Lack of experience in dealing with the issues and the judicial quagmire that results when reporting many child maltreatment cases is also an important deterrent. Underreporting of abuse also occurs when well-meaning but misguided therapists attempt to monitor and treat their abusive clients without involving the proper authorities. Some therapists think they are above the law; others simply have no idea what the law says about reporting child abuse. Perhaps the most important barrier to seeing and reporting abuse is denial. Reporters, both professionals and lay persons, are repulsed by the reality of child maltreatment and cannot accept the thought that abuse exists or is perpetrated by individuals like themselves, who may or may not regret their painful actions. The most obvious negative consequence of underreporting is that the abused child and siblings are left in dangerous circumstances, vulnerable to further abuse.

Overreporting Although physicians are required to report abuse when they believe or suspect (depending on the jurisdiction) that it occurred, they are not required to report other people's beliefs or suspicions. Some clinicians have the mistaken idea that if a mother expresses a concern that her child may have been abused, the suspected abuse must be reported, even when the clinician has investigated and has no suspicion at all that abuse occurred (e.g., an overly anxious mother who imagines that her child was sexually abused at day care, even though an objective examiner found no indications that abuse had occurred). The negative consequences of overreporting include increasing the load on an already overburdened child protective system and an unnecessary invasion into the lives of families, who are subjected to investigation, suspicion, and criticism.

TREATMENT

Child The first part of the treatment of child abuse and neglect is ensuring the child's safety and well-being. The child may need to be removed from an abusive or neglectful family to ensure protection, but emotionally feel even more vulnerable in an unfamiliar setting. Because of the high risk for psychiatric symptoms in abused and neglected children, a psychiatric evaluation is in order. Along with providing specific treatments for any mental disorders present, the therapist may have to deal with the immediate situation and the long-term implications of the abuse or neglect. Psychotherapeutic issues to be addressed with an abused child include dealing with the child's fears, anxieties, and self-esteem; building a trusting relationship with the therapist, in which the child will not be exploited or betrayed; and gaining a perspective over time of the factors that contributed to the child's victimization at home.

It is usually helpful to have the child share the painful, ugly details of the abusive experiences with the therapist. This may take time and may require therapeutic creativity and flexibility. Although some children may be able to relate the bad things that happened through ordinary conversation, other children may need a variety of play, artistic, or other projective techniques. Some children avoid the painful memories through conscious (suppression) and unconscious (repression) mechanisms. For a child who has been minimally assaulted (e.g., a relatively innocuous single episode of fondling by a stranger), it may be adaptive for the child to forget the incident and move on.

Parents Developing an intervention plan for an abused or neglected child requires assessing the parents' behavior and functioning in several respects. The psychopathology and the prognosis for achieving adequate parenting skills of both the abusive parent and the one who allowed the abuse to occur, should be assessed. The evaluator should determine whether the parent's dysfunction is confined to this child or involves other children and whether the dysfunction is short-term or long-term (reflecting a lifelong pattern). The evaluator should assess both the parent's willingness to participate in the intervention plan and the availability of personnel and physical resources to implement the various intervention strategies. One must consider the risk of additional physical or sexual abuse if the child remains in the home.

On the basis of the information obtained, several options can be selected to improve the parent's functioning: (1) eliminating or diminishing the social or environmental stresses; (2) lessening the adverse psychological effects of the social factors on the parents; (3) reducing the demands on the mother to a level that is within her capacity through day-care placement of the child or provision of a housekeeper or baby-sitter; (4) providing emotional support, encouragement, sympathy, stimulation, instruction in maternal care, and training in planning for, assessing, and meeting the needs of the child (supportive casework); and (5) resolving or diminishing the parent's inner psychic conflicts (psychotherapy).

Incestuous Behavior The first step in the treatment of incestuous behavior is its disclosure. Once the denial and collusion by the family members has been exposed, incest is not likely to recur. When the participants suffer from severe psychopathology, treatment must be directed toward the underlying illness. Family therapy is useful to reestablish the group as a functioning unit and to develop healthier role definitions for each member. While the participants are learning to develop internal restraints and appropriate ways to gratify their needs, the external control provided by therapy helps prevent further incestuous behavior. At times, legal agencies are involved to help enforce external controls.

PREVENTION

Primary Prevention Measures that reduce the occurrence of child abuse, primary prevention, can be classified on the basis of their audience or intended recipient. Universal interventions targeted to the general public include such strategies as a poster campaign admonishing parents not to shake their babies; warnings about consuming alcohol and drugs during pregnancy; and raising public awareness through the media, civic associations, church groups, and parent-teacher organizations. To some extent, children can be taught to avoid or resist being abused. However, ultimately the adults in a community must create safety and security for their children. Selective interventions are targeted to populations at high risk for child abuse. In general, for example, there should be less child abuse in a community with fewer single parents (use of birth control; greater involvement of fathers in families) and greater financial security (local jobs; social support systems). Governmental regulations may be helpful, such as the licensing of day-care centers and regulations concerning the operation of residential programs for children. Finally, one can sometimes intervene with specific persons or families that are at high risk. Counseling and parenting classes may deter parents from being abusive, although this has not been substantiated. Treatment for parents who abuse substances and services for families with a history of spouse abuse may be helpful. Individuals can help friends and relatives who appear stressed and are struggling with their parenting responsibilities.

Secondary Prevention Early detection and prompt intervention when child abuse occurs is secondary prevention. Education of the medical profession, members of allied health fields, and all who come in contact with children will aid early detection. Emergency room personnel, pediatricians, teachers, and counselors have many opportunities to identify abused children. It is hard to know how best to use the limited resources available to child protection agencies. Some critics think that too much effort is put into assessing the millions of referred cases, with relatively little attention given to interventions. For instance, an agency might put many hours into collecting information, arrive at a decision about whether a case is founded or not, engage in expensive legal measures, but offer little or no aid to help a marginal

family function better. In general, child abuse and neglect prevention and treatment programs should try to (1) prevent the separation of parents and children if possible; (2) prevent the placement of children in institutions; (3) help the parents attain self-care status; and (4) help the family become self-sufficient. As a last resort, to prevent further abuse and neglect, children may have to be removed from families who are unwilling or unable to profit from the treatment program.

SUGGESTED CROSS-REFERENCES

Forensic psychiatry is presented in Section 51.6b. Child forensic psychiatry is presented in Section 49.12. A more detailed discussion of the diagnostic process with children and adolescents is in Chapter 44. The various disorders manifested by maltreated children are discussed in the following chapters and sections: posttraumatic stress disorder, Section 46.2; identity problems and borderline disorders, Section 49.10; separation anxiety disorder and anxiety in children, Section 46.3; eating disorders, Chapter 20; feeding and eating disorders of infancy or early childhood, Chapter 41; elimination disorders, Chapter 43; mood disorders and suicide, Chapter 45; and child or adolescent antisocial behavior, Section 49.7.

49.5 CHILDREN'S REACTION TO ILLNESS AND HOSPITALIZATION

MARTIN J. DRELL, M.D., AND TONYA JO HANSON WHITE, M.D.

Illness and hospitalization are all too frequent occurrences in the lives of children and their families. Children 1 to 3 years of age average seven to nine illnesses per year, those 4 to 10 years of age average four to six per year, and those over 10 years of age average four per year. Together, a family with two adults and two children averages 21 illnesses a year. Even though most of these illnesses are minor and cause only transient disruptions of everyday life, it is estimated that 2 to 3 percent of all children have illnesses severe enough to affect growth, development, school performance, or social relationships. With more than four million child and adolescent hospitalizations each year, health care professionals must understand the impact of illness and hospitalization on children to offer appropriate interventions.

The developmental biopsychosocial model, based on work by George Engel, is the best model for understanding the impact of illness on children. This model is used in this section to identify the key developmental, biological, psychological, and social factors that come into play when children become sick (Fig. 49.5-1).

FIGURE 49.5-1 Developmental biopsychosocial model.

DEVELOPMENTAL BIOPSYCHOSOCIAL MODEL

The developmental biopsychosocial model is influenced by general systems theory. It stresses that all medical phenomena, such as a child's reaction to illness, hospitalization and surgery, can best be conceptualized through a thorough understanding of developmental, biological, psychological, and social information concerning all the key persons involved. The model is based on the supposition that each of these sets of information is worthy of study in its own right and no one, individually, can explain the complexity of health and disease. The model proposes that a true understanding can only be achieved by considering the ongoing interplay of these four sets of information. A number of main questions need to be answered in each of these four categories to get a clear picture of a case.

Developmental Sphere The main question to ask in the developmental category is: “What is the current, premorbid developmental stage and functional level of the child?” Although several responses to illness and hospitalization are typical of persons of all ages such as anxiety, regression, mood changes, and changes in bodily functions (e.g., eating, sleeping), some responses are characteristic of an individual developmental level. Different-age children, depending on their developmental level, have different key concerns or tasks that influence how they perceive all events. Thus, their understanding of illness and hospitalization also differs, depending on their developmental level (Table 49.5-1). The child's developmental level can be ascertained through the interview, history taking, and careful observation.

Age (years)	Developmental Tasks	Cognitive View of Illness	Response to Illness and Hospitalization
0 to 3	Establishing primary attachments and bond Learning to regulate attention and bodily functions Increasing opportunities for exploration and learning, yet dependent on their caregivers to protect them from pain and discomfort Limited verbal skills, affective communication predominates	Illness viewed as an external agent inflicting discomfort and pain Almost totally dependent on caregivers for relief of illness	Infants may become difficult to engage and show an intense preoccupation with their environment Sleep and feeding difficulties Procedures often elicit affective interplay—"Why are you taking them (to this or me, Mommy?" answered by "I feel your pain only too well and I'm here to comfort you"
3 to 7	Mastering separation/individuation from parents—fears of abandonment Beginning to use symbols and language Concerns with abandonment and bodily harm	Egocentricity predominates—viewing the illness, hospitalization, or procedures as a result of bad behavior Understands illness as something going on inside Illness defined only via external signs	Focus on an intact body—unrealistic fears visualized with a fantasied aggressive repertoire may escalate anxiety and confusion Can tolerate longer periods of separation Continued need for primary attachment figure
7 to 13	Mastering fears of loss of control and death Need to organize and order experiences Rules and structure have high priority	Increased understanding of illness Can accept necessary procedures on the need for hospitalization Illness is viewed as a result of wrong doing Contagion theories	Illness defined by concrete symptoms More able to understand illness from multiple points of view but unable to entertain hypothetical situations Illness improves through proper care with limited understanding of the body's role in healing itself
13 to 18	Mastering second phase of separation/individuation from parents Dependent on and heavily influenced by peers	Gradual development of an adult concept of illness Feelings of being invulnerable to illness Awareness of the complex and multiple interrelationships of factors such as a "host" and "agent" in causing illness	Attribution of self-blame continues, but decreases with age May exhibit difficulties meeting a chronic illness role that their sense of self-image/interferes to psychosexual development

Table 49.5-1 Developmental Responses to Illness and Hospitalization

Children age 3 years and under are establishing primary attachments. They are learning to regulate attention and other body functions. While they have access to opportunities for exploration and learning, their caregivers protect them from pain and overwhelming stimuli. Children in this age range have little concept of illness. They view it as an external agent that causes discomfort and pain. They depend almost totally on their external caregivers to relieve them of what bothers them.

Children 3 to 7 years old are typically concerned with abandonment, punishment, and bodily harm. They have begun separating and individuating from their caregivers on whom they still remain largely dependent. These children are better able to understand illness as something going on inside themselves, yet often they have unique ideas to explain why they are sick, including the concrete interpretation that the illness is a punishment for real or perceived indiscretions by the child.

Children between the ages of 7 and 13 years are working to master fears of loss of control and fears of death. These children have a greater understanding of illness and themselves, but they still believe that they have done something wrong or that they acquired the illness through contagion. Children at this age can be told more about their illnesses and can be more actively involved in their treatments.

Teenagers between 13 and 18 years are primarily concerned with their physical appearance, self-image, real or potential loss of peers, and fears of dependency. Adolescents understand their illnesses in ways approaching those of mature adults. They can test hypotheses logically and entertain numerous causes for their condition. They depend less on their caregivers, are more able to care for themselves, and generally prefer the company of their peers. Under stress, however, they still tend to consider illness to be a punishment for some indiscretion only known to them.

Dividing these developmental tasks by age is an explanatory artifice. In reality, the changes in both developmental tasks and cognitive abilities vary among children of similar ages and can advance unevenly. Children at all ages do the best they can with the resources they have available. As the developmental biopsychosocial

model predicts, developmental advances depend partially on the interactions among the child, caregivers, and events. Thus, two children close in age with similar caregivers may have entirely different perceptions of illness if one has been chronically ill and the other has previously encountered only minor, transient illnesses. Direct threats to physical development (e.g., illness resulting in growth delays, impaired gross or fine motor functioning, or early or delayed onset of puberty) can influence overall development. Furthermore, illness-specific factors such as disfigurement, isolation, and school absenteeism may disrupt social or identity development. Health professionals must understand developmental concepts enough to ask how the illness is affecting the child and be sophisticated enough to listen and respond to concerns or inexact theories that reflect developmentally based misperceptions.

A polite teenager was consumed with guilt whenever he got the least bit angry with his parents. When he was diagnosed with osteosarcoma, he wondered if this wasn't a punishment for his anger. He told the child psychiatrist during a consultation that he knew his anger was not really the cause, but that he could not get the thought out of his mind.

Knowledge of the impact of separation, especially on young children under stress, has prompted health care providers to change visiting policies at hospitals during the last four decades. Parents are usually allowed 24-hour visitation and at times are even provided with a cot.

Biological Sphere The main questions in the biological category are aimed at determining the biological and organic correlates of the suspected problem. This entails investigating the constitutional strengths and weaknesses of each patient, including their genetic endowment, response to medication, biological manifestations of the illness, perceptual skills, learning capabilities, ability to attach and maintain relationships, temperament, and predisposition to mental illness.

Some more-specific biological questions include: How does a child's intelligence affect the ability to comprehend the illness and comply with treatment? How does a child's temperament affect compliance with treatment? Infant psychiatrists have now described regulatory disorders that are characterized by young children having difficulties regulating such aspects of their functioning as behavior, physiology, affect, attention, and the senses. These regulatory disorders include subtypes such as hypersensitive (overreactive), underreactive, and motorically disorganized or impulsive. Are there biologically based differences in pain thresholds? Are there preexisting physical or mental disorders?

Is there a family history of mental illness? A biological predisposition (diathesis) to mental disorder could become manifest because of the stress of medical illness or the medications used to treat it.

Research shows that a small proportion of children develop mental disorders during the course of their illness and that chronic illness doubles the risk for behavioral and emotional problems. These children usually have a personal or family history of mental disorders. Current practice is to diagnose and treat children if they fulfill the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) criteria for a disorder. One must not automatically dismiss symptoms as a normal reaction to illness (the “I'd be depressed too if I had cancer” response). Diagnoses commonly encountered by consultation-liaison child psychiatrists in pediatric hospitals include adjustment disorder, acute stress reactions, posttraumatic stress disorder, anxiety disorders, and depression.

An 11-year-old boy with cancer was treated with steroids. The nurses reported that he was becoming difficult to care for and that he was refusing treatments and “acting weird.” An evaluation showed that he had become manic. His iatrogenic mania disappeared after a steroid medication adjustment.

A 7-year-old girl with both cancer and generalized anxiety disorder became hysterical during every blood test and medication injection. The doctors called a psychiatric consultant who taught her cognitive-behavioral coping skills. Over time, her hysterical response to medical procedures was significantly reduced but not entirely eliminated.

A 14-year-old girl, newly diagnosed with cancer, became increasingly quiet. She reported a change in energy and appetite and feelings of helplessness and hopelessness. She told her mother that she wanted to die. A psychiatric consultation showed that the girl was depressed. She responded well to antidepressant medication.

Psychological Sphere The main questions to ask in the psychological category are aimed at understanding how persons think about and react to their illness. Individuals have unique perceptions of these events, which are influenced by their past experiences, and their actions will be based on these perceptions. Problems may arise when various persons involved have conflicting or mismatched perceptions about the facts of any given situation. Questions to elicit the child's perception should be asked in a developmentally appropriate manner. Specifically, one might ask the child:

What is going on? Follow up with specific questions until you get a good sense of what the child thinks is going on. Ask specifically what such key individuals as the doctors, nurses, and his parents have told him. Check for discrepancies, however small, between the child and the others involved in the child's care.

How long has this been happening? Remember that young children have a different perception of time than adolescents or adults.

What happened to cause you to be sick? Check especially for idiosyncratic and pseudological explanations, which often occur, especially in young children.

What do you think will make you better? Do you think you will get better? The answers to these questions can greatly increase or compromise compliance with treatment.

Have you ever been sick before? If so, what was that like?

Do you know anyone or have you heard of anyone who was sick? Do you know anyone who was sick with the same thing you have? What happened to them? Specialty wards may contain several children with the same diagnosis, which leads to identification and special relationships. The fate, good or bad, of these children with the same diagnosis can greatly influence how a young patient and caregivers feel.

How are you feeling?

What is the worst part about being sick? Are there any good parts to being sick?

Have there been any changes (in you or your family) since you became sick?

Anything else going on with you or your family? The evaluator wants to know how the illness fits into and changes the life story, or narrative, of the child. In some cases the illness can have a positive impact (e.g., “I am a survivor of cancer!”) or a negative impact (e.g., “I am a victim of cancer!”). For some, especially those who become sick at an early age, the illness can be an organizing theme of their life.

A teenager who had been in remission for years and was considered “cured” wanted to go out for the football team; his mother was reluctant to allow this because of his childhood cancer. Another teenager in long-term remission constantly worried that his cancer would return. His worrying had caused him to restrict his activities and caused him considerable distress.

Social Sphere The main questions in the social category are aimed at understanding the strengths and weaknesses of the caretaking environment including individual, cultural, societal, and national values. Answers to these questions should give the clinician a sense of how the family and other caregivers (including the medical team) are dealing with the ill child. In keeping with the developmental biopsychosocial approach, each family member and caregiver is considered to be a separate, yet interrelated entity with its own developmental, biological, psychological, and social issues. Akin to Russian nesting dolls, the child is supported by caregivers who in turn are supported by others who in turn are supported by still others, and so forth. Like the child confronted by illness, hospitalization, or surgery, the caregivers do the best they can with the resources available to them. Thus, the following questions, similar to those asked of the child, need to be asked of the caregivers as well.

Developmental Questions Where are the caregivers developmentally? Not only children vary in their developmental stages, and adults are not homogeneous in their ability to cope. Many adults have limited ability to abstract and to understand illness.

> The only child of a teenage mother is diagnosed with cancer, and the only child of an older professional mother, who put off having a child because of her career, is diagnosed with cancer. The different developmental levels of these two mothers suggest quite different scenarios, even though the type and prognosis of the cancer may be the same.

Biological Questions Several biologically based questions concern clinicians. One such question attempts to determine the innate intelligence of the primary caregiver. Occasionally caregivers are so compromised in this area that special intervention programs are needed.

> The mother of a 12-year-old girl with cancer had dropped out of school at age 14. She had been engaged in a series of housekeeping positions before becoming pregnant at age 15. After that, she applied for and received welfare payments. The mother had difficulties comprehending the details of her daughter's illness. Special sessions were held to educate the mother, which involved showing her pictures of the medications, alarm watches, and calendars to aid in compliance. The social history showed that the more intelligent 12-year-old daughter regularly acted as an interpreter and caretaker for her intellectually compromised mother at home and in their community.

What is the temperament or personality of the caregiver? Although temperament and personality are not completely biologically determined, evidence suggests that in their development they may serve as a substrate, acted upon by the biological makeup of an individual. Temperament and personality act as a filter through which medical information, decision-making, and communication flows.

> A brilliant oncologist was incapable of taking responsibility for mistakes and always blamed other members of the team. The resulting feelings of the accused team members led to considerable tension and dysfunction on the team.

> The nurses complained bitterly about a father who told them not to give his daughter her medications if she didn't want them. The nurses complained that they were too busy for such nonsense. “He's always so bossy and blows up when he doesn't get his way. He has macho man syndrome.” They were puzzled that this same “macho man,” when initially told of his daughter's diagnosis, sweated profusely, turned white, and became nauseated.

Does the caregiver have a preexisting mental or physical disorder?

> The oncology team was quite concerned when they heard that the mother of one of their patients had schizophrenia. They were relieved when they found her to be quite compliant. The doctor on the case stated that the father made all the decisions but that the mother attended all conferences. He admitted wondering what she understood about her daughter's condition.

Has the stress of the illness triggered a mental disorder in the caregiver? Symptoms of anxiety, depression, and posttraumatic stress disorder have been described in parents of children with chronic medical conditions.

> A father began drinking when his 3-year-old son was diagnosed with leukemia. His condition deteriorated to the point where he needed to be escorted off the hospital ward by security and was verbally abusive to a staff nurse while he was under the influence of alcohol.

Psychological Questions These questions are aimed at understanding how the illness fits into and changes the story, or narrative, of the caregiver's life. How psychologically minded are the caregivers? Can they understand that the illness is a stress for themselves and other persons involved? Most importantly, can they empathize with the plight of their sick child and appreciate the child's needs?

> The mother of a 7-year-old girl with leukemia seldom visited. She stated that she had a major project at work that needed to be completed. When confronted with the impact of this decision on her child and the fact that the child was quite fearful, the mother stated; “She'll be all right. You have to be tough in this world to get along. She is always asking for attention. She's a big baby!” Work with this mother showed that she herself had been raised by emotionally distant parents who tolerated only performance achievement and discouraged any display of emotional weakness. After the mother understood her own anger and sadness about her own upbringing, she became more available to her daughter.

How do the caregivers deal with stress? What coping and defense mechanisms do they use (denial, rationalization, intellectualization)? The professional who deals with children with chronic medical conditions must constantly use more or less healthy ways of coping. The variety and importance of these response styles must be appreciated and dealt with in a manner that allows optimal coping. Individuals are often not aware of their defenses, and attempts to alter them without substituting healthier defenses can lead to worse functioning. Treatment teams have tremendous difficulties with parents who deny aspects of the diagnosis or prognosis of their children. The team often demands that parents face reality in ways they may not be able to handle, with problematic results.

> A father whose child was dying of an inoperable brain tumor seemed oblivious to this fact. The attending physician demanded that the social worker confront the father. During the meeting with the social worker, the father broke down in tears. On his way home he was involved in a minor auto accident. For a week he was unable to work and did not visit his daughter because of his injuries. When he returned, the father seemed just as oblivious. There was no indication that the social worker's intervention had been effective.

> A father from a distant town, whose 2-year-old daughter was diagnosed with leukemia, refused to admit that his daughter was sick. The nurses said that he was in “complete denial.” His wife moved in with her parents to be closer to her daughter during her hospitalizations. The father remained in the family house 50 miles away. The wife told her husband that he had better come to grips with what was going on or she would end up going her own way.

> A first-year child and adolescent psychiatry resident dropped out of his training program after becoming upset on a consultation on a 3-year-old child dying of cancer. The resident said that he couldn't stop thinking about his own 3-year-old child while doing the consultation. He found himself worrying that his own child might have cancer.

> An oncology team with a weekly psychosocial conference discussed deaths as they occurred. The team decided it might be better to discuss all the deaths at once during a monthly meeting. After the first monthly meeting, the plan was changed back to the weekly schedule. Several of the team members said that they were so upset after discussing so many deaths at once that they could not go to their rounds afterward.

Under normal circumstances, how does the caregiver deal with stressful situations? Individuals deal with stress at their own pace in their own way. These normal processes should not be confused with pathological states.

> The clinical team was concerned with a father's denial. “He never asks us any questions about his daughter's condition.” The consultant asked whether the denial impaired the treatment process in any way. The team said no. Within a week the parent was talking openly about his child's serious condition.

Are there any mismatch situations? Various key persons involved may be at different places in their progression of attempts to deal with the illness. Although each person's way of coping is not pathological in itself, problems can arise trying to balance the needs of different individuals in the group, at the same time.

A doctor wanted a parent of a terminally ill child to sign a do not resuscitate (DNR) document. The single parent refused and instead requested that a painful procedure with a small chance for success be performed. The parent wanted to “keep on fighting” and try everything. This angered the doctor who did not want to continue with a treatment that he felt would cause unnecessary pain to the child. In this quite common situation, the needs of the child, the doctor, and the parents were at odds. Yet, both the doctor and the parent are making reasonable requests from their own perspectives.

Do the caregivers have difficulties dealing with children at certain developmental ages (regardless of whether they are sick)? Often such troubles complicate the situation. The classic difficult ages are those of the toddler and the adolescent.

A mother, who was in constant battle with her teenage daughter over how much freedom the daughter should have, continued to have problems after the daughter's diagnosis of cancer. Their battles intensified as the mother became more protective of her daughter. The daughter complained that she was being treated like a baby. A consultation was called when the daughter refused to take her medications. In his interviews with the mother, the consultant found that she had had trouble with her mother at the same age and had in fact run away from home.

What is the impact of past or concurrent illnesses on the caregivers? Just as researchers base their predictions on past data, so do caregivers. The course, intensity, treatment complications, and outcome of other persons with the same illness can influence the perceptions and thus the actions of caregivers.

A mother whose own mother and grandmother had died of cancer within the previous 2 years was sure that her son, recently diagnosed as having osteogenic sarcoma with a good prognosis, would also die. The nurses found themselves arguing with the mother about whether her son would die or not. They were upset that the mother was not more hopeful.

A mother who had had cancer and was successfully treated as a teenager was consumed with guilt when her son was diagnosed with cancer. The mother was sure that her genetics had caused the cancer in her son.

Parents on an oncology unit become attached to the other parents on the unit. They become especially close to those with children similar in age to their own child or with similar diagnoses. They offer support to each other, share the ups and downs of treatment, and are devastated when any of the children dies. When this occurs, the parents go into mourning and become increasingly worried about their own children. This worry intensifies if there is more than one death in a short period.

What are the caregiver's past experiences with health care providers and systems? A bad experience can create anticipatory anxiety, complicate relationships with the health care team, and complicate treatment.

A mother was quite upset after it took several weeks for her local pediatrician to make the difficult diagnosis of leukemia in her daughter. She felt that the pediatrician had been incompetent.

She worried that the delay had compromised her daughter's prognosis. Her distrust of the pediatrician generalized to the pediatric oncologists who took over the case. The mother started to question all the suggestions of the oncologists, who became furious at having their competence challenged. The oncologists' initial efforts to educate the mother on the error of her ways just made matters worse.

Social Questions The main questions in the social category are similar to those asked about the social support system of the ill child. These questions focus on the strengths and weaknesses of the support systems of the caregivers, to describe the larger support context. What are the supports of the caregiver? Is there a supportive spouse or significant other? Is there a supportive family, friends, or a supportive religious community? Is the caregiver happily married? Studies show a slight increase in the divorce rate in families with a chronically ill child. Is the caregiver in a supportive work environment?

The oncology team was upset when it was hard to plan a family conference. The father said he had to work. When confronted with his lack of participation, the father said that his boss had threatened to fire him if he took more time off and that if he were fired he would lose his insurance coverage. Considering this new information, the family meeting was rescheduled to accommodate the father's work schedule.

What are the religious beliefs of the family? Religion plays a pivotal role in the way many families deal with illness. Religion can provide an understanding of the event and place it in a larger spiritual context that may or may not prove helpful. Various religions provide different explanations of the place of illness in life. Because of this, it is important to know the tenets of a family's religion. However, persons interpret religious doctrine in ways that reflect their own personality and past experiences.

An oncology team was challenged each time a patient who is a Jehovah's Witness was admitted because Jehovah's Witnesses refused blood transfusions. The team, through experience, has learned to respect the patient's religion while making it clear to the family that the team's medical responsibilities also need to be respected.

A Baptist minister of a child dying of cancer announced to his congregation that he had a premonition that God would perform a miracle. The family who had acquiesced to their daughter's fate and signed a DNR order, rescinded it in deference to the minister's pronouncement.

During his last visit home before his death, a 5-year-old boy was found packing a suitcase. When asked what he was doing, he smiled and said that he was going to die and was “packing his bags to see God.”

What are the prevailing cultural and societal views on illness and death? Societies and cultures vary in their views of illness and death. These variances can greatly influence the course of the illness and its treatment.

In the span of a year, an oncology team had four Vietnamese patients. All four proved difficult management cases. In a team meeting a nurse stated: “We do not seem to understand them [the Vietnamese] and they do not seem to understand us.” Two patients actually left treatment saying that they were going to seek the advice of their local healers.

Where are the medical team members developmentally, biologically, psychologically, and socially? Each team member has a unique approach to and understanding of illness. Many health care providers chose their specific professions because of their own past experiences with illness. Their understanding of their motivations may be unclear or inexact, leaving the professionals prone to over- or under-reacting to similar situations in their patients.

One of the child psychiatric consultants to the oncology team became interested in oncology because his brother was diagnosed with cancer when they were growing up. He often recounted how his brother's illness changed his family's and his own emotional equilibrium. He made sure, therefore, when consulted, to ask questions about the impact of the illness on the siblings.

What impact does health care reform have on families? In many cases, it has significantly changed the interactions between the child, family, and the health care delivery team.

The shorter lengths of stay mandated by managed care have changed the ability of the team to make relationships, to educate, and to assist patients and their families in dealing emotionally with their illness. The team must depend on other caregivers (e.g., home health care nurses) to perform the duties they themselves once did during the longer hospitalizations.

ILLNESS-SPECIFIC VARIABLES

Variables that depend on the nature of the illness may influence treatment outcome. Several of these variables interact with each other and cannot be viewed apart from the personal characteristics highlighted in the iopsychosocial model.

Chronic Versus Acute Illness A transient illness tends to be less disruptive than chronic illness in the long run. Generally life quickly regains its preillness equilibrium. Chronic illnesses pose an ongoing challenge to children and their caregivers. Most families adapt successfully and find a new equilibrium that balances the needs of the illness, the child, and the caregivers. As developmental, biological, psychological, and social situations change, new adaptations are necessary to prevent future problems.

Although all chronic conditions entail some stress and unpredictability, not all illnesses can be viewed in the same way. Children with cancer, asthma, and cystic fibrosis have dramatically different experiences with illness, hospitalization, and necessary treatments. For example, a meta-analysis of depression in children with chronic medical conditions and controls (Fig. 49.5-2) yields dramatically different results for different illnesses. The lower rates of depression in cancer may result from the propensity of this population to use denial or repression to adapt. On the other hand, the circumscribed nature of treatment may be protective. Whereas the painful crises in sickle cell anemia are intermittent, unpredictable, and long term, most childhood cancers have a characteristic treatment progression and most unpredictable events occur in a window of time rather than throughout life. The unpredictable nature of the illness in early life, as in sickle cell anemia and asthma, is stressful to the child and thus may result in higher rates of depression in these long-term illnesses.

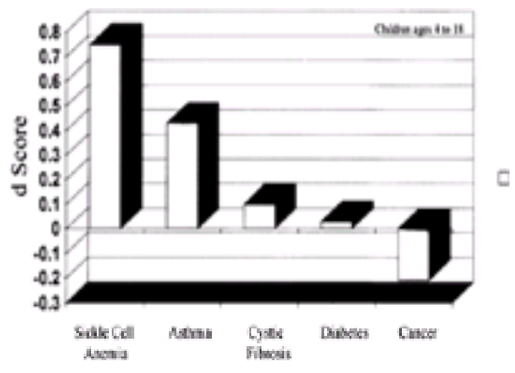

FIGURE 49.5-2 Rates of depression in children and adolescents with chronic medical conditions. A *d* score of 1 indicates depression scores that are one standard deviation apart from the control population.

Age of Onset There are developmental periods when illness can have a greater impact. Early childhood and adolescence are especially sensitive periods. In early childhood, cognition limits the child's ability to comprehend the complexities of the illness and is further complicated by fears of separation from the attachment figure. In adolescence, the illness threatens the normal push toward autonomy and necessitates more dependency on parents and other adults. A review of illness-specific developmental issues (Table 49.5-1) helps one anticipate potential difficulties and prepare preventive interventions.

Etiology The reality or the perception of how the child got the illness makes a difference. If the illness is genetic, the parent on the side of the family with the trait may have to deal with feelings or accusations of guilt or both and concern for siblings or future generations. In addition to the caregivers' concerns, the unique and developmentally influenced theories of etiology of the children can also cause concern.

Diagnosis Delayed diagnosis or misdiagnosis, especially if it is perceived as changing the course of the illness, can produce guilt or affect the family-doctor relationship. Guilt occurs when caregivers perceive that they neglected to do something that could have prevented the illness or modified its severity or course. Tension between the family and the primary care physician or between the primary care physician and the specialist can be exacerbated when the specialist is perceived as a hero for making the diagnosis. In such cases, primary care physicians are often covertly or overtly cast (or cast themselves) as dolts. Obviously, guilt is not the sole domain of the parents.

The perceived severity of the diagnosed illness is also important. The diagnosis of cancer continues to terrify people, despite the numerous advances in medical treatment that have considerably lessened morbidity and mortality. The importance of education in these circumstances cannot be underestimated.

Rare diagnoses can cause distress and bewilderment, especially when the health care worker does not have a working knowledge of the disorder. Families often report feeling isolated by having a child with a disorder that sparks no recognition among peers or medical personnel. This isolation is lessened somewhat by communication with similar families over the Internet.

Deformity and Disability As a rule, children and their caregivers experience increased difficulty when there is more deformity, disability, or both. One must ask how much the illness impairs the lives of the child and the family. Physical deformity is especially difficult for adolescents who are sensitive to issues of body image. The visibility of the deformity is important; those that show tend to be more difficult to deal with. The impact of any disability or deformity must be understood in the context of the lives of the children and their caregivers. For example, a minor disability of the knee that threatens the basketball career of an athletic adolescent is more devastating than the same disability in an adolescent fascinated by computers.

> A 7-year-old girl who was known for her thick, long, blond hair was especially devastated by her hair loss after chemotherapy.

Treatment Regimens What the treatments entail makes a considerable difference. Often treatments (surgery, chemotherapy, bone marrow transplants) with their accompanying pain, deformity, disability, and costs are perceived as worse than the primary illness itself. This is especially true when the illness onset is insidious and involves little pain and discomfort despite a potentially dire prognosis. One should not underestimate the emotional pain of young children who must go to a hospital when they are (by virtue of their stage of development) dealing with separation concerns and greatly attached to their family, home, bedroom, and so on. Young children may view the procedures involved in treatment as more traumatic than the threat of death. The perception of the trauma involved in the treatment is a strong predictor of posttraumatic stress in either the child or parent.

Prognosis The more negative the prognosis, the greater the potential for stress and risk to the family and the child. A prognosis that includes illness-related death or its threat adds a complex set of circumstances for all those involved.

INTERVENTIONS TO MINIMIZE THE RISKS OF ILLNESS AND HOSPITALIZATION

Interventions should be aimed at mitigating risk factors and reinforcing and supporting positive coping mechanisms in the child, family, and caregivers. The goal is to promote the healthiest possible functioning among all concerned and return families to a normal developmental trajectory. Although every case is different, some interventions are productive in most cases.

Be sensitive to the developmental, biopsychosocial complexities of those involved and provde a supportive relationship for the child and family. Effective health care providers need to know not only the developmental biopsychosocial complexities of those involved but also the complexities within themselves that might impede the formation of health-promoting relationships. These providers must inventory their own responses and reactions that could interfere with effectiveness, and they should be especially sensitive to types of patients or families who arouse unusual responses such as underinvolvement, overinvolvement, anger, sadness, or anxiety. If such responses occur repeatedly, talking with a colleague or consultant may help.

Educate all involved parties about the illness, and its assessment, and treatment. Our society promotes openness and informed consent, which helps the child and

family cognitively grasp their situation. Information should be presented sensitively in a developmentally appropriate manner, with an appreciation of the various responses that may be elicited. Defenses such as denial, projection, and intellectualization should be expected and be challenged only when they impede the progress of treatment or cause disproportionate distress.

Realize that children can talk about almost anything (at their developmental level). Many health care providers underestimate the capabilities of young children and make little attempt to communicate with them. This leads to many missed opportunities for both the provider and the child, who often is desperate to know what is happening.

Be available to talk to children and their parents. Make opportunities available for conversation among health care providers, parents, and children. Families may be too shy, too afraid, or too intimidated to initiate conversation. Failure of health care professionals to respond to initial and perhaps feeble inquiries for information may set the stage for a continuing cycle of missed opportunities to communicate.

Speak at the developmental level of all those involved. Everyone needs to have information delivered at a level they can understand. It is helpful to have people repeat what they have been told to ensure that they understand it. Anxiety and stress may impair the ability to hear and process what is heard. A parent may recall hearing “Your child has leukemia” and none of the treatment plan carefully explained to them during the initial hospitalization. Thus, repetition of important material is often appropriate and necessary.

Maintain family and life routines as much as possible. Particular attention should be paid to regression to developmentally earlier behaviors that do not remit over time. Overinvolved caregivers who function inappropriately and reinforce dependent behaviors that were not present before the illness need to be dealt with. A decrease in peer relationships indicates deviation from baseline functioning. If a child is hospitalized, hospital schooling, child life programs, and opportunities to be with peers should be planned. The hospitalization and treatment should not reinforce regressive forces in the child and family any more than necessary.

Identify and encourage larger support systems. Family therapists often speak of all those who are involved who can either cause a problem or help alleviate it. This approach leads to identification of persons such as grandparents, teachers, friends, siblings, and other relatives who can assist in the treatment. This larger network can be enlisted to help with problems such as how the mother will get to the hospital or who will take care of the other children while the parents are at the hospital. Both the family and the medical team must be supported and nurtured to remain effective.

Consider illness-specific support groups. These groups can often provide added, individualized support to patients and nonprofessional caregivers. Other families who have undergone similar experiences with ill children might help them.

Be on guard for psychiatric disorders. The current rule is to treat a disorder if the person has a diagnosable condition that meets DSM-IV criteria. Dealing with a mental illness while dealing with illness in oneself or a loved one is usually detrimental to the outcome of the primary illness. Studies have identified a relation between maternal distress after a child's diagnosis of cancer and the later psychological adjustment of the child. Parents at risk include those with psychiatric conditions such as depression or anxiety, higher trait anxiety, and less family support. Trait anxiety is also associated with higher rates of posttraumatic stress disorder years after the diagnosis of cancer. Thus, identifying parents in distress and providing supportive measures or treatment provides some protection to the child over time.

Treat pain aggressively. The gate control theory considers the perception of pain within a developmental biopsychosocial model. This theory emphasizes that the procedure alone does not define the level of pain, but the combination of the procedure and such variables as cognitive development, previous history with pain, and the perceived reason behind the painful procedure. One study showed that inadequate analgesia for initial procedures in young children could diminish the effect of adequate analgesia in subsequent procedures. A lack of seeing pain through the eyes of the child is thought to contribute to inadequate pain management, which is inversely proportional to the age of the child. Younger children are less able to verbalize the complex experience of pain and may exhibit compensatory behaviors (e.g., fear of separation from parents, tuning out health care workers, or temper outbursts). Children not uncommonly remain silent or deny their pain, fearing that acknowledgment will evoke further painful procedures; thus one should obtain collateral information from the parents and look for subtle signs of pain. Since perception of treatment intensity predicts later distress, therapeutic techniques (e.g., cognitive behavioral interventions or hypnosis) may provide some protection even if the actual number of procedures remains unchanged. Since pain significantly affects a child's perception of hospitalization and illness, it must be identified and treated, with as little additional pain as possible.

If there is a death, the care and support can continue. The health care team becomes an integral part of the family system when children are ill. This relationship continues after the death of the child. Follow-up sessions can often be important to the survivors. Similar attention to medical team members who get attached to patients and their families is also important. Ongoing psychosocial conferences can maintain team mental health and morale.

SUGGESTED CROSS-REFERENCES

Jean Piaget's approach to intellectual functioning is discussed in Section 3.2 and Erik Erikson's stages of development are described in Section 6.2. Normal child and adolescent development are discussed in Section 32.2 and Section 32.3, respectively. Chapter 10 contains cognitive and mental disorders secondary to a general medical condition. Finally, noncompliance with treatment (which is often similar for psychiatric conditions and medical conditions) is described in Section 27.1.

49.6 PSYCHIATRIC SEQUELAE OF HIV AND AIDS

JENNIFER F. HAVENS, M.D., SHEILA RYAN, C.S.W., AND CLAUDE MELLINS, ĦH.D.

The human immunodeficiency virus (HIV) epidemic has shifted over the last 5 years to affect growing numbers of low-income, minority, inner-city women of childbearing age. While advances in medical treatment may decrease the number of perinatally HIV-infected children and increase the life span and quality of life for HIV-infected adults and children, the sequelae of parental illness and loss will continue to affect thousands of children and adolescents. Most of these children and adolescents must struggle with familial HIV illness in the context of already troubled family backgrounds. Mental health evaluation and interventions for HIV-affected children must be informed by a clear understanding of the mental health sequelae of parental substance abuse as well as the complex and dynamic stressors of HIV illness.

EPIDEMIOLOGY

As of December 1997, there were 98,468 cases of acquired immune deficiency syndrome (AIDS) in women in the United States and 8086 cases of AIDS in children under 12, with 91 percent of the pediatric cases caused by perinatal transmission. The increased incidence of AIDS in women is also reflected in the increasing numbers of children, adolescents, and young adults who are losing one or both parents to AIDS. In 1992, David Michaels and Carol Levine projected that between 72,000 and 125,000 children and adolescents will lose their mothers to AIDS by the year 2000. No estimates are currently available of the number of children who will lose their fathers, or both parents, to AIDS. While combination drug therapies have recently been found to have the potential to reduce AIDS-related mortality, it is unclear whether these new treatments will be broadly effective and accessible, particularly to the population of parents with histories of substance abuse.

In the United States, AIDS in women and children represents a confluence of two major epidemics plaguing American cities, HIV infection and substance abuse. Intravenous drug use is the risk factor for HIV infection in 44 percent of the AIDS cases in women and heterosexual contact with a drug user accounts for a significant percentage of the remaining cases. Reflecting the risk factors for HIV infection in women, 53 percent of children with AIDS were born to women whose risk factor for HIV infection is their own or their partner's intravenous drug use. Recent findings on the efficacy of zidovudine (Retrovir) in reducing the rate of transmission of HIV from mother to infant indicate a mechanism for reducing perinatal infection. However, drug-abusing women, those at highest risk for HIV infection, may be the least likely to access this important treatment advance.

ETIOLOGY

Mental Health Risk Factors Associated With Parental Substance Abuse Risk factors for mental health problems for children with drug-abusing parents cluster in two broad areas: (1) sequelae of parenting deficiencies associated with parental substance abuse (neglect, abuse, discontinuity of attachments and disruption of placement) and (2) the biological risks associated with parental drug addiction (prenatal drug exposure, heritable parental psychiatric disorder).

Neglect, Abuse and Disrupted Attachment Associated With Parental Drug Addiction One of the most devastating effects of substance abuse is the erosion of parenting capacities essential to children's development and well-being. Children living with substance-abusing parents are at increased risk for neglect, abuse, exposure to domestic violence and disruption of attachments, all of which increase children's risk for mental health problems.

Biological Risks Associated With Parental Drug Addiction

PRENATAL DRUG EXPOSURE Several studies have described the developmental and behavioral problems of children prenatally exposed to drugs. Methodological problems in much of the research on these children limit definitive conclusions regarding the link between specific drug exposures and behavioral or cognitive outcomes. However, clearly, maternal drug use during pregnancy with its associated problems, such as inadequate prenatal care, premature birth, and low birth weight may increase children's risk for developmental, cognitive, and mental health problems.

HERITABLE PSYCHIATRIC DISORDERS Adults with substance abuse disorders have high rates of psychiatric comorbidity, in particular, affective and anxiety disorders and childhood histories of attention-deficit/hyperactivity disorder. Children born to substance abusers are at increased risk for mental health problems, because of the heritable nature of the psychiatric disorders prevalent in adult substance abusers.

Furthermore, for reasons that are probably both genetic and environmental, substance abuse in the parental generation frequently clusters in extended families. Extended families with two or more substance-abusing adult siblings are not unusual, it is rare to encounter two or even more adult siblings with HIV infection associated with substance abuse or substance-abusing sexual partners. In these families, material and emotional resources may be too strained to intervene effectively on behalf of grandchildren, nieces, or nephews affected by parental HIV illness; this lack of extended family capability may place the child at further risk.

In summary, HIV illness commonly strikes families already struggling with substance abuse and its associated problems, including impaired parenting capacities and psychiatric disorders. When a child's parent is substance abusing and HIV positive, the HIV disease may play a less significant part in the child's mental health problems than do issues related to the substance abuse.

CLINICAL FEATURES

Neurodevelopmental Sequelae of HIV Infection There have been consistent findings of significant neurological, developmental, and cognitive deficits in HIV-infected children. Two relatively distinct neurodevelopmental patterns have been described: progressive encephalopathy and static encephalopathy. Progressive encephalopathy, corresponding to the AIDS dementia complex in adults, is characterized by the loss of developmental milestones in young children and by declining intelligence quotient (I.Q.) scores and increasing difficulties with language, attention, concentration, and memory in older children. This neurodevelopmental pattern is a direct effect of HIV on the central nervous system and is associated with a poor prognosis.

Static encephalopathy, characterized by nonprogressive deficits in cognitive, motor, or language function, is not directly attributable to HIV and is most likely associated with a non-HIV risk factor, which for many HIV-infected children may involve prenatal drug exposure, prematurity, and low birth weight or heritable or environmentally mediated impairment.

Emotional and Behavioral Disorders There has been little research on emotional and behavioral disorders in HIV-infected children. Clinical reports have suggested that they are at high risk for anxiety, depression, guilt, and low self-esteem. In one of the few studies focusing on psychiatric disorders in HIV-infected children, the first author, Agnes Whitaker, Judith Feldman, and Ankel Ehrhardt found high rates of attention-deficit/hyperactivity disorder. However, these rates did not differ from those in a matched control group of children from similar backgrounds (children living in foster care who had been born to women who had used drugs during pregnancy). Features associated with prenatal drug exposure, such as prematurity, low birth weight, and heritable parental psychopathology, may actually be more potent mediators of mental health problems in children than HIV infection itself.

TREATMENT

In general, age, developmental level, or both dictate children's capacity to understand the meaning of their HIV illness. Preschoolers and young school-age children

cannot grasp the concept of chronic illness, and the strain and anxiety of their diagnosis and care falls on their caregivers. These young children are generally not informed by family members of their HIV infection. For older school-age children with a developing capacity to understand and contain information about HIV infection, a large number of issues emerge. These include learning about one's diagnosis (either through family disclosure or individual deduction); coping with secrecy, stigma and potential rejection by peers; coping with chronic illness, and anxiety.

Parents or other family caregivers often resist discussions with HIV-positive children about their health in an effort to protect them from emotional distress. Often entangled with this motivation are one or more other factors: the adult's own fear of experiencing more intense pain about the child's diagnosis; parental guilt about having transmitted the virus to the child; and concerns that the child will disclose family secrets about HIV in undesirable ways.

While for adult family caregivers and health care providers the specific diagnosis of HIV is often a highly charged, indeed an overwhelming element in communication with the children about health issues, it is in fact only a single component. The children may be more concerned about medications, medical appointments, and procedures associated with a chronic health condition or with impingement on functioning. Establishing effective communication with these children on the broad range of health-related issues is of great importance. When the efforts of family caregivers and health professionals are not achieving this goal, a therapist may need to intervene. The starting point must be listening to the children to ascertain what they know and fear and what information they actually want. Often children are seeking an admixture of medical data and affective material. It is often useful to work with the children on making a list of questions that provides a structure for adult response and helps to ensure that the children's needs frame the communication process. Ten-year-old Teresa, a child with advanced HIV disease, dictated to her therapist the following questions for her pediatrician:

> I know that it is AIDS that I have. How did I get this virus? Why do I have it and Bobby [her younger brother] doesn't have it? Did my mother do something that made me get the virus and Bobby not get it? When can I stop drinking all those pills? I asked Lucy [her nurse] when I am going to get better and she said when I drink all my pills. I drinked all my pills every day, but it's the same thing. Is it true that the pills are going to make me better? When I get married I don't want to be drinking pills in front of my husband, because he will know what I have and be scared.

Adherence to Medical Regimens HIV-infected children, like those with many other chronic illnesses, may need to adhere to complicated medication regimens, attend numerous medical appointments, and undergo frequent diagnostic procedures. Effective communication with these children about their health is the best foundation for securing their participation in these activities. Many families need considerable support in following the complex medication regimens for the child and managing the child's potential opposition to taking medication. Behavior modification techniques (especially, positive reinforcement) may be very helpful to families in dealing with these issues. Offering the child whatever measure of control possible (“Which pill do you want to take first?”) may also minimize struggles over medication.

Promotion of Optimal Development As with adults, the mental health issues for infected children change over the course of the disease. Many HIV-infected children remain relatively symptom free for long periods of time. They may not know their diagnosis, and their lives may be relatively unaffected by illness. They may, however, be stressed by the illness of a parent, substance abuse in the family, disrupted placements and ruptured attachments, or any of the other problems that so often plague the families at highest risk for HIV. Interventions for these problems and attention to promoting the children's optimal development may be more urgent matters for their mental health care during much of childhood than specific focus on HIV.

For adolescents, the normal developmental challenges of this stage, including puberty, sexuality, and the desire to fit in or be normal are seriously complicated by HIV disease. The detrimental effects of HIV on growth and pubertal development pose significant challenges for the growing number of congenitally infected young people living into their teens.

With disease progression, HIV-infected children must confront the physical and mental decline associated with AIDS. As they approach late-stage illness, they and their families must confront the terminal nature of the disease. Often, families are overwhelmed at this stage and have difficulty communicating with the children about issues related to prognosis and death. Sensitive mental health intervention by clinicians with an ongoing relationship with the children and their family can provide a place for these children to express their inevitable anxieties and fears about separation from family members and dying and help the children (if old enough) communicate their wishes about medical treatment.

AIDS Dementia In children with HIV central nervous system involvement, recognition of dementia-related behavioral sequelae and accurate differential diagnosis is clinically important for several reasons. First, parents and medical staff can misinterpret children's increasing fatigue, decreased interest in and resistance to regular activities, and regressive behavior as volitional oppositional behavior or depressive disorder. This can result in efforts to encourage them to alter their behavior when the behavior actually results from the disease process and is beyond their control. Second, early in the presentation of AIDS dementia in children, stimulants such as methylphenidate (Ritalin) can be very helpful in raising their energy level and improving their quality of life. Third, progressive organic involvement in children is an important prognostic sign, generally accompanied by severe immunocompromise and signaling the end stage of the disease. This is an important time to shift gears in the work with children and their families to help them prepare for the final stages of the child's life.

Therapeutic Support as Death Approaches As HIV disease progresses to end stage, children may experience confusion and great anxiety. Parents and other adult family caregivers and perhaps even medical and nursing staff frequently find communicating with the child about the approach of death so daunting a task that they avoid it. Dying children need a venue in which the impending death, unspeakably sad for many of the adults in their environment, can be discussed. The children need an opportunity to express their thoughts and fears and receive reassurance. For most preadolescent children, separation from family, especially from a primary attachment figure, is the most worrisome aspect of death. A therapist may be able to draw on elements in the family's belief system that sustain hope of continuity of attachment between the deceased and surviving family members.

> James, a 7-year-old boy the size of an average 3- or 4-year-old, was aware that he was terminally ill. Neither of his parents, both HIV positive, could bring themselves to speak with him about his imminent death, leaving James isolated within the family in his painful awareness. James was able to share with his therapist his fear that death would be painful and that he would be lonely and scared in the afterlife. His mother's deep religious faith offered her the consolation that James would be reunited in heaven with his maternal grandmother, and that she and his father would join him there in due course. With his mother's permission, his therapist conveyed this information to James. In his last weeks the child frequently asked his therapist to “tell me that story about heaven again” and asked for reiteration of details about the continuity of his care by his grandmother in heaven and his mother's belief that she would join him there after a while.

CHILDREN WITH HIV-INFECTED PARENTS

A conceptual model for mental health issues associated with HIV illness in families must take into account the potential complicating factors as well as the dynamic course of HIV illness, which moves through specific predictable psychosocial stages roughly paralleling the natural history of the disease. These stages begin with diagnosis of HIV infection and continue through illness progression, late-stage illness, death, and reconfiguration of the family with the children in new care arrangements.

At any stage in this process, children and adolescents may exhibit a variety of responses to parental HIV diagnosis, illness, or loss. These responses may be characterized as (1) normative responses requiring supportive counseling, increased access to existing social supports, or both; (2) responses complicated by developmental histories of poor or disrupted attachment or trauma, indicating a need for individual or family psychotherapy; and (3) exacerbations of preexisting psychiatric disorder or precipitation of new-onset disorder, in which syndrome-specific treatment must be among the interventions.

Disclosure of HIV HIV may be diagnosed at any point in the natural history of the infection. Whenever the diagnosis is made, it typically engenders anxiety about health and anticipatory grief for a potentially foreshortened future. When the diagnosed individual is a parent, these issues are compounded by concerns about continuity of care for children in the future and by questions about communicating with children and adolescents about HIV.

Infected parents frequently withhold information about their HIV diagnosis from their children; in fact, most do not tell children prior to early or midadolescence. Even without direct communication many children and teenagers develop their own suspicions or even certitude about the parent's health problems from clues like medications, symptoms, or multiple medical appointments. Children may experience a great deal of distress in the loneliness of fearing or knowing that a parent is struggling with HIV-related illness; yet because they are not supposed to know they remain unable to reach out for adult support and reassurance.

Disclosure of a family member's HIV status to children is often misunderstood to be a discrete event rather than an ongoing process. It is in fact a complex series of cognitive and emotional communications. The content of the information communicated to children, the emotional tone with which it is conveyed, and the quality of the family context all affect their understanding of the parent's health. Moreover, children's developmental level may limit their ability to absorb complex, affectively laden material.

A preschool child's limited cognitive capacity to understand the concept of HIV infection may be overwhelmed by magical thinking about undoing the presence of the virus. A school-aged child will normatively cope with difficult information about a parent's illness by denial and may opt to deny or ignore this threatening fact much of the time. Under stress, the school-aged child may revert to magical thinking that the virus can be wished away. Adolescents do not normatively defend themselves against knowledge of parental HIV by magical thinking or absolute denial, but they may rigidly compartmentalize this information and use conscious methods to distract themselves from thinking about it.

Parents and other adult caregivers of HIV-affected children should be counseled about the importance of developmentally appropriate communication about the parent's health. The child's need for the information and readiness to receive it must be accorded priority in deciding what information to communicate and when to disclose it. It is important for the adult to be honest, while respecting the child's coping mechanisms, including adaptive denial. The family's established style of communication about emotionally charged information may not be flexible enough to allow complete disclosure but may be able to tolerate communication of part of the truth without specifying the precise diagnosis. (“Mommy has an infection in her blood. She's taking medicine to keep her healthy.”) Adults should be counseled to provide children with realistic reassurance about the parent's health and about their own future care and security. HIV-negative children may worry that they themselves are infected because their parent is, and they should be assured that they and their siblings are uninfected when they can be told so honestly. When uncertainty exists about a child's serostatus or when additional reassurance is indicated, HIV testing can be very helpful.

Therapists can intervene to support a child grappling with a parent's HIV infection even when the child is “not supposed to know” about the diagnosis. Although it would be inappropriate to convey information about a parent's health that the parent does not wish to reveal, the therapist can encourage expression of the child's thoughts and feelings in an age-appropriate manner.

> David, an 8-year-old Hispanic child, was brought to a mental health clinic by his mother. She was concerned about a recent incident in which her boyfriend, while angry with her, had told David that his mother had HIV. David exhibited significant separation anxiety and sadness and was experiencing difficulty concentrating in school. His mother refused to discuss her HIV-positive status with the child and did not want the therapist to do so either. Despite the therapist's advice, his mother persisted in refusing to communicate with him about any aspect of her illness. She insisted that he did not know that she was HIV positive.
>
> In a play therapy session, David made himself a famous doctor and the therapist became his patient. David gave the therapist a blood test and announced to her that she was HIV infected and would die. David and the therapist, playing out their respective roles, then discussed the needs of the child of the infected patient (a little boy). The famous doctor contacted the infected patient's grandmother to arrange placement for the child with her after the infected patient's death. The famous doctor then counseled the infected patient against actually telling her child, as he “would be too mad about the drugs.” At the end of the session, the famous doctor (David) and the sick patient (the therapist) took a plane to Hawaii where he cured the therapist of her HIV.

Other therapeutic issues that arise for children and adolescents learning about their parent's HIV diagnosis include fear for the parent's health and anxiety about separation from or loss of their parent. Shame and a sense of social isolation because of the stigmatization of HIV infection are also common responses. Because children's self-esteem often depends on identification with the parent, they may feel that an HIV diagnosis detracts from their own self-worth. The therapist should determine the children's understanding of the meaning of parental illness and provide ongoing support to help them cope effectively with parental HIV infection and illness progression.

Progression of HIV Illness As HIV disease progresses in a parent, children are confronted with deterioration in the parent's health and ability to function as well as separations caused by hospitalizations. In this setting, children and adolescents manifest one or more normative emotional and behavioral responses to parental illness progression. In general, normative responses differ from problematic responses in degree. For example, for a toddler some increase in separation protest may be normative, while a more intensified inability to separate would be problematic; some exacerbation of tantrumming is to be expected, while extremely disruptive behavior is a warning sign. Similarly, school-age children will normatively experience a minimal to moderate decline in school performance, but a precipitous decline indicates more-significant difficulty in coping with the parent's illness.

The importance of communication with children and adolescents about parental illness and its impact on family life increases with disease progression. Normative emotional and behavioral responses can be complicated when children experience a parent's physical, cognitive, or functional decline without accurate information about the illness and prognosis. The normal sadness, anger, and anxiety experienced by children living with an ill parent can be exacerbated by the need to manage these feelings without support from adults who are unable to allow open communication about their illness.

Given the high-risk backgrounds of many HIV-affected families, children's responses to the parent's illness may also be complicated by underlying psychiatric disorder, developmental difficulties in the children's attachment to the parent, and difficulties in family environment. When working with families affected by both drug use and HIV disease, children presenting with symptoms in response to parental illness must be carefully assessed. Attributing symptomatology to HIV-related stressors alone is often clinically inappropriate.

> Jason, age 7 and repeating first grade, had a history of behavioral difficulties in school. Following his mother's hospitalization with an opportunistic infection, these problems escalated. His teacher described Jason as overactive, distracting other children, fighting both on the playground and in the classroom, and refusing to do his schoolwork. Jason's maternal aunt Yadira, who was caring for him during his mother's hospitalization, reported that Jason was also hyperactive and inattentive at home. Yadira believed that Jason's frequent changes of placement during his preschool years and the inadequacies in his care by a foster mother and his paternal grandmother also contributed to his problems.
>
> During psychiatric evaluation, Jason exhibited a short attention span and distractibility. He could not be drawn into the symbolic play with toy hospital equipment or a family of dolls that the therapist had tried to use to elicit material about his mother's illness, but when playing briefly with super heroes and Ninja Turtles, he expressed diffuse anger. Jason told the therapist that he fought with other children at school because they taunted him, saying “Your mother's a crackhead and she's gonna die of AIDS.” After further evaluation, Jason was diagnosed with attention-deficit/hyperactivity disorder. He was given psychostimulant medication and both individual and collateral supportive psychotherapeutic and psychoeducational treatment was initiated with Jason and his caregivers. Over time, treatment of the underlying attention-deficit/hyperactivity disorder increased Jason's ability to cope with HIV-related stressors.

With the pressure of increasing parental illness, the child or adolescent may experience and express intense ambivalence toward the parent, especially if the risk factor for the parent's HIV infection is understood by the child to be a negative behavior (e.g., drug use or selection of a drug-abusing partner). In these circumstances, the child or adolescent may be sad and anxious about the parent, on the one hand, and on the other, angry that the behavior that impaired past parenting will lead to further erosion in capacity as illness progresses and perhaps ultimately to abandonment of the child when the parent dies an early death. Extreme ambivalence toward the parent is perhaps the most difficult psychotherapeutic issue in working with HIV-affected children. This ambivalence may appear when the diagnosis is disclosed and continue as HIV illness progresses in the parent.

Permanency Planning As HIV progresses in the parent, caregivers may require counseling about planning for the placement of children following parental death, commonly known as *permanency planning*. Communication about HIV illness and permanency planning tend to be closely intertwined, with difficulties in one area being reflected in the other. Although it is by no means standard practice, family-based permanency planning that actively involves the children (particularly teenagers) is much more likely to have a successful outcome than planning that excludes the affected young people. Effective permanency planning can be undermined by active substance abuse and untreated psychiatric disorders in family members as well as by family dynamics related to substance abuse.

Optimally, families affected by AIDS have begun the communication and permanency planning process prior to the final stage of parental HIV illness and other adults are available to provide care and support for affected children. However, some parents, particularly those struggling unsuccessfully with mental illness or substance abuse, present to medical care settings in end-stage AIDS without having addressed these issues. In clinical experience, these are usually the most disorganized families with the highest burden of psychiatric and substance use disorder. In these families, special attention to the mental health needs of the children and

adolescents is essential. Both the lack of family preparation and factors associated with that lack of preparation signal increased risk for mental health problems in these children.

Bereavement and Family Reconfiguration Death of a parent in childhood ruptures children's attachment to the parent before they have completed the developmental tasks necessary for functioning as an independent young adult. A wide array of emotional and behavioral problems may be observed over time following the loss, including irritable mood in younger children and sadness in older ones, behavioral difficulties ranging from increased tantrumming and fighting with siblings to conduct disorders, and decreased school performance. Studies of long-term sequelae—in particular, depression in adulthood—have had mixed results, probably because of numerous confounding variables. A positive relationship between the parents prior to the death and a strong surviving parent to keep the family intact protect against elevated risk of mental health problems. Complicated bereavement is predicted by child emotional and behavioral factors predating the loss including prior emotional difficulties, emotional lability, and poor impulse control. Many of the factors associated with complicated bereavement in childhood are present in HIV-affected children and adolescents, including emotional difficulties and negative relationships with parents prior to loss and absence of a surviving parent to provide adequate parenting after death.

Grieving HIV-affected children and adolescents most commonly move into reconfigured families with extended-family members also mourning the loss of the loved one. The social and concrete service supports available to the families by virtue of the parent's AIDS diagnosis generally diminish or disappear following the parent's death. Generally, children and adolescents orphaned by AIDS move from one situation of poverty to another, with responsibility for their care falling on financially limited and often overwhelmed extended-family members. Children and adolescents who move into nonrelative foster care must make the difficult adaptation to new family members and often very different family lifestyles.

Specific issues complicating bereavement in the children of drug-abusing parents include their struggles with complex feelings about their parents, such as anger over abandonment or neglect and internalization of responsibility for parental inadequacies. The following case material shows the interaction of emotional difficulties associated with disrupted attachments and the precipitation of an affective episode in a biologically vulnerable adolescent.

> Nancy was 12 years old when her mother, Denise, died of AIDS. Denise had a long history of severe substance abuse and was diagnosed and treated for bipolar I disorder in the last year of her life. Until her mother's death Nancy was generally high functioning, a bright child with some worrisome outbursts of temper but excellent academic achievement and usually good peer relations. Although most of Nancy's care throughout childhood had been provided by her maternal grandmother, she was deeply injured by her mother's rejection, neglect, and episodes of physical abuse.
>
> In the first several weeks after Denise's death, Nancy displayed the typical mourning signs of an early adolescent: sad mood alternating with normal recreation and socializing. She then reported that her mother was appearing to her in grotesque forms at night. Nancy believed this specter was trying to frighten her. The hallucinations abated briefly with psychotherapeutic interventions designed to allow Nancy to express her intense ambivalence toward her mother. Over the next several weeks the hallucinations returned with the onset of a full-blown manic episode. Over the next year Nancy had three hospitalizations for bipolar I disorder.

A special issue that may arise in assessing a bereaved child is differentiation of illusory phenomena related to grief from hallucinations. Children and adolescents frequently experience visual or auditory perceptions of a deceased parent in the period immediately after the death or sometimes for months or years following. Illusory phenomena associated with bereavement must be differentiated from hallucinations associated with a psychotic or mood disorder. The more benign perceptions may involve the parent calling the child's name or appearing in a familiar location in the home or neighborhood. Particularly when the family's religious or cultural context provides reinforcement for such experiences, these perceptions of the deceased parent may be comforting to the child. When the child lacks cultural supports for these experiences, they may engender concealment and confusion. It often helps the grieving children to have the therapist probe gently to determine whether they are experiencing such perceptions, and if so, to reassure them and assist them in making meaning out of the experience (e.g., a child may explain this as “My mind playing tricks on me,” or “My heart misses daddy so much that it makes my eyes see him.”)

Psychoeducation for grieving children and counseling for their adult caregivers benefit many families. It is helpful to distinguish the usual course of mourning of adults (a sustained period of dysphoria, followed by a gradual return to normal mood) from the mourning that is more typical of children, especially preadolescents (a briefer period of dysphoria punctuated by apparently normal play or socializing, followed by a longer period in which grief returns and then subsides). When a child's deceased parent has been absent or otherwise deficient in their role with the child, adult caregivers may be puzzled by the child's mourning over the loss. They need to understand that the loss of inadequate parenting may in fact complicate rather than minimize the child's grieving process.

SUGGESTED CROSS-REFERENCES

Neuropsychiatric aspects of HIV and AIDS are discussed in Section 2.8. Substance-related disorders are covered in Chapter 11. Death and dying are discussed in Section 28.5.

49.7 CHILDHOOD OR ADOLESCENT ANTISOCIAL BEHAVIOR

HANS STEINER, M.D., AND S. SHIRLEY FELDMAN, ıH.D.

Antisocial behavior, which involves violating the rights of others, is an inevitable part of growing up. Through minor transgressions, at first within families and then outside in the real world, children gradually learn about societal rules and limitations. Although more serious instances of antisocial behavior are viewed as delinquent, they are also relatively commonplace, especially during adolescence. Up to one quarter of youth are apprehended by police and convicted of crimes, and the incidence of self-reported antisocial behavior is much greater than police arrests.

The relationship of antisocial behavior to psychopathology is complex. Not all antisocial behavior is psychopathological and therefore does not require treatment. Although most forms of juvenile antisocial behavior do not progress to criminality, it is quite difficult to distinguish youths with a good prognosis from those who will end up in the justice system and perpetrate severe transgressions. To help in this task, a careful delineation of normative risk-taking behavior and isolated antisocial behavior from syndromal clustering of behavior problems is necessary. Antisocial behavior must also be differentiated from more serious psychopathology, as behavioral disturbances are frequent accompaniments of many psychiatric disorders in children and adolescents, especially in boys. As there appears to be a fairly consistent progression from antisocial behavior to more severe forms of psychopathology, antisocial behavior that comes to the attention of the clinician should be regarded as a behavioral marker or risk factor for more severe problems such as oppositional defiant disorder, conduct disorder, and antisocial personality disorder.

DEFINITION

Antisocial behavior is a descriptive term referring to behavior that is hostile to the rights of others and that shows disregard for the rules and laws of a given society. Basic rights of others (e.g., ownership of property) are violated or age-appropriate societal rules (attendance at school) are broken. The behavior in question is evaluated from the point of view of a given society but is not necessarily adjudicated by the legal system. Antisocial behavior is described by the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) as follows:

This category can be used when the focus of clinical attention is antisocial behavior in a child or adolescent that is not due to a mental disorder (e.g., Conduct Disorder or an Impulse-Control Disorder). Examples include isolated antisocial acts of children and adolescents (not a pattern of antisocial behavior).

Defined from a societal perspective, antisocial behavior needs to be distinguished from related or overlapping problems such as *delinquency*, a legal term referring to juveniles committing offenses against the law, and *conduct disorder,* a psychiatric disorder that considers the behavior from a mental health perspective.

There are both advantages and disadvantages to having a clinical category such as antisocial behavior. On the one hand, by serving as a clinical marker it may help bring vulnerable youth to the attention of clinicians who can implement treatment and secondary prevention. Currently, such children are handled by probation and parole systems without adequate input from mental health professionals, despite established links between antisocial behavior and serious psychopathology. On the other hand, there is concern that a psychiatric label might be injurious to antisocial youth, as they are dealt with by the juvenile justice and school systems, or that the psychopathologization of criminal behavior might delay appropriate criminological intervention.

HISTORY

Antisocial behavior was often viewed from two different perspectives: as an internal deficit or as an ecological adaptation to extraordinary circumstances of disrupted and disorganized environments. William Healy, an obstetrician who founded the first juvenile court clinics in the Chicago and Boston areas, described delinquents as having a “constitutional deficiency,” others described them as having genetic deficits. The best representative of the ecological view was August Aichhorn, who used Freudian psychodynamics in an effort to show the adaptive value of some of the symptoms of wayward youth. The establishment early in the twentieth century of clinics attached to juvenile courts increased the tension between those who regarded delinquent youth as budding psychopaths and those who believed their behavior to be reactive to adverse circumstances. *The Mask of Sanity*, a monograph written by Hervey Cleckley that emphasized both hereditary and environmental influences, tried to integrate both these viewpoints.

Subsequently, a developmental perspective on delinquency and antisocial behavior began to replace notions of constitutional inferiority. John Bowlby, for example, revealed that many delinquents had suffered prolonged disruptions of early relationships and as a result, were “affectionless characters.” Work by Lee Robins on the natural history of delinquency established a convincing link between childhood conduct problems and adult antisocial personality disorder. As a result of this developmental perspective, epidemiological studies were carried out and evaluation moved beyond court clinics into community settings.

COMPARATIVE NOSOLOGY

In 1968 the second edition of DSM (DSM-II) differentiated between diverse antisocial reactions. The term “antisocial behavior” established antisocial behavior as a clinical construct, independent from the juvenile justice system classification of delinquency. In 1980 the third edition of DSM (DSM-III) differentiated the construct of “conduct disorder” from that of “antisocial behavior.”

The category of antisocial behavior appears unchanged in DSM since the DSM-III-R, although there is as yet no evidence on its discriminant, convergent, and predictive validity. The 10th revision of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) does not contain a similar category.

Prospective studies of youth at risk have shown that there are meaningful subtypes of antisocial behavior. One useful classification describes overt, covert, and authority-defying antisocial acts with different developmental and prognostic implications. For example, the least serious antisocial acts are typically contained in one channel during childhood, most commonly in the authority-defying channel. Covert antisocial behavior, such as stealing, typically emerges in later childhood whereas overt antisocial acts (such as violence) are usually not evident until prepuberty or adolescence. Children with the poorest prognosis tend to show early appearance of overt behaviors and disturbances in all three channels.

EPIDEMIOLOGY

Antisocial behaviors are the most common reason for referrals to child psychiatric clinics, reaching as high as 60 percent of patients seen in an ambulatory setting. They are also one of the most costly disorders, usually involving personal loss to patients, families, victims, and society. Estimates of the incidence of antisocial behavior come from population-based, longitudinal studies of populations at risk, as well as from crime statistics compiled by the National Institute of Justice. Despite the widespread incidence of antisocial behavior, some groups are more at risk for this behavior than others. More so than other age groups, adolescents are especially likely to engage in antisocial behavior, including violent crimes and crimes against property (Fig. 49.7-1). For example, although adolescents only comprise about 8 percent of the population, they commit 50 percent of violent crimes.

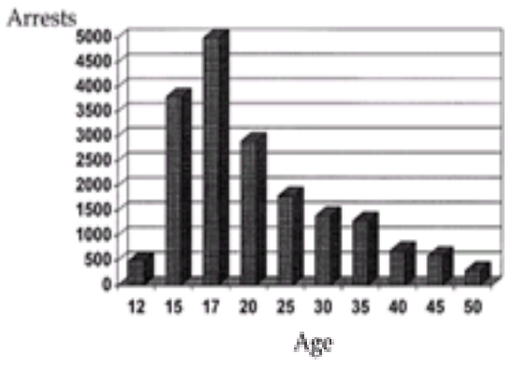

FIGURE 49.7-1 FBI index arrests by age per 100,000 population.

There are gender-specific features of antisocial behavior that become especially apparent in adolescence. First, males are two to three times more likely than females to engage in antisocial acts. Second, boys tend to exhibit more aggression whereas girls tend to commit more covert crimes and prostitution. However, recently there has been an increase in the number of violent crimes perpetrated by females, perhaps due to the inclusion of females in some gangs. Antisocial behavior used to be more frequent in urban than other settings, but this also appears to be changing. Delinquent acts are reported with about the same frequency (10 percent) in rural areas, the suburbs, and the cities.

Although not exclusively a problem of the socially disadvantaged, poverty and low socioeconomic status are common backdrops to antisocial behavior. Antisocial behavior is prevalent in communities characterized by a high level of criminality among adults, drug and alcohol abuse, overt conflict and violence, a high incidence of single-parent families, and an absence of community organization. Such environments have been labeled psychosocially toxic, an apt and especially descriptive term.

ETIOLOGY

Because antisocial behavior ranges widely in its manifestations, especially when age is taken into account, it is unlikely that there is any one set of specific etiological factors. Current data best fit a cumulative risk factor model, where the likelihood of antisocial behavior increases as risk accumulates (Fig. 49.7-2). This model can be expanded to include environmental protective factors and the individual's resilience to improve prediction as to which children succumb to criminal activity or psychopathology and which do not.

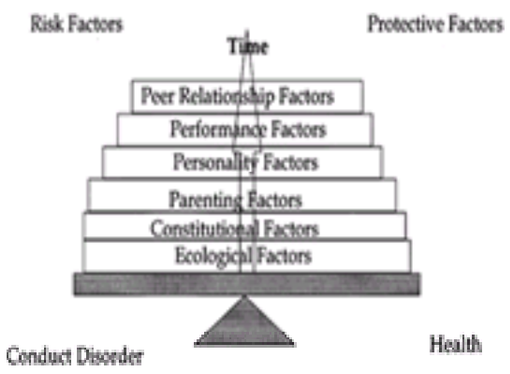

FIGURE 49.7-2 The risk/resilience model for the development of antisocial behavior and conduct disorders.

The model predicts that the greater the number of risk factors and the earlier they appear, the higher the probability that the individual will engage in antisocial acts and be characterized by serious psychopathology. The mechanism by which this occurs seems to be via multiple interactive loops—factors in the family environment interact with characteristics of the child to produce at an early age aggressiveness, impulsiveness, and a disregard for the rights of others. Such children are then rejected by peers and teachers and a new cycle of negative interactions develops.

Risk-Resilience Model It is unlikely that single risk factors operating in isolation make a major contribution to delinquency. It is more productive to think of the accumulation of diverse risks and the interaction between risks that lead to problems. Rolf Loeber has described the gradual stacking of factors in the genesis of antisocial acts. An expanded model might include a parallel pyramid of resilience or protective factors, which accentuates in part the effects of the accumulated risks.

The risk factor model highlights that many different factors, occurring at different stages of life and leaving residuals thereafter, contribute to the onset of antisocial behavior. Risk factors may even begin to operate perinatally, with such factors as the unavailability of prenatal care, maternal drug use, smoking, and poor nutrition all implicated in the development of central nervous system (CNS) impairment. After birth and throughout childhood, risk factors include difficult temperaments, insecure attachments to parents, and unavailable, inconsistent, or harsh parenting. Peer rejection and failure in academic and vocational settings also serve as markers of risk factors for antisocial behavior.

As the child grows up and as risks aggregate and accumulate over time, the child is likely to show increasing problems and deficits. In this developmental model it is increasingly difficult for current protective factors to offset a long history of risk. Once the deficits and problems become manifest as conduct disorder, treatment will be necessary if the outcome is to change.

Biological Factors Since the late 1980s there has been a steady accumulation of data implicating but not definitively proving biological risks for antisocial behavior and criminality. These factors include genetic factors, CNS insult, underarousal of the nervous system, neurotransmitter aberrations, and difficult temperament. The effect of the factors in question is seen most clearly in the face of environmental disadvantage and in the presence of other risk factors.

Heredity is the most controversial of the biological factors, with evidence stronger for adult criminality than for juvenile antisocial acts, and for nonviolent rather than violent criminality. Support for genetic factors comes from studies of family resemblance. For example, monozygotic twins are more concordant for criminality than dizygotic twins who in turn are more concordant than half-siblings. Some family resemblances, however, are not consistent with a genetic hypothesis.

Insult to the CNS either at birth or during childhood has also been implicated as a risk factor for antisocial behavior. For example, children who have perinatal damage are more likely to become criminally active 18 years later, especially if their perinatal risks are paired with maternal rejection. Support for the role of CNS factors in antisocial behavior in adults comes from brain imaging, a technique that is still in its infancy. Two hypotheses have received some support: frontal dysfunction is associated with aggressive crime and temporal lobe dysfunction is associated with sexual offending. The relationship to antisocial behavior in children and adolescents has yet to be shown.

Deficiencies in various channels of the arousal system may be a risk factor for antisocial behavior. The evidence strongly supports low resting pulse as a predictor of future criminality. Evidence from other channels, such as skin conductance and electroencephalography (EEG) is not totally consistent. Overall, the data suggest that there may be a subgroup of antisocial children who are underaroused and not likely to learn readily from and be easily socialized by people in their environment. As a result, these underaroused youths seek high levels of stimulation to raise their low levels of arousal and do this by engaging in risk taking and aggression.

Certain neurotransmitter systems, such as serotonin, noradrenalin, and *g* -aminobutyric acid (GABA), are also implicated in antisocial behavior. Aberrant levels of these neurotransmitters relate to common antecedents of antisocial acts such as aggressivity, impulsivity, and affective lability. Male hormones in humans have

yielded contradictory findings, despite support from animal studies.

Difficult temperament, characterized by irregular rhythmicity, withdrawal from novel stimuli, affective irritability and lability, and hyperactivity, has in prospective studies been shown to place a child at risk for antisocial behavior, especially in interaction with problematic family environments.

Psychological Factors Psychological correlates of antisocial behavior include neuropsychological factors, ease of learning and conditioning, intelligence, and personality factors, to name a few. Whether these are causal factors is not known, nor is it always known how they precisely might operate if they are causal factors.

Multiple neuropsychological deficits, including learning disabilities, frontal lobe dysfunction, left hemisphere dysfunction, and reduced lateralization for linguistic functions have been found in juveniles who commit antisocial acts. On the behavioral level, learning and conditioning deficits have been found under a variety of conditions. For example, antisocial youth exhibit slower classical conditioning and avoidance learning; however, the latter depends on their motivation. There are also higher-order cognitive deficits. In particular, antisocial youth have a lower intelligence quotient (I.Q.) than youth matched in socioeconomic status and age, and the deficit is particularly marked in verbal I.Q. and associated functioning such as moral reasoning. Antisocial youths also show some characteristic personality traits: problems with self-restraint, impulse control, responsibility, and suppression of aggression. These traits involving undercontrol are magnified by posttraumatic stress disorder, which is not infrequent in antisocial youth.

Despite a wealth of data on ways in which antisocial youths differ from others, research on this topic is often methodologically unsophisticated. There is a need for more long-term prospective studies and studies that match antisocial and other youths in terms of important characteristics.

Social Factors Among the many social factors that influence antisocial youths, three are particularly important—family, peers, and extended environment.

Familial Factors Parental criminality is a strong predictor of juvenile antisocial acts. This familial aggregation may reflect genetic influences or well-documented compromised parenting. Family pathology, including abuse, neglect, and sexual molestation, is common in families whose children engage in antisocial activity.

Early clinical studies implicated attachment problems as a precursor of antisocial behavior, but it is only recently that well-designed prospective (rather than retrospective) studies are being carried out. There is stronger evidence that the quality of parenting, including parental absences, lack of supervision, and ineffective parenting styles are strongly linked to aggression, impulsivity, noncompliance, and other behaviors related to antisocial behavior. An impressive body of research has described some mechanisms by which poor parenting contributes to the child's antisocial behavior. For example, parents who are inconsistent and harsh but who eventually capitulate to the coercive behavior of their offspring have undersocialized, aggressive, and impulsive children.

Family influences on children's antisocial behavior are not just limited to parent-child relations. Divorce, separation, and unhappy and conflictful marital relationship are also predictive, but less so than the parenting variables. There is recent evidence that familial variables recede in importance as the child goes through puberty. Instead, internal regulators such as restraint and the quality of peer relationships, which themselves reflect the effect of earlier parenting, become more important.

Peer Factors Negative peer influences assume importance in facilitating antisocial behavior relatively late in the developmental cycle. It is quite unlikely that peer influences alone can be the cause of serious antisocial acts. Peer influences are perhaps more important in later-onset antisocial behavior, when adolescents are particularly prone to conformity pressures. Antisocial peers provide acceptance to those youths whose behavior, personality, and social skills make them outcasts with better-socialized peers. This principle is seen most clearly in gang membership.

Extended Environment The neighborhood or ecological environment in which the child is raised has repeatedly and convincingly been shown to be part of the core risk factors for antisocial behavior. High rates of unemployment in the neighborhood, low parental social class, poor urban neighborhoods with high crime rates, and poor schools all contribute to risk. These environments are often characterized by high levels of community violence, with well-documented injurious effects on children who witness such violence.

Two other well-documented factors deserve mention. First, academic failure in school, even in the early grades, is also associated with children's subsequent antisocial behavior. Second, mass media, particularly extensive viewing of TV with violent content, also have been shown to contribute to the problem: the mindless portrayal of graphic and gratuitous violence, facilitated by the use of sophisticated computer graphics, provides undercontrolled youths with both increased arousal and models for antisocial behavior.

Protective Factors As the model suggests, there are also protective factors that attenuate risk, but much less is known about them. Protective factors refer to more than the simple absence of risk and to more than the polar opposite of stress factors. Instead, they are conceptualized as having pervasive influence on multiple domains of functioning. They exert their effect not through a simple balancing of stress factors, but by strengthening core aspects of individual functioning.

Normal or above-normal intelligence, an easy temperament, an ability to relate to others, good work habits at school, areas of competence outside school, and a good relationship with at least one parent or another important adult all offer protection against antisocial behavior and delinquency in the presence of significant risk. Prosocial peers and a good school that fosters experience of success, responsibility, and self-discipline also emerge as protective factors. The selection of nondelinquent peers, and during young adulthood the selection of a good marital partner (as demonstrated by competent social skills, a stable personality, a good work history, and capacity for good parenting) have been shown to offer protection against further criminal activity and escape from a crime-oriented career path.

It is noteworthy, however, that no studies look at the experimental manipulation of these protective variables. It would be of interest for the clinician to know if some of these protective factors can be induced or augmented and whether such a procedure would lead to a positive outcome in those at risk as well as those who are already symptomatic. To date, only studies of at-risk children who have been adopted into stable families or who as adolescents have been sent to elite boarding schools provide evidence on this issue and these are hardly controlled studies. Much of the therapeutic enterprise is based on the assumption that change is possible, but as of yet, carefully designed studies testing these or similar hypotheses have not been published.

DIAGNOSIS AND CLINICAL FEATURES

Although diagnosing antisocial behavior is relatively easy, the process of obtaining the necessary information is not. Because the patient is usually referred by others under the shadow of some potential legal transgression, it is very difficult to establish a reasonable working alliance with the patient. The sequencing of contacts with patient, parents, schools, departments of social work and probation requires perseverance and sensitivity and the purpose of the evaluation (e.g., forensic versus clinical, management versus treatment) needs to be made clear from the outset.

There are many complexities in working with antisocial children and youth. First, since children and adolescents usually underreport antisocial behavior while those around them usually overreport it, it is necessary to gain information from multiple informants including parents, pediatricians, school personnel, police, and probation workers. Second, the antisocial nature of behavior is not always apparent to the perpetrators, especially if they are relatively young and have lived in a different cultural context. Third, since single antisocial acts are the exception, it is necessary to undertake a careful examination of different domains of functioning in order to gauge the extent of the antisocial behavior. And finally, the definition of antisocial behavior depends on the age of the child: taking money from a mother's purse has a different meaning for a 4-year-old than a 12 year-old; striking one's sister at age 3 is different from hitting her at age 15.

A 9-year-old child was arrested by police for breaking into a local hardware store accompanied by two friends. The three had ridden their bikes in a suburban neighborhood until after dark and engaged in a play of “cops and robbers,” taking turns in pursuing and being pursued. To make the game more lifelike, one of the three suggested that they actually break into this store, whose owner was a somewhat gruff and intimidating man. The three decided that such an adventure would be exciting and they proceeded to smash in the glass door with a brick. Shortly after the glass broke the police arrived and arrested them. Their parents were called to come and collect their children. None of the three had any previous contact with the police or any social service agency. While they previously engaged in some mischief in the neighborhood—such as throwing toilet paper on people's houses and egging cars, none of the three had any serious infractions of societal rules, and none of the three boys had any more of these events cluster in the past few months. One of them had attention-deficit/hyperactivity disorder and some learning difficulties at school, while the other two boys had no particular risk factors for the persistence of antisocial behavior. The child with attention-deficit/hyperactivity disorder progressed in terms of his antisocial activities to the point of fulfilling conduct disorder criteria in early adolescence. Much of his future acting out consisted of drug-related offenses, that is, the use and sale of drugs, stealing, and other covert delinquent activities. The two boys without risks proceeded to develop through a normative, turbulent, and lively adolescence wihout any further legal involvement.

Antisocial behavior is even more common in adolescence, and in most cases resolves without intervention other than feedback to parents and police warnings. As in our child sample though, special risk factors may lead to a more full-blown picture of conduct disorder and multiple comorbidities that portend more poorly for the future of the adolescent.

A midadolescent boy was arrested for possession of drugs by the police and put into a diversion program because this was his first arrest. He had a history of some learning problems at school that seemed to be based on some diagnosable processing problems. These issues were adequately addressed in the school and parental home. The home environment was stable and predictable and there was no family history of a psychiatric or criminal nature. The young man had experimented with cannabis and alcohol, but there was no regular pattern of abuse or dependence. The circumstances of this adolescent's arrest were as follows: the police observed him and a friend sitting in his parent's car on a parking lot on the edge of town that was known to be the site of frequent drug deals. The two boys had gone to this place at 3 in the morning. As it turned out, the arrested youth's friend had just been kicked out from his parental home after getting into a violent fight with his father. He called the first boy to discuss his options and to seek some support. The arrested youth offered to come pick him up in a car and help him bring his belongings to a shelter. In order to do so he sneaked out of the parental home and took the parental vehicle. After collecting the friend's belongings, the boys proceeded to a parking lot that was relatively isolated to discuss the situation and do some planning. The boy who had just been kicked out of his home offered the driver some marijuana in order to calm himself. The driver refused, but stayed to help the friend through the crisis. At that point the police arrested them. The driver was sent to a diversion program, and he and his parents participated in a weeklong drug education program, following which there were no further contacts between the friends and police. The youth graduated satisfactorily and continued to graduate from college. The friend had a more complex progress. His pattern of fighting and of abusing drugs to regulate himself continued and intensified, leading to several arrests and finally to convictions of drug possession and battery. He was referred for clinical evaluation and diagnosed with conduct disorder, a depressive disorder, and intermittent explosive disorder. He was started on a treatment regimen consisting of medication targeting his depression, a remedial school program that assisted him with his difficulties in school work, due mostly to problems with motivation, and a substance abuse program, all of which were made part of his probation.

Distinguishing uncomplicated antisocial behavior from conduct disorder may not always be easy, but there are some key clinical features that indicate more serious diagnoses and that have implications for case management and treatment. These include lack of empathy and concern for others, consistent misperception of the intent of others in ambiguous social situations, lack of guilt or remorse following transgression, and low self-esteem. These features are often hidden behind a tough facade. Recklessness, poor impulse control and low restraint in stressful situations, irritability, and temper outbursts are often part of low frustration tolerance. Extensive risk taking is manifest in status offenses such as early-onset and exploitative sexual behavior, alcohol and other substance abuse, and smoking. Suicidal ideation and attempts are more prevalent than in normal teens and are equal to and sometimes greater than rates found in depressed youth.

The evaluation of a patient with antisocial problems is a complicated process that in many ways parallels the assessment of the child with disruptive behavior disorders. It may take several sessions to obtain sufficient information about the exact nature of the presenting problem. The clinician should be prepared to take a longitudinal perspective and aim at preventive interventions. Little is gained from an attitude that antisocial behaviors are normative and will eventually be outgrown. Careful vigilance and readiness to diagnose other associated conditions that might be causally linked to the behavior is a more prudent strategy.

Clinically Relevant Subtypes of Antisocial Behavior Rolf Loeber described three different forms of antisocial behavior—authority-conflicted, covert (e.g., stealing), and overt (e.g., violence). His typology is important because as antisocial behavior becomes more severe all three types of behavior are manifest with implications for prognosis. Second, inquiry into what behavioral portfolio best describes the antisocial child provides specific targets for prevention and intervention.

PATHOLOGY AND LABORATORY EXAMINATION

There are no pathognomonic medical or psychological tests for the diagnosis of antisocial behavior, but a variety of tests taken in the aggregate can help establish relevant comorbidities and a plan for management and treatment. A thorough physical examination is necessary with specific attention to vision and hearing, the evaluation of neurological conditions such as head injury and seizure disorder, as well as other medical conditions including chronic illnesses. Urine and blood drug screen may be indicated, especially when clinical evidence suggests substance abuse that the patient denies.

Several psychometric instruments, all normed for this population, might be helpful. The most frequently used is the Child Behavior Checklist, which has parent, teacher and self-report versions describing specific externalizing behaviors. The Conners Parent-Teacher Rating Scales contain a Conduct Problem Factor helpful in measuring such problems and tracking response to treatment. The Jesness Inventory and the Hare Psychopathy Checklist were developed in delinquent and criminal populations and assess information relevant to diagnoses of antisocial behavior, criminal behavior, and antisocial personality disorder.

DIFFERENTIAL DIAGNOSIS AND COMORBIDITY

Delineation from disruptive behavior disorders is most important. The diagnosis of oppositional defiant disorder is based on explicit problems with temper, anger, and manifest defiance against adults. These characteristics are not necessarily part of antisocial behavior. In conduct disorder the antisocial acts are quite repetitive and persistent, and the acts themselves are of greater severity. Antisocial behavior can occur in a wide range of other primary psychiatric diagnoses, including substance use disorders, attention-deficit/hyperactivity disorder, learning disorder, mood disorder, bulimia nervosa, posttraumatic stress disorder, mental retardation, delirium, dementia, and impulse-control disorder. Schizophrenia or bipolar I disorder may in infrequent cases also present with antisocial behavior. In older adolescents, antisocial behavior may signal early-onset personality disorders (such as borderline and antisocial personality disorders). Axis III conditions that are often associated with antisocial behavior are seizure disorder, head trauma, and chronic illness affecting CNS functioning.

COURSE AND PROGNOSIS

Longitudinal studies indicate that early onset of antisocial behavior, disturbances in multiple domains, extensive comorbidities, and a high level of ecological risk factors portend poorly for the future, especially when many of these factors are present together. Later onset and the presence of multiple protective factors make it more likely that the youth will avoid developing a conduct disorder or suffer from antisocial personality disorder. Once these diagnoses have set in, the prognosis becomes considerably worse.

Since risk taking is a normative activity in adolescents, isolated occurrences of antisocial behavior in a midteenager who has good levels of premorbid functioning and preserved functioning in the majority of current domains should not be overinterpreted. For such a youth, the prognosis is good, especially if it can be shown that some of the changes in behavior result from changes in the environment such as a move into a delinquent peer group or into a troubled neighborhood, or from a recent significant stressor.

TREATMENT

As antisocial behavior does not represent a psychopathological condition per se, the simple presence of antisocial behavior does not in and of itself call for treatment. There are, however, three initial tasks for the clinician. First, with the goal of delineating the antisocial behavior from other psychopathology, it is necessary to provide a full description of the general context in which the antisocial behaviors occurred, including both risk and protective factors in the child's life. Second, it is

recommended that the patients' progress be charted over 6 to 12 months, with serial assessments made in all major domains of functioning. These include the interpersonal domain, including family, peer, and authority relationships; intrapsychic functioning; basic physical and psychological health; academic and vocational performance; and ability to recreate without inappropriate risk taking. Third, the clinician will need to maintain contacts with parents, teachers, probation personnel, and the pediatrician in order to obtain a balanced picture of the youth's behavior.

Subsequent to a thorough assessment, preventive intervention may be undertaken, although its form will depend on the age of the child. For the family of the preschooler, home visits focusing on parent education might be indicated. During the school years, family sessions dealing with behavioral management along the lines suggested by G.R. Patterson and colleagues can be designed to disrupt coercive and abusive family cycles. During adolescence, individual exploratory sessions with the teenager, with particular attention to peer and authority relationships, may be effective. Topics might include the detailed dissection of complex social situations in which the patient clearly sees few workable alternatives to antisocial behavior and behavioral strategies to deal with aggression.

A major tool in the assessment and prevention of antisocial behavior is the use of structured settings. These are remarkably effective in controlling all but the most disturbed patients, who probably require treatment for conduct disorder and its comorbidities. Options range from augmented classrooms, such as special education or learning disorder settings, day treatment, or residential settings. Hospitalization is only indicated if there are clear and present dangers to self or others. Hospitalizations are mainly crisis driven and should not be regarded as an “inoculation” technique to prevent future recurrence.

The use of psychotropic drugs is helpful primarily when specific comorbid conditions are being addressed. However, it should be assumed that medications are of auxiliary value only and they should not be used as a replacement for more comprehensive treatment. Further, caution with psychotropic drugs is necessary because some antisocial youth live in homes and environments where medication may have street value, and thus the medication may be abused by others as well as the youths themselves.

A special problem is the management of aggression. Behavioral techniques (such as time-outs) work well, especially in young children, but they require consistent effort on the part of the parent. Sometimes, drugs may need to be given to young children to help with the management of aggression. In such cases, the drugs used for older adolescents and adults such as lithium (Eskalith), carbamazepine (Tegretol), propranolol (Inderal), clonidine (Catapres), and phenothiazines may be tried. However, the evidence for their efficacy in young children is very limited, and even in school-age and adolescent populations there is only suggestive evidence that these drugs might be helpful. Treatment plans might be modeled after the ones used for the treatment of conduct disorder. Overall, early intervention is more successful than treatment at a later stage although even the evidence for early intervention programs is not as complete as needed.

SUGGESTED CROSS-REFERENCES

Disruptive behavior disorders are presented in Chapter 40, drug and alcohol abuse is discussed in Chapter 11, attention-deficit/hyperactivity disorders are discussed in Chapter 39. Mood disorders appear in Chapter 14, posttraumatic stress disorders in Section 46.2, impulse-control disorders in Chapter 22, adult criminality and antisocial personality disorder in Section 27.3, child psychotherapy (including behavior therapy) in Chapter 48, child pharmacotherapy in Section 48.6, and development of personality in Chapter 32.

49.8 DISSOCIATIVE DISORDERS IN CHILDREN AND ADOLESCENTS

NANCY L. HORNSTEIN, M.D.

In the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) the category dissociative disorders contains a group of diagnoses with dissociative symptoms as a core element of their presentation. The five dissociative disorders are dissociative amnesia, dissociative fugue, dissociative identity disorder (known in earlier DSM nomenclature as multiple personality disorder), depersonalization disorder, and dissociative disorder not otherwise specified. Grouping these five diagnoses and placing other diagnoses with dissociative symptoms in different diagnostic categories has perhaps generated more debate in the psychiatric literature than any other DSM-IV diagnostic category. Eating disorders, borderline personality disorder, and posttraumatic stress disorder are the diagnoses most frequently listed by authors who question the clinical validity of the current DSM classification system in terms of its ability to group together diagnoses with similar etiologic, pathological, symptomatic, and psychological/psychodynamic features or interrelatedness. Other authors look to include diagnoses listed in the 10th revision of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10). *The ICD-10 Classification of Mental and Behavioral Disorders,* published in 1992 includes a number of dissociative conversion disorders, and Ganser's syndrome among the dissociative disorders. Some also consider brief reactive psychosis occurring immediately after a trauma to be a psychotic reaction primarily dissociative in nature.

Clinical phenomenology of children who meet adult DSM-IV diagnostic criteria for one of the dissociative disorders often differs from that of adults with the same diagnosis; children's dissociative symptoms are less different than are adults. Other children with extensive dissociative symptoms are thought by authors doing research on dissociative disorders in children to “fall through the cracks” of the adult diagnostic criteria even though they appear to represent the childhood counterparts of adults with dissociative identity disorder. The critical clinical importance of identifying and treating children on their way to developing serious adult psychiatric illnesses led various authors to propose a separate DSM-IV diagnostic category for dissociative disorders in children that would emphasize the unique ways dissociative symptoms manifest themselves on children as compared with adults.

Close examination of the issues underpinning the debate over the diagnostic classification of dissociative disorders reveals roots with enormous clinical importance. Dissociative symptoms appear in situations of extreme stress, fear, or anxiety in individuals across a variety of diagnoses. Some of the diagnoses grouped together as dissociative disorders have little etiologic commonality, whereas some diagnoses grouped elsewhere are etiologically more closely related to an individual dissociative disorder. Many, but not all dissociative disorders occur following trauma. In some the trauma is a single overwhelming episode, others involve repeated traumas in early childhood. All dissociative defenses or symptoms aim to modify overwhelming emotion. Disorders in which the dissociative symptoms do not involve extraordinary child abuse or life-threatening disasters may nevertheless result from psychologically traumatic conflicts. Investigating the clinical and etiological similarities and differences of diagnoses with dissociative symptoms may clarify how these disorders should be grouped in the future.

Developmental issues affect the impact of a trauma on symptom development and presentation. A similar event has enormously different effects depending on the age of the child. Children's developmental capabilities influence their ability to handle a trauma emotionally, the type of event considered traumatic, and the degrees and types of impact a trauma has. The child's environment, available adult nurturing, soothing, and integrative influences affect developmental shaping, symptom modification along with the trauma resolution that occurs over time.

Repetitive trauma, neglect, and chronic deficiencies in parenting interact with a child's ongoing development in complex ways to produce symptoms and other psychopathology (e.g., object relations, coping strategies) that evolve with time. Extreme neglect in infancy causes the ultimate dissociative withdrawal, failure to thrive; less severe deficiencies in infant nurturing and bonding result in developmental attachment disorders. Mary Main and Hillary Morgan described a category of attachment disturbance called the *insecure-disorganized/disoriented attachment category* and noted the phenotypic resemblance of these children's behavior to that typical of dissociative states. Thus, a set of dissociative symptoms in a child affects the child's development, and the child's ongoing development and environmental influences then interact with the need for dissociative defenses, the way these are expressed as dissociative symptoms, and ultimately the presentation of diagnostic pathology. Childhood dissociative disorders must be viewed as occurring along a developmental, symptomatic, and diagnostic continuum.

Further study of dissociation in young children aims to integrate the effects of trauma, neglect, and extreme parental dysfunction to understand their developmental effects over time and thus to better understand both childhood and adult psychopathology. Such increased understanding holds forth better therapeutic interventions to ameliorate the effect of trauma on an identified individual child or adult.

The research and theoretical literature on dissociative disorders in children and adolescents focuses on the DSM-IV diagnoses of dissociative disorder not otherwise specified and dissociative identity disorder. This literature addresses both children who meet the current adult DSM-IV diagnostic criteria for these two diagnoses and children with symptomatic presentations involving significant dissociative pathology thought to be on a continuum of disturbance with these two diagnoses.

HISTORY

A number of cultural changes, “discovery” of numerous victims of sexual abuse after such reports were considered fantasy by early Freudian analysts, and the new openness to investigating these areas resulting from the sexual revolution of the 1960s are a few of the factors that led to recognition of contemporary cases of multiple personality disorder. These cases led to a flurry of recognition of more adult cases after a hiatus of nearly 100 years. Professional skepticism about these case reports, difficulties encountered treating these victims of extreme early child abuse, and the need to develop new theoretical constructs to understand dissociative symptoms led early investigators back to the writings of Jean Charcot and Pierre Janet at the Salpetrière about their work with patients with hysteria. Janet clearly described patients with multiple personality disorder, and reviews of his work and that of his contemporaries helped investigators greatly in their growing theoretical and clinical understanding of multiple personality disorder.

A search for the childhood counterparts of adult patients with multiple personality disorder provided early impetus for research into childhood dissociative disorders, since virtually all adult patients reported that their symptoms began in childhood. This search was motivated by the desire to (1) identify children suffering from extreme abuse and intervening to protect them in the hope that childhood intervention could prevent further suffering from abuse and reduce later symptomatic suffering and (2) the wish to put to rest the taunts of skeptics attacking the multiple personality disorder diagnosis who were asking the question, “If multiple personality disorder starts in childhood, where are the children with this illness?”

Richard Kluft led these efforts by reporting several patients with multiple personality disorder, and he and others developed symptom predictor lists to help clinicians identify such children. He also included description of multiple personality disorder in a child treated by Despine, published in 1940 in his numerous lectures. Kluft's case series was blocked from publication for 6 years, and when finally published, it coincided with a similar case series published by J. Fagan and P. McMahon. Other small case series quickly appeared in the literature, and the interested clinician or researcher had in effect a translation from the adult phenomenological presentation of multiple personality disorder into the ways this disorder would present in childhood. This translation was critical to the field, since it was conceptually difficult to bridge the gap between the adult patients' ability to make their dissociative experiences understood via their developmental sophisticated use or language and abstract symbolization, which children lack. It was necessary to develop ways to understand and assist a child's efforts to describe dissociative experiences without the conceptual capacities of later development.

Some initial reports described children who would have met the diagnostic criteria for dissociative disorder of childhood but not for multiple personality disorders. These authors highlighted the ways in which these children's dissociative problems fit on a developmental continuum with adult multiple personality disorder. A large

clinical series by the author and Frank Putnam further elucidated the clinical similarities of children with multiple personality disorder and those with dissociative disorder not otherwise specified. Several researchers have recently developed sophisticated diagnostic tools to achieve an accurate diagnosis in children with dissociative symptoms.

Researchers studying dissociative disorders in children have shifted the focus in multiple personality disorder research from the drama of adult dissociative identity disorder to the varied developmental effects of repetitive early childhood trauma expression.

EPIDEMIOLOGY

An accurate estimate of the frequency of dissociative disorders in childhood is not possible. They are certainly not as rare as once thought. Urban child psychiatric clinics and child inpatient psychiatric units that evaluate and treat a number of children often have several documented and suspected cases at any given time. In populations of children in protective custody because of abuse, in the juvenile justice system, and in child residential facilities, the incidence increases, particularly when diagnostic screening is used to identify children with dissociative symptoms.

Although the adult literature on dissociative identity disorder states that females outnumber males three to one, the child literature reports a more even distribution. Some authors cite the tendency for women to internalize symptoms while men tend to externalize and act out to explain this female to male ratio. Other researchers have reported an unexpectedly high incidence of dissociative symptoms in men incarcerated in the penal system.

A variety of factors confound research on childhood dissociative disorders. The adult dissociative identity disorder patients who reported childhood onset of their symptoms generally did not come to the attention of child psychiatrists. Most maintained the minimum level of function needed to avoid being targeted for intervention. Hearing some of their case histories one wonders in retrospect how their illnesses could have been missed. An honest appraisal of children who slip through the cracks today is equally shocking. Our current economic structure does not encourage schools to identify children needing treatment unless they present severe behavioral management problems in the classroom; new laws require schools to pay for mental health evaluations of children they identify as needing help. Children in families with ongoing abuse are often carefully schooled not to draw attention to themselves, and their parents do not seek psychiatric attention for fear that the abuse will be discovered—with major legal ramifications.

The children who are diagnosed as having dissociative disorders are likely an atypical subset of children with these disorders. Children come to the attention of mental health professionals most frequently when some aspect of their behavior is problematic to adults. Those who disrupt classrooms, exhibit explosive, aggressive, violent behavior; commit crimes; injure themselves; attempt or threaten suicide; or are so depressed that they disturb authorities are the ones seen. Children whose families are so dysfunctional that they fail to hide abuse or disintegrate so that the child is removed to protective custody may come to the attention of mental health professionals. In overloaded urban welfare systems the usual course of mental health treatment is often too little, too late, only for the most severely dysfunctional.

Comprehensive psychiatric evaluation and treatment are increasingly unavailable for the average American family, whose insurance company simply will not pay for them. Fewer adoptive children with symptoms secondary to abuse prior to adoption from families with middle incomes are treated.

These factors skew research. The equal male to female ratio in childhood dissociative disorder may only mean that more boys are brought into the mental health system because they are more apt to exhibit externalizing symptoms that result in behavioral management problems. An important question awaiting future research is whether aggressive outbursts, self-injury, suicidal gestures, inappropriate sexual behaviors, and antisocial actions are inherent to the dissociative disorders in children, or simply reflect the kinds of disturbances that bring youngsters with dissociative disorders to psychiatric attention.

Research suggests an increased incidence of dissociative disorders in children when a parent carries the diagnosis of dissociative identity disorder. It is not known what roles a genetic tendency or capacity for dissociation, identification with the dissociating parent, or dysfunctional parenting because of dissociative identity disorder symptoms play in this increased incidence. Some family case studies that show the difficulties dissociative identity disorder patients encounter in parenting indicate areas that should be explored for therapeutic intervention while the reason for the increased family frequency is being investigated.

ETIOLOGY

Overwhelming evidence from the literature on dissociative identity disorder in adults and even more powerfully from the literature on dissociative disorders in childhood points to ongoing, severe trauma, sexual abuse, and violence among family members as causal in the development of these disorders. The typical case history details repetitive, exploitative, violent, and merciless physical and sexual abuse beginning before the age of 5. In many childhood cases this abuse is well documented; these cases include children who have been prostituted for drugs, those used to produce pornographic material, and those exposed to sadomasochistic torture. Others live in chaotic, violent households or are exposed to abuse by a series of dysfunctional adults brought into the home by a highly dysfunctional parent. Cases in which violence or sexual abuse began later in childhood are less frequent; the abuse usually began well before adolescence, and predisposing family chaos appears to have led to development of a childhood dissociative disorder.

In rare instances preschool children exposed to the severe upheaval of war, loss of family members, grotesque war trauma or the uprooting that is part of being a refugee have also been given diagnoses of dissociative identity disorder. That these diagnoses are not more common in these populations speaks to the resiliency of children and their ability to use a variety of responsive caregivers to help them achieve integrative self-functions, even in the presence of severe trauma and resultant posttraumatic stress disorder. These children may have the psychogenic amnesias, traumatic flashbacks, and dissociative phenomenon common in posttraumatic stress disorder, but the infrequency with which they develop separate self-states indicates causal factors in the development of dissociative identity disorder that go beyond severe traumatic experiences in early childhood.

Evaluating young children in the midst of war trauma, immediately after natural disasters in which injury occurred or parents were lost, or after some other extreme single trauma, such as witnessing a parent's murder, yields a number of children suffering from acute dissociative symptoms. Trance states, episodes of regression, traumatic reenactment, and traumatic flashbacks are not uncommon. Some may have persistent dissociative symptoms and may exhibit some of the behaviors listed under B and C of the diagnostic criteria for dissociative disorder of childhood. Few ever meet the full diagnostic criteria.

Dissociative identity disorder and dissociative disorder of childhood appear to have at their core not only extraordinary trauma in early childhood, but trauma that occurs at the hands of family members or as a result of extreme parental dysfunction that allows such trauma to occur repeatedly at the hands of others. This trauma is combined with disturbances in the parent's ability to form a healthy attachment to the child and the further absence of adults to help perform the integrative and self-soothing functions that cannot be performed developmentally by the young child. Deficiencies in normal parental attachment and a lack of caregivers to help the young child develop normal self-soothing and integrative functions in early childhood appear to be necessary for dissociative identity disorder or dissociative disorder of childhood to develop in response to childhood trauma occurring after the age of 6. The dynamic conflicts inherent in knowing that the parent who is depended on is also the source of trauma are inversely related to the age and helplessness of the child. The development of separate self-other internalization avoids the experience of overwhelming anxiety. Development of an integrated identity is blocked by the traumatic anxiety it would unleash, and the self-object internalizations evolve into separate personality states.

Inborn developmental abnormalities, inborn or acquired neurological problems, or other organic factors that influence a child's ability to form an attachment, be soothed, or block the development of self-integration may cause children with other diagnoses to present with dissociative symptoms. Inborn difficulties in these children interfere with normal development and may transform some aspects of commonplace occurrences into overwhelming traumas.

A developmental capacity to dissociate is likely neither sufficient nor necessary to cause development of dissociative identity disorder. Research into the capacity to dissociate appears in the literature on hypnotizability. Individual variations in hypnotizability exist, some of which may be inherited. This research also shows that hypnotizability, (correlated with the capacity to dissociate) peaks in early childhood and declines through adolescence. The persistence of high hypnotizability in college students was correlated with corporal punishment in childhood, which suggests that the dissociative capacities of young children can be retained as a result of environmental influences. An inherited capacity to dissociate may provide a protective function for a child exposed to repeated overwhelming trauma rather than represent a genetic vulnerability to develop dissociative identity disorder.

Studies on the neurobiology of trauma indicate that traumatic experiences change neurophysiological functioning and the ways in which memories are stored and retrieved. Dissociation in the face of a posttraumatic stimulus helps prevent dysfunctional panic/anxiety states but may cause traumatic stimuli to maintain their

potency over time. These areas of research promise to further our understanding of the etiology of dissociative disorders.

DIAGNOSIS

According to DSM-IV, “[t]he essential feature of the Dissociative Disorders is a disruption in the normal integrative functions of consciousness, memory, identity or perception of the environment.”

J. was fishing as he often did to help feed his family. Although he had just turned 10, he played a significant role in his family's survival, and fishing was one of the more enjoyable ways he helped. His favorite fishing hole was a short hike through the jungle from his family's village. Suddenly, he heard crashing and shouts of men running through the jungle. He saw a young man desperately run into the water, but not quickly enough to escape a hail of gunfire. He was hit several times in the back and fell, bleeding copiously, rolling as he fell so that J. recognized him as a cousin who was only 5 years older than he was—a boy he sometimes fished with, and one he admired for his stories and his wisdom and popularity in the village. As these events unfolded J. felt as though it all must be a dream. He experienced himself watching the event from high in the trees, far above his own body at risk by the water's edge. This experience lasted for the seconds it took for the young man and his pursuers to appear, the shots to ring out, and the young man to fall, revealing his identity to J. Quickly J. was back in his body diving into a safe hiding place. He had no idea how long he hid in the bushes by the water until long after the men with guns disappeared. He has a foggy image of trying to revive his cousin and realizing he was dead. He trembled as he remembered returning to tell his grandmother, but finding no words, being able only to gesture and lead his uncle to the site. He told this story in English because as he stated, “I've never been able to remember how to speak the language of my village ever since then.” His family escaped the country shortly after this incident, other family members were lost, and there was much hardship in their journey to the United States. J. was 16 when he told this story.

An important, but often difficult distinction is the dividing line between a dissociative defense, a dissociative symptom, and a dissociative disorder.

The story of J. meets the DSM-IV definition of dissociation three times. The first dissociative experience is his “out of body experience,” or brief depersonalization—it is fleeting, occurs at the moment of his greatest fear, and quickly disappears. This is a good example of a dissociative defense thats appears to help a person cope at a moment of extreme fear and stress. The common appearance of this defense in response to trauma is reflected in colloquial phrases such as “I was beside myself with terror,” “I was scared out of my wits,” “My heart leaped out of my chest at that moment,” and “I felt as though the entire experience was unreal.”

J.'s second dissociative experience was the distortion in his sense of time—how long he hid. To this day he has no idea how long he hid. He says it could have been minutes or hours. He also can't recall where the sun was in the sky, how long he had been fishing before the trauma occurred, or where the sun was in the sky when he went back to the village. He knows it was early morning when he set out fishing and that his uncle and others lit torches to find their way back to the village after he led them to his cousin. This persistent distortion in memory and perception represents a dissociative symptom relating to the trauma, but it does not affect J.'s current life enough for a diagnosis of a dissociative disorder. Alteration in time perception is a common enough symptom to generate the colloquial phrase “At that [traumatic] moment time stood still.”

The third dissociative experience, persistent amnesia for his native tongue, has a clear impact on his relationships with family and his ethnic community. He understands words spoken to him in his native tongue but needs a translator to translate from the English he has learned back into his native language. This symptom grants him the diagnosis of dissociative amnesia. Brief traumatic loss of speech is acknowledged in the everyday phrases “scared speechless” and “the cat got my tongue.”

Other common colloquial descriptions of dissociative responses to trauma culturally organize the strange alterations in integrative functions that occur. States of posttraumatic numbness, derealization, depersonalization, and trance (eyes staring blankly ahead, oblivious to surroundings) are called “shell shock,” even when they occur in response to psychologically overwhelming news rather than the traumatic experience of war. “When he first got off the phone having learned his wife was having an affair he was absolutely shell shocked and it took him some minutes to overcome a sense of numbness where he could neither feel nor react.” Dissociative conversion is a dissociative disorder recognized by ICD-10 and in the expression “my legs gave out under me when I heard the news.” Dissociative alterations in identity are known also in their mildest form as a “normal reaction to trauma” in describing a person no longer feeling like themselves or the entire world turning upside down in an instant.

Nonpathological dissociative behaviors are part of our normal human repertoire; an example is being so lost in thought you drive miles past your exit before your consciousness of your surroundings reemerges. Another example involves staring off in a glassy-eyed daydream (in the elevator perhaps), prompting friends to wave their hands in your face and say, “Earth to Mars.”

Developmental Considerations The diagnosis of dissociation in childhood in terms of the DSM-IV definition of a dissociative disorder is complicated by developmental progressions in perceptions of time, identity, and adult reality. Knowing how child development affects conflict resolution is important in assessing whether a child is developmentally on track or significantly delayed in giving up some normative dissociative defenses. Not knowing how long an hour takes to pass is expected in a 6-year-old child but may be a dissociative symptom in a 10-year-old. Young children may not believe they are lying when they insist they did not do something you just saw them do. They can believe it did not happen because they wish it had not, reflecting developmental progressions integrating reality with emotionally satisfying fantasy life.

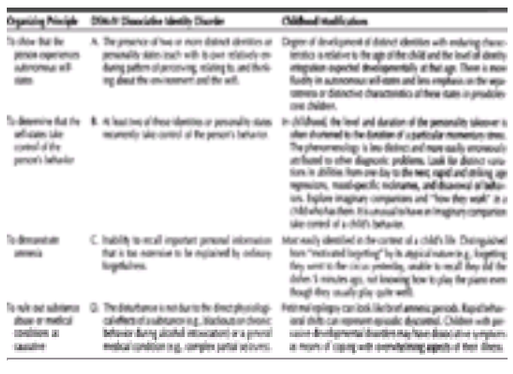
L. and his brother were roughhousing with their aunt. L., age 5, overly zealous in his desire for physical conquest over the others, suddenly popped his aunt in the nose. The aunt pulled herself free of the boys and went into the bathroom to put ice water on her nose. When she returned to face the raucous L. and explained that he had really hurt her when he hit her in the nose, L. yelled out, “I didn't hit you, you hit me.” L.'s astonished aunt protested his assertion, whereupon he stormed off and locked himself in the bedroom. After a little time, L.'s aunt went to the bedroom door and explained that everybody makes mistakes sometimes and whatever happened she was sure they could have some safe fun together making some artwork. L. emerged and told his aunt it was O.K., they could be friends again. For 5-year-old L., the thought that he had hurt his aunt was overwhelming. In telling him so she “hit” his feelings. He revised reality to go along with his feelings, and he was certain he was telling the truth. He had to flee his aunt's attempts to intrude on this reality because it was too upsetting. He could only come out after he was reassured of their friendship, although she had not behaved angrily or been rejecting. A discussion of lying had no meaning to him at his stage of development.

The knowledge that wishes don't alter reality grows in the early grade school years, as does constancy in the perception of self and others. A 3-year-old child can have the worst mommy in the whole world when she insists the child put on boots to go outside and the best mommy in the world 5 minutes later when she fixes a broken toy. If you remind the 3-year-old of saying the best mommy was the worst 5 minutes before, the child is genuinely confused. Similarly, being scolded as a bad child can feel like the end of the world without hope of ever recovering former good graces without adult assistance. Such fluctuation in object relations in an older child could contribute to the development of borderline personality disorder development with its dissociative shifts between all good and all bad self and other perceptions. Examples of psychologically motivated dissociative confusion between reality and fantasy abound in clinical experience with individuals with dissociative disorders. It is helpful to be cognizant of the age when this is a normative response to internal conflict when devising a therapeutic response.

Z. had an intense emotional relationship with her demanding, self-involved boss. He could do no wrong in her eyes. Her life revolved around his whims and tantrums; she gloried in his praise and never questioned his expectations or her neglect of her own and her family's needs. When her boss got into trouble with the IRS he placed the blame on Z., who in fact had no role in preparing any aspect of his tax reports. The boss fired Z. to “look better.” Z was disconsolate. She was sure there was some mistake and tried to think of ways to force her boss to realize this. Eventually, as her efforts for contact were rebuffed, her dissociate symptoms (which though present, had never brought her to professional attention) worsened, and she was given the diagnosis of dissociative identity disorder. Z. had frequent episodes of amnesia and found herself with items she had no recollection of owning and saw no need for—clothing she saw as frivolous, expensive stuffed animals, male clothing in her size. She found herself in police custody for breaking into her boss's office and stealing files. She could not believe she had done this, although she was told police discovered her at the scene of the crime with the files in her hands. In therapy an alternate personality emerged who identified “himself” as Z.'s teenage friend X. X. and Z. saw themselves as completely distinct individuals. X. denied having female physical attributes. X. explained that he was angry with the boss and that he was trying to get proof that Z. was not involved in the IRS problems. Z. could not in any way relate to X.'s feelings, opinions, or actions. Discovering X.'s “origins” in Z.'s childhood (to fend off sexual abuse by Z.'s father) allowed these two dissociated aspects of Z.'s identity to acknowledge their relationship to each other and the impossible conflict Z. had in coping with her idealized father's sexual abuse of her. Critical to achieving this therapeutic movement toward integration was the therapist's comment that Z. could acknowledge her father's sexual abuse and still admire other things about him. The child's difficulty in integrating good and bad when they are extreme played an important role in Z.'s development of dissociative identity disorder in childhood and its symptomatic worsening when a conflict arose about exploitation by an idealized male in Z.'s adult life.

Imaginary companions are developmentally unremarkable in a 6- or 7-year-old child even though they represent split-off aspects of self. In an adolescent, an imaginary companion may indicate a dissociative identity disturbance. One simply cannot apply adult criteria of alterations in integrative functions of memory, consciousness, identity, and perception to help identify a dissociative disorder in a child of 3, or 6, or 8. This definition has validity only as an adolescent moves closer to adulthood and the clinical phenomenology of a childhood dissociative disorder comes to mirror that seen in adults with these disorders. Dissociative symptoms in childhood represent developmental lags in integrative functioning relative to the child's age when traumatically derived difficulties obtaining or maintaining age-appropriate integrative functions manifest in the face of developmental demands.

The DSM-IV discussion of dissociative identity disturbance includes information not present in the revised third edition of DSM (DSM-III-R) that acknowledges the research findings on dissociative disorders in children and the ways their presentation differs from that of adults, which were published in the years between these two editions. “In preadolescent children, particular care is needed in making the diagnosis because the manifestations may be less distinctive than in adolescents and adults” and “in childhood, the female-to-male ratio may be more even.” Table 49.8-1 lists the DSM-IV criteria for dissociative identity disturbance, the organizing principles behind each criterion, and important considerations for applying the criteria to preadolescent children.

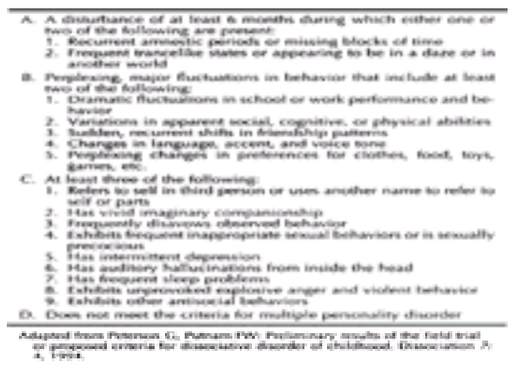


Organizing Principle	DSM-IV Dissociative Identity Disorder	Childhood Modifications
To show that the person experiences autonomous self-states	A. The presence of two or more distinct identities or personality states (each with its own relatively enduring pattern of perceiving, relating to, and thinking about the environment and the self).	Degree of development of distinct identities with enduring characteristics is relative to the age of the child and the level of identity integration expected developmentally at that age. There is more fluidity in autonomous self-states and less emphasis on the organization or distinctive characteristics of these states in preadolescent children.
To demonstrate that the self-states take control of the person's behavior	B. At least two of these identities or personality states recurrently take control of the person's behavior.	In childhood, the level and duration of the personality takeover is often circumscribed to the duration of a particular momentous stress. The phenomenology is less distinct and more readily erroneously attributed to other diagnostic problems. Look for distinct variations in abilities from one day to the next, rapid and striking age regressions, mood-specific incitations, and dissociative behaviors. Explore imaginary companions and “how they work” in a child who has them. It is unusual to have an imaginary companion take control of a child's behavior.
To demonstrate amnesia	C. Inability to recall important personal information that is too extensive to be explained by ordinary forgetfulness.	Most easily identified in the context of a child's life. Distinguished from “motivated forgetting” by its atypical nature (e.g., forgetting they went to the circus yesterday, unable to recall they did the chicken 5 minutes ago, not knowing how to play the piano even though they usually play quite well).
To rule out substance abuse or medical conditions as causative	D. The disturbance is not due to the direct physiological effects of a substance (e.g., blackouts or chaotic behavior during alcohol intoxication) or a general medical condition (e.g., complex partial seizures).	Petit mal epilepsy can look like brief amnesia episodes. Rapid behavioral shifts can represent episodic dissociation. Children with post-traumatic developmental disorders may have dissociative symptoms as means of coping with overwhelming aspects of their illness.

Table 49.8-1 Modifications to DSM-IV Dissociative Identity Disorder Diagnoses to Account for Childhood Symptoms

The DSM-IV diagnosis of dissociative disorder not otherwise specified is given to dissociative individuals who do not fit criteria for other dissociative disorder diagnoses. The diagnostic criterion reads as follows: “Disorders in which the predominant feature is a dissociative symptom (i.e., a disturbance in the normally integrative functions of identity, memory, or consciousness) that does not meet the criteria for a specific dissociative disorder.”

Children with dissociative disorders who do not meet the criteria for a diagnosis of dissociative identity disorder currently fall into this category. Researchers consider this inadequate for two reasons. First, often the failure to meet criteria for dissociative identity disorder is a function of the child's age and developmental level. Given the level of personality organization in the preschool-age child, a child of this age can rarely be diagnosed with dissociative identity disorder despite a complex syndrome of dissociative symptoms and difficulty developing integration of self-states. Second, many researchers argue that a meaningful constellation of dissociative symptoms occurs in children with histories of extreme trauma and abuse that although not organized well enough to meet the criteria for dissociative identity disorder, nevertheless deserves attention. Many consider these children to be at risk for developing dissociative identity disorder as they get older and some have documented cases of children with dissociative disorder not otherwise specified who meet the criteria for dissociative identity disorder later in childhood. Gary Peterson and Frank Putnum organized the symptomatic constellation of children diagnosed with dissociative disorder not otherwise specified from their own and others' research and coined the diagnostic concept “dissociative disorder of childhood.” Although not included in DSM-IV, most in this field hope to have this diagnosis included in later editions of DSM. The proposed diagnostic criteria for dissociative disorder of childhood are listed in Table 49.8-2.



A. A disturbance of at least 6 months during which either one or two of the following are present:
   1. Recurrent amnestic periods or missing blocks of time
   2. Frequent trancelike states or appearing to be in a daze or in another world
B. Perplexing, major fluctuations in behavior that include at least two of the following:
   1. Dramatic fluctuations in school or work performance and behavior
   2. Variations in apparent social, cognitive, or physical abilities
   3. Sudden, recurrent shifts in friendship patterns
   4. Changes in language, accent, and voice tone
   5. Perplexing changes in preferences for clothes, food, toys, games, etc.
C. At least three of the following:
   1. Refers to self in third person or uses another name to refer to self or parts
   2. Has vivid imaginary companionship
   3. Frequently disavows observed behavior
   4. Exhibits frequent inappropriate sexual behaviors or is sexually precocious
   5. Has intermittent depression
   6. Has auditory hallucinations from inside the head
   7. Has frequent sleep problems
   8. Exhibits unprovoked explosive anger and violent behavior
   9. Exhibits other antisocial behaviors
D. Does not meet the criteria for multiple personality disorder

Adapted from Peterson G, Putnam FW. Preliminary results of the field trial of proposed criteria for dissociative disorder of childhood. Dissociation 7: 4, 1994.

Table 49.8-2 Proposed Diagnostic Criteria for Dissociative Disorder of Childhood

The criteria in Table 49.8-2 perform several functions important to the clinician evaluating a child with dissociative symptoms. Criterion A identifies a child who has significant dissociative pathology; neither recurrent amnesia nor frequent trancelike states are normal at any developmental age. Criterion B is sensitive to difficulties in a child's development of integrative functions. Criterion C refers to symptoms and behaviors frequently representing dissociative phenomenon that in the absence of a dissociative disorder might implicate other problems or diagnoses. Multiple personality disorder, mentioned in criterion D, was the DSM name for dissociative identity disorder prior to DSM-IV. The aim of this new diagnostic category is to identify children with a dissociative syndrome that is on a developmental continuum with dissociative identity disorder. This aim continues the historical aim that fueled the early development of research on childhood dissociative disorders. The opportunity to prevent further trauma, intervene, and treat the disorder early enough to prevent a serious adult mental illness and to develop further understanding of the impact of childhood trauma is a powerful motivator of research in this field.

CLINICAL FEATURES

Several instruments are now available to assess dissociative symptoms in children. They are enormously helpful for systematic evaluation of children suspected of

having dissociative disorders or for determing the extent of the dissociative pathology present. Some are brief enough to be used as screening tools in populations of children at risk for these disorders. In an ideal world this type of screening would be a part of the intake evaluation of a child in the child welfare or juvenile justice system and would be conducted during any investigation of child abuse. They are invaluable aids for clinicians seeking to gain experience interviewing children about their dissociative experiences, since the questions are to a child's developmental level.

Interviewing children about dissociative experiences is initially difficult. It requires above-average attunement to how children conceptualize their experiences. Children younger than preadolescents have difficulty with abstract concepts, early-school-age children have no sense of time as an organizing factor for placing life events, and few children have any experience describing any aspect of their sense of self. How does one begin asking about amnestic episodes for example? Anchoring inquiry in the events of the child's daily life is useful and examples are helpful. Often the clinician is modeling for the first time a way to discuss different types of experiences.

> *Sometimes kids have things happen to them that seem kind of strange, I'm wondering if any of these kinds of things ever happened to you? One kid told me that sometimes his teacher was doing one thing, like math problems, and then all of a sudden she was asking him to read aloud in his book. All the other kids knew where they were in the book, but he didn't even know he was supposed to have his book out, or what happened to the math problems. Did you ever have anything like that happen? What? Tell me about it*. Be aware of some children's natural tendency to want to answer these new questions—especially if they like you and want to please you—by acknowledging similar experiences. Always have them describe the experience before you accept it. A yes responder says, “Oh, yeah, I got in trouble for that yesterday.” *What happened?* “I didn't know where we were supposed to be in the reading book.” *Were you fooling around or anything that got you lost?* “Yeeees, well Bobby poked me with his pencil and then I was trying to kick his foot under the chair.” *Yeah, it's easy to get lost with that stuff going on*.
>
> The dissociative disorder child (same question): “Well no, um, maybe yes.” *Tell me a time you think might be like that*. “Uh, everybody got up for recess, but I didn't know, and then the teacher was kind of yelling my name a few times, why wasn't I getting in line. I didn't know, I thought we were still doing social studies.” *Were you fooling around with anything so you didn't know?* “I think, daydreaming?” *What were you dreaming about?* “I don't know, sometimes, I just go away somewhere.” *Where do you go?* “Um, well someone tells me I go to Hawaii.” *While you're still in your seat in class? Who tells you that?* “Boney” *Who is Boney?* “Some guy.” *Where is he from?* “Hawaii, except sometimes he lives in my head.” *How do you know he's in your head?* “He talks to me.” *Does Boney ever do things besides talk?* “In my head?” *Out of your head, in the world*. “How did you know that? He does, people blame me for it, but I didn't do it. They say they saw me but it wasn't, it was Boney.” *How does that work? How can people see you do it but really it's Boney?* “Boney just gives me a strong feeling and I have to shut my eyes and then he comes over me, out of my mouth and nose and eyes. Then I'm walking and my hands are doing things but I don't know what they're doing, because it isn't me, it's Boney.”

These interview excerpts are essentially verbatim. They illustrate interviews regarding dissociation with children who are still in the cognitive stage of concrete operations and give an example of a child's experience of having an alternate personality take over his behavior. Besides the concrete nature of their descriptions, children frequently have not elaborated their dissociative experiences in the ways adults do; this child readily acknowledges it is his body that did the action, which is not unusual. In late adolescence and adulthood, the alter is described as having a separate body. As cognitive abilities develop further and a child's sense of identity becomes more fully established and developed, the individual with dissociative identity disorder needs greater distinctness from the alternate personality states to avoid threatening anxiety. The child with dissociative disorder of childhood with fluid, transient self-states becomes the child with dissociative identity disorder as greater organization is possible developmentally or needed developmentally to fend off anxiety. Children have little opportunity to elaborate and express “separateness” in dissociated self-states; the clinician must look for more subtle manifestations of split-off, dissociated personality states.

Children with dissociative disorders are often amnestic to emotionally laden events. Schoolyard fights, punishments, explosive outbursts, and separations from caregivers trigger dissociative episodes. Older children may confabulate memories for these or lie about remembering because they know they are expected to remember and have often been punished for lying when they earlier told their accusers they did not remember committing some infraction. Patient inquiry into the details of the experience often helps reveal the amnesia the child is covering up, and some children who realize that you are interested in their experience of what happened rather than seeking a confession and remorse tentatively open the door to disclosing more about their dissociative experiences.

Children who have dissociated aspects of self, even when these are not elaborated into separate identities, lack integration across spheres. Knowledge, skills, relationship preferences, clothing, toy and food preferences, personality style, voice and speech patterns, and accents may vary between these dissociated aspects of self. Observational data in a variety of settings are thus important for differential diagnosis. The lack of integration between these dissociated aspects of self in children with either dissociative identity disorder or dissociative disorder of childhood goes beyond defensive imaginary constructs. Psychological testing may show wide fluctuations in the same skill from day to day. Hearing tests and eye examinations can also yield different results for different personalities or alters.

DIFFERENTIAL DIAGNOSIS

Differential diagnosis in children with dissociative disorders is complicated both by dissociative symptoms mimicking those of other diagnoses and by the variety of symptomatic disturbances brought about by trauma. Difficulties in affect regulation produce symptoms of irritability and affect lability. The psychodynamic legacy of child abuse includes fragile self-esteem, rejection hypersensitivity, self-blame, and moods that plummet into helpless, hopeless dysphoria at the slightest alteration in the caregiver's responsiveness. Some exhibit identifiable alternate personalities who blame themselves for the abuse and are chronically suicidal and intensely depressed. Small events that are linked in some way to past trauma can trigger the emergence of these personalities bent on self-destruction.

> For example, anytime M., age 14, wonders why I seem to care about her, this thought triggers a belief that I could not possibly care if her parents did not, and M. falls into a deep suicidal depression. Movies about child abuse also trigger M.'s depressed states even when she only reads a review. If M. admires some accomplishment or attribute in another, she is certain she's inadequate and forever doomed to rejection. She recognizes that she can be demanding but cannot recognize the traits that cause others to like her despite her problems. It's difficult to progress in therapy when efforts to discuss problem areas trigger violent self-retribution for having problems.

Not surprisingly, children, like adults diagnosed with dissociative disorders, frequently have held previous diagnoses of depression or bipolar disorder and show little or no response to antidepressant medication; moods that may be down or euphoric for weeks shift to the opposite in a matter of seconds in response to external events, a new relationship, or special recognition and change depression into giddiness. Conduct and behavioral problems are common in children diagnosed with dissociative identity disorder and dissociative disorder of childhood. These children (and adults with this disorder) often have no history of behavioral problems before they were removed from the abusive situation. In part this is related to their failure to develop internal controls for behavior. Survival meant tight responsive attunement to abusive caretakers. Similarly, adults with dissociative identity disorder become more symptomatic in good relationships. Out-of-control behavior is often managed initially through intensive therapeutic focus on establishing boundaries, a type of nonabusive external control that allows time for internal controls to develop.

An abused child often has difficulty understanding others' intentions and actions and may respond violently to perceived threats, have low frustration tolerance, or react strongly to manage feelings of helplessness. Children with dissociative disorders are frequently accused of lying because of their amnestic episodes and may have separate personality states that suddenly emerge to handle a situation through violence. Identification with the aggressor often plays a role in the dynamics of aggressive symptoms. Diagnoses of episodic dyscontrol are at times made erroneously because of the sudden, at times inexplicable, temper outburst. These children do not have the classic triad of enuresis, cruelty to animals, and fire setting associated with conduct disorder children on their way to developing antisocial personality disorder.

Because of dissociative symptoms, children with dissociative indentity disorder and dissociative disorder of childhood often have difficulty regulating attention and concentration as they drift in and out of dissociative states. Many have comorbid diagnoses of posttraumatic stress disorder. The combination of inattention, posttraumatic hypervigilance, and increased startle reactions often lead to misdiagnoses of attention-deficit/hyperactivity disorder. Dissociative states may also appear to be partial complex seizures. In the presence of dissociation, do not attempt to treat “presumptive seizures” without an electroencephalogram (EEG) showing epileptiform waves.

Dissociative problems with maintaining focus and dissociative “scrambling” of incoming information, along with fluctuations in knowledge and abilities associated with emergence of disparate personality states mimic a variety of learning disorders. For example, it was not unusual for the dissociative youngsters on the author's

inpatient unit to test as having auditory processing problems that fluctuated from day to day.

The traumatic experiences and the instability of relationships that produce dissociative identity disorder and dissociative disorder of childhood also produce anxious, traumatized children. Constant anxiety is a hallmark of these conditions. This can be relationship anxiety, where nothing can be taken for granted from one moment to the next; marked anxiety at bedtime with difficulty going to sleep—never knowing what might happen (often the children's abuse occurred in the night), or anxiety about certain activities reminiscent of emotionally difficult or traumatic experiences. Panic reactions are common as is invasive, traumatic imagery. Self-soothing abilities are often virtually absent.

> An 11-year-old boy with dissociative identity disorder experienced severe bowel impaction as a result of avoiding use of the bathroom. When he did have to enter the bathroom he often emerged in a confused, disorganized state. At times he was discovered huddling in the corner of a stall. It eventually came out that his father had repeatedly and violently sodomized him and he had scarring and resultant pain with defecation that triggered severe flashbacks to his abuse.

Dissociative phenomenon can also appear as psychotic states. Extreme anxiety, recent trauma, or times when their minds are flooded with traumatic material and flashbacks can cause these children to switch rapidly between different self-states, causing disorganization or catatoniclike withdrawal into a trance state. Unlike psychotic illness, fluctuations occur between these states and better organization, and stresses can be identified that trigger these states. Traumatic relationship anxiety can also occur in these children, producing a remote, glassy appearance that can mimic flat affect but is in fact dissociative regulation of extreme affect. Alternate personality states are frequently experienced as “voices” in the head. At times the hallucinations can appear to be coming from outside and be accompanied by visual hallucinations of abusers or alter personalities. One clear distinction between dissociative and psychotic disorders is the rapid response to establishing a safe, soothing environment. The key to successful differential diagnosis lies in observing children for behaviors that “don't fit” into the present diagnostic paradigm, seeking to understand the underpinnings of symptoms and behaviors, and keeping in mind that extreme measures are called for in extreme circumstances; thus bizarre dissociative phenomena may make perfect sense when they are seen in the context of the experiences that produced them.

COURSE AND PROGNOSIS

The literature is optimistic about treatment of dissociative disorders in childhood. The greater fluidity of the dissociative symptoms and the absence of more-solidified defensive organization makes therapeutic intervention more successful and quicker and often produces better mental health than is possible for adults with dissociative identity disorder. Follow-up at new developmental stages is recommended, as they may reveal conflicts that could not be resolved or were not active at the developmental stage when treatment initially occurred. Without treatment, some children with dissociative disorder of childhood will go on to develop dissociative identity disorder. Perhaps many will, but this is not an ethical experiment. There are documented instances of children with dissociative disorder of childhood developing more-classic dissociative identity disorder during treatment, as new developmental milestones are reached. Children with dissociative identity disorder are not likely to experience resolution of the disorder without treatment.

TREATMENT

Successful treatment involves first securing a safe, nurturing environment for the child. Without this, they will need their dissociative defenses and any therapy should be limited to supportive interaction. Safety and nurturing are needed at their highest level. These children need an environment of emotional involvement with them and if at all possible, love. The dysfunctional object relationship experiences of these children are combined in equal measure with trauma to create disturbances in their integrative functions of memory, perception, self, consciousness, affect, and object constancy.

Therapy combines an object-relational psychodynamic focus with cognitive-behavioral interventions. Active assistance in developing self-soothing skills is provided through imagery and suggestion. When behavioral acting out of aggressive and self-destructive impulses occurs, the therapist works to establish structural boundaries in the therapy to provide external regulation while internal regulation of behavior is developing. Use of medication, is not recommended, except for producing sedation in crisis situations.

49.9 GENDER IDENTITY AND SEXUAL ISSUES

ALAYNE YATES, M.D.

SEXUAL DEVELOPMENT

Sexual growth is composed of several developmental lines: (1) psychosexual growth, which contributes to personality formation; (2) gender, which contributes to the sense of self, self-worth, role, and identity; and (3) eroticism, which contributes to sexual responsiveness. The three components interrelate, complement, and sometimes conflict with one another.

EROTIC DEVELOPMENT

Sexual interest or activity in prepubescent children is often assumed to be abnormal, potentially dangerous, or indicative of child abuse. Historically, these concerns are related to the Calvinist perception of sexuality as an evil force spawned by the devil and the somewhat later romantic perception that children are innocents whom parents and other adults must protect from evil.

The sexual revolution of the 1960s and 1970s recognized that adult sexual dysfunction was probably related to earlier sexual inhibition or trauma but the revolution never addressed early erotic development. In the 1980s and 1990s exploration of normal development was further compromised by the association with child sexual abuse. New rules were formed to protect children; for instance, preschools, which had permitted some age-appropriate exploration, no longer allowed boys and girls to visit the toilet at the same time. Eventually the concept of sexual abuse came to include anything sexual that could involve children, casting doubt upon events such as sibling sex play, children bathing with parents, and teachers hugging pupils.

Research in Child Development Research in early erotic development is sharply limited by social constraint. Parents, schools, and review boards are unlikely to permit the direct questioning of children about their sexual interests and experiences. Therefore, most of the information available comes from questionnaires administered to caregivers or from the direct inquiry of children who have been or are thought to have been sexually abused. Parent questionnaires can yield valuable information, but most children over the age of 5 or 6 conceal their sexual activities from adults; those who do not are likely to have behavior problems.

Research on sexually abused children inevitably associates sexual activity with emotional and behavioral problems and therefore is of little use in understanding normal development. However, the study of sexually abused children does illustrate the process of eroticization, which occurs to some extent in all children. Young, sexually abused children can become highly eroticized, which most reliably differentiates them from nonabused youngsters. They may initiate fondling and oral sex with others and they often react to nonsexual situations as if they were sexual. Once established, this pattern is remarkably resistant to change.

Researchers ascribe the hypereroticism of sexually abused children to re-enactment of trauma, a symptom of posttraumatic stress disorder, which results from the fact that the sexual behavior is inflicted on children and that they have no control over it. Yet many abused children without posttraumatic stress disorder have also become highly erotic, perhaps because they have simply learned to be very sexual. Abused children receive more erotic stimulation and less punishment for being sexual and they may have learned to enjoy it more. This does not change their status as victims or make the sexual abuse less of a crime, but it does challenge society's notion of the innocent child.

Assuming that children are sexual and that early eroticism has something to do with adult sexual function or dysfunction, the obvious next step would be to study how normal children learn to be sexual or, conversely, how they acquire sexual inhibitions. A comprehensive longitudinal study of normal erotic development would answer some of these questions and determine which biopsychosocial factors add to or detract from healthy sexual function in adult life. Such a study could define risk and protective factors for posttraumatic stress disorder when children are exposed to sexual events or sexual trauma, and could provide information on whether current educational programs to prevent sexual abuse help or harm normal erotic development.

Virtually all children are born sexual. Infant boys have erections from the time they are in utero; infant girls lubricate vaginally when their genitals are cleansed shortly after birth. Infants of both sexes stimulate themselves and, in some cases, experience orgasm in the first year of life, although the peak of masturbation is somewhat later, at age 2 to 3 years. From the age of 4 months, infants anticipate diapering with pleasure, gurgling, and chortling, grabbing the parent's hand and placing it on the genitals. Toddlers enjoy exhibiting their genitals to parents and they often initiate bathtub or toilet sex play. Activities such as these help children define themselves as boys or girls but, as most parents know, they are also extremely pleasurable. Half of all preschool children engage in some form of heterosexual or homosexual sex play, mostly consisting of looking at or touching the genitals, tickling, or rubbing against each other, as in the games “Doctor” and “Barbie and Ken.” Activities such as undressing and showing off the genitals, touching one's own genitals or those of another child, scratching one's crotch, touching women's breasts, and peeking at others who are naked are commonly reported by parents.

Self-pleasuring and sex play is associated with emotional health and good parenting in the preschool years. After age 6 the presence of observed sexual activity is more likely to be associated with acting out or “high-risk” behaviors, probably because internalizing youngsters do not engage in, or hide, sexual activity whereas more aggressive, externalizing youngsters demonstrate many upsetting behaviors, some of which are sexual. Nothing is known about the sexual interests or activities of school-aged internalizing children and so they are often presumed to be asexual. By the same token, little is known of the sexual adjustment of internalizing adolescents whereas a great deal is known about adolescents who display a variety of high-risk behaviors.

Biological or temperamental factors must play a role in erotic development. Inhibited children are more likely to suffer from separation anxiety when they are young and from depression as they mature; this inhibition and depression could contribute to sexual problems in adult life. However, biological factors alone cannot account for most sexual problems in adults; social and psychological factors are usually involved.

Sexual development is influenced by the confusing messages children receive from their parents and the media. Sexual activity is presented as fascinating and great fun on television but as naughty or dangerous by parents and teachers. Bodies are idealized on magazine covers but youngsters are chastised if they show their underpants. Children who are not helped to reconcile these messages may conclude that values and moral standards change depending on who is talking or the channel to which the television is tuned.

An overriding effect on erotic development is society's critical attitude toward the body, which focuses on how it should look or perform instead of how good it appears and how pleasurable it can feel. Many preschool children and almost half of grade-school children are already dissatisfied with their body and attempt to change it through diet or exercise. Body dissatisfaction escalates after the onset of puberty in girls and remains high into the adult years; it is often accompanied by self-criticism and irrational fears about social and vocational failure. These elements can contribute to the development of an eating disorder and persons with eating-disorders frequently suffer from sexual dysfunction.

Body dissatisfaction is usually attributed to the media's emphasis on diet and slimness. However, the media could just as well be responding to the demands of its audience. The reason why body dissatisfaction has increased sharply in recent years is not known but could be related to sociocultural changes such as the rapid increase in dual-wage families. Children are often separated from their parents at an early age and are expected to become relatively independent. This is a normative crisis of considerable magnitude that tests the limited resources of toddlers. Because children experience the need to be held and fed in the body, they may

reject the body in order to achieve greater autonomy.

SEXUAL ANATOMY: MALE AND FEMALE

Genetic influences determine whether a person is born male or female. The fetus is initially and intrinsically female; an anatomical male is produced if the Y chromosome is present to promote testicular development and the production of testosterone which is then converted to dihydrotestosterone. If the gonads are removed before the eighth week of fetal development, the embryo will develop as a female. The androgen-estrogen balance determines gender differences in the size and number of nuclei contained in brain neurons, synaptic development, and dendritic branching patterns.

However, the relationship between chromosomes and clinical outcome is complex. Individuals with sex chromosome abnormalities such as 47, XXY, 47, XYY, and 47 XXX do not present with gender identity disorder, requests for sex change, or unconventional sexual orientation. Other mechanisms than the action of gonadal steroids could determine sexual dimorphism. In mammals, differentiation is fostered by gene products such as SRY, a testis determining gene on the Y chromosome. Other factors such as gene linkage disequilibrium may play a role.

Fetal testosterone permanently alters the developing brain through the migration of neurons, exerting an organizing influence on the hypothalamus, the preoptic area, and the amygdala during the sixth to the twelfth week of fetal development. Brain organization takes place only within brief critical periods, but its affective, behavioral, and cognitive effects last a lifetime. Testosterone-affected brains become larger and heavier due to an increase in cortical gray matter. Sex difference or dimorphism is also present in the corpus callosum, cerebellum, amygdala, and planum temporale. Perinatal testosterone exposure causes a nucleus located in the preoptic area of the hypothalamus to become two and a half times larger in males, with twice the number of neurons; this nucleus is probably involved in sexual orientation. The development of the female fetus is not as well understood as that of the male. Follicle-stimulating hormone is present in the pituitary of males and females by the tenth week of gestation. It increases markedly in females between the twelfth and twentieth week of gestation, the same time that males are experiencing a surge in testosterone. Follicle-stimulating hormone fosters the development of ovaries and the production of ovarian hormones.

Gender-specific effects of sex hormones on the brain include: (1) language organized primarily on the left side of the brain in males and on both sides of the brain in females, (2) increased language and fine motor skill in females, (3) greater visual-spatial ability in males, and (4) gender-specific repertoire of sexual and nonsexual behaviors. In addition, sex hormones regulate and are regulated by neurotransmitters, neuropeptides, growth factors, and neuroactive steroids.

Sex hormones continue to affect mood, cognition, and behavior throughout life. Testosterone fosters aggressiveness and activity in males and intensifies sexual thoughts, feelings, and behaviors. In the past, high levels of testosterone were thought to promote impulsive aggression and social maladjustment in males; recent work indicates an association instead with social dominance and success. A reciprocal feedback system operates whereby perceived success in social or competitive arenas increases testosterone levels whereas stress decreases testosterone levels.

Although estrogen is thought to be a female hormone, cross effects within the brain are currently being investigated. Male animals who are unable to respond to estrogen become uncoordinated in sexual and aggressive pursuits, and females unable to respond to estrogen exhibit uncharacteristically fierce territorial aggression, including attacks on males.

Normal youngsters experience an increase in sex hormones during the first 2 to 4 years of life, in conjunction with relatively robust erotic interest. Then hormone levels drop and they remain relatively low until several years before puberty. This juvenile phase, roughly equivalent to latency, seems to be secondary to cortical inhibition. Puberty begins with a dramatic rise in gonadotrophins, growth hormone, estrogen, and testosterone.

Prepubescent girls require a certain percentage of body fat for menarche to occur. Extremely lean gymnasts and dancers retain their prepubescent habitus. Leptin is a recently discovered hormone that resides in fat cells and that signals the brain when there is sufficient body fat to accomodate puberty. Leptin increases in girls but decreases in boys during puberty, as testosterone appears to supress leptin. When leptin is injected in immature female animals, they mature much earlier than others.

GENDER IDENTITY

Gender identity is how a person perceives the self as male or female. The human infant is born with a bias toward a certain gender identity, one that is created or reinforced by the maleness or femaleness of the brain. Brain bias usually matches the genital or anatomical sex as both develop in utero in response to fetal and maternal hormones. By the age of 2½, children can clearly and consistently state whether they are male or female, and they recognize others as male or female. By age 6 to 10 they know if their gender identity matches their anatomical sex.

Sex Assignment When the genitals are ambiguous, a decision to rear the child as male or female is usually made shortly after birth, with completion of surgical reconstruction by the child's third birthday. Decisions are based on the presence and adequacy of the genital apparatus, expected socio-sexual functioning, and the parents' preferences. The objective is to achieve, as far as possible, a gender-congruent physique. The female sex is favored because it is easier for the surgeon to construct a vagina than a functional phallus.

Most children adapt to the assigned sex even when it does not match the original anatomical sex. Contradictory feelings and behaviors resulting from prenatal hormonal influences are usually accommodated as long as the child's physical appearance is gender appropriate and the parents are not unduly confused or conflicted about the decision. However, clinicians have begun to question routine sex assignment because the sex chosen may be at odds with brain programming and the brain may have the final word. A boy whose penis was accidentally destroyed at the age of 8 months had his testicles removed, his perineum reconstructed, and was reared as a female. Yet he refused to play with girls' toys and insisted on standing to urinate. At age 14, he refused to live as a female, even though he was still unaware that his sex had been reassigned; he was eventually surgically reassigned once again as male.

Sex assignment is completed early in order to facilitate the formation of gender identity and to avoid gender confusion. Once acquired, gender identity was thought to be set for a lifetime; however, gender may be more plastic than originally thought. Genetic males with 5-alpha-reductase deficiency who appear to be female and who are raised as females usually make a rapid, decisive transition to the culturally favored male gender when they virilize at the time of puberty. If they had been raised unassigned, as boy, girl, or intersex, reassignment would not have been necessary. In recent years, society has become more tolerant of transgender behavior. A small but growing number of adults live in a mixed or intersex state, sometimes receiving hormonal but not surgical treatment. A provisional assignment as male or female, without surgery, may be an option for some children in the future.

Caution is advised in assigning gender before the child is old enough to state a clear preference and to demonstrate gender-role behavior. However, if after receiving counseling the parents are unable to tolerate sexual ambiguity, early assignment is still indicated. Sex assignment ultimately rests upon our ability to assess the maleness or femaleness of the human brain. This may be possible within the next decade, enabling early, accurate decisions on sex assignment.

GENDER ROLE

Gender role refers to a collection of attitudes and behaviors that are typically male or female. Boys and girls display different play and work preferences, extracurricular interests, and courting patterns. Preferences are based on differing patterns of information processing and emotional responsiveness.

Although gender role is largely culturally determined, genetic or biological factors play a part. Across many cultures men are more active, aggressive, and competitive from an early age. Boys gravitate toward action toys and play out battle-and-capture scenes. Similarly, girls choose dolls and play out the desire to care for and teach children. When angry, girls are more likely to lash out verbally while boys are more likely to lash out physically. Girls worry about the people they care about whereas boys worry about performance.

Although gender identity is usually set from age 2, gender role often remains malleable until age 5, especially in females. By the time children enter kindergarten, most boys and girls feel compelled to act according to gender-specific rules and expectations. These are enforced primarily by peers who tease and ostracize effeminate boys and, to a lesser extent, girls who act like boys. Social sanctions are even more apparent in adolescence when appearance, courtship, and sexual performance are dictated by gender-specific scripts. Most adolescents readily accept these constraints because they enjoy the praise of peers and family and the

security of group membership.

Prenatal Influences The brain is the ultimate discriminator between male and female and it provides the biological substrate for gender role. Women are more proficient in verbal and affective communication and men display greater logical, analytical, and spatial abilities. These gender-specific patterns are related to male fetal development. Higher testosterone levels in the male fetus foster a delay in right-hemispheric development and greater left-hemispheric specialization.

In humans, prenatal hormones influence gender role most clearly in the choice of toys and pattern of play. Less clear, but still fairly convincing, is the case for hormonal influence on aggression and sexual orientation. Girls with congenital adrenal hyperplasia are exposed to increased androgens before and after birth and they often prefer playing with boys' toys. If they are not treated until age 8, they display a masculine pattern of arousal in that they quickly respond to visual erotic stimuli, experiencing strong, genitally located erotic arousal. They report fewer-than-expected fantasies of marriage, pregnancy, or motherhood and they are more likely than controls to become lesbians. Boys exposed to antiandrogens display lower energy levels, less aggression, and less heterosexual activity in adolescence, whereas girls exposed to prenatal antiandrogens appear more traditionally feminine than other girls.

In spite of these and other positive findings, there is a vast body of literature that is not only confusing but also reveals many negative findings about the effects of prenatal exposure to hormones. This may be because insufficient attention has been paid to the brief critical periods during which the hormones exert an effect. Based on current research, the overall influence of prenatal hormones seems to be less than the overall influence of the environment, whether this is translated to the child by social reinforcement, role modeling, or through dynamic, intrapsychic forces. However, today biological factors are viewed as more important than they were in the past.

CROSS-GENDER IDENTIFICATION

Symptoms of cross-gender identification are usually recognized in the preschool years, typically in boys who dress in women's clothes, prefer to play house, and avoid rough play. They may sit to urinate and openly express the wish to become a girl. Girls with a cross-gender identification dislike wearing dresses and prefer to play with boys. They may expect to grow a penis and become a man. Cross-gender identification extends to fantasy, with boys enjoying romantic comedies and girls gravitating toward action heroes.

Cross-gender identification is the conviction of belonging or the desire to belong to the other sex. It is almost always reflected in behaviors such as cross-dressing. Male cross-sex-typed behavior exists across various cultures regardless of how the culture views homosexuality. The behavior surfaces at approximately the same age and is resistant to change, all of which suggests that biological factors are its chief determinants.

Boys with cross-sex-typed behavior are likely to be shy and inhibited. Like other shy and inhibited boys, they tend to be anxious in the early years and to suffer from separation anxiety disorder, often becoming depressed later in life. This suggests that cross-sex-typed behavior and gender identity issues are not an isolated finding but part of a broader picture that includes sensitivity to attachment disruption and a predisposition to affective disorder. The cross-gender behavior could be the child's way of managing separation anxiety by becoming more like the mother.

Gender identity disorder is distinctly uncommon in males and extremely rare in females. Most young children with cross-sex-typed behavior do not qualify for a diagnosis of gender identity disorder because the behavior is not extreme or they are not distressed enough about their situation. Those who develop gender identity disorder represent a more disturbed subgroup with marked behavioral and peer problems; more than half qualify for a diagnosis of *separation anxiety disorder* perhaps related to temperamental variables or an overly close and ambivalent relationship to the master.

Boys with gender nonconformity are perceived by adults and girls as more attractive or handsome than other boys, which suggests that they are well accepted by parents, teachers, and female peers. However, in grade school and junior high they are likely to be labeled “sissy” or “fag” by male peers and can become isolated and depressed. Most learn how to moderate their behavior so that they are more accepted by peers and this favorable adaptation prevents them from developing gender identity disorder. A few youngsters, usually those who are markedly different from their classmates, become so affectively and cognitively preoccupied with their gender discordance that they cannot function socially or academically. In adolescence they dwell on their appearance, which is a preoccupation more typical of adolescent females. If this persists, it often leads to depression and sometimes suicide.

Three quarters of boys with cross-sex-typed behavior later become homosexual or bisexual. This is the case whether or not they have had therapy, have been able to suppress the incongruent behavior, or have developed gender identity disorder. Later in life a tiny minority, convinced that they are really female, take hormones, live as females and may request sex change surgery. The outcome for girls with cross-sex-typed behavior is unclear and there are no prospective studies.

SEXUAL ORIENTATION

Sexual orientation refers to an individual's overall sexual responsiveness to men, women, or both. Once established, sexual orientation is usually but not always constant throughout life. Approximately 4 to 6 percent of men and 2 to 3 percent of women are exclusively homosexual; a smaller percentage describe themselves as bisexual. Other cultures reveal a similar percentage of homosexuals. Homosexuality is not a disorder of gender identity and does not connote psychopathology; homosexual men may or may not be effeminate. They differ from the rest of the population in being somewhat less devoutly religious and better educated.

Gay men describe themselves as having felt different from their same-sex peers from early childhood. Lesbian women report having felt less feminine and less beautiful than peers, imagining that they were male, preferring boy's games, and being called “tomboy.” However, many women who are not gay also report these experiences.

Gay men usually become aware of homoerotic fantasies in early adolescence. At the same time they may have erotic fantasies about women. This generates confusion and considerable conflict, which in turn contributes to the high rate of suicide and school drop out among gay youth. Indecision and bewilderment often persist until a clear homosexual identity is established in early adulthood.

Compared to gay men, bisexual men are more conflicted, alienated, and depressed. This could be related to greater biological discordance or to greater difficulty in defining an identity in a society that prefers neat categories. Also, bisexual men with deep-seated problems may be less able to define themselves as male or female.

Compared to gay men, lesbians are more flexible and less conflicted about adopting a lesbian role and identity. Lesbian adolescent girls are less likely to be rejected by peers and to have more social support available. It is fairly common for girls to experiment sexually with female peers and for heterosexual married women to enter a homosexual relationship following divorce. Also, more women than men claim to be bisexual.

Etiology Certain animals are known to engage in sexual activity with members of the same sex; a smaller number are exclusively homosexual. Homosexual relationships can help the individual survive or foster the survival of the group. In some species, females who engage in sexual activity with each other are more willing to share food, to forage together, and to groom each other.

Psychosocial Factors Psychosocial forces cited in the literature and thought to further male homosexuality include: (1) separation-individuation issues, with an overly close or hostile-dependent relationship with the mother; (2) mothers' fear and devaluation of men; (3) parental preference for a girl; (4) trauma, including death of a caregiver; and (5) an emotionally distant or absent father.

Analytic theorists suggest that lesbian relationships are often a search for the bodily pleasure found in the early mother-daughter union. Early erotic experiences that can bias sexual orientation may also include frequent enemas, prolonged molestation, and sex play. Homosexual men and women report more early anal-erotic and homoerotic experiences within the family than do heterosexual individuals.

Genetic Factors Genes are strong contenders as progenitors of sexual orientation. Genes may influence sexuality by changing the organization or the structure of the brain or by affecting the production of neurohormones and transmitters. Minute changes in endogenous hormones could subtly recast attitudes, thoughts, emotions, and behaviors. Alone, or in conjunction with environmental influences, this could bias the individual toward homosexuality.

Family studies support a genetic basis for homosexuality. Homosexual men are more likely than other men to have homosexual brothers. Monozygotic homosexual

twins are more than twice as likely as dizygotic twins to be homosexual. Genetic influences are noted in lesbian women also. However, other variables must play a part because a significant number of monozygotic twins are discordant for homosexuality. More than one gene, as well as other biological and environmental influences, are likely to be implicated.

When the extended family of known homosexual persons is examined, more than the expected number of homosexual persons is found, but only on the mother's side of the family. This suggests transmission via the X chromosome. Indeed, researchers have correlated homosexuality with the inheritance of five markers at the tip of the long arm of the X chromosome, in the Xq28 region.

If homosexuality is largely genetic in origin, then children of heterosexual parents adopted by homosexual partners would not be more likely than the rest of the population to be homosexual. Although other factors such as role modeling and these parents' strong wish to raise a heterosexual child are also involved, these children are no more likely than the rest of the population to become gay or lesbian.

Brain Structure Differences in the brain structure between heterosexuals and homosexuals would ultimately result from genetic influences. Differences reported include an increase in the size of the suprachiasmatic nucleus of the hypothalamus, diminished size of one of the sex dimorphic interstitial nuclei of the anterior hypothalamus, and an increase in the size of the anterior commissure. Genetically male transsexuals who from an early age have been convinced that they are female demonstrate a smaller nucleus in the preoptic area of the hypothalamus, a nucleus that is typically larger in males and that plays an essential role in male sexual behavior. The auditory system of lesbian and bisexual women seems to function more like the auditory system of men. This finding must be replicated.

Brain Hormones Steroid hormones, including estrogens and androgens, were thought to be produced only in the adrenals and the gonads. Recently, endogenous steroid hormones have been found in localized areas of the brain. These hormones are called *neurosteroids* because they are formed by neurons in the same way that the gonads and the adrenals produce steroids. Neurosteroids may organize localized areas of the brain toward maleness or femaleness in the prenatal period and may affect postnatal behavior directly or through the earlier organizational changes. The existence of a third, independent hormonal pathway could explain why some men who look and behave very masculine are homosexual or why some persons are able to maintain sexual function following castration.

Another possibility that is currently under investigation is that prenatal stress and a deficiency of enzymes involved in steroid synthesis could predispose the fetus toward homosexuality. Corticotropin (ACTH) administration significantly increases production of the cortisol precursor 21-deoxycortisol in homosexual men and women, compared to nonhomosexual subjects; a similar increase occurs in the mothers of homosexual men.

Peripheral Hormones Earlier research tried to establish a link between homosexuality in males and lower plasma testosterone levels but no such link has ever been demonstrated in males. About one third of lesbian women, however, do present with higher levels of testosterone than the average woman but these levels are still well below the levels found in men. Small increases could result from differences in social dominance or self-efficacy.

Immunological Factors Homosexual men are far more likely than other men to be born late in the birth order and to have more older male siblings. Conversely, parents who produce many sons are more likely to produce extremely effeminate, homosexual sons. Effeminate boys with gender identity disorder also tend to be born late and to have older male siblings. Several explanations are possible, one of which is based on immunology. Long before a mother gives birth to a male fetus, fetal cells are circulating in her bloodstream. These persist for as long as 27 years following the birth of the child. The presence of male cells could provoke an immune reaction against Y chromosomal material, which theoretically could lower prenatal brain testosterone in later-born males, thus affecting the structure and function of the brain. Later-born male infants are known to have lower levels of testosterone than first-born males, and infants spaced closely have lower testosterone than infants born 4 or more years apart.

Homophobia A strong antigay bias, called *homophobia,* exists in our society. Homophobia is based on social sanctions by which anyone who deviates from expected norms of gender role may be criticized or rejected; sanctions are stricter for males than for females. Individuals who repress homosexual inclinations are more strongly homophobic than those who are less inclined toward homosexual impulses. In essence, they reject the homosexual parts of the self by rejecting all that is homosexual. If a biological basis for homosexuality is established, homophobia should diminish and it would be easier for individuals to accept themselves and to appreciate the uniqueness and diversity of human nature.

49.10 IDENTITY PROBLEM AND BORDERLINE DISORDERS

VICTOR M. FORNARI, M.D., AND DAVID PELCOVITZ, ꟻH.D.

IDENTITY PROBLEM

The development of an identity has been the subject of much debate, and numerous efforts have been made to describe the process that leads to identity formation. Failure to negotiate an identity is described in the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) as an “identity problem” in the section entitled “Other Conditions That May Be a Focus of Clinical Attention.” As defined in the DSM-IV, the criteria for identity problem make it very difficult to use rigorous research methodology to clarify this condition's validity.

Over the past four decades the syndrome of identity confusion was described by Erik Erikson in his classic paper “The Problem of Ego Identity.” Erikson described a group of adolescents who failed in the negotiation of the moratorium provided by society between childhood and adulthood. Adolescents who experienced difficulties with the formation of an identity shared clinical features with individuals with borderline personality disorder. Identity formation has been described by Erikson as a control task of adolescence.

> The young person in order to experience wholeness, must feel a progressive continuity between that which he has come to be during the long years of childhood and that which he promises to become in the anticipated future; between that which he conceives himself to be and that which he perceives others to see him and to expect of him ... Identity is a unique product, which now meets a crisis to be solved only in new identifications with age mates and with leader figures outside the family.

Definition The concept of identity problem represents the DSM-IV current nosology “when the focus of clinical attention is uncertainty about multiple issues relating to identity such as long-term goals, career choice, friendship patterns, sexual orientation and behavior, normal values, and group loyalties.” Identity problems may appear as a feature of a variety of other psychopathology during adolescence, such as mood disorders, borderline personality disorder, posttraumatic stress disorder, and schizophrenia.

History Identity crisis during adolescence gained widespread attention during the late 1960s and early 1970s when many adolescents rejected their parents' mainstream values, and ideals and chose alternative lifestyles.

Identity disorder was considered a childhood variant of borderline personality disorder. Identity disorder was included in the third edition of DSM (DSM-III) and retained in the revised third edition (DSM-III-R) without any systematic research. There have been no systematic empirical research studies to date regarding the diagnosis of identity disorder. Some believe that in certain individuals the symptoms may reflect normal development and in others be a manifestation of established mental disorder.

Comparative Nosology DSM-III and DSM-III-R included the category identity disorder as one of the disorders usually first evident in infancy, childhood, or adolescence. The disorder was described for children and adolescents with “severe subjective distress regarding uncertainty about a variety of issues relating to identity,” which resulted in social or school functional impairment. These symptoms were required to be present for at least 3 months and not result from a mood disorder or a psychotic disorder.

The relation between identity disorder and borderline personality disorder has not been established. Most adolescents who struggle with issues regarding their identity and values do not develop borderline personality disorder. In DSM-IV, however, identity disorder was deleted from the classification of psychiatric disorders. As David Shaffer and his colleagues describe in their review of DSM-IV childhood disorders, it was decided that identity disorder could not be substantiated as a valid psychiatric syndrome, defined by reliably ascertained signs and symptoms and clearly distinct from other psychiatric disorders. In addition, it was difficult to distinguish identity disorder from the normal crisis of adolescence.

Epidemiology No reliable information exists on the frequency of occurrence, age of onset, or prevalence of identity problem. Identity problem does not qualify as a mental disorder but is related to identity concerns specific to a developmental phase. Therefore, it may be impossible to determine the true epidemiology of identity problem.

In *From Teenage to Young Manhood: A Psychological Study,* Daniel Offer and Judith Offer describe approximately one third of a model sample of adolescent boys who experienced a tumultuous course during their adolescence. This description resembles the features of identity problem. It is generally assumed that identity problems are more prevalent in industrial societies than in developing countries. This is based on the belief that traditional cultures remain bound by a set of stable values, ideals, and norms. Authority and hierarchy are clearly defined and leave little room for personal choice. Industrial societies offer a wide array of choices in occupations, relationships, lifestyles, and ideals. Greater emphasis is placed on personal, educational, and occupational achievement, with adolescents often leaving home by age 18 to attend university. In contrast, in developing countries, greater emphasis is placed on the extended family and the importance of traditions.

Etiology As in all human development, a variety of factors may contribute to the ultimate outcome. Identity problem may have predisposing factors, which may be biological, psychological, or social. The cause of identity problems is generally multidimensional and can best be evaluated on the basis of the development tasks outlined by Erikson in 1968 and Peter Blos in 1975. The task challenging the adolescent is to sort out, integrate, and develop a sense of identity following the dramatic transformation brought about by puberty and its concomitant physical changes. Following these changes, there is heightened sexuality with reproductive capacities. This brings with it greater demand for psychosocial separation from parents to find greater independence and the capacity for adult sexual intimacy. Erikson states that achieving a sense of inner identity results in persons experiencing themselves as “whole.” According to Blos, a central task of adolescence is to elaborate on the separation.

Diagnosis and Clinical Features The category of identity problem can be used when the focus of clinical attention is uncertainty about multiple issues relating to identity such as long-term goals, career choice, friendship patterns, sexual orientation and behavior, moral values, and group loyalties.

Friendship Patterns In a recent review of over 80 empirical studies investigating the role of friends in child development, Andrew F. Newcomb and Catherine L. Bagwell present impressive evidence regarding the crucial part that friends play in forming a healthy identity, fostering a positive self-concept, and promoting healthy psychological functioning. In recent years, a number of studies have also demonstrated the existence of a strong positive correlation between healthy friendships and school success and effective problem-solving skills. Rejected children tend to fall into two groups: disruptive children with high levels of aggression and socially withdrawn children who make easy marks for their peers. The work of Susan Harter and her colleagues has demonstrated that in both childhood and adolescence friends tend to be similar to one another in abilities and outlook. Rejected children tend to become friends with other rejected children, and aggressive children with other acting-out children. It is therefore not surprising that studies find that a major predictor of antisocial behavior is a situation in which an adolescent's peer network is composed of friends who smoke, drink, use drugs, or have a negative attitude toward education. Conversely, children who are attracted to friends with positive outlooks are more likely to develop positive school-related attitudes, career aspirations, and achievement.

A child's ability to interact appropriately with friends is a major contributor to formation of a healthy identity. Although infants may have regular contacts with other infants, peer relations are thought to exist in infancy in only a very loose sense. During the second year, for the first time, toddlers engage in simple reciprocal play that gradually gives way to parallel play, typically between ages 2 and 3. Social interaction during this period is typified by an awareness of each other's play without an accompanying sharing in a common goal. Cooperative play typically begins by age 3 and is consolidated by increasing interaction with peers in preschool

programs and other social activities arranged by parents. Between the ages of 3 and 6, most children begin to seek out the company of peers, prefer to associate with a member of the same sex, and actively engage in play that involves imitating adult roles with which they are trying to identify. Between the ages of 6 and 12, the children's circle of friends gradually widens, and social interactions become better organized. With the onset of adolescence, the range of acquaintances broadens, and friends are typically recruited from a wider pool on the basis of common values, interests, and styles. During adolescence, intimacy becomes an increasingly important component of friendship. Sharing thoughts and feelings with peers in a supportive and validating atmosphere is a key ingredient in the formation of identity.

In evaluating possible identity problems in children, the following aspects of the child's relationships with friends should be considered: (1) the number of friends (a consistent finding in the literature is that the amount of time the child spends with peers relative to that with family members increases from infancy through adolescence); (2) the quality of friendships (e.g., most girls show an increasing capacity for self-disclosure and intimacy in their friendships during the preadolescent years); (3) the behavioral and emotional difficulties of friends (since a major contributor to a child's identity, values, and behavior is shaped by friendships, a child or adolescent who interacts mainly with behaviorally disordered children is at increased risk for a variety of emotional and academic difficulties).

Sexual Orientation or Behavior Evaluation of normal and sexual behavior in children must be informed, in large part, by prevailing cultural, religious, and ethnic values. Since the norms for such behavior are constantly shifting, the mental health professional must be familiar with the standard in each child's neighborhood, school, and culture. Calvin Friedrich and his colleagues conducted the most widely cited empirical studies on normative child sexual behavior. He concluded that overt sexual behavior in boys increases from ages 2 to 4 and then gradually declines until age 12. In contrast, in girls overt sexual behavior steadily declines from ages 3 to 12. During the early school years, behaviors associated with adult sexuality (e.g., masturbating with objects, French-kissing, placing the mouth on another child's sex parts) are relatively rare in American children and should raise the possibility that the child might be sexually abused or overstimulated by inappropriate exposure to adult sexuality. Differences in the behavior of infant boys and girls tend to be subtle. Although some empirical evidence indicates that before the toddler years, boys tend to be more active and girls more vocal, it is not until approximately the age of 2, that clear differences in behavior emerge. Boys are more likely to prefer blocks, transportation toys, and rough-and-tumble play, while girls prefer more sedentary activities such as doll play and art work. The research of Kenneth Zucker, Richard Green and other experts in gender identity points to the importance of not viewing marked cross-gender behavior in young children as “just a phase.” A noticeable difference in patterns of sex-typed behavior during the preschool years should raise the possibility of a diagnosis of gender identity disorder. Many children with gender-atypical behavior will not display the persistent, intense distress required for this diagnosis, nor will they repudiate their basic sense of being male or female. Even if the child does not meet full criteria for gender identity disorder, a pattern of cross-gender interests in toy choices, fantasy play, or sex of playmates should raise the possibility of atypical gender development. An association between childhood gender nonconformity and adult sexual orientation has long been documented by the research of Zucker, Green, and others. Many, though not all, gay or lesbian adults recall a childhood marked by preference for cross-gender play. Adult retrospective research has also determined that although same-sex sexual orientation is often recognized by the child at an early age, the process leading to the insight that this is not just a phase typically does not emerge until adolescence or later. In many adolescents, this process is accompanied by a painful struggle that may entail periods of denial, suppression, and failed attempts at developing romantic or sexual relationships with the opposite sex. Achieving positive self-identification and ultimate integration and acceptance of sexual orientation may require the assistance of a mental health professional who is sensitive to the complex challenges to identity formation faced by these children and adolescents.

Values and Moral Development The gradual development of a child's sense of what is right or wrong, independent of the presence of parents or other adult authority figures, is a major component of overall identity. The pioneering work of Jean Piaget and Lawrence Kohlberg on the developing sense of morality in children has been expanded in recent years through a series of longitudinal studies conducted by (among others) Nancy Eisenberg and her colleagues and by the research of Barbara Stillwell and her associates.

Toddlers have only the most rudimentary conception of morality. This is perhaps best illustrated in their play, which typically involves no formal rules. As the child approaches the preschool years, a rigid set of rules emerges, albeit in a manner that is viewed by the children as inflexible and as fixed in stone as the laws of physics. The external conscience, which is present in most preschoolers, is characterized by an ability to label behaviors “good” or “bad” as derived from the outside authority of parents or other adults. This view gradually gives way to the child's conception of right or wrong as determined by self-interest; they obey rules or cooperate with peers as long as they get something in return. During the elementary school years, children's values reflect concern with the approval of others and an accompanying desire to display stereotypically “good” behavior. As development proceeds, a more sophisticated view of morality emerges. In sophisticated adolescents, moral reasoning is based on a belief that society must be based on laws and regulations. Individual needs are not considered more important than societal needs. Stillwell's research has demonstrated that during early adolescence, children acknowledge the importance of rules and regard for the feelings of others as important determinants of morality. Their conscience is viewed as a component of their personality, which they at times listen to, at times argue with, and at times ignore. In midadolescence, the “confused conscience” is described by Stillwell and her colleagues as a period of conflict and indecisiveness with the “gray” zones of good and evil. Conflicting messages adolescents receive from their peer groups and adult authority figures are reflected by adolescents' confusion regarding what they consider their true values. In late adolescence this period of uncertainty gives way to a more integrated conscience marked by flexibility, increasing ability to handle ambiguous moral situations, and a return of confidence regarding moral values.

When a child or adolescent displays values with sharp discrepancies from those of the family, culture, or society, the clinician should determine whether this reflects atypical identity development, risk for conduct problems, or part of a more normative process of identity development.

Career Choice Vocational identity is an important component of overall identity. In adults, having a job that is performed competently and is valued by society is an important contributor to a stable identity and a sense of general well-being. Recent longitudinal research has documented better long-term psychosocial and educational outcomes in at-risk children who can maintain a part-time job through adolescence. Research conducted by the second author and his colleagues for the DSM-IV posttraumatic stress disorder field trials on the sequelae of interpersonal victimization found that victims of child abuse are likely to have lower career aspirations than their nonabused counterparts.

Wim Meeus and other researchers have documented various approaches that adolescents may take in developing their occupational identity. Good outcomes are associated with adolescents who are satisfied with their occupational choice after openly exploring a variety of alternatives. Choosing a moratorium, in which options regarding occupational choice are left open and various alternatives are explored as part of a long-term process of defining ultimate occupational identity, is also viewed as a generally adaptive approach to defining this aspect of identity. Difficulties with the adolescent's emerging identity may be present when the adolescent indicates premature foreclosure by dealing with anxiety regarding the future by chosing a career course without exploring any options. Difficulty with vocational choice may also be indicated by adolescents who show signs of identity diffusion that may be indicated by a total lack of concern regarding planning for a future vocation or a view that luck will take care of finding a satisfactory vocation. Adolescents who take either of these two paths should be evaluated, as studies have found this approach to vocational choice to be associated with more difficulties with self-concept, educational achievement, and social adjustment.

Jane was a 16 ½-year-old white girl in the 11th grade, the middle of three children and resided with her parents. She had an older brother who was a junior in college and a younger sister in the 8th grade. Jane was referred for psychotherapy because of a concern about “poor school performance and poor choice of friends.” Jane reported to her therapist that she had lost interest in school because she was not clear what her future career goal would be. Feeling that she could not be as good a student in high school as she had been in grade school, she had withdrawn from academic work, and her school performance deteriorated. Previously very social, Jane began to withdraw from friends and hang out with peers with behavior problems. Jane's parents were concerned about the company she was keeping, and they would frequently argue about where she was going. Jane began to use marijuana to make herself relax and described a sense of uncertainty about her future goals and her friends. Jane's older brother, an accomplished student, was successfully completing his junior year in college, and Jane felt that she could never live up to his standards. A younger sister was in honor classes, and Jane felt inadequate compared with her. Although in good physical health, with no history of medical problems and no prior mental health contact, Jane exhibited significant distress.

On mental status examination, she appeared her stated age and related in a friendly and cooperative manner. Her mood appeared neutral, and her affect was wide range and appropriate. She stated, “I don't know why I'm here. I don't think I have a problem. My parents think I have a problem.” There was no evidence of suicidal or homicidal ideation. She was oriented to person, place, and time and appeared of at least average intelligence. Her fund of information was commensurate with her educational background. Jane did not meet criteria for major depressive disorder, an anxiety disorder, alcohol or other substance use disorder or any personality disorder.

Jane was struggling with her long-term career goals, her friendship patterns, and her position in her family. Jane struggled to accept her capacities as compared to those of her older brother and younger sister. The focus of therapy was on issues related to her emerging identity rather than any Axis I or II disorder.

Pathology and Laboratory Examination There are no specific laboratory tests or results for identity problem. No studies have established any consistent neuropathological or imaging techniques specific for this clinical entity.

Differential Diagnosis Identity problem can be differentiated from the normal conflicts of adolescence. Normal adolescence is not generally associated with deterioration in occupational, school, or social functioning.

Normal adolescents may argue with their parents, but their relationship with them remains intact. Adjustment disorders by definition are secondary to a specific stressor and are time limited. Although precipitating stressors may often occur at the onset of an identity problem, concerns with identity issues such as career choice, gender identity, and future plans are far less prominent in the adjustment disorders.

Identity problem must be differentiated from identity concerns that may represent the prodromal manifestations of schizophrenia, schizoaffective disorder, schizophreniform disorder, and mood disorders. Psychotic symptoms such as hallucinations and delusions or disturbances in thinking processes such as thought blockage, tangentiality, or flight of ideas are not present in identity problem. Adolescents who are struggling with identity issues may have subjective anxiety and confusion, which often makes the initial differential diagnosis difficult.

The most difficult differential diagnosis is that with borderline personality disorder. Confusion regarding identity concerns may be present in both conditions. In borderline personality disorder, the dramatic clinical picture includes a much more complex set of diagnostic criteria such as chaotic, unstable sexual and interpersonal relationships, alternating idealization and devaluation, intense anger, self-destructive behaviors, and chronic dysphoria. Borderline personality disorder does not resolve in several months to a year but generally persists throughout adulthood, often with significant morbidity and mortality.

Course and Prognosis Because there has been no systematic research to validate identity problem as a mental disorder, no data exist regarding the natural course of this disorder with and without treatment.

Treatment Because identity problem remains a poorly defined clinical entity, little is known about the most effective intervention strategies. There have not been any systematic studies testing the efficacy of treatment approaches; thus the literature includes only untested clinical accounts. The clinical literature emphasizes establishing a therapeutic alliance as a critical step in psychotherapy with adolescents with identity problem (i.e., developing an empathic and supportive relationship with a therapist who can engage the adolescent to clarify the conflicts). The capacity to collaborate productively allows the adolescent to address maladaptive coping mechanisms.

Family therapy can be clinically useful despite the lack of systematic studies demonstrating significance. Family therapy may help parents understand their adolescent child's new developmental level. Parents can then attempt to communicate more effectively without excessive struggle for control.

Group psychotherapy may offer the adolescent an opportunity to minimize a sense of isolation and provide a way of relating to peers and receiving peer feedback. Psychopharmacotherapy is not indicated for identity problem. Medications may be used to address specific symptoms such as anxiety or depressed mood.

BORDERLINE DISORDERS

Perhaps no disorder evokes as much negative emotion, intense hatred, or images of rage as borderline personality disorder. As adolescents, these young people often elicit contempt if not frankly murderous impulses; however, few if any disorders have been as controversial. Many consider it a legitimate diagnostic entity; others regard it as a “waste basket” for individuals who do not fit neatly into any other single category. Some believe that many individuals who receive this diagnosis may have a form of complex posttraumatic stress disorder, particularly following chronic child sexual abuse. The existence of borderline personality disorder during childhood and adolescence remains hotly debated because, it has been argued, adolescence is an active period of personality development. Borderline disorders often do not reflect the currently accepted DSM-IV diagnosis of borderline personality disorder, but rather are a variety of childhood manifestations often characterized by severe forms of psychopathology on the border between neurosis and psychosis.

The concept of borderline disorders in children and adolescents remains controversial. In 1990, Paulina Kernberg wrote that borderline personality disorder exists in children under age 12. Indeed, Kernberg argues for acceptance of the concepts of childhood personality and childhood personality disorder. Theodore Shapiro argues against such concepts; he believes it is problematic to use a designation designed for adults that does not take into consideration the developmental issues of childhood.

Definition Borderline disorders may reflect the diagnostic criteria outlined by DSM-IV for borderline personality disorder: a pervasive pattern of instability of interpersonal relationships, self-image, and affects, and marked impulsivity beginning by early adulthood and present in a variety of contexts, indicated by at least five of nine specific symptoms. Borderline conditions may also represent something quite distinct. They may be characterized by a wide variety of severe childhood psychopathology.

History During the past 50 years, clinicians have described seriously troubled children whose disturbance in ego functions was less severe than that in psychotic children but more serious than that displayed by neurotic children. In 1949 Margaret Mahler and her colleagues categorized these children at the mild end of a clinical and developmental range that extends to the most severe psychotic conditions, the autistic and symbiotic psychoses of childhood. Mahler proposed the terms “benign” or “borderline” psychosis, a precursor to the idea of a schizophrenic spectrum in which borderline represents a less severe form.

In 1954 Rudolf Ekstein and Judith Wallerstein proposed the term “borderline” to describe children who were not on the way to psychosis but rather behaved in a “characteristic pattern of unpredictability which is paradoxically one of their most predictable aspects.” Thus, the concept of “borderline” as a stable clinical entity was defined by ongoing and rapid shifts in ego functioning. These early efforts generated an interest among psychoanalysts that led to further speculation about the developmental and clinical aspects of borderline children. Between the late 1950s and the late 1960s a number of authors described children with a wide range of difficulties. These children displayed low frustration tolerance, uneven development, a tendency to withdraw into fantasy or to regress into primary process in response to stress, and multiple somatic and anxiety symptoms.

By 1975, the important and influential work of Otto Kernberg defined borderline as a level of personality organization. Several types of personality disorders including schizoid, paranoid, antisocial, and narcissistic generally function at a borderline level of personality organization, according to Kernberg.

In DSM-IV, borderline personality disorder is designated as one of the Cluster B (or dramatic) personality disorders. This is consistent with the empirical, atheoretical approach of DSM-IV, which also includes narcissistic, antisocial, and histrionic personality disorders in Cluster B.

Comparative Nosology Personality disorders have been defined as relatively enduring and pervasively maladaptive patterns of experiences, relationships, and coping styles. Children and adolescents are involved in fluid developmental processes in which their personalities and bodies are changing at different rates, creating equilibrium changes in their relationship to their family and friends and within themselves. Is it valid to assign the diagnosis of a personality disorder to a child or adolescent? Are there enough data to support a distinct diagnostic entity of borderline or borderline personality disorder in childhood? Is there a clinical continuity between borderline children, borderline adolescents, and borderline adults? Does *borderline* refer to a discrete disorder as DSM-IV suggests or a level of developmental attainment as Kernberg describes? What is the relationship between borderline disorders and common Axis I diagnoses of children such as conduct disorder, attention-deficit disorders, anorexia nervosa, substance abuse, posttraumatic stress disorder, and depressive disorders? These and other important questions remain unanswered.

The common comorbid association of Axis I disorder raises the question whether borderline is really a complicated form of Axis I disorders. The common finding of a history of sexual abuse raises the question whether borderline is a pejorative designation for individuals who suffer a complex posttraumatic stress disorder as a consequence of protracted abuse as suggested by the second author and Sandra Kaplan and their colleagues. The diagnosis of complex posttraumatic stress disorder requires that an external stressor cause the pattern of symptoms seen in this syndrome. This represents a departure from the atheoretical approach taken by DSM-IV.

Developmental research has begun to generate some data concerning the notion of personality disorders in childhood. Prospective studies have shown how deviant

attachment patterns, tempermental constellations, and disturbances in early childhood relationships can evolve into extreme rigidity in relationships, coping mechanisms, and experience. Kernberg has contended that children can indeed display personality disorders. Basing her assumptions largely on clinical experience, Kernberg has advocated the validity of the concept of borderline personality in children under 12 years of age. Theodore Shapiro has cautioned that a good deal of research is needed to establish the validity and reliability of borderline personality disorder in childhood and adolescence.

One retrospective study has questioned the ability to discriminate between borderline and nonborderline children. More-recent studies by Pamela S. Ludolph and colleagues and Stuart J. Goldman and colleagues suggest that semistructured interviews such as Gunderson's Diagnostic Interview of Borderlines and DSM-III-R criteria can be applied to children. Longitudinal follow-up studies are needed to clarify whether children diagnosed as borderline grow into adolescents and adults with borderline personality disorder.

Epidemiology The first longitudinal study examining the childhood antecedents of a range of DSM-III-R personality disorders in a community-based sample was reported by David Bernstein and his colleagues in 1996. Although recent evidence supported the view that adolescence is a period of risk for the onset of personality disorders, little was known about childhood antecedents of adolescent personality disorders. Two well-controlled studies support the continuity of borderline symptoms from childhood through adolescence and adulthood. Bernstein and his colleagues reported in 1993 that personality disorders in adolescents peaked at age 12 in boys and age 13 in girls and declined thereafter.

The prevalence of personality disorders in adults was reported by the National Institute of Mental Health Epidemiologic Catchment Area program in the second stage of the Eastern Baltimore Mental Health survey in 1981, published in 1994. The adult subjects were directly examined by psychiatrists using a semistructured method that allowed diagnosis of all DSM-III personality disorders as well as comorbid DSM-III psychiatric disorders. The prevalence of personality disorders was reported to be 5.9 percent (9.3 percent when provisional cases were included). Men were reported to have higher rates than women. Individuals who were separated or divorced had the highest rates. Reliable epidemiologic data regarding borderline personality disorders in children and adolescents are limited.

John F. Clarkin and Cynthia Sanderson estimated the prevalence of borderline personality disorder in adults to be about 2 percent of the general population, about 8 to 10 percent among individuals seen n outpatient mental health clinics, and about 15 to 20 percent among psychiatric inpatients. It ranges from 30 to 60 percent among clinical populations with personality disorders. Borderline personality disorder is about five times more common among first-degree biological relatives of those with the disorder than in the general population. There is also an increased familial risk for substance-related disorders, antisocial personality disorder, and mood disorders. Borderline personality disorder is three times more frequent in women than men.

The pattern of behavior seen in borderline personality disorder has been identified in many settings around the world. Adolescents and young adults with identity problems, especially those accompanied by substance use, may transiently display behaviors that give the impression of borderline personality disorder. Such persons display emotional instability, existential dilemmas, uncertainty, anxiety-provoking choices, conflicts about sexual orientation, and competing social pressures to decide on careers.

Etiology A variety of theories exist regarding the etiology of borderline personality disorder. Each theory presents a different perspective, with varying amounts of theoretical and empirical support. Currently, a combination of genetic, biological, and environmental factors is believed to contribute to the abnormal behaviors related to deviant personality development.

Biological Factors Several studies have examined the incidence of psychopathology in first-degree relatives of individuals with borderline personality disorder. Borderline personality disorder patients have significantly higher rates of depressive disorders, alcohol use disorders, and antisocial personality disorder than schizophrenia patients. This and other family data suggest that borderline personality disorder is related to the affective spectrum of psychopathology and not to the schizophrenic spectrum. However, the relation of borderline personality disorder with concurrent or comorbid schizotypal personality disorder may be part of the schizophrenic spectrum and may exist in a subgroup of patients.

Evidence for biological and neurotransmitter causality in borderline personality disorder is compelling. The serotonin system, in particular, has been associated with low levels of behavioral inhibition in individuals with antisocial behaviors. Biological abnormalities in individuals with borderline personality disorder have been associated with affective instability, impulsivity, anxiety, and cognitive disorganization. Several small open trials of the selective serotonin reuptake inhibitor fluoxetine (Prozac) in individuals with borderline personality disorder demonstrated improvement in such core symptoms of the disorder as impulsive aggression following treatment. These and other findings support a role for 5-hydroxyindoleacetic acid in borderline personality disorder and have generated interest in the use of specific pharmacological probes to clarify further the role of serotonin in this disorder. In one study, subjects with borderline personality disorder were challenged with oral methchlorophenylpiperazine (mCPP) or placebo. Following mCPP the patients experienced decreased anger and fear. The male patients with borderline personality disorder had higher cortisol concentrations than the normal male subjects and marginally blunted prolactin responses after receiving mCPP. These results suggest serotonergic dysfunction in borderline personality disorder.

Positron emission tomography has been used over the past decade to probe for biological differences in regional cerebral blood flow in persons with borderline personality disorder. These individuals were reported to have a significant decrease in frontal cortex metabolism in one area above the canthomeatal line and significantly increased metabolism in another area above the canthomeatal line. These and other studies have investigated the hypothesis of a relation between frontal lobe cerebral rates of glucose metabolism and a lifetime history of aggressive impulsive difficulties.

There has been increased interest in the role of biological markers of borderline personality disorders. The dexamethasone suppression test, the thyrotropin-releasing hormone test, and sleep studies no longer indicate that borderline personality disorder is related to depression, although there is probably an affective subgroup. There may be new evidence that some subgroups of borderline personality disorder overlap with schizophrenia. There is new evidence regarding serotonin studies and new directions for understanding suicidal, aggressive, and impulsive traits. The tendency to mood lability, anger, and irritability in individuals with borderline personality disorder clearly interferes with development of a cohesive sense of self. Parents of these individuals, often vulnerable themselves to mood and personality disorders, and their children become involved in coercive cycles of anger and rejection followed by desperate attempts at resolution. The child psychiatric literature has long described the atypical ego development, impulsivity, and learning problems of many borderline children and adolescents.

Strong clinical overlap exists between the symptoms of the disruptive behavior disorders, particularly attention-deficit/hyperactivity disorder and conduct disorder, and those of borderline personality disorder. Other investigators report a link between learning disabilities and disruptive behaviors in children and borderline personality disorder in adulthood. Attention-deficit disorders and reading disorders can both affect a child's development in a number of ways. Because the actions of inattentive and impulsive children seem to occur rather than result from choice, they experience little sense of guilt or control. Studies have found that juvenile delinquents whose behavior is dominated by borderline and impulsive symptoms constitute two of four overlapping psychological subtypes. These individuals often have little understanding of their own inner psychological world, and these impulsive angry youngsters often fuel the chaos in their families. A direct linear relation between constitutional vulnerability and development of borderline personality disorder in children and adolescents cannot be drawn. Most children with attention-deficit/hyperactivity disorder, mood disorder, or separation anxiety disorder do not go on to develop borderline personality disorder. In addition, there are children who develop borderline personality disorder who do not have attention-deficit/hyperactivity disorder, mood disorder, or separation anxiety disorder. Biological factors in the development of borderline personality disorder can be related to the disorder in at least two ways. A vulnerability may increase the likelihood of other problems, thus creating an environment that can result in borderline personality disorder, or the biological vulnerabilities may increase the symptoms or their severity, increasing the chance of bringing children with the disorder to diagnosis and treatment. Thus, clinical surveys of children with borderline personality disorder may need caution, because they represent an unclear reflection of biological factors in these disorders.

Psychodynamic Factors Most psychodynamic theories related to the development of borderline personality disorder have suggested significant deficits in the area of interpersonal relationships, particularly in separation individuation. Failing to internalize early mother-child caring because of hypothesized difficulties in normal separation individuation, the borderline child or adolescent often feels empty and anxious and lacks a stable sense of self. Psychoanalytic theories include a range of hypotheses to explain the cause of borderline personality disorders in children and adolescents.

Mahler's ideas regarding separation individuation and Otto Kernberg's theories regarding splitting have provided the most important framework for psychodynamic clinicians. Children between the ages of 1 and 3 go through a series of developmental stages during which they develop the capacity to internalize some of the soothing functions previously performed exclusively by caregivers and they develop an awareness about themselves and begin to integrate the good and bad images of the self and the object. These developmental processes allow children to begin to accept the reality of their existence as separate individuals and to develop object constancy. *Object constancy* refers to the ability to maintain relationships in spite of separation from or frustration with their loving caregivers. Both Kernberg and Mahler assert that difficulties in these developmental processes result in borderline psychopathology. According to Kernberg, the central feature of borderline psychopathology is the ongoing effort to hold onto all good idealized images of the self, which has to be protected from constantly lurking all-bad introjects activated

by separation, frustration, or the object's failure to live up to idealized expectations.

James Masterson describes certain patterns of mother-infant interaction that interfere with the separation individuation process and lead to borderline psychopathology. In this view, mothers of future borderline individuals find gratification in their child's dependency and reward passive dependent, “clingy” behavior. Gerald Adler postulated that the central feature of borderline psychopathology is the individual's inability to evoke the memory of a soothing, comforting object when facing distress. That deficit in internalization is attributed to the failure of the parent to provide an adequate holding environment as described by Donald Winnicott. As a result, an inner sense of emptiness, reliance on transitional objects such as drugs or food to provide comfort and soothing, and manipulative efforts to produce the attention and involvement of others develop.

Glen Gabbard summarized the various psychodynamic models of the development of borderline personality disorder and stressed the importance of the various early developmental theories regarding both the separation individuation process and constitutional vulnerabilities. These psychodynamic hypotheses tend to exaggerate maternal responsibility and ignore the role of others, particularly abusive and neglectful parents, in the pathogenesis of borderline personality disorder in children and adolescents.

Environmental Factors In recent years, dissatisfaction with the validity of applying the construct of borderline personality disorder to childhood victims of physical or sexual abuse has increased. At the same time, clinical and empirical studies of childhood victims of interpersonal trauma have demonstrated a subset of individuals who, following exposure to traumatic events, manifest a constellation of symptoms not fully captured by the reexperiencing, arousal, and avoidance symptoms that constitute posttraumatic stress disorder. Research during the past decade has shown that the impact of trauma on psychological adaptation differs at different stages of development and that earlier trauma affects subsequent maturational processes. The research of Bessell van der Kolk and his colleagues has shown that traumatic experiences, particularly if they occur in childhood or adolescence, interfere with the development of self-regulatory processes and with the capacity to manage subsequent stresses. In particular, the research of Richard Famularo and other experts in the field of child abuse and neglect demonstrated that childhood victims of physical and sexual abuse manifest a variety of symptoms more traditionally associated with a diagnosis of borderline personality disorder.

Profound changes in affect regulation and self-identity have long been noted in the clinical and research literature on childhood victims of interpersonal trauma. Most noteworthy is the consistent finding that childhood victims of neglect, physical abuse, and sexual abuse or a combination are at much greater risk for extended periods of anger, unmodulated aggression, apprehension, guilt and fear, alterations in their relationships to caregivers, and difficulty with intimacy. Research has also shown that age-appropriate psychological defenses used to cope with early traumatic experiences, such as denial and dissociation, are frequently used by traumatized individuals during periods of subsequent stress.

Virtually all of the nine criteria for borderline personality disorder have been noted in childhood victims of abuse. Affect dysregulation is described in the four criteria that include difficulty controlling anger, affective instability, impulsivity, and suicidal behavior, (criteria 4, 5, 6, and 8); alterations in relations with others is seen in the sensitivity to abandonment and unstable interpersonal relationships (criteria 1 and 2); disturbance in the sense of self is described in the identity disturbance criterion (criterion 3), and one of the most researched sequelae of abuse, dissociation, is the ninth borderline criterion. It is therefore not surprising that a number of recent investigations have documented histories of early interpersonal trauma in most adults and children diagnosed with borderline personality disorder.

A number of recent clinical and research studies have investigated the suitability of the diagnosis “complex posttraumatic stress disorder” to capture the broad range of sequelae of interpersonal victimization. As described by Pelcovitz and his colleagues, in preparation for the DSM-IV posttraumatic stress disorder field trials, which had an investigation of the validity of such a diagnosis as one of its goals, a list of symptoms typically seen in trauma survivors was generated by a survey of experts in the field and systematic review of the literature on the emotional and behavioral sequelae of childhood sexual abuse, physical abuse, crime, rape, incarceration in concentration camps, torture, and spouse abuse. This process led to a consensus definition of complex posttraumatic stress disorder that was in turn investigated in the field trials. Ironically, although not the intention of this team of investigators, these symptoms overlapped significantly with the diagnosis of borderline personality disorder. The symptoms of complex posttraumatic stress disorder include alterations in the following domains of functioning: alterations in regulation of affect and impulses, including difficulty modulating anger and sexual impulses, suicidal behavior, and risk taking; alterations in attention and consciousness, including amnesia and transient dissociative episodes; alterations in self-perception, including feelings of ineffectiveness, shame, damage, guilt, and responsibility for the trauma; alterations in relations with others, including difficulties with basic trust, a tendency to enter situations in which revictimization is likely, or responding to the trauma by victimizing others in the same manner that one was victimized; somatization, somatic symptoms for which no physical cause has been found; and alterations in systems of meaning, including feelings of despair and hopelessness and loss of previously sustaining beliefs. In DSM-IV, the symptoms of complex posttraumatic stress disorder are described under the “Associated Features” of the posttraumatic stress disorder diagnosis. In the 10th revision of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10), a virtually identical diagnosis is included in the category of lasting personality changes following catastrophic stress.

In recent years a series of empirical studies conducted by van der Kolk, the second author, and Susan Roth, have provided support for the validity of the complex posttraumatic stress disorder diagnosis. As predicted by trauma theory, complex posttraumatic stress disorder is more prevalent in victims of early trauma than of adult trauma, is more likely to be diagnosed in survivors of interpersonal than of man-made trauma, and has shown promise as a construct likely to generate more-effective treatments for trauma survivors than more traditional treatment approaches to borderline personality disorder.

Diagnosis and Clinical Features According to the DSM-IV, diagnostic criteria include the following; borderline personality of disorder is a “pervasive pattern of instability of interpersonal relationships, self-image, and affects and marked impulsivity, beginning by early adulthood and present in a variety of contexts...”

John was 17 years 9 months old when he presented for urgent consultation 6 weeks prior to high school graduation, referred by his high school psychologist because of concern that he was depressed. On presentation, John had made six cigarette burns along his left arm and three on his right arm. In addition, John reported having made several scratches with an Exacto knife 1 year before on his left arm. Blond and fair, John presented with blue-green hair. Prior to that, he reported that he had dyed it black several months before and then “cut it all off.” Subsequently, he dyed it orange, then purple, then pink. He was currently failing two subjects and getting a D in a third, and he reported that he was “smart but not interested in doing the work.” He had no prior contact with mental health professionals. John's school psychologist had referred him to the emergency room several days before, but John ran away, and this consultation was an effort to see “if there was any serious problem.” John's parents divorced when he was 18 months old, and he reported no subsequent contact with his father. John was the product of a full-term planned pregnancy with no complications in the newborn period. He was weaned from the bottle at 12 months of age, and other developmental milestones were reported normal. John lives with his maternal grandmother, mother, and older sister. In school, John did well through the 9th grade, but in the 10th grade his grades began to drop; in the 11th grade he did very poorly. As a senior, he has done hardly any work and there is concern that he may not graduate. He has no physical problems but does report allergies to pollen.

John reports chronic suicidal ideas for the past 2 years and cutting and burning himself on and off. He describes these self-mutilating behaviors as punishing himself for something wrong he has done and stops when he feels satisfied. John reports feeling comfortable only when depressed and feeling uncomfortable when not depressed and describes intense periods of crying that may shift into hysterical laughter. He describes several instances when he opens his eyes and does not know where he is for several minutes and then hears what people are saying but doesn't seem to make sense of it. He denies any history of physical or sexual abuse and denies drug or alcohol use.

A full-scale I.Q. of 116 placed him in the high average range and may underestimate his true potential. John is preoccupied with senses of worthlessness and guilt and accepts his sad fate of being chronically unhappy and empty as inevitable. He has significant difficulty with interpersonal relationships and lacks comfort with social skills. His social communications are likely to be strained. Interactions that involve sexual functioning are particularly distressing. He clings to avoidance stances to limit anticipated rejection. John reports “I am best when I am by myself.” He struggles with an ongoing sense of confusion regarding his life and his future.

Steven was a 3 ½-year-old white boy attending a therapeutic preschool, who lived with his mother, twin brother, and two older sisters. His mother was legally separated from his father. He was referred to a neurologist to rule out any neurological problems. The neurologist then referred Steven to the child and adolescent psychiatry outpatient department for psychiatric assessment. Steven and his mother were interviewed for 2 hours, and telephone contact was made with mother's therapist. The social worker at Steven's therapeutic preschool was contacted by telephone and forwarded clinical evaluations and psychological testing results.

“I don't know how to manage my son Steven. He has violent and aggressive behavior, like killing animals, kicking, punching, biting others, breaking furniture, smearing feces, banging his head and smashing things.” Mother said he had been aggressive from the beginning. Mother was married for 9 years and for the last 2 years has been legally separated. There had always been verbal and physical fights between his parents. Steven witnessed much aggression in the home. When he was 4 months old, his mother left him with his father and went to work; when she came back, he was “black and blue.” A similar incident occurred again. Mother described Steven as having a history of aggressive, impulsive, out-of-control and destructive behaviors. He spoils furniture at home, throws things, soils walls, and fights with his siblings. Steven killed some small animals such as hamsters and walked away without any concern or remorse. Mother also reported that Steven played with his feces and smeared it on the walls. When angry, Steven bangs his head. Mother was embarrassed to take him anywhere because he might fight with others or destroy property. According to the mother, Steven had been a difficult child from the beginning. He was attending a therapeutic preschool for his behavioral problems and, according to the mother and social worker, was not showing much improvement there.

He was physically healthy with no known medical problems. He was not on any medications. Steven had a history of head trauma at age 3. Computed tomography indicated a fractured skull. Steven's parents were legally separated, and for the last year his father had no contact with Steven or his siblings. Steven's father does not pay child support consistently. Mother disciplines Steven by yelling and restraining him by holding him. One maternal grandmother had diabetes. One of mother's uncles had multiple sclerosis. Steven's father is a substance abuser (alcohol, cocaine, marijuana, and heroin). The paternal grandmother was also an alcoholic. Patient's twin brother Frankie has similar but less severe problems. One sister has attention-deficit/hyperactivity disorder.

Steven's mother worked as a night shift cleaner and received food stamps. She was cooperative but very overwhelmed by Steven's behavior. Steven related age appropriately to interviewer. He participated in play for a while. He was cooperative and tolerated separation from his mother well. The therapist noted the boy's general appearance: casually dressed and looked stated age. His motoric behavior and coordination was mildly hyperactive, with no obvious incoordination. His attitude toward the examiner was that he related well and he was friendly. Steven made fair eye contact. He was alert, oriented to person, place, and time. Speech and language consisted of short sentences. His mood appeared neutral, with a full-range affect. Form of thought was coherent. Content of thought was violent: “When I get big, I am gonna kill you.” Child's perception of the problem was vague. Three wishes and sense of self could not be elicited. The patient was aggressive and impulsive. No obvious perceptual abnormality was observed. Apparent intellectual functioning was average.

Attention and concentration were limited. Memory was intact. His general fund of knowledge was age appropriate, and his abstraction abilities were concrete; however, his insight and judgment were limited. Steven exhibits aggressive, impulsive, hyperactive behavior, and poor impulse control. He witnessed and experienced severe family violence in the past and may be reenacting that behavior.

Pathology and Laboratory Examination Biological abnormalities have been described in individuals with personality disorders. Decreased 5-hydroxyindoleacetic acid concentrations in cerebrospinal fluid were correlated with increased impulsive-aggressive behavior. Challenge studies have suggested that serotonin dysregulation is associated with specific core symptoms found in patients with personality disorders. Results of research with pharmacological probes suggest serotonergic dysregulation in borderline personality disorder.

Differential Diagnosis Because borderline disorders lack specific criteria, a definition is needed. If the adult criteria for borderline personality disorder are being used, the differential can be made. Borderline personality disorder is often comorbid with depressive disorders, and when criteria for both are met, both may be diagnosed. Because the cross-sectional presentation of borderline personality disorder can be mimicked by an episode of depressive disorder, the clinician should avoid giving an additional diagnosis of borderline personality disorder on the basis of only cross-sectional presentation determining the pattern of behavior to be long-standing.

Other personality disorders may be confused with borderline personality disorder because they have certain features in common; thus these disorders must be distinguished on the basis of differences in their characteristic features. However, if an individual has personality features that meet criteria for one or more personality disorders in addition to borderline personality disorder, all can be diagnosed. Although histrionic personality disorder can also be characterized by attention seeking, manipulative behavior, and rapidly shifting emotions, borderline personality disorder is distinguished by self-destructiveness, angry disruptions in close relationships, and chronic feelings of deep emptiness and loneliness. Paranoid ideas or illusions may be present in both borderline personality disorder and schizotypal personality disorder, but these symptoms are more transient, interpersonally reactive, and responsive to external structuring in borderline personality disorder. Although paranoid personality disorder and narcissistic personality disorder may also be characterized by an angry reaction to minor stimuli, the relative stability of self-image as well as the relative lack of self-destructiveness, impulsivity, and abandonment concerns distinguish these disorders from borderline personality disorder.

Antisocial personality disorder and borderline personality disorder are both characterized by manipulative behavior, but individuals with antisocial personality disorder are manipulative to gain profit, power, or some other material gratification, whereas those with borderline personality disorder are directed more toward gaining the concern of caretakers.

Both dependent personality disorder and borderline personality disorder are characterized by fear of abandonment; however, the individual with borderline personality disorder reacts to abandonment with feelings of emotional emptiness, rage, and demands, whereas the individual with dependent personality disorder reacts with increasing appeasement and submissiveness and urgently seeks a replacement to provide caregiving and support. Borderline personality disorder can be further distinguished from dependent personality disorder by the typical pattern of unstable and intense relationships.

Borderline personality disorder must be distinguished from personality change due to a general medical condition, in which the traits emerge because of direct effects of a general medical condition on the central nervous system. It must also be distinguished from symptoms that may develop in association with chronic substance

use (e.g., cocaine-related disorder not otherwise specified).

Borderline personality disorder should be distinguished from identity problem, which is reserved for identity concerns related to a developmental phase (e.g., adolescence) and does not qualify as a mental disorder.

Disruptive disorders often need to be differentiated from borderline personality disorders. Attention-deficit/hyperactivity disorder appears to be a constitutional vulnerability or risk factor for development of borderline personality disorder. Physical and sexual abuse are common antecedents to both borderline personality and conduct disorders. Conduct disorders can also be associated with other personality disorders as well as depressive disorders and learning disorders.

Course and Prognosis The course of borderline personality disorder varies considerably. Most commonly there is chronic instability in early adulthood, with episodes of serious affective and impulsive dyscontrol and extensive use of health and mental health resources. Impairment from the disorder and the risk of suicide are greatest in the young-adult years and gradually wane with advancing age. During their 30s and 40s, most individuals with this disorder gain stability in their relationships and vocational functioning.

Treatment Borderline personality disorder in children and adolescents remains controversial and poorly understood despite efforts by clinicians to study this disorder. The heterogeneous symptomatology in children and adolescents with borderline personality disorder makes optimal treatment planning difficult. The entire range of psychiatric treatments available to child and adolescent psychiatrists have been adapted for youngsters with borderline personality disorder, including short-term inpatient psychiatric hospitalization, residential treatment, day hospital, psychopharmacotherapy, individual psychotherapy, group psychotherapy, and family therapy. Most treatment planning is based on clinical experience rather than data demonstrating efficacy for a particular treatment modality. Often youngsters with borderline personality disorder require brief psychiatric hospitalizations followed by a variety of outpatient psychiatric treatments. It is not uncommon for children and adolescents to be involved with a variety of systems of care including the mental health system, the special education system, the social service system, and the juvenile justice system, as well as numerous private practitioners.

To effectively plan for treatment of individuals with borderline personality disorder requires individualizing the treatment approach for each youngster. Some children and adolescents with borderline personality disorder may require extended treatment because short-term care is inadequate. Often the systems of care involved with an individual are poorly coordinated and there is growing awareness of the need to provide seamless systems of care with close coordination and case management to optimize outcome. Rigorous research in this area is lacking.

The primary goal of treatment of a child or adolescent with borderline personality disorder is to provide a safe therapeutic environment in which youngsters can work on their maladaptive defensive operations, continue their education, address their specific psychiatric symptoms, and improve their family functioning.

Inpatient Psychiatric and Residential Treatment Children and adolescents with borderline personality disorder often require inpatient psychiatric treatment because of concern about self-destructive, suicidal behavior. Psychiatric hospitalization affords an opportunity to provide a safe, therapeutic environment while comprehensive evaluation determines the most appropriate interventions and level of care. These youngsters can be particularly complex, and the therapeutic environment must be sensitive to their multiple needs and potential risks of self-destructive behavior.

Inpatient psychiatric care of these complex youngsters requires an empathic milieu with firm and consistent limits to contain the impulsive and maladaptive behaviors they often exhibit. The level of care that a child or adolescent with borderline personality disorder requires is often determined by the organization of the family, the capacity of the youngster to be safe, and the availability of ommunity resources and services to work with the family. Multiple treatment modalities are often required, and case management ensuring coordinated and integrated care has been clinically useful. Failure to coordinate the care results in a fragmented attempt at healing that often reflects the individual's own sense of personal fragmentation.

Children and adolescents with borderline psychopathology may unwittingly undermine every treatment attempt. Testing limits, splitting the treatment staff, and devaluating the treatment team present particular challenges for those involved with caring for these youngsters and their families. The therapeutic milieu must provide support, structure, and firm limits. Psychopharmacology, special education, and therapeutic activities all provide important adjuncts to the therapeutic program in hospitals. Individual, group, and family therapy become an important opportunity for therapeutic change.

The primary goal of psychiatric hospitalization is to prevent self-destructive behaviors. In addition, confronting the individual's maladaptive coping mechanisms can be done in the hospital while providing a safe environment. Hospitalization may present an opportunity to educate families about the severity of the symptoms and the need for treatment and to engage the child or adolescent in the therapeutic process.

Shorter stays, managed mental health care, and other financial issues are obstacles to obtaining appropriate inpatient psychiatric care for children and adolescents with all forms of psychopathology, including borderline personality disorder. Inpatient treatment may determine the need for ongoing residential care. The lack of available residential care often makes premature discharge to the community necessary. Certain youngsters who benefit from inpatient care and are able to return to the community to continue their treatment in less restrictive settings may benefit from day treatment or individual, group, and family psychotherapies. For most children and adolescents, inpatient psychiatric hospitalization provides an opportunity to stabilize a crisis, complete a thorough assessment, develop an alliance with the child and the family, and initiate appropriate treatment.

Individual Psychotherapy The literature describes the use of individual psychotherapy for the child or adolescent with borderline personality disorder. The primary task for the therapist is development and maintenance of a therapeutic relationship with the child. Confronting the child's maladaptive behaviors is generally avoided in an effort to maintain therapeutic alliance. Most of the literature discusses psychoanalytically oriented individual treatment, emphasizing that the psychotherapeutic approaches should be ego supportive. Others describe the importance of the therapist as an auxiliary ego and a stable figure available for internalization.

The beginning phase of individual psychotherapy aims at having the child or adolescent develop the notion that collaborative activity with the therapist may be useful. Clinical experience rather than empirical research suggests that one to two sessions per week may be necessary to foster the therapeutic alliance. Children and adolescents with borderline personality disorder may idealize their therapist and feel that they have found the perfect therapist. However, the initial phase of treatment may be marked by devaluation of the therapist and the child or adolescent's need for control of these treatments. It is generally accepted that therapists must clearly define the limits from the outset of treatment and provide the structure necessary to maintain the therapeutic alliance. Premature interpretation of negative affects is discouraged. Reality-oriented and supportive therapy is recommended. Working with children and adolescents with borderline personality disorder is particularly challenging for the therapist because of the strong feelings that are elicited in the countertransference. Therapists may feel manipulated, idealized, and seduced and must work against their own reaction to avoid acting out against their patients.

Kernberg underscored the importance of understanding these countertransference reactions as clues to the patient's internal world. Therapists can facilitate development of the therapeutic alliance by allowing the child or adolescent to save face. It is often helpful for the therapist to acknowledge the difficulty in relinquishing the familiar coping mechanisms. This may allow children and adolescents to begin to regain some control over their own lives.

The work of Marsha Linehan in adults has gained wide acceptance. Dialectical behavior therapy is, for the most part, the application of a broad array of cognitive and behavior therapy strategies to the problems of borderline personality disorder. This approach may have practical benefits when adapted to children and adolescents with borderline personality disorder.

Individual psychotherapy for children and adolescents with borderline personality disorder is an important mainstay in their overall recovery. The individual therapy must be incorporated into the appropriate level of care, based on the acuity of the patient's current clinical symptoms.

Family Therapy Family therapy for children and adolescents with borderline personality disorder can be important to the overall recovery of these children and adolescents. Maladaptive family relationships that may have led to the difficulties need to be pointed out in an effort to develop more-adaptive ways for the family members to relate to one another. In addition, a child or adolescent with borderline personality disorder produces enormous dysfunction in a family because of the stress that this disorder generates.

Cognitive behavioral approaches have been used to help parents learn to set more-consistent limits. Despite various theoretical and technical differences among family therapists, there is general agreement on strengthening parental competence. Parents often need assistance to enhance their ability to nurture and care for their children as well as to set effective and consistent limits. The family therapy of borderline youngsters during psychiatric hospitalization is important because this is

a time when parents generally feel out of control and incompetent. The therapeutic staff must develop an alliance with the parents and promote the relationship between the clinical staff and the parents to work together to facilitate the child's development. Failure of the therapeutic staff and the parents to work together may aggravate the child's pathological symptoms.

The family therapy that goes on as part of a multimodal treatment informs both the individual psychotherapist and the therapeutic milieu staff about the context in which the child or adolescent lives. Family involvement in the treatment can be crucial. Empirical studies on the efficacy of family therapy in the treatment of children and adolescents with borderline personality disorder are needed.

Psychopharmacotherapy Children and adolescents with borderline personality disorder have been treated with a variety of psychopharmacological agents addressing various key psychiatric symptoms. Antidepressant medication, stimulants, anxiolytic agents, antipsychotic agents, mood stabilizers, and anticonvulsants have all been used. Controlled studies have not been conducted with borderline children, although several have been conducted with borderline adults. The clinical literature suggests a rather broad consensus that specific pharmacological agents alone or in combination may be beneficial in the treatment of children and adolescents with borderline personality disorder. Some researchers advocate targeting specific symptoms; others have found the use of antipsychotic agents alone or in combination with other medications to be clinically useful. Currently, psychopharmacotherapy for children and adolescents with borderline personality disorder lacks empirical data. Clinically, psychotropic medication can decrease impulsivity and anxiety and elevate mood. Like other elements of the treatment of children and adolescents with borderline personality disorder, the meaning of medications for the child and the family must be examined. The paucity of empirical data to guide pharmacological intervention calls for more studies to determine the most effective medication treatment for children and adolescents with this disorder.

49.11 ADOLESCENT SUBSTANCE ABUSE

OSCAR G. BUKSTEIN, M.D., M.P.H.

Psychiatrists, other mental health professionals, educators, and politicians are increasingly identifying substance use and abuse by children and adolescents as a critical public health problem. Despite attempts to limit access to psychoactive substances by young persons, the use of such substances is common among adolescents and growing in some groups. Substance use can have profound acute and chronic effects on the behavior and emotional status of adolescents. Substance abuse can affect the psychosocial development of adolescents. However, clinicians and researchers are only now developing an understanding of substance use disorders in adolescents and attempting to develop effective methods of treatment and prevention.

DEFINITION

Both substance abuse and dependence require a maladaptive pattern of substance use. Substance abuse criteria include use resulting in inability to meet major role obligations, legal problems, and an increase in risk-taking behaviors or exposure to hazardous situations. Criteria for substance dependence include the physiological criteria of tolerance and withdrawal symptoms, use resulting in abandonment of important activities, spending increasing time in activities related to substance use, using substances for a longer time than planned, and use despite the existence of worsening problems due to the substance use. The most common manifestation of substance use problems in adolescents is impairment in functioning, usually interpersonal or family conflict and academic failure. Withdrawal symptoms are much less common in adolescents than in adults. Other common symptoms include a reduction in activities because of use and using more than intended and tolerance.

COMPARATIVE NOSOLOGY

Like its predecessors, the third edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III) and the revised third edition (DSM-III-R), the fourth edition (DSM-IV) substance use disorder criteria were developed for adults, with few empirical data to support their use for adolescents. The DSM-III diagnosis of substance dependence, especially alcohol dependence, could rarely be applied to adolescents because of the infrequent occurrence of clinically significant withdrawal symptoms. DSM-III substance abuse was defined in terms of pathological use and impairment in social or occupational functioning. The attribution of problems or consequences specifically to substance use is particularly problematic for adolescents whose coexisting psychiatric disorders and other psychosocial problems could also explain the impairment in functioning.

DSM-III-R and DSM-IV represent a substantial change from DSM-III. The definition of dependence was broadened to include clinically significant behaviors, cognitions, and nonphysiological symptoms that indicate substantial involvement with substance use. The broadened definition likely increased the number of adolescents meeting dependence criteria. DSM-IV differs from DSM-III-R in requiring clinically significant impairment or distress, switching the criteria of substance use resulting in failure to fulfill major role obligations from a diagnosis of dependence to one of abuse, and adding recurrent substance-related legal problems to the criteria for abuse.

The attribution of the many problems observed in adolescents who use substances remains a critical problem in the diagnosis of substance use disorders. Substance use per se should not be considered evidence of a substance use disorder. Almost all psychoactive substances are illegal for adolescents, and certain negative consequences may result from legal or cultural proscription rather than directly from the substance use or related behaviors.

EPIDEMIOLOGY

Alcohol is the substance of choice for most adolescents. According to the University of Michigan Monitoring the Future 1996 survey of high school students, 79.2 percent of twelfth graders, 71.8 percent of tenth graders and 55.3 percent of eighth graders report lifetime use. Although 26.8 percent of eighth graders report ever having been drunk, by the tenth and twelfth grades this percentage had risen to 48.5 and 61.8 percent, respectively. In terms of regular drinking, 30.2 percent of twelfth graders, 24.0 percent of tenth graders, and 15.6 percent of eighth graders report having five or more drinks on a single occasion in the preceding 2 weeks.

From 1991 to 1996 the proportion of high school students reporting the use of any illicit drug in the past 12 months increased from 27 to 40 percent for twelfth graders, from 20 to 38 percent for tenth graders, and from 11 to 24 percent for eighth graders. Marijuana accounted for much of this increase during the early 1990s. Almost 5 percent (4.9 percent) of twelfth graders reported daily marijuana use, and 36 percent reported use during the past year. Among eighth graders, 18 percent reported marijuana use within the past year.

The annual prevalence in the use of a number of other substances also rose in the early 1990s. In 1996, 4 percent of eighth graders and 9 percent of twelfth graders reported lysergic acid diethylamide (LSD) use in the preceding year. Annual prevalence rates for amphetamines were 9 percent for eighth graders, 12 percent for tenth graders, and 10 percent for twelfth graders. In 1996 2.8 percent of twelfth graders reported the use of methamphetamine (“ice”) and nearly 5 percent reported the use of methylenedioxymethamphetamine (MDMA, “ecstasy”) during the past year. The annual prevalence of other substances remained low in 1996. Heroin was used by 1.6 percent of eighth graders and 1 percent of twelfth graders. Cocaine was used by 4.9 percent of twelfth graders and 3 percent of eighth graders, while crack cocaine was used by 2.1 percent of twelfth graders and 1.8 percent of eighth graders during the preceding year.

The percentage of students reporting they had smoked cigarettes during the past 30 days rose by almost 50 percent (14 to 21 percent) in eighth graders from 1991 to 1996. Thirty percent of tenth graders and 34 percent of twelfth graders reported a 30-day prevalence of cigarette smoking in 1996. Daily cigarette use was reported by 22.2 percent of twelfth graders. Thirteen percent of twelfth graders reported smoking half a pack a day or more.

In general, male adolescents use substances of all kinds more than females do. Overall, white and Hispanic students are more likely than African-American students to report lifetime alcohol use and heavy episodic use. African-American students are more likely to report both lifetime and current marijuana use.

Few studies have examined the prevalence of substance use disorders in general population samples. Rates of lifetime alcohol abuse or dependence range from 5.3 percent in 15-year-olds to 32.4 percent in 17- to 19-year-olds. The lifetime prevalence of drug abuse or dependence ranges from 3.3 percent in 15-year-olds to 9.7 percent in 17- to 19-year-olds.

ETIOLOGY

While most adolescents will try alcohol and many will try other substances at some point during their adolescence, the risk for substance use and potential development of substance use disorders and related problems differs among adolescents and appears to be related to any number of risk factors. The age of onset of substance use is a prominent risk factor for early onset of substance use and rapid progression to the use of various illicit substances.

Risk factors for substance use and abuse can be related to individual characteristics such as the presence of early childhood disruptive behavior problems, aggressive behavior, poor academic performance, risk-taking behaviors, and favorable beliefs and attitudes about substance use. A number of biological characteristics also appear to place adolescents at risk for substance use and abuse, including increased latency of the P3 component of evoked potentials and

differences in static ataxia (body sway).

Temperamental deviations are associated with an increased risk for psychopathology and substance abuse. For example, children with a difficult temperament manifest externalizing and internalizing behavior problems by middle childhood and in adolescence more commonly than children whose temperament is normative. Increased behavioral activity is noted in both youths at high risk for substance abuse and those having a substance use disorder. Other temperamental trait deviations found in high-risk youth include shorter attention spans, increased impulsivity, and such negative affect states as irritability and emotionality.

The environment may account for many risk factors. Parental or family risk factors include parental beliefs and attitudes about substance use; tolerance of substance use; lack of closeness and attachment between parent and adolescent; lack of involvement, supervision, or discipline of the adolescent; and parental substance use. Peer-related variables such as peer substance use, peer attitudes, and a greater orientation of the adolescents to peers (as opposed to their parents) are also important risk factors. Community characteristics such as low socioeconomic status, high population density, physical deterioration, and high crime are also associated with higher levels of substance use in young persons.

The risk and natural history of adolescent substance use and related problems are best viewed from a developmental perspective. Several studies have established a common sequence, or stages, of substance use among adolescents. Most adolescents eventually try “gateway” drugs such as alcohol or cigarettes, which are legal for adults and thus easily accessible by adolescents. Progressively fewer adolescents progress to use of marijuana or other illicit substances and more serious substance use. Different risk factors appear to be more critical at different stages of substance use. For example, the adolescent's initial experiences with substances usually take place in a social context and involve peer-related factors. Later stages of substance involvement are determined by other major categories of risk factors such as parental and individual risk factors and psychological distress. Substance use and deviant and other risk-taking behaviors commonly occur together in adolescents. Problem behavior theory suggests that substance use, deviant behavior, deviant attitudes, and environments that promote these behaviors cluster together.

DIAGNOSIS AND CLINICAL FEATURES

The optimal assessment of the adolescent suspected of having a substance use disorder involves not only substance-use-related behaviors but also other domains of psychosocial functioning, including psychiatric and behavior problems, school or vocational functioning, family functioning, social competency and peer relationships (including social skills), leisure and recreational activities, and current medical status.

Substance use is a multidimensional behavior that requires thorough evaluation of several dimensions of substance use behavior in addition to quantity and frequency of substance use. Critical dimensions of substance use behavior include *pattern of use* (i.e., quantity, frequency, onset, and types of agents used), *negative consequences* (i.e., school/vocational, social/peer/family, emotional/behavioral, legal, and physical), *context of use* (i.e., time/place, peer use/attitudes, mood antecedents, consequences, expectancies, and overall social milieu) and *control of use* (i.e., view of use as a problem, attempts to stop or limit use, other DSM-IV dependence criteria).

Because substance use is usually an overt behavior, the clinician must often depend on the youth's self-report of substance use, related behaviors, and resulting problems. Although self-reports appear to be reliable in some populations, specific populations such as extremely antisocial youths may report less use than drug clinic samples. The clinician may attempt to substantiate suspected use by reports from third parties or through the use of urine or blood toxicology. Toxicology tests detect the presence of a substance, not a pattern of abuse or dependence, but they may be a useful check on the truthfulness of an adolescent's self-report as well as an ongoing check of substance use during and after treatment.

A variety of instruments are available and others are being developed to assist in screening and detailed assessment of substance use and related behaviors and problems. The common use of instruments developed for adults or those that lack standardization and validation may be inappropriate for adolescents.

DIFFERENTIAL DIAGNOSIS AND COMORBIDITY

A number of psychiatric disorders are commonly associated with substance use disorders in youths (Table 49.11-1). Many adolescents who use substances also display a variety of other deviant behaviors. It may be difficult to attribute dysfunction to a particular deviant behavior such as substance use rather than to other deviant behaviors, the entire syndrome of deviant behavior (i.e., conduct disorder), or other psychiatric disorders. Conduct disorder and constituent criteria such as aggression usually precede and accompany adolescent substance use disorders. Clinical populations of adolescents with substance use disorders show rates of conduct disorder ranging from 50 to almost 80 percent. Although attention-deficit/hyperactivity disorder is commonly noted in substance-using and substance-abusing youths, the observed association is likely due to the high level of comorbidity between conduct disorder and attention-deficit/hyperactivity disorder. Earlier onset of conduct problems and aggressive behavior in addition to the presence of attention-deficit/hyperactivity disorder may increase the risk for later substance abuse.

Disruptive behavior disorders
Conduct disorder
Oppositional defiant disorder
Attention-deficit/hyperactivity disorder
Mood disorders
Dysthymic disorder
Cyclothymic disorder
Major depressive disorder
Bipolar disorder
Anxiety disorders
Posttraumatic stress disorder
Social phobia
Bulimia nervosa
Schizophrenia

Table 49.11-1 Psychiatric Disorders Commonly Comorbid With Substance Use Disorders in Adolescents

Onset of mood disorders, especially depressive disorders, frequently precedes or follows the onset of substance use and substance use disorders in adolescents. The point prevalence of depressive disorders in these studies ranged from 24 to over 50 percent.

The literature supports substance use disorders among adolescents as a risk factor for suicidal behavior, including ideation, attempts, and completed suicide. Possible mechanisms for this relation include acute and chronic effects of psychoactive substances. Adolescent suicide victims are frequently using alcohol or other drugs at the time of suicide. Short-term substance use may produce transient but intense dysphoric states, disinhibition, impaired judgment, and increased level of impulsivity or may exacerbate preexisting psychopathology including depression or anxiety disorders.

Aggressive behaviors are present in many adolescents with substance use disorders. Consumption of such substances as alcohol, amphetamines, and phencyclidine (PCP) may increase the likelihood of subsequent aggressive behavior. The direct pharmacological effects resulting in aggression may be further exacerbated by the presence of preexisting psychopathology, the use of multiple agents simultaneously, and the frequent relative inexperience of the adolescent substance user.

A number of studies of clinical populations show high rates of anxiety disorders among youth with substance use disorders. In clinical populations of adolescents with substance use disorders, the prevalence of anxiety disorder ranged from 7 to over 40 percent. The order of appearance of comorbid anxiety and substance use disorders appears to vary, depending on the specific anxiety disorder. Social phobia usually precedes abuse, while panic and generalized anxiety disorder may more often follow the onset of substance use disorders. Adolescents with substance use disorders often have a history of posttraumatic tress disorder. Bulimia nervosa is also common in adolescents with substance use disorders. As suggested by studies showing language deficits in youth affected by or at high risk for substance use disorders, learning disorders may also show an increased incidence of comorbidity. Multiple psychiatric disorders, both internalizing and externalizing types, are often noted in populations of adolescents with substance use disorders.

Psychiatric disorders in childhood, disruptive behavior disorders as well as mood or anxiety disorders, increase the risk for development of substance use disorders in

adolescence. The etiological mechanisms have not been systematically researched. A number of possible relationships exist between substance use disorders and psychopathology. Psychopathology may precede substance use disorders, may be a consequence of preexisting substance use disorders, may influence the severity of substance use disorders, may not be related, or may originate from a common vulnerability.

COURSE AND PROGNOSIS

Most adolescents who use substances do not go on to develop substance use disorders in adolescence or adulthood. Generally, levels of substance use peak in late adolescence or early adulthood. Life events such as education, career attainment, marriage, and parenthood tend to decrease or stop substance use. However despite such maturational processes, substance use can disrupt the ability of adolescents to negotiate the developmental tasks of adolescence and young adulthood.

Psychoactive substances by virtue of their pharmacological properties affect the mood, thought processes, and sensory perception of their users. Adolescent substance users are more likely to be novice users with minimal tolerance, and they may experience more noxious or adverse reactions to substances than more experienced adult substance users. Inexperienced adolescent substance users may not appreciate the extent of their impairment from use or intoxication.

Substance use by adolescents has a number of short-term consequences. Accidents and trauma, including driving motor vehicles or bicycles while intoxicated, and drownings are common in adolescents who are using substances. Adolescent perpetrators of violence and their victims are commonly under the influence of, or have histories of, substance use disorders. Early onset of sexual behavior, another high-risk behavior, is more common among adolescents with early-onset substance use. Although adolescents constitute a relatively small percentage of individuals with human immunodeficiency virus (HIV) disease, the frequently long latency between HIV infection and the onset of symptoms suggests that many may have become infected as adolescents.

TREATMENT

Research on the outcomes of adolescent substance abuse treatment has lagged behind research on the predictors, course, and correlates of treatment outcome among adults. Unfortunately, data indicate that most adolescents return to some level of alcohol or other drug abuse following treatment. Despite these outcomes, studies have identified specific predictors of treatment outcome, including patient or adolescent characteristics, social support system variables, and program characteristics. Adolescents in substance abuse treatment begin substance use at an earlier age, progress rapidly to the use of “hard” drugs, and usually use multiple drugs. Other clinical features of adolescents entering treatment include often high levels of coexisting psychopathology or early personality difficulties, deviant behavior, school difficulties including high levels of truancy, and family disruption and substance abuse. Several pretreatment characteristics predict completion of treatment by adolescents: more severe alcohol problems; greater use of drugs other than alcohol, marijuana, and tobacco; a higher level of internalizing problems; and lower self-esteem. Premorbid psychopathology such as conduct disorder is negatively correlated with treatment completion and future abstinence. Although factors such as severity of substance use may predict short-term treatment outcomes, most longer-term outcomes may depend on social and environmental factors. This is consistent with studies that suggest that relapse in adolescents is more often associated with social pressures to use rather than situations involving negative affect, as is usually found in adult relapse. Attendance at self-support or aftercare groups is associated with higher rates of abstinence and other measure of improved outcome than those in adolescents who did not attend such groups. Table 49.11-2 outlines current approaches for treating alcoholism in adolescents.

Approach	Components and/or Focus
12-Step model	Group meetings (e.g., Alcoholics Anonymous) Group counseling Worksheets Family sessions or groups
Behavioral intervention	Relapse prevention Development or improvement of refusal skills, social skills, and problem-solving skills Anger control training Leisure-time management
Family therapy Behavioral	Parent management training Contingency contracting
Strategic-structural	Restructure maladaptive patterns
Systemic	Address behavioral limit-setting and intergenerational conflicts
Contextual	Integration of emotional, behavioral, cognitive, and spiritual aspects of family
Mixed	A combination of various family therapy components
Educational and vocational assistance/rehabilitation	Achieve basic level of academic skills and completion of a secondary education
Medications for coexisting psychiatric disorders Depression and other mood disorders	Antidepressants and lithium
Attention-deficit/hyperactivity disorder	Stimulants

Table 49.11-2 Current Approaches and Their Components for Alcoholism Treatment in Adolescents

Despite a higher level of return to substance use among adolescents after treatment, abstinent teens may expect decreased interpersonal conflict, improved academic functioning, and increased involvement in social and occupational activities. Patterns of substance abuse among adolescents appear to become more stable between 6 and 12 months after treatment. Reviews of treatment outcome conclude that treatment can be effective and is certainly better than no treatment.

A number of treatment program characteristics are associated with improved abstinence and lower levels of relapse. They include longer duration of treatment, available follow-up or after-care treatment, family involvement, and the availability of social support services.

Until recently, there were few data to establish the superior effectiveness of a particular treatment modality over alternative treatment modalities. Several investigators have demonstrated the effectiveness of family-based approaches—in comparison with nonfamily-based interventions—in treating adolescent substance use disorders. Scott Henggeler and associates' multisystemic therapy represents a family-ecological systems approach with interventions targeting family functioning and communication, school and peer functioning, and community functioning. In addressing the frequently multidimensional adolescent substance use disorders and associated problems, multisystemic therapy focuses on multiple targets and using many treatment techniques including family therapy and behavioral therapies. Multisystemic therapy is integrative and comprehensive but targets specific, identified areas of dysfunction.

A number of cognitive-behavioral treatments, including many previously used with adults (e.g., relapse prevention), may show promise as treatment modalities for adolescents with substance use disorders. Problem-solving and social skills training appear to be effective for populations of conduct-disordered youth.

Many treatment programs for adolescents continue to be based on the 12 steps of Alcoholics Anonymous (AA) or Narcotics Anonymous (NA). Attendance at self-support groups appears to predict abstinence and other measures of improved treatment outcome.

Pharmacotherapy can potentially treat withdrawal, counteract or decrease the subjective reinforcing effects of illicit substance use, and treat comorbid psychopathology. Unfortunately, there has been no systematic research evaluating the efficacy and safety of any psychotropic medication in the treatment of adolescents with substance use disorders. Although clinically significant withdrawal symptoms appear to be rare in adolescents, little rationale exists for using detoxification protocols different from those used for adults. The use of agents to block the reinforcing effects of various substances, aversive agents (e.g., disulfiram [Antabuse]) or those that relieve craving during and after acute withdrawal has been studied in adults but has received scant attention in adolescents. Aversive pharmacological treatment with agents such as disulfiram is rare in adolescents.

The high prevalence of coexisting psychiatric disorders in adolescents with substance use disorders presents additional targets for pharmacological agents. Potential targets for pharmacological treatment include depression and other mood problems, attention-deficit/hyperactivity disorder, severe aggressive behavior, and anxiety disorders. Unfortunately, few data in the literature demonstrate the efficacy of pharmacological agents prescribed for adolescents with substance use disorders and comorbid psychiatric disorders. However, a recent study indicates that these agents have limited clinical utility. In general, clinicians should use the same caution in considering pharmacological treatment for adolescents with comorbid substance use disorders and psychiatric disorders as they do with adolescents with psychiatric symptoms alone.

Substance use disorders may increase the potential for intentional or unintentional overdose. Some pharmacological agents may have inherent abuse potential. Critical issues in the use of pharmacotherapy include (1) avoiding the precipitation or exacerbation of psychiatric symptoms by the abused substances, (2) the need to achieve some level of abstinence or control of substance use before making more optimal assessment of symptoms and starting pharmacological treatment, (3) the potential of acute drug effects resulting in intentional or unintentional overdose, and (4) the potential abuse of the pharmacotherapeutic agents themselves. The treatment of attention-deficit/hyperactivity disorder in those with substance use disorder remains problematic because of the abuse potential of central nervous system

(CNS) stimulants by the patient, family, and peers. In addition to close supervision of medication compliance, clinicians should consider the use of effective agents with much lower abuse potential such as the tricyclic drugs, bupropion (Wellbutrin), and pemoline (Cylert).

Although not specifically studied, the multiple areas of possible dysfunction in adolescents with substance use disorders and the many available treatment modalities suggest a multimodal approach. Treatment matching, or matching patients with specific characteristics with appropriate levels of care and types of treatment modalities, received much attention in the adult literature. Psychiatric severity may be the best-identified guide to matching patient characteristics with specific treatment modalities.

Prototypical Treatment Increasingly, over the past decade, the previous emphasis on residential treatment for adolescents with substance use disorders has been replaced by less costly and less intensive alternatives such as outpatient treatment or intensive outpatient treatment. Residential stays are becoming much more variable, with significantly more-limited goals for treatment. In intensive outpatient treatment, the adolescent attends a program several afternoons or evenings a week while continuing to reside at home and attend school. The predominant treatment approach continues to be based on the 12-step approach of AA or NA. Each treatment setting offers the same modalities, but at a different level of intensity or frequency. Residential treatment, while more costly, offers more structure and total control of the adolescent's environment and thus access to substances of abuse. Further research is needed to determine whether residential treatment has any advantage over community-based treatments.

Typically, 12-step programs focus on several issues, confronting the adolescent's denial about substance use as a problem and teaching the adolescent about the process of recovery. The schedule is usually highly structured. Most of the treatment is carried out in group formats where adolescents may challenge one another about the veracity of their statements or therapeutic work. The content of group therapy can include 12-step work, family issues, and psychoeducation about the effects of substances and substance use and the process of recovery including relapse and relapse prevention. Attendance at AA or NA meetings and urine screening for the presence of illicit substances are common features. Adolescents may spend some time in individual therapy either working on 12 steps or other assignments or on specific problems such as depression or physical or sexual abuse victimization. Family therapy in both individual and multifamily formats is part of most programs. Increasingly, cognitive-behavioral elements such as anger control or social skills are being included in treatment, under the general guise of coping skills. Many, but not all programs have psychiatric consultation available to assess other possible comorbid psychopathology and to provide psychopharmacotherapy for such problems as attention-deficit/hyperactivity disorder, depression, or bipolar I disorder.

Another treatment controversy is the use of toxicological methods on bodily samples, usually urine, to detect substances. Technology being developed may extend screening to hair samples and using urine screening to detect recent alcohol use. The use of urine screening at initial assessment may be limited, as a positive result only indicates that the adolescent has used one or more substances and not whether significant problems with use exist or how much or frequently an adolescent is using one or more substances. Urine drug screens, especially relatively inexpensive radioimmune assay kits, may be valuable adjuncts in follow-up to detect ongoing substance use by the adolescent. Usually screens are requested by therapists at random intervals for at least several months following the adolescent's entry into treatment. Adolescents, therapists, and family should be aware of the consequences of both “dirty” (those indicating the detection or presence of one or more illicit substance) and “clean” (absence of any illicit substance) urine samples prior to the onset of a screening program.

Fred is a 16-year-old male admitted to substance abuse treatment for the second time, following a relapse and threats of suicide. He was initially admitted to an inpatient program following a serious suicide attempt. He reported a long history of disruptive behavior and academic failure since childhood. He was increasingly truant and difficult for his family to control. During his first treatment episode, he reported an onset of substance use at age 11 years, a rapid progression in substance involvement since age 13 years, then current use of marijuana on a daily basis, drinking alcohol up to several times a week, frequent trips on LSD, and experimentation with a variety of substances. Fred attended group sessions focusing on his initial denial of a substance use problem and then learned the process of recovery while attending other groups and AA and NA meetings. Family group sessions showed him and his parents the need for better communication and more adaptive interactions. Fred gradually responded to the structure of the treatment program, although he had frequent problems with anger control when confronted by peers or staff or when frustrated. Depressive symptoms failed to remit following 2 weeks of abstinence, and Fred was given fluoxetine (Prozac). He showed a rapid improvement in mood and treatment compliance. Upon discharge, he was attending NA meetings and outpatient therapy. However, family conflict soon recurred, and Fred became noncompliant with outpatient treatment, medication, and meetings. He resumed old relationships with deviant peers and relapsed into daily marijuana use and occasional alcohol use.

Prevention The most effective intervention for adolescent substance use or use disorders is preventing the initial development of substance use or pathological patterns of use. Although a consensus exists regarding the importance of prevention efforts, there is a lack of agreement of a conceptual goal for prevention; that is, what should be prevented—use, abuse, or dependence? While some would have interventions directed at the prevention of various use patterns or consequences of substance use, a broader view of prevention would target the risk factors for the development of substance use or substance use disorders. Targeting risk factors likely requires a host of measures involving the educational, mental health, and welfare systems and is certainly more costly than more direct interventions for substance use behaviors. However, primary prevention efforts aimed at risk factors may prove more effective and influence the development of a wide range of problems and psychosocial dysfunction in children, adolescents, and their families.

Prevention efforts are based on various theoretical models of adolescent substance use and abuse development. Most prevention interventions are based on social learning models. If one can change what young persons are exposed to and what they learn from their environment, then behavioral changes will follow. These interventions include educational approaches, family-based interventions, and community-based projects. Educational approaches include three basic methods: (1) knowledge and attitude, (2) values and decision making, and (3) social competency or skills. Although educational, individually focused, family-focused (e.g., parent training), and community-focused (e.g., advocacy groups, media campaigns and regulatory changes) prevention interventions are an increasing part of the total prevention effort, the variety of critical risk factors for the development of adolescent substance use and abuse suggests the targeting of multiple risk factors or influences as part of comprehensive prevention efforts. The successful prevention programs appear to be those that target salient risk factors, are skills oriented, have sufficient intensity and duration, have follow-up, and respect the socioeconomic and cultural realities of the targeted communities.

SUGGESTED CROSS-REFERENCES

Specific substance-related disorders with diagnostic tables are covered in Chapter 11. Conduct disorder is discussed in Chapter 40, and childhood mood disorders are discussed in Chapter 45. Family therapy is covered in Section 48.5, and cognitive-behavioral treatments are covered in Section 48.3.

49.12 FORENSIC CHILD AND ADOLESCENT PSYCHIATRY

STEPHEN P. HERMAN, M.D.

Forensic child and adolescent psychiatry has come of age. Born of an inchoate juvenile justice system a century ago, tempered by a profound realism about the limits of psychoanalysis to cure the ills of society, and matured by endless requests for psychiatric assistance in courts throughout the land, forensic child psychiatry has finally come into its own as an important and exciting subspecialty. Child and adolescent psychiatrists are now frequently involved in conducting medico-legal evaluations in custody and other child placement cases, criminal matters, allegations of sexual and physical abuse, competence of child witnesses, damages arising from psychological and physical trauma, school-related cases, and other circumstances. Although most child and adolescent psychiatrists prefer to avoid this work and all its complications and special anxieties, few escape involvement in some aspect of the legal system, and all at some time or another will have patients who themselves are caught in its grasp.

Organized medicine and medical educators have accepted the need for training and demonstrated competence in forensic psychiatry. In 1988 the Accreditation Council for Graduate Medical Education formally included forensics as a required part of training in child and adolescent psychiatry. In 1992 the field was officially recognized as a subspecialty of psychiatry by the American Board of Medical Specialties. The American Board of Psychiatry and Neurology held its first examination for added qualifications in forensic psychiatry in 1995. Some knowledge of this area is required of all child and adolescent psychiatrists, whether or not they choose to become forensic practitioners.

HISTORY

Forensic child and adolescent psychiatry, initially a stepchild of the child guidance movement of the late nineteenth and early twentieth centuries, evolved as a natural response to the public's concern about juvenile crime. Until this enlightened era, children had no special rights under law, were easily exploited, were subject to criminal proceedings identical to those of adults, and had no special legal venue. The country's first juvenile court was established in Chicago in 1899. Maine, the last state to create such a court, did not do so until 50 years later. Thus, a system of juvenile and family courts, which is taken for granted today in the United States, is actually a relatively recent development.

For most of this century, those psychiatrists working as consultants within family courts had little or no formal training in child psychiatry and the law. They learned by doing; there were no published standards for performing various forensic examinations, little attention was paid to ethical considerations, and scholarly publications were scarce.

Fortunately, the field has matured, primarily in the past 25 years, into a discipline with a significant body of literature, practitioners who have received advanced training in forensic fellowship programs, and published standards and practice parameters that have greatly improved the quality of the work done in this area. Unfortunately, of the nearly 30 national fellowship programs offering advanced training in forensic psychiatry, only a few specialize in children and adolescents. And although all child and adolescent psychiatry training programs must now provide some exposure to forensics, limited availability of experienced teachers and mentors and few working liaisons with the legal system mean that most child psychiatrists have extremely limited exposure to this field.

LEGAL SYSTEM

Forensic child psychiatry operates at the interface of clinical psychiatry and the legal system. The field removes child psychiatrists from the safe haven of the office and often places them in the arena of the adversarial process—a setting quite foreign, sometimes confusing, and often anxiety provoking. Clinicians choosing to practice forensics, therefore, must have some background knowledge of the legal system.

In the United States sources of law are federal and state statutes and case law stemming from court decisions. State courts determine the common law for each state, and federal courts are empowered by the Constitution and any additional laws passed by Congress. The federal court system comprises district courts (which conduct trials), federal courts of appeal, and the United States Supreme Court. State court systems vary but usually comprise trial courts, an appellate division, and the state's supreme or highest court. States may also have specialized courts, such as courts of probate or family court.

Child and adolescent psychiatrists engaged in forensic practice are frequently involved in judicial proceedings that are either civil or criminal, decided by a judge or a jury. Criminal cases involve serious offenses punishable by loss of liberty (e.g., imprisonment, execution) or by a fine. Because of the serious ramifications of having the state restrict personal liberty, criminal convictions require the highest standard of proof, *beyond a reasonable doubt*. Civil litigation includes negligence or malpractice cases and family law issues such as child custody disputes and termination of parental rights. The burdens of proof in civil cases are lower than in criminal cases: *a preponderance of evidence* and *clear and convincing evidence*.

Within this legal framework, the rights of children have evolved slowly but surely in the United States. From being originally viewed as a valuable and productive asset of their parents in the labor they could perform, to being protected as needy individuals by the strength of the government *(parens patriae),* to having the United States Supreme Court finally recognize that they are protected by the Bill of Rights and the Fourteenth Amendment, children have at last been recognized as having fundamental rights that must be protected and maintained. Against this backdrop the forensic child psychiatrists practice their specialty.

Finally, forensic practice differs from therapeutic practice in a significant way: in general, the patient's rights of confidentiality and privilege, usually protected (with some exceptions) during psychotherapy, are waived during a forensic evaluation. By definition, the forensic evaluation is part of a legal process. If a report is written, others will read it. The forensic evaluator may have to testify. The forensic psychiatrist explains this to the subject of the evaluation before it begins.

FAMILY LAW

Child Custody Child custody disputes are probably the most common legal proceedings involving child and adolescent psychiatrists. Of the one million children a year who experience divorce in the United States, approximately 10 to 15 percent are in litigated cases. A child psychiatrist who is not routinely evaluating such cases has most likely treated a child or adult going through this complex and emotionally draining process.

Child custody disputes throughout recorded history have reflected a society's view of the child in the family. The practice of courts becoming involved in such private family affairs is fairly recent. The history of this issue traces movement from seeing children as essentially owned by their father to considerations of what is in their best interests. Judicial decisions have been informed by various presumptions, such as “the tender years” and “the best interests of the child.” The tender years presumption existed well into the twentieth century. It held that young children (from birth to about age 7) were usually better off with their mothers, who were generally assumed to be better skilled in nurturing and raising their offspring. This presumption was replaced in the last third of the twentieth century by “the best interests of the child,” which is the current law in the United States. This presumption holds that the focus of a child custody case should be the child, and courts ought not lean toward one parent or the other strictly on the basis of sex. Further, there may be situations in which custody should reside with a nonparent rather than a parent, if that represents the best interests of the child. To help courts determine a child's best interests, judges have increasingly turned to child psychiatrists to evaluate families and make recommendations.

Child custody cases, complex and emotion-laden in themselves, have become even more complicated by special issues that commonly arise. These can include a mentally ill parent, a homosexual parent, a stepparent or grandparent seeking custody, parental kidnaping, allegations of sexual abuse, relocation cases, and cases arising from advances in reproductive technology.

In general, child psychiatrists ought to be court-appointed, impartial experts when evaluating such cases. Serving as a neutral evaluator avoids the shadowy status of hired gun and gives the clinician the greatest credibility in the eyes of the court. Recently, the American Academy of Child and Adolescent Psychiatry published Practice Parameters for Child Custody Evaluation, which sets forth guidelines for this forensic evaluation. The psychiatrist sees the litigating adults and the children, separately and in conjoint interviews, holds collateral interviews with important figures such as therapists and teachers, writes a cogent and complete report setting forth the data gathered and how that data led to the clinician's conclusions, and sometimes defends the report by testifying in court.

Adoption Adoption continues to be a major avenue for becoming a parent; and, as with society itself, this process has undergone much change. Forensic evaluations may be required in complex adoption cases, particularly when there is a question of whether an adoption is or was fraudulent or when a birth parent who had apparently given up a child is demanding the return of the child. These cases often cross state lines and international boundaries. Debate continues in the United States about the virtues or drawbacks of transracial adoption. The child and adolescent psychiatrist may be called as an expert witness to testify about the best interests of a child who is the subject of such proceedings.

Termination of Parental Rights Common law presumes that parents are competent to provide appropriate care and nurturing to their children. The state does not interfere unless there are egregious deviations from acceptable parenting behavior. When that is thought to occur, usually after child protective services have been involved with a family, a state may petition to terminate parental rights. Such termination ends the parental-child relationship in every way. It also may free the child from the uncertainties of foster care and allow for permanent placement and adoption. In the United States Constitutional law, as interpreted by the United States Supreme Court in 1982, requires the burden of proof in such cases to be clear and convincing evidence. Some states go further and use the standard of beyond a reasonable doubt.

When such cases arise, agencies commonly consult with child psychiatrists, who are asked to evaluate the parents and sometimes the children to give an opinion on the validity of a petition for termination. The psychiatrist reviews all of the historical data and assesses the parents to see whether they have a serious psychiatric disorder, whether they demonstrate any hope of rehabilitation, and whether their children would be in danger if returned to them. The forensic evaluation leads to a report and, frequently, courtroom testimony.

Two parents were locked in a bitter custody dispute over their 4-year-old son. Throughout the litigation, the father made numerous allegations that his wife was physically abusing the boy, burning him with cigarettes, sticking him with pins, poisoning his milk, and terrifying him by holding his head underwater while giving him a bath. The father had called Child Protective Services numerous times, had taken his son to every emergency room in the city and had sent out milk samples for toxicological analysis. All physical examinations and laboratory tests were normal, and no doctor or city social worker had ever confirmed signs or symptoms of abuse. Yet, the father persisted in his accusations.

The court-appointed child psychiatrist recorded the father's complaints but also failed to confirm abuse. In the joint interview with father and child, the boy was playing at the dollhouse. His father picked up a miniature bathtub and told him, “Billy, show the doctor how Mommy pushes your head underwater and tries to scare you. Go on, Billy, show the doctor.” The child refused and became quite anxious. He moved away from the dollhouse.

The child psychiatrist concluded that the father suffered from delusions about abuse and that these delusions were harmful to the child, because he acted upon them and caused the child to undergo many unnecessary examinations and tests. He recommended that for these and other reasons, custody be awarded to the mother. He also recommended supervised visitation for the father. The judge granted custody to the mother but initially did not order that the father have supervised visitation. When he was with the child, the father continued to take him to emergency rooms. After another year, the judge stopped the visits altogether.

Child custody cases show no sign of abating. Attempts at mediation and arbitration have sometimes been successful in localities where they may be mandated or available on a private basis. However, parents will continue to seek relief within the adversarial system. There will most likely be more cases involving relocation issues. For example, a custodial parent may wish to move to another state because of employment not available locally. The noncustodial parent, still very much involved with the children, sues to prevent the exspouse from moving with the children. Most likely the best-interests presumption will be applied here as well.

There will be more cases involving allegations of sexual abuse and consequently evaluations-within-evaluations, in which the psychiatrist will be asked to assess the validity of the allegations as part of the custody evaluation. To do so requires specialized skills, discussed elsewhere in this book.

Finally, there will be more litigation born of the astonishing advances in reproductive technology. Children may be conceived today by such techniques as in vitro fertilization, artificial insemination of sperm, oocyte donation, and surrogacy. Custody disputes have already arisen over frozen embryos. With tens of thousands of potential viable frozen embryos being maintained currently in the United States, such cases are inevitable. The role of the forensic child psychiatrist in these complex cases will be hotly debated.

CIVIL LAW

Civil litigation, in which there are issues of psychological damages arising from negligence, frequently requires a child or adolescent psychiatrist to serve as an expert witness. Because this is an adversarial process, forensic evaluations may be performed for the plaintiff (the individual bringing the law suit) or the defendant (the person accused of negligence). Child psychiatrists may be asked by an attorney to evaluate a child represented by that attorney or a child who has been examined by a child psychiatrist for the adversary. In the latter case, the forensic child psychiatrist will be asked by the attorney to refute, if possible, the diagnostic conclusions made by the expert for the other side.

Posttraumatic Stress Disorder A common diagnosis, often the centerpiece of a civil trial, is posttraumatic stress disorder. In a typical lawsuit, a plaintiff child (or the parents) allege psychological damages, specifically posttraumatic stress disorder, resulting from the negligence of the defendant. In a civil case such an allegation of personal injury falls under tort law. Since 1970 case law has become more sympathetic to claims of psychic injury. Such injury is recognized as occurring concomitantly with physical injury, when a person is nearby and in danger of physical injury (the zone of danger), or when physical injury to another is witnessed.

A forensic child psychiatrist examining a plaintiff child for that child's attorney must first make the diagnosis of posttraumatic stress disorder, satisfying the criteria of the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV). Beyond that, however, the psychiatrist will be asked to give an opinion about whether the psychiatric disorder resulted from specific actionable behavior by the defendant. A child psychiatrist hired by the defense, on the other hand, would be asked to refute the diagnosis of posttraumatic stress disorder, or conclude that (whatever it is) the disorder did not result from the defendant's alleged negligence.

Such evaluations by child and adolescent psychiatrists are fraught with problems, especially if clinicians allow themselves to be used by attorneys to benefit their client. As in all areas of clinical practice, psychiatrists are first and foremost physicians, advocating what they believe to be clinically accurate and truthful, not what neatly fits into a lawyer's strategy.

Other Issues Other civil cases in which forensic child psychiatrists might be involved include the psychiatric hospitalization of children and assessing psychic damages from physical or sexual abuse. In evaluating such cases for either side, the child psychiatrist must carefully assess the degree of impairment in the child, offer hypotheses about causation of the psychic injury, discuss the prognosis with special attention to further growth and development, and consider any necessary treatments and their costs.

A defendant's attorney asked a child psychiatrist to examine a 7-year-old boy. Two years before, his client had driven his car into another car, which then jumped a curb, pinning the child beneath the wheels for nearly a half hour. Miraculously, the child suffered no broken bones or neurological injuries. However, for months after the accident, he had nightmares, developed phobias about being near automobiles or on sidewalks, cried frequently, complained of multiple somatic problems, and refused to play outside with his friends after school.

His parents sued the driver of the first car and claimed the accident caused their son to suffer posttraumatic stress disorder. The defense attorney secured the child's records from kindergarten, first grade, and part of second grade. The child was doing well in school. The defense held that the child did not suffer from posttraumatic stress disorder because of his excellent school performance.

The defendant's child psychiatrist expert reviewed the school records, examined the child, and met with his parents. He concluded the child did have posttraumatic stress disorder but continued to work very hard in school. He found the parents' report of the child's behavior to be credible, and he concluded that the symptoms were a direct result of the accident. The defendant's lawyer settled the case out of court.

Cases involving allegations of posttraumatic stress disorder in children will continue. The forensic child psychiatrist will have to follow the literature closely and keep up with developments in the field regarding the diagnosis and etiology of this disorder. Forensic child psychiatrists may also be asked to participate in cases involving psychic damage from alleged sexual harassment. Several cases have already emerged from school districts across the country, accused by parents of not intervening adequately when one student allegedly sexually harasses another. Child psychiatrists will be asked both to testify about normative behaviors at various developmental stages and to assess supposed damages from behaviors alleged to be harmful–as well as harassing.

Finally, cases concerning psychological trauma from physical and sexual abuse will continue. Child psychiatrists will evaluate psychic damages from abuse contemporaneous with the injury. Experts will also continue to be involved in cases arising later in childhood or in adulthood in which plaintiffs allege psychic injury from sexual abuse alleged to have been committed against them when they were children. Such cases may include so-called repressed-memory cases. In all such circumstances, the forensic expert will need to stay abreast of both current scientific developments and state and federal laws.

CRIMINAL LAW

Child and adolescent psychiatrists commonly perform forensic evaluations in criminal cases. These can involve assisting the court as a neutral evaluator or working with either prosecutors or defense attorneys. In addition to trial-related evaluations, child psychiatrists can be involved in the preadjudication phase by assessing immediate psychiatric needs of a juvenile detainee, participating in a waiver hearing (to determine whether the child will be tried as an adult), or evaluating competence to stand trial. In the postadjudication phase, the psychiatrist can assist the court in sentencing recommendations, long-term treatment alternatives, or the determination of probation.

Knowledge of the juvenile court system and its strengths and weaknesses is essential for the forensic child psychiatrist working in this area. Likewise, the clinician must appreciate the indications for waiver hearings and the grounds for judicial determination that a minor be tried as an adult. Although the juvenile court system operated for decades as supposedly child oriented and protective, the United States Supreme Court, in the landmark case *In re Gault,* determined that the system sometimes did not accord juveniles rights equal to those of adults. This decision held that in delinquency cases, juveniles must be accorded basic due process rights: the right to notice of charges, the right to legal counsel, the Fifth Amendment privilege against self-incrimination, and the right to confront witnesses. Another important Supreme Court case, *In re Winship,* held that the standard “beyond a easonable doubt” must be followed in delinquency hearings.

The forensic child psychiatrist evaluating a child defendant in a criminal case performs a comprehensive examination regardless of the side making the referral. All previous records must be obtained and both family members and the child who is charged must be interviewed. The report is tailored to the needs of the attorney or the court or both. For example, the clinician might be asked to present diagnoses and their prognoses or to assess dangerousness or recidivism. The child psychiatrist may also be asked to evaluate the juvenile in the context of a possible insanity defense. Clearly, the forensic evaluator of the delinquent child must not only appreciate local statutes and legal principles, but must also be grounded in developmental issues, factors correlated with antisocial behavior, clinical diagnosis, and appropriate treatment alternatives.

A 13-year-old boy was charged with the brutal murder of a 4-year-old child. In his signed confession, the teenager said that for no apparent reason, except that he felt angry, he choked the child, fractured his skull with a large rock, and then sodomized him. The public defender asked a child psychiatrist to evaluate the accused in the hopes of shedding some light on this seemingly senseless act.

The child psychiatrist interviewed the adolescent and all members of his immediate family. He reviewed school and medical records and ordered psychological, endocrinological, and neurological evaluations. The child had stigmata of a congenital dysmorphic syndrome caused by an anticonvulsant drug taken by the mother while pregnant. The boy had breath-holding spells as an infant and toddler and intermittent rage attacks throughout his life. He had been known to torture animals. He had few friends.

Under state law, the child was tried as an adult. The forensic child psychiatrist testified that the teenager suffered from intermittent explosive disorder and should be held in a psychiatric institution for many years. He recommended intensive group and individual psychotherapy along with medication to control the rage. The jury, however, found the young man guilty of second-degree homicide, and the judge sentenced him to the maximum allowed by state law, 9 years to life. The child was remanded to a juvenile detention facility until his eighteenth birthday, at which time he will be transferred to an adult prison. Inside the detention facility, he receives no specific psychiatric treatment.

With United States government predictions of more juvenile arrests for serious crimes in the next decade, forensic child psychiatrists will be busy. They will most likely be participating in more waiver hearings, assessing more violent children, making more predictions of future violence, and working in and evaluating juvenile detention centers. In their reports and trial testimony they will be called upon to offer hypotheses about the causes of violent antisocial behavior in children and adolescents, and they will need to stay current with new research.

OTHER FORENSIC ISSUES

Child and adolescent psychiatrists may be involved in forensic evaluations outside the more common venues of the family or criminal court. For example, they may be called upon to make certain recommendations for a student with special needs under the landmark Education for All Handicapped Children Act of 1975. This law requires that all handicapped children, regardless of the severity of their condition, be provided a free and appropriate public education in the least restrictive environment. Handicapped children are defined as those who are mentally retarded, learning disabled, physically disabled, or emotionally disturbed. A treating or evaluating child psychiatrist may be called upon to testify at various hearings required under the law. Knowledge of the law's implications as well as the particular child will be critical to performing a proper evaluation.

Occasionally, a child and adolescent psychiatrist may be asked to become involved in a malpractice suit against another child psychiatrist. This involvement may be for the plaintiff or the defendant's side. Malpractice cases in child psychiatry may arise for a number of cited reasons including failure to give informed consent to parents, medication errors, inappropriate behavior toward a child, failure to warn a third party of endangerment, abandonment, diagnostic error, or disclosure of private information. The forensic child psychiatrist evaluates the data carefully before offering an expert opinion. Malpractice cases are complicated and arouse strong emotions. Forensic psychiatrists must monitor their own potential for countertransference under these circumstances.

From time to time, a child psychiatrist may be asked to testify in general or regarding a specific case about children as witnesses. Such cases may arise when there are allegations of sexual abuse or when a child either witnessed or is the victim of a crime. The forensic expert's role is to educate the court about what is known about children's memory and recall. This area is currently under intensive investigation.

FUTURE DIRECTIONS

The future will be busy and challenging for forensic child and adolescent psychiatry. Courts will continue to grapple with calendars clogged with child placement cases. Juvenile crime rates are expected to remain high, and judges will continue to turn to forensic experts for guidance in these complex cases. As the field

continues to grow in terms of practitioners and an increasing body of scholarly literature, some changes and improvements are in order.

Forensic child psychiatry needs more standards for various kinds of evaluations. The Practice Parameters on Evaluating Allegations of Sexual Abuse and Child Custody Evaluation published by the American Academy of Child and Adolescent Psychiatry are steps in the right direction. The field needs better clinical consensus on evaluating criminal behavior, participating in civil litigation, and the uses and misuses of the child psychiatrist expert witness.

Although more forensic psychiatry fellowships are becoming available, few offer extensive experience in forensic child and adolescent cases. More training opportunities are needed in this field. As an additional way to teach younger clinicians, more experienced child psychiatrists should offer to serve as mentors, guiding and acting as role models for those new to the field.

In addition, the time may now be right for establishment of an international society for forensic child and adolescent mental health professionals. Forensic clinicians who are psychologists, social workers, and psychiatrists have much to learn from one another.

Finally, the revolution in communications and information can benefit forensic practitioners, as it has so many other professionals. The Internet is a repository of numerous World Wide Web sites devoted to forensics as well as legal sites of interest to psychiatrists. Both major recent court decisions and historic, landmark rulings are available on the Internet. Law schools have their own websites, as do associations such as the American Bar Association. There is even a website providing the audio from oral arguments before the United States Supreme Court. Thus, information pertinent to forensic practice will become more accessible and it will be easier to communicate with colleagues all over the world.

SUGGESTED CROSS-REFERENCES

Forensic and ethical issues are discussed in Chapter 54. Posttraumatic stress disorder and other anxiety disorders are covered in Chapter 15. Chapter 22 covers intermittent explosive disorder and other disorders of impulse control. Child abuse is discussed in Section 49.4. Section 49.2 discusses adoption.

49.13 ETHICAL ISSUES IN CHILD AND ADOLESCENT PSYCHIATRY

DIANE H. SCHETKY, M.D.

Ethical codes are characteristic of all professions and serve to regulate behavior, safeguard the public, and promote trust. The basic ethical theories and principles discussed in Section 49.12 were first codified by the American Medical Association (AMA) in 1847. The AMA Code of Ethics underwent many revisions and in 1973 was incorporated into the American Psychiatric Association's (APA) Code of Ethics with Added Annotations Applicable to Psychiatry. The American Academy of Child and Adolescent Psychiatry (AACAP) developed its Code of Ethics in 1980. This Code addresses the relationship between the child and parent and the potential for conflicting interests between child, parent, and society. It also emphasizes developmental considerations that enter into ethical decisions and special issues related to the confidentiality of child and adolescent patients. In 1995 the AACAP added Annotations to the AACAP Ethical Code with Special Reference to Evolving Health Care Delivery and Reimbursement Systems.

In the United States physicians are expected to adhere to the ethical code of the AMA. Child and adolescent therapists who are not physicians are expected to follow the ethical codes of the professional organizations to which they belong. Neither the APA nor AACAP Codes of Ethics address forensic issues. The child and adolescent psychiatrist who practices in this area should be acquainted with the Ethical Guidelines for the Practice of Forensic Psychiatry published by the American Academy of Psychiatry and Law.

SPECIAL ISSUES

Agentry Special ethical issues arise in treating child and adolescent patients because of their developmental immaturity and minority status. Even though a child is the identified patient, he rarely presents on his own and is more likely to be seen because of behavior that is troubling to others. Referral sources, be they parents, guardians, physicians, schools, or the courts, often have their own agenda in making a referral, an agenda that may or may not coincide with the child's agenda. The therapist needs to refrain from colluding with agendas and focus on what lies in the patient's best interest.

> A typical scenario is the Green family, who come to Dr. Riley telling him that he came highly recommended by their pediatrician and pastor. They complain that their 15-year-old son, Josh, talks back, won't communicate with them or inform them of his whereabouts, is obsessed with his rock band, dresses like a street person, and refuses to attend church with them. The final straw that led them to seek professional help is the ring that Josh now wears in his eyebrow. Mr. and Mrs. Green are hoping that Dr. Riley will bring back the son they used to know. Josh doesn't see what the big deal is and tells Dr. Riley that everything would be fine if only his parents would get off his back, trust him, and allow him to make some of his own decisions. He is doing fine in school and is enrolled in honors courses. He reassures Dr. Riley that, contrary to his parents' fears, his interest in rock music will not cause him to take drugs and drop out of school, which is what happened to his mother's younger brother.
>
> Dr. Riley decides to ally himself with neither the parents nor Josh's agendas, choosing rather to focus on issues of separation-individuation. Yet another issue for him to consider is whether Josh is even in need of treatment and whether he can justify seeing him under his managed-care plan for what appears to be a parent-child problem. He realizes the decision for treatment also lies in Josh's hands and that Josh's parents forcing Josh to return against his will is likely to be counterproductive. He might choose to work just with Mr. and Mrs. Green, but must weigh this against whether it would preclude Josh from seeing him if he chooses to return at a later time; alternatively, he might consider a brief course of family therapy.

Collaterals Given that children are less able than adults to provide past history and family history, the child therapist must often rely on collateral sources of information to piece together a history and formulation. In addition to meeting with parents, this often involves seeking information from collateral sources such as schools, courts, and pediatricians. These contacts may also be important in implementing treatment plans. The therapist needs to be sensitive to the concerns of both patient and family in initiating these contacts and must seek proper consent for release of information. Some parents may willingly consent whereas others fear stigmatization or do not trust that recipients of the shared information will maintain confidentiality.

How aggressive the child therapist should be about pursuing contact with a school might depend on the extent to which a child's problem is affecting his ability to function in school.

> For instance, Ryan, age 10, is falling behind in school because his morning rituals prevent him from getting to school on time. Once there, he constantly checks and rechecks his paperwork and tests for errors. He has difficulty completing assignments, and excessively questions and seeks reassurance. Ryan's school needs to know that obsessive-compulsive disorder underlies his indecisiveness. School, family, and therapist need to work together towards developing a plan to help Ryan deal more constructively with his anxiety. Most schools also want to be informed if a child is taking medication and about possible adverse effects. The clinician needs to be cautious about how much family history to share with the school and should generally limit it to that which is directly relevant to the student's problem.

Countertransference Working with children and adolescents brings out special countertransference issues. It is easy for the inexperienced therapist to overidentify with the child and to blame the parents for a child's problem. Therapists may also overidentify with adolescent patients and unwittingly encourage their acting out or anger with parents if they have not worked through their own adolescent issues. Fantasies of rescuing a child from a bad home or from parents who do not appreciate her may also occur and impede work with the family and child. Fortunately, blaming the parent has become less common as we have come to appreciate that many childhood disorders are biologically based. Another antidote for this sort of countertransference is parenthood, which inevitably instills instant humility and empathy in the therapist. Some childless therapists may come to view a child patient as a longed-for child and give her special treatment. Child therapists may also experience erotic countertransference either towards patients or their parents and have great difficulty processing these feelings because of their forbidden nature. Therapists must deal with countertransference issues so that they not lead to acting-out behavior, which is potentially harmful to the child and can impede treatment.

CONSENT

Obtaining Informed Consent Obtaining consent with minors is complex because generally they are not considered competent to make legal decisions until age 18. Exceptions exist in most states for emancipated minors, those seeking birth control, treatment of sexually transmitted diseases or substance abuse, and in emergency situations. Some states allow mature minors to contract for treatment. Therapists who choose to treat an adolescent without parental permission should be aware of the laws in their state and the risks they might incur. By about age 11 or 12, children reach the stage of formal operational thinking and are capable of comtemplating various courses of action, understanding contingencies and consequences, and considering hypotheticals. Studies have demonstrated that adolescents are capable of making complex decisions; indeed, courts afford considerable weight to the wishes of adolescents in custody and visitation decisions.

In most instances it is the parent or guardian who will make treatment decisions for the child; nonetheless, children and adolescents should be asked for their consent to the proposed treatment. Consent is not legally binding but conveys to the child that his input is valuable; it also allows the child to express veto power.

Conditions of informed consent require that one: (1) be given information about the nature and extent of the psychiatric problem, (2) be made aware of risks and benefits of the proposed treatment, (3) be told what treatment alternatives are available, and (4) be capable of voluntary consent. How much information is disclosed is in most states based on the materiality of information standard, which holds that the information disclosed should be based on what a reasonable person would

want to know in order to make a decision under similar circumstances. Parents and adolescents also need to know if drugs are proposed that do not have approval from the Food and Drug Administration (FDA) for use in children and the rationale for using them. Very few psychiatric drugs have been tested in children, hence their lack of FDA approval. However, the FDA does not limit the physician's prescribing habits and there is a body of research emerging on new uses of drugs for conditions and age groups for which they were not intended (e.g., quanfacine [Tenex] for attention-deficit/hyperactivity disorder and selective serotonin reuptake inhibitors [SSRIs]) prescribed for children. Discussions about treatment and potential risks or side effects should be documented in charts. Written consent is also advisable when using antipsychotic agents or medications that are likely to carry serious risks.

Ethical Conflicts Pertaining to Consent Ethical conflicts arise when parents disagree on proposed treatment.

> Mrs. Schulz, who is recently divorced, seeks therapy for her 6-year-old son, Aaron. Mr. Schulz, who has shared custody and is liable for the costs of treatment, insists that Aaron is fine when he is with him and sees no need for treatment. He suggests that if there is a problem it lies with his ex-wife. Dr. Jain, who has evaluated Aaron and believes he needs treatment for depression, now finds herself in a bind. Legally, she only needs the consent of one custodial parent to see a child but she recognizes that without the consent of the father he is likely to undermine therapy. She must decide what is in Aaron's best interest in the long run. She later wishes she had chosen to involve the father in the initial evaluation or perhaps not have conducted the evaluation without his permission.

Conflicts may arise between patient, parent, and therapist over medication compliance.

> Twelve-year-old Jennie, who has bipolar I disorder, has done well on lithium over the past 5 years. She suddenly announces to Dr. Daniello that she wants to stop taking her lithium. On exploring the reasons for this, he learns that Jennie's classmates are calling her a “druggie” for having to take lithium and that she still experiences occasional lithium-induced enuresis and fears embarrassment if she goes to a friend's house overnight. Jennie's anxious mother proposes bribing her. The more she pushes, the more Jennie balks. Dr. Daniello ponders how much autonomy he should give this preadolescent regarding the decision to discontinue medication. He appeals to her wish for autonomy and her intellect and reminds her of studies they have previously discussed showing decreased effectiveness of lithium when it is stopped and then reintroduced. He suggests a compromise in which she skips her evening lithium if she is going on an overnight visit. He reminds her that taking medication is her decision, that neither he nor her mother will force it upon her, and suggests she think about what she wants to do. Jennie returns for her next appointment feeling more empowered and says she's decided to stay on her lithium.

Release of Information to Third Parties Older children and adolescent patients as well as their parents should be consulted in decisions about release of information to others. They need to know what is going to be released, to whom, and for what purposes. Reports should be written such that they can be read by parents or adolescents, which requires sensitivity and tact. Once a report is released, the author of it often loses control over who sees it. Particularly in forensic matters, reports are likely to be shared with parents. In custody evaluations children need to be informed at the onset about the lack of confidentiality.

Child and adolescent psychiatrists often work in collaboration with other therapists. This may involve medication management, supervision, or consultation. The success of these relationships often hinges on good communication. It is recommended that parents and collaborative therapists sign a consent form that spells out respective responsibilities and lines of communication.

Consent for Research As the field of child and adolescent psychiatry becomes more research based, children and adolescents are increasingly being sought out as research subjects. Factors to be considered include age of the child, risk the research poses to the child, invasiveness of the research, and the prospect that the research will benefit the child. Levine notes that, “Past policies and practices designed to protect vulnerable persons from unwanted or unwarranted burdens actually deprived them of important benefits.” Some authors propose a system of age-graded consent for moderate-risk protocols.

CONFIDENTIALITY

Defining Confidentiality Confidentiality refers to the clinician's obligation to keep material shared in the course of a professional relationship from third parties, unless confidentiality is waived by the patient or guardian. The term *confidentiality* is often confused with the term *privilege,* which refers to the patient's right to bar the clinician from testifying about professional material in a judicial or quasi-judicial proceeding. Confidentiality is the clinician's obligation whereas privilege is the patient's right. Confidentiality is the cornerstone of therapy, without which patients would be reluctant to share information necessary to diagnosis and treatment.

Guidelines governing the minor's right to confidentiality are less clear than those for adult patients. Parents may feel that they are entitled to information about their child, especially on such topics as sexuality and substance abuse. The therapist, on the other hand, needs to respect the adolescent patient's need for confidentiality and to preserve the therapeutic alliance. Compounding this dilemma is the fact that parents may waive the therapist-patient privilege on behalf of the child, even though the waiver is not truly informed because they do not know what is in the child's record. This may occur in custody battles where one parent thinks information from the child's therapist will aid their side. The therapist may feel that release of sensitive information is detrimental to the child or to the parent-child relationship. In such a situation, the therapist should appeal to the attorney requesting the information or to the judge. A compromise proposed by the APA is that the petitioner must first demonstrate why the information is relevant to a custody determination and why it cannot be obtained from other sources. If this threshold is crossed, the judge or another professional could then review the material and decide on its relevance or appropriateness.

Limits of Confidentiality Most child and adolescent therapists at the onset of therapy spell out the limits of confidentiality to the families they are working with and clarify how communications with parents are to be handled; they also need to discuss the limits of confidentiality in regard to insurance plans. Additional limitations to confidentiality include behaviors harmful to self or others. When disclosures need to be made to parents, the patient may be given the option of telling them himself, or of discussing it with parents and therapist together. Other exceptions to confidentiality include laws on reporting child abuse, which are mandatory in all states. A physician who fails to report suspicion of abuse may be liable for civil as well as criminal sanctions. If an abuse report needs to be filed, parents should be so informed. In some states physicians may also have a duty to protect third parties under *Tarasoff I* and *Tarasoff II* (i.e., the 1976 and 1982 rulings of the California Supreme Court in the two cases of *Tarasoff v. Regents of University of California*).

BOUNDARIES

Purpose of Boundaries The APA's *The Principles of Medical Ethics with Annotations Especially Applicable to Psychiatry,* Section 1, stresses the need for the patient to be able to trust a psychiatrist knowing that professional ethics preclude the exploitation of patients for personal gain. The need for continued vigilance about boundaries in the doctor-patient relationship is also emphasized. Good boundaries promote good therapy and greatly diminish the likelihood of a malpractice suit. Boundaries maintain professional roles, define limits, provide security to the patient and therapist, and lessen the risk of exploiting patients for personal gain. Numerous forces threaten to derail the therapist's boundaries, including countertransference, the primal productions of children, dual relationships, undue pressure from others, greed, and psychiatric impairment in the therapist.

Maintaining Boundaries Maintaining boundaries is an ongoing process that begins prior to accepting a patient and continues through therapy and after termination. It is important to screen new patients for potential conflicts of interest. Treating the children of friends, colleagues, or employees is rife with difficulties. The therapist is rarely neutral at the onset and usually has access to information from outside therapy that she cannot use in therapy, but that may color her perceptions. Also, the therapist may become privy to information about her friends and colleagues that she would rather not know and will need to compartmentalize and not use it outside the office. For instance, she may learn through her young patients that her dentist beats his wife, that Dr. Jones down the hall cross-dresses, or that the neighbor with whom she car pools is a closet alcoholic. It is usually preferable, although often difficult, to turn down these tainted requests for professional help that come from friends and colleagues and to refer them elsewhere. In communities with few resources, the therapist may have no alternative but to see the family. In cases where the pathology is minimal (which is impossible to know at the onset) and where boundaries are maintained vigilantly, the therapist may be able to pull off a successful intervention. However, the therapist's relationship with the family in question will never be the same again.

Dual Relationships Child and adolescent therapists often find themselves in dual relationships with their young patients such as when their own children participate in soccer, scouts, and youth groups with their patients. It may be awkward if a therapist's daughter wants to have a play date with one of her parent's patients. The older one's children become, the less control one has over the friends with whom they choose to associate. Difficulties also arise when spouses have no knowledge of the therapist's case load and may inadvertently have contacts with patients or their families. Confidentiality needs to be preserved unless the situation becomes untenable.

In small towns, out-of-office contacts with patients and their families are daily occurrences that the therapist has to learn to deal with. Successful management of these encounters requires that the therapist respect patient boundaries, process these encounters in therapy, and not do anything in public that she would not want her patients to see. Some of these encounters may even be of therapeutic value and encourage the young patients to see the therapist as a real person who has a life outside of the office.

Forensic Issues Often therapists are pressured to testify in court on behalf of their patients. This may occur at the request of patients or parents who believe that such testimony will help their case or in response to subpoenas from either party. It is common in child custody cases where the therapist has been treating the child of divorcing parents. Therapists may agree to testify expecting their testimony to be helpful, but it may just as likely end up being harmful. Testifying on behalf of a patient is rife with pitfalls. Therapists lack the objectivity of a forensic evaluator and often have a more limited data base. Patients or parents of patients may waive privilege unaware of what is in their records or how it might be used to discredit them. Once on the witness stand, therapists lose control over the patient's record and may have to disclose things that were said in confidence. They also risk having to say things that may jeopardize their therapeutic alliance with the patient and the patient's parents or that may harm the child-parent relationship.

The importance of not wearing two hats cannot be stressed enough and therapists should avoid rendering forensic opinions on patients they are treating or have treated in the past. There are several alternatives, including recommending an outside forensic evaluation when legal issues arise. The therapist may share information with the forensic evaluator but does not have to render recommendations on sensitive matters such as which parent a child should live with or commitment of a patient to a youth facility. This arrangement also makes it less likely that forensic issues will derail therapy. If faced with a subpoena from the patient's attorney, the therapist may appeal to the attorney issuing the subpoena and point out how testimony might be harmful to the patient and to therapy. The psychiatrist may also appeal to the court to quash a subpoena. If forced to testify, therapists should do so in as narrow a fashion as possible, limiting themselves to factual data such a diagnosis, dates of treatment, and treatment needs rather than giving opinion testimony. A useful response to being questioned in court is: “Having observed the patient only from the vantage point of a treating clinician, I have no objective basis for rendering an expert opinion, with a reasonable degree of medical certainty on a legal as opposed to a clinical question.”

If the legal issue concerns tort litigation, the litigant automatically tenders medical records in bringing about a claim for damages. In such cases, the therapist may be compelled to testify more broadly on the litigant's mental functioning prior to or subsequent to the action for which relief is being sought.

Boundary Violations Common boundary violations include financial conflicts of interest, exploitation of fame and notoriety, exploitation through writing, double agentry, socializing with patients, and sexual exploitation. These are not unique to child and adolescent psychiatry. It is prudent to adhere to the maxim “once a patient, always a patient” and consider each new patient who enters the office as one less potential friend. Transference rarely ends with treatment and by not socializing with former patients and their families the therapist leaves the door open should they choose to return to treatment at a later date.

Minor boundary violations, such as giving special treatment to a particular patient, are common and can be easily corrected if recognized; more ominous is a repeated pattern of boundary violations. Typically, in these scenarios the therapist uses the patient or his family to meet her own needs or fails to differentiate her own needs from those of the patient. Where there is a pattern of repeated boundary violations, therapists are advised to seek consultation or therapy.

ETHICAL ISSUES WITH MANAGED-CARE ORGANIZATIONS

Conflicts of Interest With the advent of managed care, some physicians are confused about where their allegiances lie. For instance, a child psychiatrist advises a managed-care organization for whom he works that it should not insure a particular child because the child requires such extensive services. Ethics demand that the patient's interests are foremost, but new economic pressures threaten to corrupt many physicians. Examples of policies designed to shape physicians' behavior are financial penalties for giving too much treatment or making too many referrals and the threat of being delisted if one does not comply with managed-care policies or advocates too vigorously for a patient.

The phenomenon of gag orders amply demonstrates how physicians cannot serve two masters. Fortunately, most states have now enacted legislation that forbids withholding from patients information that they need in order to make informed treatment decisions. This situation exemplifies the inherent conflict between business ethos, which stresses profit for investors, and medical ethics, which stresses doing no harm and advocating for the patient's well-being. Child and adolescent psychiatrists who chose to contract with managed-care organizations may refuse to sign gag orders and insert in their contracts statements such as “First and foremost, I will follow the ethical code of The American Academy of Child and Adolescent Psychiatry.” Patients should be informed if their therapist is practicing under an incentive plan or has any conflicts of interest in regard to the care delivered to them.

Advocates of managed care argue that this system of health care delivery is ethical because it stresses the concept of justice for all in an era of limited health resources. This would be plausible if report cards on managed-care companies showed that they were providing better care to the poor, elderly, and chronically ill; however, such has not been the case. Rather, surveys demonstrate that managed care prefers to enroll the cream of the crop; patients with more serious or chronic problems are relegated to Medicaid and Medicare or remain uninsured. Currently 40 million Americans, including 10 million children, are uninsured.

Many child therapists become frustrated in their efforts to advocate for their young patients' health care needs under managed care. They feel forced into giving less than optimal service or face the ethical temptation of exaggerating symptoms in order to gain needed approval of services.

It has been noted that inpatient units face many dilemmas and the gatekeepers encounter a barrage of ethical conflicts with each referral. Typically, the medical director is faced with highly complex cases that pose a high degree of risk. Children have the right to be treated in the least restrictive environment, yet this may not be available. In some cases the patient's needs may exceed the resources of a particular inpatient unit. The insurance company may be unwilling to pay for a higher level of service or will only consent to admission to a facility that is at a great distance from the patient's home.

> For instance, one medical director of a managed-care company from a distant state, with no knowledge of Maine geography, denied an inpatient admission for a suicidal, syncopal teenager with an eating disorder and would only authorize a day treatment program 2 hours from home to which she would have to drive herself on icy roads. His rationale for denial of inpatient care was that she was not yet in medical danger.

The staff of inpatient units are pressured daily by case managers to accelerate a patient's care (e.g., to initiate medication before an evaluation is complete, or to discharge a patient as soon as she is no longer suicidal). Staff must also deal with anxious parents worried about the cost of treatment once insurance benefits are exceeded and about their ability to handle a child who is prematurely allowed to go home. Should a therapist even accept patients whose insurance will not pay for minimally acceptable treatment? What is the therapist's liability and responsibility once benefits are cut off? Amidst the scramble for patients and the atmosphere of diminishing reimbursement, it is easy to be swayed by the need to keep an inpatient unit full or to maximize one's outpatient practice. However, patient care must not be compromised, nor should therapists jeopardize their integrity by contracting with plans that offer substandard care.

Need for Child Advocacy Subscribers are also confused by new systems of health care delivery and are often unclear about whether a case manager is looking out for their interests or those of the managed-care company. Many people are ill informed about the constraints of managed care and their rights and need their therapist's help with advocacy for their children. The 1995 AACAP Annotations to the Ethical Code stresses avoiding actions detrimental to the child and the need for the child and adolescent psychiatrist to reduce the deleterious effects of actions by others on the child. This translates to aggressive child advocacy, appealing managed-care decisions that are detrimental o the child, and demanding publicly accessible justifications for decisions.

Providers who choose to work within a managed-care network can educate policymakers about the unique treatment needs of children and that working with parents and children takes time. Providers can pressure companies to respect professional ethics and to develop their own code of ethics regarding patient care. Good managed care should include choice, competence, compassion, and doctor-patient relationships that are free of conflict and that promote continuity of care. Child therapists also have an important role to play in working with their professional organizations and legislators to come up with better solutions for equitable health care. Medical ethics existed long before the advent of managed care and will continue to exist long after managed care as long as physicians refuse to capitulate to financial pressure.

REPORTING ETHICAL VIOLATIONS

Section 2 of the APA's Principles of Medical Ethics states “A physician shall deal honestly with patients and colleagues, and strive to expose those physicians deficient in character or competence, or engage in fraud or deception.”

It is never easy to report a colleague and yet it is a task that is sometimes necessary to protect patients and the profession and to rehabilitate colleagues when possible. Concerns about ethical violations by psychiatrists should be reported to the district branch of the APA. If the clinician in question is not a psychiatrist, complaints should be filed with the relevant professional organization. Ethical complaints must be filed in writing and, once received, they are carefully investigated and, if warranted, go to a hearing. Ethical violations may result in sanctions such as admonishment, reprimand, suspension, or expulsion. Decisions regarding licensure are made by state licensing boards who conduct their own independent investigations. In some instances, violations may result in complaints being made with both the APA district branch and the state licensing board. Members who have committed ethical violations may face criminal and civil complaints filed by the plaintiff as well. If there is question of substance abuse or mental disorder, referral to the Impaired Physicians Committee may be appropriate.

A frequently asked question is whether a therapist must report abuse by a physician or former therapist when it is disclosed in therapy. Any abuse disclosed by a child to a mandated reporter must be reported to protective services if the abuse is within the family, and to the district attorney or appropriate law enforcement agency if it occurred outside the family. In contrast, if the patient bringing the complaint is an adult, it is usually the patient's decision whether or not to file a complaint and with which agency or organization, although this may vary from state to state. If the patient chooses not to report the abuse the therapist can be placed in a very awkward position regarding the risk that the alleged offender poses to other patients. It also pits the therapist's ethical duty to report a physician's alleged misconduct against his duty to maintain the patient's confidentiality. As with many ethical dilemmas, the therapist is left weighing competing principles.

49.14 SCHOOL CONSULTATION

RICHARD E. MATTISON, M.D.

HISTORY

School consultation has long been a common component in the clinical practices of child psychiatrists. School consultants have frequently focused on advising special educators who are teaching problem students. The need for mental health services by the 400,000 to 500,000 students receiving special education for their school behavioral or emotional problems is being emphasized anew. Epidemiological studies have begun to demonstrate that the majority of youth in the United States who need mental health intervention do not receive such care. When they do, a large proportion receive services in the schools, although the exact nature of how such services are delivered is not yet clear. Consequently, school mental health clinics are being investigated to reach the many unserved students with mental health needs. Thus, as school consultation grows and matures, the need is also increasing for more objective research and for increased collaboration with educators. Also, child psychiatry has begun to re-examine the instruction of trainees in school consultation to ensure their adequate preparation.

SCHOOL CONSULTATIVE PROCESS

Models for school consultation have largely been derived from the work of Gerald Caplan. A psychiatrist, usually under contract with a school district or a special education agency, is usually asked to perform a client-centered consultation, that is, the consultees are school personnel who have questions about a specific student. However, the principles of interaction with school staff are also applicable to a psychiatrist meeting with school personnel concerning a private patient. One model for a desirable sequence of steps is: information acquisition, initial meeting with school staff, student interview, parent interview, feedback meeting with school staff, feedback meeting with student and parent, and report.

Information Acquisition Prior to consultation the psychiatrist should receive from the school any formal reports that are in the student's file. Such history will provide the consultant with some initial understanding of the student prior to the meeting with the school personnel, thus helping the consultant to gather a more informed history from the school staff. Additionally, a teacher rating scale, such as the Achenbach Teacher Report Form, can help the psychiatrist gain an objective understanding of the student's current functioning in school.

Initial Meeting With School Staff A meeting with school personnel should precede interviews of the student and the parents. As the consultee, the teacher or school staff should first be encouraged to voice their concerns about the student and then to identify the specific questions that they wish the consultant to address. The psychiatrist will then expand and clarify this information, as well as any issues that previous reports may have raised. Although the staff may focus on one area of school dysfunction, the consultant must gain a comprehensive understanding of all the key areas of school functioning: attendance, academic (achievement levels and learning skills), social (peer and adult), behavioral, and emotional. School personnel should also be asked for their knowledge of the student's functioning at home and in the neighborhood, as well as environmental stressors. Finally, the staff should be questioned for their reasoning about causes of the student's school problems.

Student Interview Interviewing the student first will usually help to relieve the student's anticipatory tension about the meeting being important to the student's school future. The pupil should be told that the psychiatrist has been asked by the school staff for advice about the student's difficulties in school, but that confidentiality will be maintained. The youth's view of school functioning (in all major areas) should then be ascertained, including thoughts on the school's concerns if the student does not spontaneously remark on those issues. After this initial discussion of school matters, a standard comprehensive interview or mental state examination should then be conducted, beginning with any problems or worries that concern the student outside of school.

Parent Interview Next, the parents should be interviewed; the consultation process should be explained and their knowledge and thoughts about the school staff's current concerns should be ascertained. During this initial segment the parent should also provide the student's past school history because the school staff may have an incomplete educational history, especially if the child is in secondary school. A standard history should also be gathered from the parent, as would be obtained during an initial evaluation in the psychiatrist's office. Particularly important are parental concerns about the child outside of school, any past psychiatric problems the student may have had (including past and current mental health intervention), and family atmosphere.

Feedback Meeting With School Staff The consultant should begin with a summary of the interviews with the student and the parent(s), carefully protecting confidentiality. Diagnostic hypotheses should be given next, which will provide the school staff with a rationale for the consultant's final feedback step, that is, answers to the educators' initial consultation questions. The psychiatrist should then facilitate discussion by the school team, a multidisciplinary debate during which the consultant's own thinking on the case can be refined, especially to be sure that the initial questions of the staff have been addressed and that issues that were not raised at first have been identified.

The feedback meeting to the school staff should conclude with collaborative treatment planning for the student to include not only intervention steps in the school but also treatment needs to be met by community services. Team members can be especially helpful with actualizing treatment suggestions that the consultant may suggest for the classroom and school. At the conclusion of this feedback, staff should have a clear understanding of what school interventions will be undertaken with the student, and one member should become the case coordinator. They should also be aware of what community mental health services will be suggested to the student and the parent; the identified coordinator can follow through with the family to ensure that the outside help is obtained.

Feedback Meeting With Student and Parent Optimally, the case coordinator identified from the school team should participate in this feedback, as that staff member will be responsible for moving the case along both in and out of school. Separate feedback to the parents and then to the student is desirable in order to promote unimpeded reactions and questions that might not occur in joint feedback. Case coordinators should be identified as such and permission should be asked for their participation. Consultants should then explain their reading or diagnosis of the student's situation, followed by recommendations for school and community services that the psychiatrist and team have developed. Questions should be encouraged from the family to ensure their maximum understanding. Planning should begin for community services, especially to determine if the consultant is needed further (and thus proper written permission obtained). For example, the psychiatrist may need to phone the student's pediatrician to discuss a trial of stimulant medication, contact the child's current therapist to share the consultation and thus assist in treatment direction, or contact a mental health professional selected by the family to discuss the student's working diagnosis and probable treatment needs.

Report Preparation A good consultative report can not only influence the care of the student positively in the period after the consultation, but also potentially in subsequent school years by new school staff. Current school staff will return to the report to further develop their understanding of the student as well as the treatment rationale and school components. The report can also be very helpful to community mental health professionals who become involved in the case, and thereby promote their collaborative effort with the school team.

Consequently, a good report of a school consultation should provide a clear description of the student's symptoms in and out of school, both past and present, including a differential review. The student's medical and developmental history should be summarized, as well as any mental health treatments to that point of time. Pertinent family history should be highlighted, especially stressors. The mental state should be thoroughly described. Diagnoses from the fourth edition of *Diagnosis and Statistical Manual of Mental Disorders* (DSM-IV) should be stated as well as the consultant's formulation. Most importantly, at the end of the report each original question from the consultee should be answered, accompanied by any appropriate treatment suggestion for both in and out of school.

Finally, release of the consultation report must be strictly controlled. Parent or student permission, or both, should be gained before the report is sent to any external resource by the school or the consultant. Internally, the school must closely control which school personnel may have access to the report because it is a confidential, professional document.

COMMON PSYCHIATRIC DIAGNOSES

Attention-Deficit/Hyperactivity Disorders In general, school personnel have now become much better educated about the clinical features of attention-deficit/hyperactivity disorders through workshops, courses, and readings targeted for teachers. However, questions continue for consultants concerning treatment, especially medication and classroom interventions. Consultants must be careful to continue to teach or remind teachers of what medicines can and cannot do. For example, psychostimulants can positively affect concentration and hyperactivity, but they do not impart socialization skills or anger management, which must often be taught in conjunction with medication. Thus, psychiatric consultants can help teachers to become good observers of children's responses to these medicines, which will greatly help the physicians who regulate the medication.

School staff are often frustrated by a lack of communication with the doctor who is regulating a child's medicine. In such a case, the staff should first obtain written parental permission to communicate with the physician about the student's medicine (i.e., when necessary, the school should initiate and maintain communication with a child's doctor to increase the certainty of proper medication management). Then staff can select an objective teacher rating scale for attention-deficit/hyperactivity disorder, complete the instrument regularly for the student, and mail it to the physician. These instruments usually contain extra space where staff can briefly write their observations about the medicine's effects on a child, note any adverse effects, and ask specific questions of the doctor. Such a step by school staff can often stimulate proper communication with a physician.

Although teachers are now more knowledgeable about the clinical picture of attention-deficit/hyperactivity disorder, their skills in classroom intervention with such students are often not as advanced. When a consultant has determined that a child with the disorder needs classroom intervention, the capabilities of teachers and their support staff in the school must be ascertained. Depending on the answers to these key questions, the consultant will better understand what to advise.

The need to improve teachers' skills in addressing the specific problems of students with attention-deficit/hyperactivity disorder is now being recognized and addressed in different manners. Self-taught teachers can continue to increase their skills with a growing practical literature. Pressure is increasing on teachers' colleges to include basic instruction on this disorder in course work. Certain universities have begun to offer consultation packages to school districts, especially to train and maintain local personnel as resident experts in this condition. Finally, recognizing that very often even knowledgeable teachers do not have time to properly address these student's needs (especially children with complex or serious clinical pictures), some school districts are beginning to train special paraprofessionals to work in classrooms containing children with attention-deficit/hyperactivity disorder and thereby to more effectively provide intervention. For example, the Child Development Center at the University of California-Irvine has been at the forefront of establishing models of school-based intervention for such students (parallel teaching, paraprofessional, and multicomponent treatment).

Consultants must be versed in the interventions that have proven effective with attention-deficit/hyperactivity disorder in the classroom. Although many techniques appear promising, the actual supportive literature is small, partly because much of this research has been conducted in clinical treatment settings rather than in schools (where the prerequisite of data-based intervention is less easy to attain and where teacher resistance is an important consideration). Most research has focused on contingency management, followed by self-management and lastly actual academic instruction. Positive or token reinforcement, often in conjunction with response cost or time out, has proved to be effective in reducing activity level, increasing time on task, and improving academic performance. Manipulation of academic instruction or materials has also been shown to enhance academic performance. In contrast, cognitive-behavioral therapy has not proven as effective as anticipated in reducing core symptoms of the disorder. Efficacy may be compromised by the lack of a specific home or parent component and is usually enhanced when used in conjunction with medication, which is the most effective single treatment. Thus, multimodal treatment has been the desired standard of practice and is currently the focus of a multisite, longitudinal study of efficacy. However, at this time school consultants should remember that proven, cohesive educational programming for students in actual school settings is in the development stage. Although some necessary components appear to be understood, their application in real classrooms by regular teachers must be further developed, a task with which school consultants can be helpful.

Conduct Disorders This diagnostic category has proven very difficult to treat in any setting. Thus, psychiatrists consulting on students with conduct disorder will frequently meet school staff who are exasperated and pessimistic. Nevertheless, several important steps may improve such tense situations. For example, in a student with a conduct disorder, the consultant must accomplish a thorough differential to rule out common comorbid conditions such as attention-deficit/hyperactivity disorder, learning disorders, substance abuse, and mood disorders. These disorders must not be overlooked, especially because established treatments can improve their symptoms, which may in turn decrease conduct symptoms or allow more effective concentration on the conduct disorder.

Relatedly, school personnel will hope that a medication exists for quick assistance of students with conduct disorder. Unfortunately, consultants must instruct teachers that medicines have not proven very helpful with this disorder, except possibly lithium (Eskalith) or another mood stabilizer when unpredictable, uncontrollable aggression exists. However, an important medication issue often does exist in students who have conduct disorders. When such students have a comorbid condition that is responding well to a medication, staff must ensure that the medicine is given regularly. If the parents are unreliable (a common finding in the parents of children with conduct disorder), then staff members should get parental permission to give morning, noon, and even afternoon doses at school. Teachers should also alert the prescribing doctor about this need; the doctor may in turn be able to prescribe a long-acting version of the medicine to address the situation even better.

Commonly, consultants will be presented with students who have conduct disorder (without comorbidity) who are responding poorly to school interventions, but are also receiving little help for a stressful home environment (which may or may not have been defined). Students with conduct disorder are at risk for the experience of ongoing exposure to physical abuse or other violence, parent psychiatric illness, and disruptive parenting, which may be counterbalancing school measures. Teachers may be frustrated in dealing with such families, which in turn affects their work with the child. Therefore, a consultant must be sure that home stressors are defined and addressed as best as possible. This may necessitate extra time with the family during the consultation to clarify the issues, or a home visit to determine the actual atmosphere in which the student lives (such visits can also effectively be conducted by staff). Such extra time may well disclose situations that may be remedied: a woman who needs protection from her abusive boyfriend, a father who needs referral for his alcoholism, a mother who needs immediate treatment for her depression as well as in-home instruction on adequate parenting, a juvenile officer who has not yet contacted the school, or a student in need of a constructive after-school program. Thus, consultants must be ready in cases of conduct disorder to expend extra energy to ensure that comprehensive treatment is occurring as optimally as can be accomplished in that community.

Advice to school staff on school intervention must be realistic, that is, with the appreciation that conduct disorder is too often treatment resistant (especially with increasing patient age) and that no entirely successful protocol has been established for use in schools. However, much is known but too seldom is consistently applied by school staff, which is one roadblock preventing progress in students with conduct disorder. Some general principles have evolved that appear to be necessary for any progress: long-term application, home-school collaboration, peer involvement, and a systematic, integrated school program. Specific school components include social skills training, adult praise, individual and group positive reinforcement contingencies, time-out, and cost contingency. This difficult work by school staff can be greatly assisted by a recent landmark book on school interventions for students with conduct disorder: *Antisocial Behavior in School: Strategies and Best Practices*.

Finally, school consultants may also be asked about the general problem of school violence, a topic which requires a different working knowledge than the issue of conduct disorder. In order to offer credible help to school staff, consultants must keep familiar with this growing area—for example, by reading current reviews on school violence, which will then lead to more specific references of interest to the consultant. Any psychiatrist beginning to address this problem area should understand that it is a large and difficult undertaking, which involves early intervention (including preschool), multiple interventions for multifactorial causes, participation of the entire school staff, and collaboration by the school with parents and with community agencies, including juvenile authorities.

Ricky was a 9-year-old third grader who had recently been suspended from school after bringing a Swiss Army knife to school and showing it to classmates in the bathroom. The consultant to the special education system was asked to assess the boy's violence potential. He was also asked to help the multidisciplinary team decide if Ricky had conduct disorder and needed a special education classroom because of deteriorating behavior, including defiance and fighting.

This boy had shown some difficulties since kindergarten such as talking in class, disrupting others, being away from his desk, and not staying on task. Previous teachers had tolerated these problems because he generally redirected well, was usually in a good mood, and was liked by the other kids even though he often could not keep his hands to himself.

However, Ricky had changed since summer vacation. He seemed more irritable which caused him problems with everyone. With teachers, he redirected less well and began yelling that they were picking on him. He got increasingly angry when peers joked with him and began to swing at them. After such interactions he would often cry but not talk.

Testing by the school psychologist found Ricky to be rather closed about home, although he implied that there were some problems there. He was more open about his distress at school. He no longer liked school because “I'm always getting into trouble,” “Nobody likes me anymore,” and “I'm dumb.” Basic psychoeducational testing showed that his concentration was poor and his reading comprehension was at least one grade level behind, but that his intelligence quotient (I.Q.) was normal. His teacher completed a checklist for attention-deficit/hyperactivity disorder which scored positive for the disorder.

During the consultant's interview with the mother, she described the same problems at home. Although lovable, Ricky had always been a “handful,” and the family doctor was “watching him for hyperactivity.” However, since the summer the two of them were arguing much more. He had also begun to push around his little brother and was staying inside more. Her opinion of the knife incident was “one of the impulsive dumb things which he does from time to time.” She attributed his worsened behavior during the school year primarily to her separation from Ricky's father just before school started. Her husband's drinking problem had recurred this summer. When he began threatening her, although he did not physically abuse her or the children, she threw him out. His communication and visiting with the family had been erratic since that time, and he had not yet sought help for his alcoholism. She had been through this before with him, and although she was sad and edgy, she still hoped he would “come around.” The mother worried that without help Ricky was going to become a “truly bad boy,” which she did not feel was currently the case.

The consultant interviewed Ricky and found him rather open. Despite his interpersonal problems, he still liked his teacher and classmates. His solution to his school problems was for everyone to leave him alone if they saw he was “grumpy,” which he said was his most common mood lately. (He denied suicidal or homicidal ideation and vegetative symptoms.) He also wished he did not have to read so much in third grade because it was hard. As for the knife incident, he had not gotten into much trouble before for bringing toys to school; however, he should not have done it this time. He pointed out that, as usual, he wasn't thinking well; he remembered hoping it might win him a new friend, with no intention of using it as a weapon. Although he often felt grumpy or sad, he felt happy when he was in his room watching television or funny videos or playing with his computer (which did not get mad at him). There he was away from his brother and neighborhood friends and staying out of trouble for fighting with them. He was also away from his mother because she “was more grumpy, too.” However, he noted that they both worried about each other, and about how his father was doing. Ricky was also angry at his father for drinking again and not being around, and he worried that his parents might get divorced.

In his feedback to the school staff, the consultant did not feel the knife incident was indicative of potential violence, but more likely an impulsive occurrence. Rather than a conduct disorder, the psychiatrist felt Ricky had a chronic attention-deficit/hyperactivity disorder (combined type) and comorbid reading disorder—both previously untreated. These disorders were interacting adversely with an adjustment disorder with mixed disturbance of emotions (increased irritability) and conduct (defiance and fighting), related to the summertime occurrence of the father's drinking and the parents' subsequent separation. The knife incident was especially disconcerting to the school staff in light of another boy bringing a gun to school and accidentally wounding a classmate earlier in the year at a different city school.

As for school intervention, the consultant and school staff decided to further test Ricky for a possible reading disorder and then provide the appropriate help. The teacher was able to begin specific classroom interventions for attention-deficit/hyperactivity disorder, and would help Ricky assess his mood state each morning (related to home life). If he was especially grumpy then or during the day, the school guidance counselor would make herself available to talk to him. Fighting would continue to collect the school's regular punishment. In feedback to the mother, the psychiatrist suggested that he review with her family doctor the probable diagnosis of attention-deficit/hyperactivity disorder and need of a psychostimulant trial. He also suggested that individual or family therapy could help Ricky (and her) deal with the separation experience. The mother agreed with both suggestions. The consultant, family doctor, and school staff would work out the best therapy resource and get back to the mother. Finally, the school staff would update the consultant in approximately 1 month to reassess the boy's progress.

Depressive Disorders School staffs have become more knowledgeable about depressive disorders as they have learned about the common relationship of suicidal behavior and depressive illness, and as psychiatry has increased its efforts at educating the public about mood disorders. Nevertheless, consultants still face common situations in the diagnosis and treatment of depressive disorders in children and adolescents.

Teachers are now more likely to be concerned about a diagnosis of depression in a student who shows withdrawal, decreased performance, or persistent sad affect. However, they may still remain less likely to consider the possibility of depression in a student with new irritability, agitation, loss of concentration, or disruptive behavior. Teachers must be reminded that these acute externalizing symptoms can be associated with major depressive disorder in young students, and therefore they must consider, and observe for, less overt symptoms of depressive disorder. This step by an educator can lead to early diagnosis and treatment, before the externalizing symptoms receive growing negative attention and exacerbate the student's clinical state.

In contrast to underdiagnosis, consultants will encounter teachers who overdiagnose depressive disorders with the hope of a student's quick improvement through medication. A psychiatric consultant may then thoughtfully help the teacher begin to discern symptoms of major depressive disorder from depressive symptoms associated with stressful adjustments, comorbid disorders such as learning disorders and chronic dysthymic disorder. Also, teachers must be reminded that although the ability to treat depression in children and teenagers with medication is improving through the use of selective serotonin reuptake inhibitors (SSRIs), the appropriate clinical indication for use of antidepressants is primarily major depressive disorder.

Therefore, psychotherapeutic intervention is often the first treatment of choice in children with depressive disorder. Research in this therapeutic modality is limited in children and adolescents, but indications are promising for cognitive-behavioral therapy. In particular, consultants should be aware of school-based, group cognitive-behavioral approaches that are being developed for the treatment of depression in adolescent students. One well-advanced promising example is the Adolescent Coping with Depression Course, in which a small group of adolescents with depression is taught important skills for surmounting depression during 16 2-hour, after-school sessions. Different methods of instruction (lectures, discussions, role-playing, and homework) are used to teach relaxation, evoking pleasant events, dispelling irrational and negative thoughts, social skills, communication, and problem-solving; a parallel course can also be conducted with parents.

In association with depression, consultants will be asked about suicide-related issues. Recent school-based efforts at primary (courses) and secondary (screening) prevention have not yet proven very productive, except to push schools toward dealing with student mental health issues in a more serious and coordinated manner and with emphasis on both primary and secondary components. Some research has proven helpful; for example, when a student suicide has occurred, schools should especially concentrate on the evaluation of close friends of the student and pupils with known psychopathology, especially affective illness and previous suicidality. Thus, schools should have a protocol established to deal with the aftermath of a suicide by one of their students, as well as active suicidality in one of their students; psychiatric consultants with their knowledge of this specific literature can assist school personnel.

MENTAL HEALTH SERVICES IN SCHOOLS

Mental health services have traditionally been delivered in schools in a standard manner, with which consultants interface. Most public schools have designated staff to assist children with mental health problems; a school centrally located in a school district may also have special educators to work with students classified with behavioral or emotional problems. However, newer mental health services are evolving, which include the screening and monitoring of students at high risk for behavioral or emotional disorders, and the development of school-based mental health clinics.

School Staff Most regular classroom teachers can deliver modest mental health interventions to students; for more intensive programming, they need additional

trained manpower in their classes or frequent coaching from another specialized member of the school staff. When a teacher is concerned about the behavior or emotional state of a student, advice will usually be sought from the school guidance counselor (often a former teacher with a Master of Arts degree in Counseling). The counselor can screen the child for the seriousness of the problem, and then deliver help to the student with or without the teacher if the situation is not too serious. However, if the problem is more major, the counselor will suggest community mental health evaluation to the parents. School guidance counselors often also conduct group counseling for common problems experienced by schoolchildren, such as parental divorce or poor socialization skills. Finally, counselors can frequently assist consultants as case coordinators both in preparation for a consultation and in the later management of a treatment plan.

School psychologists usually have the most sophisticated knowledge among school staff on children's psychological problems. Thus, they can serve as invaluable resources for school psychiatric consultants, for example, in the design and execution of a behavior modification treatment plan. Unfortunately, the availability of school psychologists is often compromised by demands on their time to conduct primary testing or retesting of students. Many leaders in school psychology are currently trying to reverse this trend by advocating that school psychologists become more involved in the school-based assessment and treatment of children with psychiatric disorders. For example, with a carefully selected psychoeducational battery, a properly trained school psychologist can expertly assess a student for attention-deficit/hyperactivity disorder, refer a student for diagnostic confirmation and treatment planning, and then collaborate with the family's doctor to assess medication effects in school and to help the teacher deliver specific cognitive-behavioral techniques in the classroom.

Screening for Psychopathology School-based empirical procedures are being developed to economically and efficiently screen schoolchildren for the presence or risk of psychiatric disorders, both generally and specifically (e.g., disruptive and depressive disorders). Two important general models are emerging. First, the Achenbach battery of instruments (child interview or self-report plus parent and teacher behavior checklists) can be used to identify schoolchildren with significant psychopathology and then to plan and monitor their treatment. Initial work has begun to demonstrate how this battery can distinguish students who need special education.

A second model, the Systematic Screening for Behavior Disorders (SSBD) has been more thoroughly tested and utilized. The SSBD can screen children in kindergarden through grade 6 to identify students at risk for developing behavior disorders. The multigate screening process consists of three stages. In the first stage classroom teachers rank their pupils according to externalizing and internalizing problems (from specific lists of characteristics), and the top three in each dimension are considered to have passed gate one. In the second stage, these top children are then rated by their teachers on the Critical Events Index (a list of serious specific behaviors), and on the Combined Frequency Index for adaptive and maladaptive behaviors. Those students who exceed the normative-based cutoffs of the two instruments pass through this second gate and enter the third stage. In this last stage the designated students are observed in academic and playground (peer) settings and coded with specific observation protocols for their academic and social skills. The children who exceed these cutoffs and pass through this last gate can then be referred to a school's child study team for further monitoring, pre-referral intervention, consideration for community mental health services, or even special education evaluation. So far, the psychometric properties of the SSBD have proven sound, especially its ability to identify grade-school students with significant behavioral or emotional problems. Nationally, many school districts are investigating this screening system for standard implementation. Thus, consultants should be aware of the SSBD and other screening batteries if a school district asks for advice about such procedures.

School Mental Health Clinics In the past, rare community programs linked to schools were developed to actively evaluate and treat problematic students referred by teachers, but in the past, community mental health agencies and clinicians have primarily cared for only those students referred by schools who actually made office appointments. In addition, collaboration and communication between school staff and mental health professionals have generally been poor in the joint treatment of youth with psychiatric disorders. However, this undesirable situation now shows some promise of change with a movement toward establishing mental health clinics in schools.

Various reasons have stimulated this new direction. Epidemiological evidence has been accumulating that indicates that the majority of youth with psychiatric disorders do not receive any mental health treatment, and if they do, the intervention is commonly school based. Simultaneously, as school-based clinics have grown to provide for the general medical needs of adolescents (who commonly do not seek medical services in the community), clinical experience and research have begun to show that 30 percent or more of students attending school-based clinics seek help for psychological problems, for which such clinics are not properly staffed. Finally, pressure has grown on schools to provide counseling for special-education students who have dysfunctional behavioral and emotional problems. Guidance counselors may not be sufficiently licensed to deliver this mental health service or may have burdensome administrative demands, thus forcing schools to contract with community mental health professionals. Thus, driven by these intersecting reasons, a government-funded movement is beginning to develop mental health clinics in schools.

Currently such programs are just being developed and described, and the literature is limited. Some models already exist in a limited number of schools, from a modest satellite of a local community mental health center, to a full-service mental health clinic that also educates teachers as well as psychiatric trainees. School psychiatric consultants will have various roles in such clinics, from traditional consultation to actual service delivery (with the advantage of easier access to teachers and other school personnel for better coordination of treatment).

SPECIAL EDUCATION

Psychiatrists frequently serve as consultants to specialized school staffs serving students classified by the special-education category of *serious emotional disturbance*. Since 1975 through the Education for All Handicapped Children Act (EAHCA) (Public Law 94-142), children with disabilities, including behavioral and emotional, have been entitled to a free and appropriate public education. This basic educational right has been expanded through Public Law 99-457 (which in 1986 amended the previous EAHCA) and Public Law 102-119 (the 1991 Individuals with Disabilities Education Act [IDEA], which was reauthorized in 1997). The latter defines *serious emotional disturbance* as a condition having one or more of the following over a long period of time and to a marked degree and adversely affecting educational performance: an inability to learn that cannot be explained by intellectual, sensory, or health factors; an inability to build or maintain satisfactory interpersonal relationships with peers and teachers; inappropriate types of mood or behavior under normal circumstances; a general mood of unhappiness or depression; and a tendency to develop physical symptoms or fears associated with personal or school problems. A recent controversial issue is the consideration of conduct disorder by many states as a exclusionary criterion for serious emotional disturbance classification.

A consultant may be asked to help school staff determine if a student meets the criteria for serious emotional disturbance. If a student is already classified as having the condition, the consultant may advise on a revised treatment plan (also termed *individualized education plan*, which is required for any special-education student). Finally, although a student may not meet criteria for serious emotional disturbance, the student may show enough school dysfunction to qualify for educational assistance under Section 504 of Public Law 93-112 (Rehabilitation Act of 1973).

Students with serious emotional disturbance may be served for a flexible part of their school day in a regular school's resource room, which usually also serves students in other special-education categories. Or the setting may be more intensive in a separate self-contained classroom of the regular school or in a separate public or contracted school for children with serious emotional disturbance. In the more intensive settings, typically a special education teacher and trained aide educate 8 to 12 students with this condition. Token reinforcement programs are usually employed, with individualized tailoring to meet each student's academic, behavioral, and emotional needs. Groups are often used, for example, to improve socialization skills. Specific protocols on techniques may be utilized with targeted students or subgroups to treat such issues as depression, self-esteem, or anger. The staff are supported by school social workers and psychologists, in varying degrees of allotted time.

Empirical knowledge about students with serious emotional disturbance and their outcomes is gradually being established to assist educators and psychiatric consultants. Over 400,000 students (approximately 1 percent of the nation's student population) are classified as having serious emotional disturbance, predominantly boys (85 percent). They commonly have high rates of family stressors (divorce, abuse, or parent psychiatric illness) and externalizing psychiatric disorders, and the majority are underserved by community mental health professionals. Parent and teacher checklist ratings usually both indicate serious dysfunction, often two standard deviations above normal. When compared to students who are evaluated but subsequently not recommended for serious emotional disturbance classification, these students show significant differences: lower socioeconomic level, more abuse experience, more family stressors, greater diagnostic comorbidity, more serious clinician ratings, and higher externalizing ratings by teachers and clinicians.

Thus, these students present serious, complex clinical pictures and are among the most psychologically dysfunctional youth in any community. Their school staff clearly needs the consultative support of psychiatrists; indeed, these students should be one of the primary patient populations served by child psychiatrists. When working with such teams, consultants must be prepared to help teachers refine their cognitive and behavioral interventions with students, to communicate classroom observations to community physicians and psychiatrists to help them adjust medications for students with serious emotional disturbance, and to meet with and stimulate families to seek community interventions. The latter point is of primary importance because many families of such students need wrap-around services from

different agencies as an optimal treatment plan, although too often such coordinated care does not exist.

Past outcome literature for these students has been limited and pessimistic. These students annually have the highest dropout rate among special education children, approximately 35 to 40 percent. Follow-up studies of students after high school have shown poor employment history and high arrest rates. However, a recent longitudinal investigation has demonstrated a more optimistic picture for younger students in terms of successful completion of programming (high-school graduation or transfer back to complete regular programming). Furthermore, in a related study of the predictive value of baseline factors, four objective enrollment variables have been identified that significantly predict unsuccessful outcome for new students newly diagnosed with serious emotional disturbance (dropping out or transfer to an intensive community juvenile or psychiatric program): increasing age, the presence of a conduct or oppositional disorder, the presence of a verbal intelligence quotient (I.Q.) significantly lower than the performance I.Q., and the absence of a depressive or anxiety disorder. The converse is true for the prediction of successful outcome. Thus, prognostic information is beginning to emerge to help consultants and special educators understand which characteristics of newly diagnosed students are most predictive of success and which are indicative of poorer prognosis and the subsequent need for very careful treatment planning.

Consultants should be aware of research directions within the field of special education. Leaders are emphasizing the need to establish a more empirical base and to rigorously apply and study emerging successful treatment interventions (established in clinical populations not in special education) in these students in actual classrooms for children with serious emotional disturbance. Faculties are re-examining the interventions taught to prospective teachers and school psychologists to ensure the practicality of the techniques and the ability of the trainees to execute these methods with students. Collaboration with other disciplines is also being encouraged both in the clinical care and in the research of these students.

FUTURE DIRECTIONS

The traditional practice of school consultation by psychiatrists may well change in the future. Since children with dysfunctional psychopathology currently often receive mental health services in schools, such services will most likely continue to expand in order to reach more students. Thus, more psychiatrists will be doing increased school-based work, and must understand and be appropriately trained for collaborative intervention in the school environment. With this opportunity for easier multimodality treatment, they must be knowledgeable about school interventions that are efficacious for the specific child psychiatric disorders. Also, unlike the current primary focus on case consultation, schools may wish for more program consultation in the design and delivery of mental health services in the school, for which school consultants must be well prepared to advise.

Consultation to specialized programs may also change. These special education students already do not receive sufficient mental health services, and their numbers may grow secondary to the current insurance limitations on psychiatric hospitalization and residential treatment. Thus, the need for psychiatric consultation to staff for children with serious emotional disturbance will increase, along with the nature of the consultations as these special classrooms address the new short-term and long-term needs of their increasingly diverse students. Indeed, school programs for children with serious emotional disturbances may receive new interest as a therapeutic modality by mental health professionals.

Finally, as school consultation grows and changes, its empirical base must improve from its current initial stage. By its nature, such studies must be collaborative with educational investigators. Although some basic instrumentation exists to conduct such research, other important methodological components do not; for example, a structured interview of teachers for DSM child psychiatric disorders. Such increased objective studies will not only benefit school consultants, but also potentially benefit the treatment of child psychiatric disorders in general as current treatment studies rarely study school interventions. With increased knowledge about effective intervention with children in the very important environment of the school, the overall care of children and adolescent psychiatric disorders should benefit.

SUGGESTED CROSS-REFERENCES

Attention-deficit disorders are discussed in Section 39.1, disruptive behavior disorders are discussed in Chapter 40, and mood disorders in Chapter 14. In addition, learning disorders are presented in Chapter 35.

49.15 PSYCHIATRIC PREVENTION IN CHILDREN AND ADOLESCENTS

NORBERT B. ENZER, M.D., AND STEPHANIE L. HEARD, M.D.

Astounding, virtually inestimable successes have been realized in child health through prevention. However, despite the fact that many identify the preventive work of William Healy in Chicago during the first decade of the twentieth century and the subsequent spread of the child guidance movement as one of the important historical roots of American child psychiatry, prevention in child psychiatry has been characterized more by hope and rhetoric than by investment and success. Perhaps, as the century draws to a close there is reason for a somewhat more optimistic outlook in the future.

Historically, prevention in regard to general child health focused on infectious diseases and drew heavily on the sciences of epidemiology, microbiology, and immunology. Infectious diseases yielded to epidemiological study and the perception that the emergence of disease in individuals could be explained by factors in the host, the agent, and the environment. This conceptualization contributed enormously to the prevention of communicable diseases in children via immunization and the reduction of such diseases as typhoid fever and cholera via sanitation and protection of the water and food supply.

Work on infectious disease taught some useful lessons. William Foege's strategy of “search and containment” rather than mass vaccination alone for smallpox may be the precursor to the contemporary concept of at-risk populations. Immunization to increase the resistance in particular populations proved incredibly successful, and the last human case of smallpox was reported in 1977.

Unfortunately, despite the splendid success of the battle against smallpox, generalizations are limited. There is no animal reservoir for the smallpox virus and no human carrier state. Transmission is only from person to person and only during the active phase of the rash. Immunity is long lasting after recovery (if it occurs) or vaccination and is evident from visible scars. Not only has the disease disappeared from the world, so has the variola virus. Although achieving similar success with other diseases is unlikely, it is evidence that concerted, massive effort can have astounding results. When faced with an endemic necessary agent, enhancing host resistance is clearly a wise choice. The successes of poliomyelitis, rubeola, tetanus, and other vaccines speak for themselves.

But the history of medicine has examples of primary prevention efforts that succeeded without the knowledge of a necessary offending agent. In 1847, Ignaz Semmelweis showed that the incidence of puerperal fever was reduced if physicians and midwives washed their hands between deliveries—decades before Koch and Pasteur and the germ theory of disease. Puerperal fever had a necessary offending agent but crude antiseptic practice reduced morbidity without any specific knowledge of the cause. As unthinkable as it seems today, Semmelweis' approach was controversial at the time, and he was the target of ridicule.

Later, other factors were more fully appreciated. The tubercule bacillus was clearly the necessary agent in tuberculosis but was not always sufficient to produce disease. Host factors such as adequate nutrition and environmental factors such as better housing seemed to increase resistance to the organism well before there was a clear understanding of the body's immune system. Our understanding of these multiple factors and the development of effective pharmacological agents clearly contributed to the major decline several decades ago in the prevalence of tuberculosis. The current increase in incidence can be explained by impaired host immunity (due to acquired immune deficiency syndrome [AIDS]), changes in the agent (drug resistance) that decreased its susceptibility to antitubercular medications, and such factors as homelessness and poor nutrition in some.

Some diseases are largely, if not wholly, genetically determined (e.g., Huntington's disease, sickle cell anemia, and hemophilia). In genetic disorders, unlike infectious disease, a single host factor is necessary and sufficient to produce disease. Education and genetic counseling have proved useful in many of these disorders, and more-specific interventions have reduced morbidity and mortality.

Although the number of disorders in which specific genetic patterns are the necessary and sufficient cause may well be limited, one's genetic makeup can increase the risk of disease in virtually every system, including cardiovascular disease, cancer, arthritis, and some mental illness, particularly affective disorders and schizophrenia. The potential of genetic alterations as preventive interventions no longer seems to be futuristic science fiction.

Along with the remarkable advances in molecular genetic knowledge has come a similar recognition of the etiologic influences of environmental toxins—carcinogens in air and water, lead, and perhaps even certain foods. Equally toxic to the developing child are life stresses, inadequate nutrition, poverty, homelessness, trauma, inadequate parenting, prejudice, violence, and other noxious influences to which a child may be exposed at critical times in development. Reducing the potency and prevalence of these factors has proved to be extremely difficult and complex. Nevertheless, all of medicine now looks to multiple causality, risk factors, and complex interactions among them to further explain disease and broaden our understanding of illness.

RISK FACTORS IN CHILD AND ADOLESCENT PSYCHIATRY

Prevention in child and adolescent psychiatry is focused strongly on identifying populations at risk and reducing the factors that contribute to increased risk. Table 49.15-1 lists some of the many risk factors identified in the literature. Risk factors correlate with poorer mental health outcomes in populations but not necessarily in individuals, and although some factors may appear to have higher rates of correlation than others and thus appear more potent, certain factors may carry the likelihood that others will also be present. Risk does seem to increase when the number of risk factors increases, but it is not the number of factors alone that seems to increase negative outcomes. Context, the point in development when an event occurs, and any protective factors that may be present also influence outcomes.

Chronic illness or disability, particularly those involving the central nervous system
Limited academic skills
Emotional abuse or neglect
Physical or sexual abuse
Death in the family
Psychopathology in parents
Conduct disorders in parents
Substance abuse in family or child
Suicidal behavior in family
Separations and losses
Family discord and divorce
Economic distress in family
Poverty
Racism
Neighborhood violence
Limited social and educational opportunity
Environmental toxins
Natural disasters
Accidents

Table 49.15-1 Risk Factors for Children and Adolescents

Although child-oriented professionals are often tempted to focus on risk factors in the social environment or family, the child's contribution must not be ignored. Central nervous system problems that result in obvious disabilities (e.g., motor, perceptual, speech, or language problems), seizures, or mental retardation clearly

increase risk. However, more-subtle problems of temperament, appearance, and even interest or talents that depart from parental expectations or values may create a high level of risk for some.

Certain risk factors are more potent at particular times in the development of the child or the life of the family. These are dynamic, constantly changing interactions. Perhaps this is why the identification of patterns or clusters of risk factors that predict specific disorders, problematic behaviors, or maladaptations has been elusive. Similar clusters of risk factors may be associated with different outcomes, and analysis of the histories of individuals with similar disorders often yields only limited recognizable predictive patterns. Perhaps in the future certain discrete causality patterns will aid prevention or amelioration of mental and behavioral disorders, but this seems unlikely, at least in the near future.

Our current knowledge of mental disorders demands that prevention efforts recognize an enormous array of risk factors whose potency depends not solely on the strength of each factor alone or in combination, but on the number of factors present, the response of individual children and their families to the various events or interactional patterns in their environment, the time in the development or life cycle when the factors occur, and the personal, interpersonal, and material resources that dictate whether the response will be adaptive or maladaptive.

PROTECTIVE FACTORS

Less attention has been given to protective factors—those that seem to create resistance or counterbalance risk factors. Nevertheless, there is a growing recognition that they are important and may help explain why similar risk patterns do not affect all children equally. Protective factors can only be defined in relation to risk factors occurring in similar social or environmental contexts. Among the protective factors that have been identified are warm and supportive parenting; effective social support systems; effective limit setting; competent academic, interpersonal, and social skills; and adequate social and educational opportunities.

TARGETS OF INTERVENTIONS

The obstacles to major investments in preventive child psychiatry are formidable and the results of efforts intended to be preventive are often inconclusive. Until recently, the lack of a widely accepted nosology has been a major handicap. In addition, etiologic knowledge is limited and disagreements are based more on theory and belief than on scientific information. The target of a particular preventive intervention is often unclear. Is it a specific, diagnosable disorder occurring during childhood or adolescence or some general maladaptive behavior that interferes with maximum functioning? Is it a disorder that occurs in adulthood, a specific disorder or a pattern of behavior that interferes with social functioning and success? Or is the intervention intended to increase general adaptability and resilience?

Efforts aimed at promoting general well-being and developmental success have often been associated with prevention. Many of society's ills clearly affect children directly and indirectly; some negative consequences may be fairly subtle and may not appear for years while others are more immediate. Table 49.15-1 shows that the list of risk factors is lengthy, and many are widespread. Because some of these problems are so pervasive and heart wrenching, they have often been the focus of much political rhetoric and, at times, action. Unfortunately, often in the lives of many children these factors occur in combination, and the interactions between them are not well understood. Consequences differ from one individual to the next, with some suffering little while others experience various patterns of profound maladaptation.

None of these social factors can be considered a necessary and sufficient cause for any subsequent specific, definable psychopathology. Nevertheless, numerous statistical correlations persuasively suggest causal relationships and motivate many to call for action.

Addressing society's ills in deliberate and organized ways has often proved fruitless. Proposed solutions are frequently controversial and lack evidence that they will be effective. Some programs in the past that were enthusiastically supported have clearly not achieved the successes that were expected, particularly when they attempted to change behavior in large population groups (e.g., reducing smoking and drug and alcohol abuse use among teenagers).

In contrast, promoting the use of car seats and bicycle helmets for young children seems to have reduced accidental injuries and deaths. Like efforts to reduce smoking and alcohol consumption, these efforts have been supported by law. The difference is that the use of car seats and bicycle helmets focuses on specific, immediate injuries in young children and actions by parents, whereas smoking and alcohol and drug consumption involve the behavior of adolescents and often, delayed consequences.

Targeted Social Forces Despite uncertainty, some large-scale social programs seem to have achieved enough success to receive sustained support. Perhaps the most widely known is the Head Start Program, begun in the 1960s. Originally designed to enhance the early school performance and social development of underprivileged children, Head Start involved summer programs for 4- and 5-year-old children and the early results were positive.

A follow-up study to evaluate its effectiveness was awarded to the Westinghouse Learning Corporation 4 years after the start of the program. This study found that certain early results were not sustained and raised serious questions about the program, particularly its cost-benefit. The particular finding that increases in intelligent quotient (I.Q.) were not sustained into elementary school led to the conclusion that the program was a failure. Later analyses of the methods used and the particular outcomes that were assessed concluded that the study was flawed in several ways. Changes in I.Q. were used instead of school achievement; all local programs were assessed equally, with no adjustment for differences in quality or early results; and little consideration was given to of less specific outcomes. Much later evaluations demonstrated broad, general effectiveness with better school progress, fewer school dropouts, less delinquency, and better work records after high school. In retrospect, analyses suggested that the lack of even more sustained benefit was due to the brevity of the intervention and the ongoing negative influences of the social environment.

Evaluations of a number of other early intervention programs establish that there are lasting effects such as increased graduation from high school, reduced grade failures, and fewer children referred to special education. However, the risk factors are exceedingly complex, cumulative, and often not outweighed by opportunity. More children and families are participating in early intervention programs that have broad goals not too dissimilar from those of Head Start, although they may be conceptualized differently and involve other specific intervention techniques. The risk factors are at least the same and for many even more severe and complex, so positive effects are more limited, and public support may be less enthusiastic. Unfortunately, expectations can be very high, and positive outcomes that fall short of those expectations are often seen as failures. Well-intentioned programs, even some with positive early results have been abandoned without sufficient time for full intervention or to assess long-term outcomes.

Damaging Agents Early interventions that address highly specific factors not directly related to social forces have been more clearly effective. These often involve the avoidance of particular damaging agents. The effects of phenylketonuria, lead poisoning, and fetal alcoholism can be reduced by specific early intervention. Neonatal screening and the elimination of phenylalanine from the young child's diet has reduced the devastating behavioral problems and early mortality associated with this inborn error of metabolism. Reduction in lead concentration in water supplies and removal of lead from paints has reduced lead poisoning in children with its subsequent influence on central nervous system functioning and learning.

Lead-based paints in old homes are a source of lead intake for some children. Early and regular screening with adequate treatment if necessary can reduce the risks of biological damage but not the initial risk. The control of lead in the environment and the required removal of lead paint from old, inhabited buildings has raised arguments about cost-benefit of this approach compared with the cost of screening and treatment. Furthermore, since lead poisoning is less frequent now, is true primary prevention worth the cost? This issue is of concern in other areas of prevention in child mental health. Even when knowledge is sufficient and methods of prevention are proved, is society willing to bear the cost of preventing relatively rare disorders when effective treatment is available?

Fetal alcoholism raises a different issue. Even modest consumption of alcohol during pregnancy can damage the fetus and result in the syndrome of fetal alcoholism. Unlike the situation with lead poisoning, the elimination of fetal alcoholism does not depend upon community action nor can it be reduced by legislation as lead poisoning could. However, the lack of will of society, individuals, or both clearly limits the effectiveness of prevention in these specific disorders as well. Lead concentration in water supplies is still too high in some communities and far too many women consume alcohol during pregnancy despite public education efforts and prenatal care.

Resistance to Intervention It is perhaps not surprising that some efforts at early intervention have such limited success even though evidence suggests that the potential is much greater. Resistance to intervention at a community or individual level is complex, and efforts to reduce resistance are often simplistic. Although a lack of funding for prevention is frequently cited as the principal limiting factor, even that is not a simple matter, and programs with low cost-benefit ratios still meet resistance. Far too many children are still not being fully immunized, and the number may be increasing among some groups of children. Programs requiring greater

funding with less-specific, proved results; more-complex interventions involving changes in attitudes, beliefs, and behaviors; and those that threaten values or other community priorities are clearly more difficult to implement and sustain.

Much early intervention is focused on education, enrichment, and socialization with the assumption that the intervention will compensate for, or increase resistance to, risk factors. These programs often engender great enthusiasm and high expectations. But the increasing frequency and intensity of real world risk factors and their complexities mitigate against success, strengthen skepticism, and diminish public support.

Scientific evidence of benefit is not always the critical factor in convincing the public and its leaders of the value of preventive or therapeutic programs in health or mental health. Groups have embraced approaches with no evidence of success. Nevertheless, positive outcomes from carefully planned and studied interventions are of inestimable value, and evidence does exist for some programs.

CURRENT APPROACHES

In 1964, coincident with the federally supported Community Mental Health movement, Gerald Caplan published the first major American textbook exclusively devoted to prevention in child psychiatry. He defined three categories of preventive interventions in mental health. *Primary prevention* focused on preventing disorders or problems in the future, and usually the targets were normal populations. *Secondary prevention* addressed problems in their very early stages and was intended to reduce or delay the development of related or more serious problems. *Tertiary prevention* was largely defined as intervention aimed at reducing the duration or impairment of disorders or problems. Looking back at Caplan's work shows just how far prevention has come in the past quarter century. Enthusiasm for primary prevention, as defined by Gerald Caplan, has waned because of costs, lack of sustainability, methodological difficulties, and the lack of evidence of sufficiently positive results. But there has been growing interest in other types of intervention. Although more recent programs are often far less inclusive, they are more focused and more thoughtfully conceptualized and they have better follow-up. Research has expanded enormously; over 30 percent has been published since 1990.

More recently, following a study by the Institute of Medicine, prevention has been conceived as including only those interventions prior to the onset of significant problems. This discussion considers only efforts that can be considered primary or secondary prevention. The Institute of Medicine suggested new terminology—*selective preventive intervention* for primary intervention targeted at high-risk populations, such as families with parental substance abuse and *indicated preventive intervention,* which focuses on children with mild behavioral symptoms. *Universal intervention* is often used as a substitute for *primary prevention*.

PRIMARY PREVENTION (UNIVERSAL INTERVENTION)

Many programs that can be classed as primary prevention have been tried, and they often differ substantially in their approaches. Some attempt to intervene with all children or parents in particular groups, irrespective of the presence of risk factors, for example, all children in a particular school, all at a particular grade level in a school district, all kindergarten parents or families living in a geographic region. This approach can be considered to have a universal target population that is normal, at least in theory. Among such efforts are programs to reduce teenage smoking and substance abuse, adolescent pregnancy and sexually transmitted disease, and programs intended to enhance social and interpersonal development.

Opposition Opposition to primary prevention programs can be substantial, at times spilling over into contentious exchanges between opponents and supporters in the community. The introduction of drug and sex education programs in schools has been particularly troublesome, but programs on social skills, conflict resolution, and affect sensitivity training have met with resistance as well. The resistance has taken many forms—the belief that such programs intrude into the prerogatives or values of parents, that the outcomes will result in promoting the very behaviors the programs intend to diminish, that the resources invested in the prevention are better devoted to teaching traditional academic skills and knowledge, or that there is little evidence that the intervention will be successful. Nevertheless, community efforts to promote the welfare and protection of children, reduce violence, and enhance opportunities continue, largely outside the purview of psychiatry. Some evidence suggests that such efforts as the direct involvement of children in school-based education can reduce the risk of trauma to children from sexual abuse and violence. Do not underestimate the intensity of the controversy. Its ripple effect has influenced school board composition; the curriculum in science, social studies, and literature; and library holdings. Prevention can be truly controversial, and community understanding and support is critical.

Although multilevel interventions are more likely to show positive results, single-level programs have been successful. Teaching parenting skills to parents at risk for child abuse has reduced the critical initial episodes of abuse. Likewise, parental monitoring of adolescents after educational programs has reduced teenage drug abuse.

Some programs, previously considered primary prevention, may now be better classified as selective preventive intervention in keeping with the Institute of Medicine definition. These programs address target populations that are at risk for problems yet to emerge, such as children whose parents have been diagnosed with mental disorders, who have been abused, or who are homeless or living in severe poverty. Other target populations include children or families who are at the point of critical and often especially stressful transition, such as divorce, death in the family, or entrance into a new and unfamiliar school, and those who require substantial medical and surgical care.

Levels of intervention also differ. Some can be considered environmental, involving the community as a whole, a school, peer groups, or the family; others may focus on the individual. Interventions frequently include more than one level, and multilevel interventions seem more likely to have positive results. Children facing substantial surgical procedures may be the focus of individualized specific techniques to inform, reduce apprehension, and increase compliance. Their parents may participate in education, support group activities, and training in the care and emotional support of the child; and the activities of hospital staff are changed specifically to attend to the psychosocial needs of child patients and their parents.

Prevention programs require recognition that many individuals and factors interact with one another in dynamic ways. These transactions are multidimensional. Parent affects child—child affects parent; school affects child—child affects parent; parent affects school—school affects peers; peers affect child, and so on. The transactions are complicated, changing, and powerful.

Evaluation Evaluating primary prevention programs is difficult. Establishing the existence of lasting positive effects is hampered by all of the problems inherent in long-term interventions and outcome studies. Positive effects must be defined as well as changes that should not be attributed to the intervention. Nevertheless, studies have shown successes; and some metanalyses of multiple studies support effectiveness in follow-up. Notable specific universal programs include Head Start; a substance abuse prevention program with life skills training of seventh graders with reinforcement in the eighth and ninth grades; and a 6-year school-based program to reduce substance abuse, delinquency, and school failure among low-income urban children. Two examples of successful selective preventive intervention programs are the Comprehensive Child Development Program targeted at low-income families and the Strengthening Families Program aimed at children of families with substance abuse problems.

SECONDARY PREVENTION INDICATED PREVENTIVE INTERVENTION

Secondary prevention is intended to reduce the probability that children and adolescents with early or minimal signs of maladaptation will develop more serious dysfunction or specific clinical disorders in the future. It depends upon three fundamental assumptions: (1) those with early disorders can be identified, (2) they are at greater risk for more serious problems in the future, and (3) secondary preventive intervention will improve later adaptation and function.

Although one cannot predict which of those children with early or minimal problems will develop more serious problems, it is clear that as a group they are more likely to have greater difficulties in the future. They are at greater risk than their normal peers. Although one cannot predict specific future problems, patterns or sequences of compounding problems often appear in specific children.

Poor academic performance in early grade school may be followed by discouragement, damaged self-concept, poor peer relationships, behavior problems in school, a reputation of being a troublemaker, and later depression and perhaps rebelliousness and substance abuse in adolescence. Interpersonal aggressiveness in a preschool child may lead to harsh discipline, punishment, increasing and more-generalized anger, social isolation, contact with law enforcement, and later, more-specific delinquent behavior.

The complexities of these sequences and the interactions between child, parents, peers, teachers, and others should not be underestimated. The child who is not doing well in school may be under considerable pressure from parents or teachers to work harder or get special assistance and may, as a result, be prevented from

participating in a variety of nonacademic activities that can be so useful in social development and peer interactions. Labeling a child “stupid,” “lazy,” or a “troublemaker” may actually create a self-fulfilling prophecy and reinforce the problematic behavior. The act of identifying early or minimal problems in a child runs a similar risk, particularly if appropriate intervention is not available or accessible.

Selection and Assessment Although space does not permit a full discussion of the many varied approaches to screening to identify children with early or minimal problems, it is the first step, and the approaches usually involve informal reports from parents, teachers, peers, and others in contact with the child. Unfortunately, such early reports often do not receive sufficient concern, even from expert professionals. Such reactions not only can delay further evaluation, they may reassure parents and create greater expectations, perhaps further compounding the problems. Formal screening using psychometric or sociometric instruments and behavioral inventories has proved useful. Whatever screening methods are used to identify children who may benefit from a preventive intervention, a more complete assessment is then necessary. Similar problems may have different origins, and both the strengths and protective factors and the problems and risk factors must be considered.

Multiple levels of assessment are most useful. The first level may involve informal reports or more-formal simple screening instruments such as peer rating scales or brief behavior check lists completed by parents, teachers, or both. The next level may involve direct observations, psychological tests, or interviews with children, parents, and teachers. The third level involves more-complete individual evaluation of those who have passed certain thresholds at the earlier levels. Such approaches must be carefully implemented to avoid outcomes that are overly inclusive and yet be sensitive enough to avoid significant underidentification.

Resistance Along with resistance similar to that generated by primary prevention programs, secondary prevention programs may generate resistance because of the continuing stigma regarding emotional and behavioral problems and psychiatric disorders. The identification of problems or even potential problems may threaten parents. Even if parents recognize a problem, they may consider it a disciplinary problem, laziness, or a variation of normal (“that's just the way the child is”) or believe that the problem is not in the child but rather in the school or the relationship with the teacher. Since secondary prevention almost always requires the active participation of parents, their views of the problem and the proposed interaction and their capacity or willingness to be involved limit many efforts.

Outcomes Beginning with the Primary Mental Health Project at the University of Rochester in the mid-1950s, a great many school-based secondary prevention programs have been reported. Overall, some of these programs have effectively enhanced the adjustment of the children or adolescents in the target populations. The outcomes of multiple secondary prevention programs that addressed different target populations, with different types of problems, using different intervention techniques have been reviewed. In general, children with externalizing behavior problems, internalizing problems, poor peer elationships, and poor school achievement all showed positive effects. Those with externalizing behavior problem showed the most-positive change, and those with poor school achievement had the least-positive results. Of the various techniques used, behavioral and cognitive-behavioral approaches were the most effective. Although outcome studies of school-based secondary prevention programs aimed at reducing the frequency of specific disorders are often inconclusive, evidence suggests that better results may be possible. Several studies have shown that episodes of affective disorders can be reduced by school-based programs.

School-based behavioral and cognitive-behavioral programs have been less effective for children with academic problems than for others, but numerous programs have demonstrated that children with learning problems can be helped if interventions are implemented early enough—often before entry into elementary school—and if the interventions are comprehensive and of sufficient duration. Effectiveness may require changes in the schools themselves, including staff development, collaborative decision-making, social skills training, and parental participation.

Prevention Outside School Secondary prevention efforts go well beyond those in schools. Home-based interventions often are part of broader community efforts to reduce child abuse, and they have been shown to enhance the effectiveness of parenting programs. Such programs have also been effective in enhancing cognitive development and in promoting general health care. However, these programs are often considered costly by some and intrusive by others, and parental involvement is critical whether the interventions are within the home or elsewhere.

The problem of foster care is particularly important especially when it results from a judgment that the natural home of a child is unsuitable or unsafe. Truly professional foster homes are useful but unfortunately not readily available. Foster parents supported by readily available and regular professional support and consultation are a positive alternative. However, the experience of many children remains one of multiple foster homes and increasing difficulties.

ROLE OF PSYCHIATRISTS IN PREVENTION

Although few general and child and adolescent psychiatrists have been involved in the design, implementation, and evaluation of primary and secondary prevention programs, others have assessed or given therapy to children or adolescents and their families who needed more-individualized attention. Others have functioned as advocates for prevention in schools, communities, and the political arena. However, most general or child and adolescent psychiatrists have not devoted much attention to prevention, and many find it difficult to define a role for themselves. Many may feel ill prepared, for although accredited training programs must provide some teaching in prevention, few offer more than some lectures on the subject.

Individual practitioners can have a preventive influence within their own practices without substantial changes. Recognizing potential risk factors and inquiring about these factors into the assessment of all referred children may identify children at greater risk who might benefit from some intervention short of a full treatment program for a particular disorder. Obviously, general and child and adolescent psychiatrists are not the only physicians for whom such behavior is appropriate. In fact, it may be even more appropriate for pediatricians, family physicians, and other primary health professionals. Further, such attention should not be limited to physicians who see children or adolescents. All need to raise the question “what about the children?” in their contacts with adult patients who are parents or potential parents.

Of particular importance is the presence of psychopathology in parents, especially psychosis, depression, substance abuse, alcoholism, and antisocial behavior, or a history of abuse or neglect in their own childhood or current family discord, disruption, or abuse. In such cases, comprehensive inquiry into the development and functioning of the children is critical, and a direct assessment of the children may be required. Intervention will depend upon the findings of assessment, but no intervention is possible unless the questions are asked. The presence of diagnostic criteria for a specific disorder must not be the sole basis for preventive intervention. Likewise, reports from parents, teachers, or others that suggest deviations in development or socialization or academic difficulties should be taken seriously and not dismissed as variants of normal without sufficient clinical evidence. All too often a wait-and-see approach is taken without adequate assessment or specific follow-up planning. Careful documentation of clinical findings is essential to permit follow-up comparisons and assess progress or the lack of it.

Practitioners must be aware of the resources in the community that are available to families who need a preventive intervention in addition to, or instead of, a therapeutic one. Support groups for divorcing parents, the spouses and children of substance- or alcohol-abusing parents, and parents of children with attention or learning disorders, and classes on child development and parenting are examples of the resources available in many communities. Enrichment and socialization opportunities for children and adolescents often available through school systems, the YWCA and YMCA, Boys and Girls Clubs, and others can increase self-esteem, skill development, and the productive use of time.

Practitioners need to have a preventive attitude—a belief that early recognition and intervention can be helpful and that the effects of risk factors can be minimized, protective factors can be enhanced, and the path to psychopathology or maladaptive behavior can be altered.

OUTCOMES RESEARCH

Research into the outcomes of prevention programs is difficult, and results are often inconclusive. Nevertheless, meta-analyses of multiple studies do suggest that prevention in child and adolescent mental health can yield positive results. The conceptualization of intervention and the methods of evaluation are as critical in prevention as they are in any outcome research. Large sample sizes are often required because many disorders or problems have very low base rates, but large samples run the risk of subject attrition. The assessment must occur over a long enough time to determine the duration of effects. However, time can work against conclusive findings because children continue to develop, families and social environments change, and new risks or protective factors may develop.

SOCIAL POLICY REGARDING PREVENTION

The need for prevention in child and adolescent mental health seems obvious. In 1990 the National Advisory Mental Health Council estimated that 12 to 22 percent of this nation's children and youth needed mental health services. Estimates suggest that less than one in four receives any formal mental health intervention, and for

those who do, it is often inadequate or inappropriate.

Certain risk factors increase the incidence of disturbances and the gap between the need for service and appropriate intervention. Poverty is the single most important environmental risk factor, and the poor are less likely to receive appropriate intervention. The Bureau of the Census reported in 1994 that 23 percent of the nation's children lived below the poverty level. If current trends continue, one third of children will live in poverty by the year 2000. Severe or chronic psychopathology in parents is associated with the mental health of their children. With estimates that 20 percent of the adults in the United States have active mental disorders and markedly decreased isolation of the mentally ill, this must be considered the most important family risk factor. Children are less likely to receive appropriate intervention, and when combined with disadvantaged minority status, race creates a powerful risk. It is unrealistic to assume that the needs of these children and adolescents can be met solely by treating those with defined psychiatric disorders.

As a nation we suffer from certain simplistic notions—that prevention is much less expensive than treatment; that mental illness and behavioral disorders can be prevented through education; that family values will offset immoral, self-destructive or aggressive behaviors and dysfunction; and that personal strength and hard work will overcome social adversity. There are contrary views as well—that the problems are so severe and widespread that nothing will make a difference. Unfortunately, grandiose promises in the past have created a pervasive disbelief in preventive mental health and psychiatry that makes it difficult to sustain even those programs that have shown positive results.

In the mental health arena, stigma clearly plays a role in limiting society's commitment to prevention in mental health. Despite some pockets of resistance, prevention in other areas (e.g., cancer, heart disease, infectious disease, and drunk driving) seems to have more public support and commitment. Along with the stigma associated with the mentally ill, it is an all too prevalent view that mental disorders or maladaptive behavior results from inherent weakness, lack of will power, poor motivation, or a lack of responsibility for one's behavior.

The economics of prevention are controversial and it is often difficult to provide cost-benefit data. Agreed-upon definitions of cost and benefits and standards for comparative analyses are lacking in most cases. But even if more information existed, there would likely be controversies regarding community, state, and national priorities, and these priorities are influenced by social and political philosophies, religious and ethnic belief systems, and individual values—all of which are diverse and often controversial.

Few credible cost-benefit analyses of prevention programs are available. Credibility depends on careful design that includes all costs and relevant benefits and enough time to show that any benefits are durable. Even with these standards, evidence indicates that some preventive programs for children can be cost-effective. Despite this evidence, it is likely that prevention will continue to have lower priority than the treatment of individuals with defined mental disorders. This follows the pattern established in most states that assigns top priority for mental health treatment to those with the most severe or chronic disorders even though it is possible to produce a greater change in many of those with less severe or more acute problems.

The drive to reduce health care costs has created a situation in which the assessment of a child or adolescent with minimal symptoms and in whom a formal diagnosis is impossible must often be financed outside the provisions of a health insurance plan or a health maintenance organization, and interventions in such cases are seldom supported at all.

Several states are moving to privatize mental health services, and more seem likely to follow. Whether any preventive services at one time required in community mental health centers will survive remains to be seen. The United States' commitment to prevention in child and adolescent mental health must be considered in the context of the general needs of children and their families. The effects of welfare reform on children remain to be seen as the number living in poverty increases. There is a lack of sufficient and competent out of home care (day care) as the number of single-parent and both-parents-employed households increases and the local and national debate regarding public education continues while school buildings crumble and school bonds fail to be approved by the public. The possibility that these and other social risk factors may become even more pervasive and affect even more children and families cannot be ignored.

Social and political controversies surround many issues that affect the lives of children, and in many areas the United States does far less well by its children than other developed nations despite its wealth. Clearly, perhaps more now than before, as the proportion of elderly adults in the population increases, the nation needs national policy that truly addresses the needs of all children and their families. In the arena of child mental health and child psychiatric disorders, there is a need for balanced, comprehensive approaches including direct clinical services, universal programs to reduce risk factors, strengthen protective factors, and enhance the general welfare and adaptability of all children and targeted preventive interventions for those who do not benefit sufficiently from universal programs but as yet are not in need of direct clinical service. The burden of suffering from child psychiatric disorders is very high and its costs are enormous. Simplistic solutions are unrealistic.

However, major advances in knowledge through research can produce greater public support. Community-based coalitions of several agencies, voluntary organizations, and an apparent growing involvement by business suggest the possibility of a brighter future, but the real world risk factors of poverty, racism, violence, family disruption, and limited opportunities for successful development of all children remain major obstacles.

SUGGESTED CROSS-REFERENCES

Section 4.2 discusses sociology and psychiatry, while Section 5.1 discusses epidemiology. Section 7.8 covers psychiatric rating scales, and Section 28.4 covers genetic counseling. Family therapy is discussed in Section 30.5 and Section 48.5, and public and community psychiatry is discussed in Section 52.1. Section 49.1 covers psychiatric aspects of day care, Section 49.11 covers adolescent substance abuse, and Section 49.14 covers school consultation. Mood disorders are discussed in Chapter 14 and Chapter 45. Chapter 35 discusses learning disorders, Chapter 37 discusses communication disorders, Section 39.1 discusses attention-deficit disorders, and Chapter 40 discusses disruptive behavior disorders. The future of psychiatry is covered in Section 55.3.

CHAPTER 50. ADULTHOOD

CALVIN A. COLARUSSO, M.D.

As they leave childhood and adolescence behind and journey through young adulthood and midlife, men and women attempt to achieve the following:

1. Separate psychologically from the parents of childhood and achieve self-sufficiency in the adult world
2. Find a gratifying place in the world of work
3. Experience sexual and emotional intimacy within a committed relationship
4. Become a parent
5. Accept the aging process in the body
6. Integrate the growing awareness of time limitation and personal death
7. Maintain physical and emotional intimacy in the face of the powerful physical, psychological and environmental pressures of midlife
8. Facilitate the emergence of children into adulthood
9. Develop and sustain friendships with individuals of different ages and backgrounds
10. Continue to play
11. Leave a legacy for future generations by facilitating the development of younger individuals

LEGACY OF THE PAST

There is little new under the sun when the subject is man himself, so it is not suprising that ancient civilizations contained rather sophisticated ideas about the life course. In the sixth century BC, Solon described six periods of adulthood and assigned appropriate developmental tasks to each. In the following century Plato described the educated man as one who used enlightened reason to contemplate the realities of human life and the reasons for his existence. The developmental flowsheet of Confucius described how at 15 he set his heart upon learning, by 30 he planted his feet firmly on the ground, by 40 he no longer suffered from perplexities, at 50 he knew the biddings of heaven, and at 60 he allowed himself to follow the dictates of his heart. Concerns with time, age, and change pervade ancient Japanese thought as well. There adulthood was viewed as a time of life requiring effort and attention as the individual strove to become freer of the self to gain the highly respected wisdom of old age.

The ancient writings describe a chronological life cycle, the adult in a constant state of dynamic change and flux, a continual need to define the adult self, a preoccupation with time as an expression of awareness of a limited life span and individual mortality, and a struggle between love of self and responsibility to the society in which one lives.

PIONEER ADULT DEVELOPMENTALISTS

The scientific study of adulthood is essentially a phenomenon of the twentieth century, stimulated by the writings of four men (Table 50-1). In 1908 Arnold Van Gennep (1873–1957), a cultural anthropologist, described the importance and meaning of the universal rituals that surround such events as pregnancy, childbirth, menarche, betrothal, and death. The rituals are ceremonies whose essential purpose is to enable individuals to pass from one stage in life to another.

Pioneers	Contemporaries
Erik Erikson (1902–1994)	Calvin Colarusso
Sigmund Freud (1856–1957)	Daniel Levinson
Carl Jung (1875–1961)	Robert Nemiroff
Arnold Van Gennep (1873–1957)	Bernice Neugarten
	George Vaillant

Table 50-1 Developmental Theoreticians

Sigmund Freud (1856–1937) formulated the first modern theory of child development. Intrinsic to the predictable developmental progressions were basic transformations, regressions, and advances. Essential to Freud's theory of development is the idea that the mind changes constantly as a result of the ongoing interaction among mind, body, and environment.

The pioneer who focused primarily on the adult years was Carl Gustav Jung (1875–1961). He described a continuing process of physical and psychological separation from parents during the 20s and 30s, and viewed age 40 as a time of significant psychological change, growth, and transition. The archetypes “puer” (young) and “senex” (old) that Jung saw as fundamental polarities stimulated modern adult developmentalists.

The fourth major pioneer, Erik Erikson (1902–1994) provided the first integrated psychosocial view of individual development through eight stages from birth to death. For him, development lies not in stability per se, but in the changes necessary to transcend successive contradictions, conflicts, and states of disequilibrium. Current-day developmentalists owe a profound debt to the work of Erikson.

Erikson's theory has recently been used to examine the developmental and sexual issues facing seropositive gay males with particular reference to the polarities of identity versus role confusion and intimacy versus isolation. Other investigators, studying the adult development of women, have found that women do not conform to the sequencing aspect of Erikson's stage model because in our society they tend to be more relationship oriented. Thus intimacy may occur as a dominant theme earlier in development. In addition, identity and intimacy are conceptualized as concurrent processes for both men and women. The unfolding of one leads to the further delineation of the other and affects the related polarities of self and other, masculine and feminine, and agency and communion.

CONTEMPORARY ADULT DEVELOPMENTALISTS

A comprehensive understanding of adult development is beginning to emerge from studies conducted over the past 30 years. The study of childhood preceded the study of adulthood because of social and psychological factors such as the spread of compulsory education and Freud's discovery of the influence of childhood experiences on adult psychopathology. The recent shift of interest to the adult years builds on this knowledge and may be due to the increased life span and the need to understand and accommodate the rapidly growing number of middle-aged and elderly individuals. Among the most influential current theoreticians are the

following.

Daniel Levinson and his associates devised a psychosocial theory of male development that proposes a life cycle consisting of distinctive, identifiable eras of approximately 20 years extending from birth to death. Within these eras are alternating periods of 6 to 7 years of stability followed by 4- to 5-year intervals of transition, each with its own tasks to be mastered. These concepts are clinically useful since many patients, particularly the healthier ones, tend to present themselves during periods of transition when internal and external conflicts are increased.

Levinson's theory is currently being used as a framework for the study of various groups. Application of his concepts of developmental periods to the existing data on older gay men indicates that the stereotype of lonely, depressed, sexually frustrated, aging gay men may not be a valid picture of the cohort.

Gender-oriented research has begun to question whether adult transitions are the same for men and women. Levinson's alternating intervals of stable structure and transition have been used to delineate the developmental and transitional periods experienced by Army officers from preadulthood to midlife. The study examined the impact of living and working within a highly ordered, systematic organizational structure such as the military on the way in which these adult lives unfold. Levinson's outline of adult phases was found very useful in understanding intellectual and emotional life within a career military setting. The impact of regimentation and a clearly delineated future for young adulthood and midlife tended to mute the distinctions between periods of transition and stable structure. The effect of a military career on mid and late adulthood postmilitary life remains a fertile field for investigation.

The Harvard Grant Study has followed longitudinally the life course of 268 undergraduate students from 1939 to the present. The current director, George Vaillant, has used these data to study adaptation in adulthood, particularly ego mechanisms of defense. Illustrating the developmental nature of intrapsychic processes in the adult, Vaillant demonstrated that the psychologically healthier members of the research sample used mature defenses such as suppression, altruism, sublimation, anticipation, and humor more frequently in midlife than they had in late adolescence and young adulthood, thus illustrating the effect of ongoing, dynamic developmental processes. In agreement with all other major dynamic theories, Vaillant found conflict to be an integral, inescapable aspect of normal development.

More recently, since the subjects of the Grant study are now in the developmental phase of late adulthood, Vaillant has used a modified version of Erikson's stage model to organize the process of psychosocial maturation in the latter third of life, focusing on the Eriksonian tasks of generativity and integrity by rating longitudinal case histories of the Grant Study subjects. Success or failure to engage and master these developmental themes was closely correlated with patterns established earlier in development in this select group of men who were originally chosen for their emotional and physical health and have now been followed for more than half a century (ages 18 to 65).

Through the study of adults in nonclinical settings Bernice Neugarten and her colleagues have emphasized the psychological importance of an increased awareness of aging and the personalization of death, as expressed in body monitoring and a tendency to view time in terms of time left to live, rather than time since birth. Middle-aged adults develop a sense of competence that was unrealized earlier in life and have a unique perspective on the younger and older generations. As middle age progresses, people become more introspective and develop an increased sense of interiority.

On the basis of their experience as clinicians and psychoanalysts, Calvin Colarusso and Robert Nemiroff propose a broad theoretical foundation for adult development (Table 50-2) by suggesting that the developmental process is basically the same in the adult as in the child, because, like the child, the adult is always in the midst of an ongoing dynamic process, continually influenced by a constantly changing environment, body, and mind. Whereas child development focuses primarily on the formation of psychic structure, adult development is concerned with the continuing evolution of existing psychic structure and with its use. Although the fundamental issues of childhood continue in altered form as central aspects of adult life, attempts to explain all adult behavior and pathology in terms of the experiences of childhood is considered reductionistic. The adult past must be taken into account in understanding adult behavior in the same way that the childhood past is considered. The aging body is understood to have a profound influence on psychological development in adulthood, as is the growing midlife recognition and acceptance of the finiteness of time and the inevitability of personal death.

Development is a life-long, dynamic process that is basically the same in childhood and adulthood
Basic themes from childhood continue to affect psychic development in adulthood, but adult functioning and symptomatology are an amalgam of both childhood and adult experiences
Recognition and acceptance of the finiteness of time and the inevitability of personal death are major psychic organizers in adulthood, both in the promotion of normal development and the formation of symptomatology

Table 50-2 Hypotheses About Development in Adulthood

Although Colarusso and Nemiroff, following Erikson, divide adulthood into 20-year periods, developmental phases are not considered to be as useful in adulthood as they were in childhood because developmental themes do not appear with the chronological precision or the phase specificity that they have in childhood. For example, the developmental milestones of infancy appear within a span of a few weeks or months. The phases of Margaret Mahler's separation individuation theory and Jean Piaget's cognitive developmental sequences cover months or a few years at most. By contrast, the experience of biological fatherhood can occur over a span of 60 years or more, and the intrapsychic effects vary markedly, depending on the phase of development in which parenthood occurs. A more precise understanding of adult experience may be achieved by using the concept of “adult developmental tasks.” They are the psychological responses to such major life experiences as work achievement, parenthood, and retirement, which, as the result of actual occurrences or psychological considerations, produce intrapsychic changes in all persons in a particular age group. Used together, the concepts of adult developmental phases and tasks can deepen the clinician's understanding of the effect of past and present experiences on the evolving mind.

YOUNG ADULTHOOD (AGES 20 TO 40)

Shift From Biological Growth to Aging The shift from physical progression to retrogression, from growth to aging, occurs in young adulthood. This strikingly obvious and developmentally significant event has scarcely been addressed in the literature on adulthood. The effect of biological maturation on mental evolution has been extensively described in the developmental theory of childhood. For instance, Freud described the libidinal progression from erogenous zone to erogenous zone and built his conceptualization of oral, anal, oedipal, latency, and adolescent stages upon this biologically determined sequence.

There is no interval between the end of maturational progression and the beginning of aging. The two overlap during the young adult years, but aging gradually replaces growth as the dominant biological influence. Evidence of this shift includes slowing of reflexes, loss of skin tone, early signs of balding (in some during the 20s), and the far more dramatic loss of the procreative function in women in the late 30s and early 40s.

Transition From Adolescence to Young Adulthood The transition from adolescence to young adulthood is characterized by real and intrapsychic separation from the family of origin and the engagement of new, phase-specific tasks (Table 50-3). Various authors have described this process as the shedding of family dependencies to become a member of society at large, the shift from preadolescent idealized parental images to postadolescent idealized ethics and values, and the gradual shift from the family of origin to the family of procreation.

To develop a young-adult sense of self and other: the third individuation
To develop adult friendships
To develop the capacity for intimacy; to become a spouse
To become a biological and psychological parent
To develop a relationship of mutuality and equality with parents while facilitating their midlife development
To establish an adult work identity
To develop adult forms of play
To integrate new attitudes toward time

Table 50-3 The Developmental Tasks of Young Adulthood

The Berkeley Guidance and the Oakland Growth Studies are long-term investigations of normal development that were begun in 1929 and 1932, respectively. They indicate that psychological adjustment in adulthood is not easily predicted from adjustment during adolescence. This important observation supports the idea that conflicts in adulthood can lead to the reworking of past issues with better resolutions or to the onset of new forms of pathology.

The same idea is incorporated in Levinson's characterization of transitions, intervals of approximately 5 years of change and turmoil that occur between periods of relative stability. The transition from late adolescence to young adulthood occurs between ages 17 and 22. During these years the individual resolves the issue of childhood dependency enough to establish self-reliance and begins to formulate new, young-adult goals that eventually result in creation of new life structures that promote stability and continuity.

Another important intrapsychic aspect of the transition is a redefinition of the childhood and adolescent past. For the first time, an entire phase of life is consigned to the past. This gradual, painful process brings closure to an epoch of life and forces redefinition of aspects of psychic structure, particularly the superego and ego ideal.

Developmental Tasks of Young Adulthood

Developing a Young-Adult Sense of Self and Other: The Third Individuation Establishing a self separate from parents is a major task of young adulthood. For most individuals the emotional detachment from parents that takes place in adolescence and young adulthood is followed by a new inner definition of themselves as comfortably alone and competent, able to care for themselves in the real and intrapsychic worlds. This shift away from the parents continues long after marriage and parenthood result in the formation of new relationships that replace the progenitors as the most important individuals in the young adult's life.

Psychological separation from the parents is followed by synthesis of mental representations from the childhood past and the young adult present. For instance, as their children grow, young parents reengage memories of their own childhoods and fuse their experiences as parents with memories of their own progenitors from a generation ago. The separation-individuation process in infancy is responsible for establishing a stable sense of self and the capacity to relate to others. The psychological separation from parents in adolescence has been called “the second individuation” and the continued elaboration of these themes in young adulthood, “the third individuation.” The continuous process of elaboration of self and differentiation from other that occurs in the developmental phases of young (20 to 40) and middle (40 to 60) adulthood is influenced by all important adult relationships. At its core are ties to children, spouse, and parents (i.e., the family), the same psychological constellation that shaped the first and second individuations.

Adult developmental theory postulates a growing complexity in relationships as the individual moves from developmental phase to developmental phase. The first individuation is a rather exclusive affair between infant, mother, and father. During the second individuation relationships expand to include important nonfamilial relationships such as friends and mentors. The transition from the second to the third individuation is a young-adult experience, stimulated by growing intrapsychic separation from the parents and the loneliness that follows in its wake. Sooner or later most young adults attempt to fill the real and intrapsychic voids left by separation from the parents of childhood by establishing a family of procreation. Other aspects of the third individuation deal with the developmental tasks of intimacy, parenthood, and separating from parents.

Developing Adult Friendships Freud described friendship as an expression of libido, stemming from the same source as sexual love that has sexual union as its aim. In the relationship between the sexes, the impulses force their way toward sexual union, but in other circumstances they are diverted from this aim or are prevented from reaching it though always preserving enough of their original nature to keep their identity recognizable. But human relationships, including friendships, are not based on love alone. Like all other human interactions, friendships are also based on aggression. The character of friendship is determined by the aim-inhibited expression of the aggression, not by its absence.

Using a psychodynamic framework, friendship may be defined as an extrafamilial object relationship based on mutuality, equality, and freedom of choice, in which the expression of sexual and aggressive impulses is predominantly aim inhibited. However, because of the power of emotion, friends can be transformed into lovers or enemies and sometimes back again into friends. This tendency toward fluidity is common in childhood, whereas the maintenance of a stable state of friendship over an extended period of time is more characteristic of adulthood.

From the latency period onward, friendships are an integral part of human experience, a vital form of relationships. At each subsequent developmental phase, including adolescence and young adulthood, the character and substance of healthy friendships are determined in part by the mutual need to engage and resolve major phase-specific developmental tasks.

At times developmental pressures strain the capacity for friendship to the limit. In early adolescence, in particular, the strength of the drives vis-a-vis the ego often breaks down aim inhibition, as observed in both homosexual and heterosexual experimentation between peers. But, generally speaking, at no other time in life do friendships play such a prominent role in the developmental process. At this time, they facilitate the engagement and resolution of such developmental tasks of the phase as separation from parents and beginning integration of adult sexual and work identities.

In late adolescence and young adulthood, before marriage and parenthood, friendships are often the primary source of emotional sustenance. In the years between the family of origin and the family of procreation, the young adult has little opportunity to gratify impulses within a committed relationship and experiences the loneliness of young adulthood. Roomates, apartment mates, sorority sisters, and fraternity brothers, as indicated by the names used to describe them, are substitutes for parents and siblings, temporary stand-ins until more permanent replacements are found.

The emotional needs for closeness and confidentiality are largely met by friendships. All major developmental issues are discussed with friends, particularly those in similar circumstances. As marriages occur and children are born the central emotional importance of friendships diminishes. Some friendships are abandoned at this point because the spouse objects to the friend, recognizing at some level that they are competitors. Gradually there is movement toward a new form of friendship, couples friendships. They reflect the newly committed status but are more difficult to form and maintain because four individuals must be compatible, not just two.

As children begin to move out of the family into the community, parents follow. Dance classes and Little League games provide the progenitors with a new focus and the opportunity to make friends with others who are at the same point developmentally and receptive to the formation of relationships that help explain, and cushion, the pressures of young-adult life.

Developing the Capacity for Intimacy: Becoming a Spouse Erikson defined the major developmental dichotomy of young adulthood as intimacy versus stagnation. Intimacy includes the capacity to experience others' needs and concerns as being as important as one's own. The ability to be intimate has its origins in the early parent-child relationships, the successful resolution of the oedipal complex, and adolescent sexual experimentation. But it does not become a sustainable capacity until young adulthood, apparent in the highest functioning individuals by the fourth post–high school year.

The developmental shift from sexual experimentation to the desire for intimacy is experienced in young adulthood as an intense loneliness, resulting from the

awareness of an absence of committed love similar to that experienced in childhood with the parents. Brief sexual encounters in short-lived relationships no longer significantly boost self-esteem. Having mastered the mechanics of capable sexual performance, mere repetition no longer provides emotional satisfaction. Increasingly, the desire is for emotional involvement in a sexual context. The young adult who fails to develop the capacity for intimate relationships runs the risk of living in isolation and self-absorption in midlife.

Significant intrapsychic change occurs when intimacy is achieved. Through the repeated fusion of sex and love, the self is increasingly linked to the partner. As sexual thoughts, feelings, and practices are repeated in relation to the loved one the superego becomes more tolerant and flexible. Sexual identity is refined as feminine or masculine aspects of the self are projected onto, and accepted and loved in, the partner. The ego ideal is altered by inclusion of the partner's goals for the couple's future, particularly in regard to such young-adult issues as the desire for children and career ambitions.

The development of the capacity for intimacy encourages the acceptance of the equal status and complementary nature of the male and female genitals. Repeated experiences with foreplay, intercourse, conception, pregnancy, childbirth, and psychological parenthood provide the optimal environment in which to abandon infantile notions of phallic superiority and replace them with the recognition that female and male genitalia are equal and interdependent for sexual pleasure, intimacy, and reproduction.

For most individuals in Western culture, the experience of intimacy increases the desire for marriage. Longitudinal developmental studies indicate that no single variable predicts mental health as clearly as the capacity to remain happily married over time.

Becoming a Biological and Psychological Parent Although biological parenthood is not limited to young adulthood, it is experienced by most individuals for the first time during this phase of development. Consideration of the developmental line of sexual identity during childhood will place parenthood in a developmental context. During the first 18 months of life a basic sense of maleness or femaleness called “the core gender identity” is established. By age 3, children become aware that there are two sexes; then during the oedipal phase, sexuality is explored within relationships. During latency subjective family, community, and cultural attitudes about masculinity and femininity are integrated. During adolescence the maturational changes of puberty stimulate interest in the use of the adult body as a sexual instrument, first with the self, then with others. Then in young adulthood the developmental experiences of intimacy and parenthood are added.

Biological parenthood initiates the process of psychological parenthood, the mental state in which healthy young adults become increasingly attached to and involved with their children. For both parents-to-be, pregnancy adds a new dimension to sexual identity by confirming that their sexual apparatus can perform the primary function for which they were intended. After birth, each interaction with the infant enhances the heightened sense of sexual completeness and stimulates the desire to lovingly engage the baby who is so strongly identified with the self. When a young couple become parents for the first time, a family is created. Its structure is identical to the family of origin except for the reversal of roles. As the former children, now the parents, minister to their creation, they undergo profound intrapsychic change as a result of the simultaneous reexamination of their own experiences as children and the growing sense of themselves as adults.

Parenthood intensifies the relationship between the new parents. Through their physical and emotional union the couple has produced a fragile, dependent being who needs them in the interlocking roles of father and mother. This recognition expands their internal images of each other to include thoughts and feelings emanating from the role of parent. The superego and ego ideal are expanded to include the role of parenthood, and as they live together as a family, the lovers' relationship to each other changes. They become parents relating to one another and to their children.

Becoming a parent also stimulates further individuation from the members of the family of origin. Assuming the roles that were formerly the exclusive prerogative of their progenitors, the new parents develop parity. Further, constant conscious and unconscious comparisons of child-rearing practices heighten an internal sense of difference while paradoxically reinforcing connectedness and continuity between the generations.

Finally, the ability to be instrumental in the midlife development of one's parents by providing them with the experience of grandparenthood is striking evidence of the shift in the power balance between the generations, foreshadowing the not-too-distant future when the elderly parents may become dependent upon their children for physical and psychological well-being.

Separating Psychologically From Parents and Developing a Relationship With Them of Mutuality and Equality While Facilitating Their Midlife Development Real and intrapsychic relationships with parents undergo dramatic changes during young adulthood. This experience may be divided into three phases that build upon one another.

PHASE I Psychological separation from parents continues. Not all aspects of the first and second individuations are resolved by the end of adolescence. Both, but particularly the more-recent second individuation, continue to be engaged during young adulthood. The ability to function relatively independently of parents, without using them as a major source of comfort, security, and direction, comes to fruition during the young-adult years.

Building on the developmental achievements of adolescence, this process is greatly facilitated by marriage and parenthood. As the spouse is internalized as a significant partner and children assume roles of increasing intrapsychic importance, the power of earlier parental introjects is gradually diminished. These childhood memories and images are further transformed by their fusion with current representations of the spouse and the self in conjunction with the functions of both as lover and parent. Every young adult brings from childhood a detailed plan (largely unconscious, but firmly institutionalized in the superego/ego ideal) of how a husband or wife and parent should act. These idealized expectations must be modified by current reality if they are to be adaptive.

PHASE II Once the roles of spouse-parent-provider have been assumed, the stage is set for the establishment of an inner sense of equality and mutuality with parents. This occurs as young adults marry, become parents, work, develop adult friendships, and become part of a community. As these adult experiences become the substance of everyday life they transform the intrapsychic relationship with the parents of childhood from one of dependency and need to one of mutuality and equality.

However, parents remain important as long as they live, since only parents and children place one in the center of a genetic continuity that spans three generations. As middle age approaches with its preoccupation with time limitation and personal death, the intrapsychic importance of this genetic immortality increases.

PHASE III Equality and mutuality with parents may continue for many years or may be short-lived, depending on the mental and physical health of the parents. At some point the adult child will be confronted with the psychological and possibly physical task of caring for vulnerable, dependent parents who no longer function independently. When this occurs, the memories from childhood of the dependent, immature self and the aging parent of the present stimulate the child to reenter the parent-child dyad, now reversed, and assume the role of caretaker.

Simultaneously, through their interactions, living parents and grandparents provide examples of how the developmental tasks of middle and late adulthood may be engaged. As the young adult parents and their children internalize these examples the foundation is laid for interactions in the years to come when their roles will be reversed.

Longitudinal studies that have traced personality development through childhood and into adulthood indicate that the adult personalities of children closely resembled those of one or both parents. This similarity may be attributed not only to the earlier adult-child interaction but also to their continuing relationships as adult to adult.

Both parents have an effect, not just the parent of the same sex. In fact, identification with the parent of the opposite sex tends to increase in young adulthood because heterosexual identity is more secure, strengthened by marriage and psychological parenthood. The young adult is then freer to incorporate valued aspects of the character of the opposite-sex parent, particularly in regard to the engagement of the developmental tasks of middle and late adulthood.

Establishing an Adult Work Identity Establishing a work identity is a critical developmental task of young adulthood. When this developmental line is relatively conflict free, there is a smooth progression from high school to on-the-job training or from high school to college and graduate school. In most advanced countries opportunities to change jobs or acquire further training to enhance career advancement remain open throughout the young-adult years. In more closed or class-oriented societies, such as China or the United Kingdom, decisions about career choice are made in adolescence on the basis of intellectual potential and academic achievement. Once excluded from the educational track the individual has little subsequent opportunity for formal academic advancement.

The transition from learning and play to work may be gradual or abrupt, but at some point, usually in the late teens or 20s, work becomes a central intrapsychic and real activity. Then, the pleasures of play or learning or both must be subordinated to the temporal and emotional demands of job or career. Depending upon choice of

career and opportunity, work may become a source of ongoing frustration or an activity that enhances self-esteem and gradually leads to a shift in identity from child to adult and from player to worker.

> A young-adult female patient had greatly enjoyed her 5 years in college and only reluctantly accepted a job with a large real estate firm. During college she had had limited interest in her appearance, and she began work in clothing borrowed from family and friends. She scoffed when her boss began to criticize her dress and gave her an advance to buy an upscale wardrobe; but she began to enjoy the fine clothing and the respect engendered by her appearance and position. As her income began to rise, work became a source of pleasure and self-esteem and the way to acquire some of the trappings of adulthood.

Young adults, regardless of career choice, must assume the role of mentee and work with mentors to acquire the information and skills necessary to forge a work identity. The relationship with the mentor is based on infantile identifications, but this adult process is not a duplication of the parent-child experience. The relationship with the mentor normally goes through three phases. The first phase, a psychological fusion with the mentor, is followed by an internalization of aspects of the mentor's ideas and attitudes. Eventually, psychological and physical separation from the mentor leads to further individuation.

Clinicians who recognize the importance of this critical developmental process will be extremely sensitive to the presence (or absence) of material about work and relationships. In some patients, problems with work may be a major symptom, rooted in significant internal conflict; in others work may be the unrecognized source of interference with other developmental themes.

> A 28-year-old lawyer who worked 80 hours a week did not recognize that his social isolation was of his own making. Chronic fatigue and lack of time were the rationalizations he used to avoid considering more deeply seated needs to avoid sex and intimacy.

Developing Adult Forms of Play Young adulthood is when the ability required to perform most of the physical games learned in childhood and adolescence reaches a peak and then declines. Most individuals do not realize their childhood fantasies about athletic fame and fortune and must realistically appraise their capability and mourn what was not achieved. Aspirations for athletic fame are not easily relinquished, however. Some are maintained through identification with sports figures who are now chronological contemporaries. These identifications may continue into middle and late adulthood—these are the true fans. For others, however, new interests and acceptance of the aging process stretch the credibility of comparisons between youthful heroes and the middle-aged self until such identifications become impossible, which leads to a diminished interest in spectator sports and a search for new forms of play.

Some patterns of childhood play continue into the adult years, existing side by side with new forms of play that reflect the growing importance of spouse and children. These range from tennis or jogging with one's partner to mental games, such as bridge, with friends. Involvement in the play activities of children is a powerful source of narcissistic gratification for some parents, providing a second chance to realize childhood goals through identification with the success of sons or daughters. In the psychotherapeutic setting, material about childhood play is a rich source of information, whose exploration may lead to unexpected revelations and insight. The exploration of adult play activities may have similar benefits. For example, the failure to moderate physical activity in keeping with the aging process in the body may result in physical injury that precipitates anxiety or depression and exposes conflicts about aging and other young-adult issues.

Integrating New Attitudes Toward Time

TIME SENSE IN YOUNG ADULTHOOD Time sense in the 20s rests on psychic structures built in childhood and adolescence. In the early 20s, consignment of childhood to the past can produce a brief, latency-like temporal calm that is built upon both the resonance between conscious aspirations and unconscious expectations and the realization that the future is long enough to postpone some decisions, undo mistakes in career or object choice, and start again if necessary. But by the mid-20s, time sense is increasingly influenced by the search for adult structure and new objects—career definitions, friends, lovers, and spouse and children—to replace the temporal organizers of childhood, mother and father.

Subjective time sense in the 30s differs qualitatively from that in the 20s because midlife issues emerge and gradually become dominant. For example, as signs of physical aging become more apparent, the phenomenon of loss is translated into a growing awareness of personal time limitation. This is particularly true for women, who must confront the approaching loss of procreative function, which affects subjective time sense in as dramatic a manner as the onset of puberty did in early adolescence. The “30-something” individual must also assess relationships and work achievement differently. Significant progress toward establishing the family of procreation to replace the family of origin is expected, as is work and financial achievement.

RELATIONSHIPS Relationships significantly influence subjecting time sense in young adulthood. The relationship to the spouse is one of the most important intrapsychic organizers of time sense in adulthood. This temporal commitment is made in the most demanding terms, and like no other mutually consensual relationship in life, marriage defines the expectation of how time will be used as well as conceptualized consciously and unconsciously. Over time, a long-lasting, mature love relationship becomes as significant an organizer of time sense in adulthood as the relationship between parent and child was in childhood.

However, becoming a biological parent is the quintessential temporal experience of young adulthood. The ability to reproduce provides humans with their only immortality; through genetic transmission a part of the self will live on after death. Biological parenthood coupled with the capacity to love and remain invested in one's offspring leads to major psychological and more specifically temporal reorganization. Future sense is expanded, and the past is extensively reworked as the parent consciously and unconsciously relives each developmental stage with the child.

NORMAL TEMPORAL FUNCTIONING AT THE END OF YOUNG ADULTHOOD In temporal terms, normal functioning implies that as individuals approach 40, they have accepted the aging process in the body, integrated the use of time with productivity, separated psychologically from Mother and Father time, begun to deal with the notion of personal death, and forged new ties with contemporaries and children who give new meaning to the present and future. So equipped, the young adult approaches middle age ready to engage, master, and integrate the monumental temporal challenges that lie just ahead.

One of the most profound influences on development in adulthood is the increasingly conflictual awareness that personal time is limited and one will die. This painful realization is both a source of conflict and psychopathology and a developmental stimulus that forces a new appreciation of the preciousness of time and a reordering of priorities.

Coming to terms with time limitation is a central psychological task of middle age. Implicit in this statement is the conviction that temporal awareness and management in midlife has a greater impact on development, healthy and pathological, than at any other point in the life cycle.

Changes in Psychic Structure in Young Adulthood In young adulthood the ego increases its ability to control impulses consistently, delay gratification, limit and control aggression, channel energy into work and other sublimated activities, and separate from parents and form new loving relationships.

Defenses The longitudinal Grant Study of a population of Harvard undergraduates determined that these men were twice as likely to use the mature defenses of sublimation, suppression, anticipation, and humor in young adulthood as they were in adolescence. In middle adulthood the change was even more dramatic; mature defenses were used four times more frequently than in adolescence. In addition, by midlife the subjects used relatively fewer immature defense mechanisms (i.e., acting out, projection, hypochondriasis, and masochism). A defensive shift toward optimism and idealism has also been observed in young adults, reflecting the need to cope with growing preoccupations with two fundamental features of human life, inevitable death and the existence of hate and destructive wishes inside each person.

Intelligence and Cognition Studies in the 1940s proposed that the intelligence quotient (I.Q.) increased into the 20s and then declined throughout the remainder of life. This notion has persisted despite detailed longitudinal studies that convincingly demonstrate that in the absence of a cognitive disorder, intelligence increases throughout young and middle adulthood.

This conclusion is confirmed by new post-Piagetian ideas about intelligence in adulthood. Like Freud, Piaget ended his theory with adolescence, describing attainment of the capacity for abstraction as the highest order of thinking. More-recent studies indicate that the nature of thought in adulthood is far more complex. Piaget's constructs have been extended to include a stage beyond formal operations, called “structured analytic thought.” Going beyond simple abstraction, the young-adult thinker begins to grasp the connectedness of sets of relationships, that is, the relationship between systems.

Progressing beyond formal operations, some adults develop the capacity for dialectical thinking. While formal thinkers focus on universals, dialectical thinkers are

relativists, recognizing the relation between ideas and facts that creates “truth” within a particular system of thought or historical period. Contradiction and paradox are integral aspects of adult thinking that lead to new ideas and synthesis.

Some young adults and middle-aged adults may progress beyond formal operations and dialectical thought to autonomous thought. Whereas the formal operational thinker analyzes relations within a closed system and the dialectical thinker understands that some truths are relevant, the autonomous thinker integrates logical and irrational aspects of experience and recognizes how the thinker participates in the creation of truth. Other studies support the notion that thinking becomes increasingly relative in adulthood because of the newly emergent ability to synthesize experience and emotional and contradictory ideas. Biologically intact individuals can continue this developmental evolution in thinking into late adulthood.

REALITY TESTING The ability to test and comprehend reality grows in complexity in young adulthood for a number of reasons. Greater comfort with the inner world lowers the tendency to distort internal and external stimuli. Greater experience in living increases the capacity to manage everyday events autonomously and with less stress. The ability to think and reason increases qualitatively; phase-specific developmental tasks such as the growing awareness of time limitation and personal death are engaged.

For many, the continued elaboration of these ego functions during young and middle adulthood results in an enhanced capacity for introspection and the emergence of wisdom, that special ability to understand and interpret human experience from the viewpoint of the second half of life.

Female Development A radical change in the theory of female development was crystalized in 1976 when the *Journal of the American Psychoanalytic Association* devoted an entire supplement to female psychology. Female development was conceptualized as following its own line from birth onward, which differed from Freud's proposal that male and female psychic development was identical until the oedipal phase. Further, penis envy was no longer recognized as a major component of female development during the oedipal phase. The supplement was also noteworthy in extending the consideration of female development into adulthood.

Aspirations for a career and motherhood are particularly pressing issues for women in young adulthood. The absence of a single, socially prescribed role for them provides opportunities for both growth and considerable inner turmoil. Therapists are treating increased numbers of disillusioned young-adult women—and men—who concentrated on their careers and did not marry and have children. Accomplished in the workplace, they complain of loneliness, depression, and isolation.

The loss of the ability to have children in their 30s and early 40s is the most striking developmental difference between the sexes in young adulthood, and it affects almost every other developmental line.

> A childless 38-year-old, divorced lawyer sought treatment for herself and her live-in boyfriend of 2 years. She was anxious to marry and have children, but he was hesitant. She had become increasingly depressed over the past several years, as her awareness that the passage of time was diminishing her chances to have children deepened. After several months of therapy the boyfriend decided to leave the relationship.

Developmental theory suggests that psychopathology results from the failure to engage and master major developmental tasks during the phase in which they are central themes. This remains true throughout the life cycle. An awareness of the basic biological and psychological forces that underlie normal young-adult development can provide individuals and clinicians with the knowledge needed to prevent such young-adult psychopathology.

MIDDLE ADULTHOOD (AGES 40 TO 60)

Concepts of time, aging, and death are the currency of midlife development. Consequently, therapeutic attention can no longer focus entirely on the past. It must also include current reality and the struggle to adapt to ever-changing time, since these issues are at the core of understanding and treating individuals between the ages of 40 and 60. Despite growing awareness of aging and death, the middle years are the best time in life for many. Middle adulthood is the golden age of adulthood, similar to the latency years in childhood but much longer. Physical health, emotional maturity, competence and power in the work situation, and gratifying relationships with spouse, children, parents, friends, and colleagues all contribute to a normative sense of satisfaction and well-being.

Transition From Young to Middle Adulthood The transition from young adulthood to middle adulthood is slow and gradual, with no sharp physical or psychological demarcation. The aging process picks up speed and becomes a powerful organizing influence on intrapsychic life, but the change is gradual, unlike adolescence. Mental change is experienced in a similar fashion, slow and imperceptible, without a sense of disruption.

Development in young adulthood is embedded in close relationships. Intimacy, love, and commitment are related to the mastery of the relationships most immediate to personal experience. The transition from young adulthood to middle age includes widening concern for the larger social system and differentiation of one's own social, political, and historical system from others. Authors have described middle adulthood in terms of generativity, self-actualization, and wisdom.

Developmental Tasks

Integrating the Potential for Attachment and Loss: The Fourth Individuation The fourth individuation refers to the elaboration of separation-individuation processes in middle adulthood (ages 40 to 60). One of the most powerful influences on these processes in midlife is the ironic awareness that one will die and be deprived of involvement with loved ones, at the very time that a mature understanding of the importance of others for one's health, happiness and security is at its peak. This paradox is particularly poignant in middle adulthood because fulfillment is based in no small measure on the incredible richness of involvements that grow by leaps and bounds between 40 and 60. Unlike the 20s and some of the 30s, when in the midst of the third individuation individuals have left their family of origin and not yet created a family of procreation, midlife men and women are immersed in relationships with spouse, children, elderly parents, in-laws, friends, and colleagues and are forging new ties with new individuals of great personal importance, grandchildren. At no other point in life is the potential for attachment— and loss—so great. Accepting this juxtaposition of interdependence with others and the inevitability of total separation and loss is a central developmental task of middle adulthood that must be engaged and mastered if developmental progression is to continue (Table 50-4)

To integrate the potential for attachment and loss: the fourth individuation
To accept the aging body
To accept time limitation and personal death; time sense in middle adulthood
To reappraise relationships; to let children go, achieve a relationship of equality with them, and integrate new members into the family
To accept the reversal of roles with elderly parents
To develop midlife friendships
To become a generative mentor and plan for retirement
To give play new meanings and purposes
To become a grandparent

Table 50-4 The Developmental Tasks of Middle Adulthood

Accepting the Aging Body Physical decline begins to affect psychological development in the 20s and begins to have a significant effect in the 30s. By midlife, however, because of the universal awareness of aging and the marked increase in major illnesses and peer group death that occur then, thoughts and feelings about the aging body become a major, sometimes dominant influence on mental life. The appearance of the midlife body takes on a different significance. Efforts to remain trim and fit are no longer made to develop a sense of identity or to separate and individuate as they were in young adulthood. The struggle in midlife is to maintain body integrity in the face of anxieties about aging, failing health, and the potential loss of independence. Awareness of change in physical appearance and function is constant. In addition to changes in public presentation such as vision, hair color, and skin tone, more private aspects of physical functioning change, such as cessation of menstruation, altered sexual functioning, increased urinary frequency, and diminished force of the urinary stream.

The reaction to these dramatic biological changes varies considerably from individual to individual, as evidenced by the responses to the menopause. Formerly thought to be a direct result of decreased production of estrogen, more-recent studies indicate that emotional lability, depression, irritability, and other somatic and psychological complaints are individual responses that are present to varying degrees in a minority of women. Only cessation of menstruation and hot flashes occur universally, because they are the direct result of diminished estrogen production.

The physical changes just described are experienced mentally in the form of body monitoring—a continual, conscious and unconscious, comparison of the midlife body with the body of youth. This painful process leads to a conflict between wishes to deny the effects of aging and the need to accept the loss of a youthful body. The normative result is mourning for the lost body of adolescence and young adulthood. Attempts to deny aging include the inappropriate use of plastic surgery, fusion with younger bodies, and exaggerated physical competition with younger individuals. The acquisition of possessions such as rare art, expensive automobiles, and fine clothing is also used as substitutes for the body. Since the aging process continues for the rest of life, there is no resolution of this conflict, but in the healthy individual, the gradual acceptance of aging produces a major change in the body image and increases the pleasures that the midlife body can provide, particularly if it is cared for properly.

Accepting Time Limitation and Personal Death: Time Sense in Middle Adulthood Because of the aging process in the body, the death of parents and contemporaries, the growth of children into adulthood, and grandparenthood and the approach of retirement, midlife individuals come face to face with their mortality and with the painful, but unavoidable, realization that the future is limited and they will die. An extremely powerful psychic organizer, acceptance of the inevitability of personal death precipitates reexamination of all aspects of past and present life and reassessment of how the time left to live will be used.

DEATH AWARENESS Freud observed that we show an unmistakable tendency to put death aside, to eliminate it from life. Our instincts do not respond to a belief in death, and in the timelessness of our unconscious, we are convinced of our immortality. An understanding of a developmental line of time sense from childhood and young adulthood helps explain how experience counters this unconscious (and conscious) wish and false belief in immortality and culminates in midlife in a poignant, painful, monumental conflict between irrationality and reason that, more than any other, defines the mature adult and the essence of the human condition.

Childhood is characterized by a tendency to deny the inevitability of personal death because of the immaturity of the psychic apparatus, the forward thrust of maturation, and the limited understanding of the concept of time. Little in the anabolic thrust of the developmental process indicates a personal end.

Then, in late adolescence, the loosening of intrapsychic ties to the parents elicits a sense of history that includes the realization that a part of the self and an entire epoch of life (childhood) is in the past and irretrievably lost. But this dawning recognition is quickly defended against by the optimism and idealization of youth, a semisuccessful attempt to deny the two fundamental features of human life—the inevitability of death and the existence of hate and destructive impulses inside each person. Gradually, a more contemplative pessimism replaces the youthful belief that the power of stasis, the status quo, and catabolism can be overcome. With youth behind them, normal midlife adults must confront their finiteness as the defenses against the acceptance of time limitation and personal death crumble before the power of new physical, psychological, and environmental experiences.

Then, too, parents, friends, and contemporaries die. The death of a parent, in particular, undercuts the childhood sense of unending continuance and safety that was provided by the good-enough parent. One is left alone, unprotected by the infantile notion of parental omnipotence, with the staggering realization that the child must die, just as the parent did. As the older generation disappears from the scene, the younger generation approaches adulthood. The transformation of children into physically and sexually mature adults also shatters the parent's sense of perpetual youth, because identification with young, immature children is no longer possible as they become bigger and stronger than their progenitors.

Through genetic extension, through the process of identification of parent-child-grandchild, middle-aged grandparents, for the second time in their lives, participate in the creation of new life—the creation of time. Through genetic continuity, children and grandchildren provide the only form of physical immortality that exists. The dynamic relationship between grandparents and grandchildren cannot be fully understood without comprehending the temporal bonds that define this relationship. Grandchildren draw grandparents toward the beginning of life, toward tender years when time itself seemed to exist in unlimited supply, and away from the painful awareness of old age, time limitation, and death.

The realization that time is running out is also painfully thrust into consciousness by the growing awareness that many cherished ambitions and goals will never be realized and that there is not enough time left to achieve new ones of equal importance. Further, a personal end is also forcefully brought into focus by the loss of power and prestige in the workplace or the realization that the highest level of achievement possible has been reached. Power belongs to the young, who have the time to begin new ventures and bring them to fruition in the distant future. As one patient, a highly successful professional, put it: “I've become redundant. The heirs apparent can do everything I can and a lot that I can't. My time in the spotlight is just about over. Soon it will be lights out!”

TIME SENSE IN MIDDLE-AGED WOMEN Puberty focuses and defines gender differences in temporal attitudes, which continue to expand during the remainder of adolescence and adulthood. With the beginning of menstruation, a woman's sense of time is influenced by her “monthly,” her “cycle.” Later, in sexual relations, the female is less constricted temporally; she has no refractory period following climax.

Pregnancy produces another sexually defined cycle for the female. This quintessential psychobiological event that spans 9 calendar months is divided into temporal phases—early, middle and late—and has a clear beginning (intercourse) and end (labor and delivery).

In young and middle adulthood gender differences continue to manifest themselves, most notably through the loss of the procreative function in the late 30s and 40s. The running down of the biological clock leads to the end of this interval and produces two paradoxical effects on middle-aged time sense. The cessation of menstruation is a temporal watershed, forcing a mourning reaction related to the loss of both procreative capacity and its power to imbue time with a sense of youthful purpose and productivity and the awesome ability to create time through the creation of new life. The inability to engage and master this mourning process is a significant dynamic factor in the problematic and pathological responses to the menopause that are seen in some women.

However, after the mourning process related to the menopause is successfully worked through, a major developmental transformation in subjective time sense occurs. No longer dominated by the time tables of the monthly menstrual cycle or the possibility of pregnancy, women are free to use time in new, egocentric ways. This sense of liberation is one of the dynamic factors supporting the contention that a problematic reaction to menopause and the empty nest are not usual responses.

A significant developmental task of middle adulthood for both sexes is the ability, free of significant conflict and guilt, to use increasing amounts of time for egocentric purposes. For women, this task is thrust into the forefront of the developmental process and driven by the menopause. But in both men and women, the newly found temporal freedom and sense of exhilaration that accompanies it become quickly fused with generative activities. In other words, the self is aggrandized by giving to, and caring for, younger generations and identifying with their abundant future and temporal riches. When this fusion occurs, the focus on giving to, and caring for, the young continues a pattern that was begun with parenthood but is now driven by a different dynamic force, namely, the need to react to the midlife confrontation with awareness of time limitation and personal death.

Maintaining Intimacy in the Face of Significant Physical, Intrapsychic, and Environmental Interferences Whereas the young adult is preoccupied with developing the capacity for intimacy, the midlife individual is focused on maintaining intimacy in the face of deterring physical, psychological, and environmental pressures. In a long-standing relationship, these pressures include real and imaginary concerns about diminished sexual capability, emotional withdrawal due to preoccupation with developmental tasks, and the realistic pressures related to work and providing for dependent children and sometimes elderly parents as well. In relationships that begin in midlife all of the above factors may operate, but in addition, the maintenance of intimacy may be compromised by the absence of a common past, age and generational differences in interests and activities, and the difficulties involved in forming a stepfamily.

For sexual intimacy to continue, the participants must accept the appearance of the partner's middle-aged body and continue to find it sexually stimulating and accept the normative changes that occur in sexual functioning. For those who master these developmental issues, the partner's body remains sexually stimulating. Diminished sexual ability is compensated for by feelings of love and tenderness generated over the years by a satisfying relationship. Those who cannot accept the changes in the partner's body or their own stop having sex, begin affairs, or leave the relationship, usually in search of a younger partner.

Normative changes in midlife sexual functioning include diminished sexual drive and an increase in mechanical problems. Men have greater difficulty getting and sustaining erections and experience a longer refractory period after ejaculation. Because of diminished estrogen production women experience a thinning of the vaginal mucosa, a decrease in secretions, and fewer contractions at the time of orgasm. These physical changes are powerful psychological stimuli that produce

normative and pathological responses in every patient in this age group. Because the subject matter is embarassing and difficult, many patients avoid this area entirely and resist attempts by the therapist to introduce the subject.

The demands of raising children interfere with the privacy and emotional equilibrium required for intimacy, as do the pressures and responsibilities of work. Fatigue and diminished interest are common denominators in these circumstances. Patients with deeply rooted problems with sexuality or relationships may use aging, work, and relationships with children or elderly parents as a means of rationalizing their conflicts and refusing to analyze them.

Reappraising Relationships Midlife is a time of serious reappraisal of marriage and committed relationships. In the process individuals struggle with the question of whether to settle for what they have or search for greater perfection with a new partner. For some the conflict rages internally and is kept from others; others express it through action that takes the form of affairs, trial separations, and divorce.

Recent research on happy marriage indicates that these couples, despite internal and real conflict, have found or achieved a special goodness-of-it between their individual needs, wishes, and expectations. They regard this fit as unique and probably irreplaceable. In the eyes of these couples, marital success is based on the ongoing, successful engagement of a number of psychological tasks. Among the most important are providing a safe place for conflict and difference, holding a double vision of the other, and maintaining a satisfying sexual life.

The decision to leave a long-standing, committed relationship has great consequences not only for the two individuals involved but also for their friends and loved ones. The effect on children, in particular, is especially profound, extending far beyond childhood. The effects on the abandoned spouse, parents, and close relatives may be nearly as severe.

Various forms of therapeutic intervention such as marital counseling, individual psychotherapy, and psychoanalysis can be extremely effective in helping uncertain individuals decide what to do or helping those who leave deal with the consequences of their decision on the abandoned partner, children, and other loved ones. Problems relating to intimacy, love, and sex can occupy a prominent position in an outpatient practice.

A 55-year-old patient, Mrs. A., sought treatment “in order to leave my marriage. We've been married for 35 years but I haven't loved my husband for the last 20. I've been so dependent on him all of my adult life that I don't know if I have the courage to leave.” Twice-weekly psychotherapy that lasted 15 months helped her leave her husband, start a business, and begin a new relationship. “I have less money and I'm scared about the future, but I feel alive and in control of my life. I think Bill is happier, too.”

A 43-year-old patient, Mr. S. was continually preoccupied with his marriage during his 4-year analysis. Sexually inhibited during adolescence, he “married the only girl in the world who knew less about sex than I did.” Exploration of his sexual inhibitions led to a decision to stay in the marriage. “I've learned in this analysis that sex is not the rare, extraordinary thing I thought it was as a kid; billions of people do it every day. I know I could go out and sleep with a lot of different women, but how different, or better, would it actually be? Jane and I have built a pretty good life together. She's changed a lot and so have I. I think we can make the next 20 years better than the last 20.”

Mr. V. was distraught when his wife of 21 years left him for another man. During the first 2 years of psychotherapy he worked through his feelings of abandonment. Then at age 52, in a compulsive attempt to reassure himself about his deeply damaged sense of masculine competence, he began sleeping with many different partners. Repeated interpretation diminished the pattern, but 4 years after the divorce he was still unable “to take a chance on getting close to a woman again.” Six years after the divorce, after detailed consideration in therapy, he remarried.

Fifty-year-old Mrs. T. left her “wonderful” husband because “I've missed something. I just have to get out on my own.” Married at age 18, “after going from my parent's home to his home,” she recognized that her rage at her husband for “not being all the other men I could have married, for closing off all the living I could have done” was irrational but uncontrollable. “I have to live on my own for awhile, to see if I can do it, before it's too late.” Fully intending to return to her husband, she continued exploring the infantile and adult issues that precipitated the separation, leaving the future of the marriage in doubt.

Letting Children Go, Achieving Equality, and Integrating New Members Into the Family During middle adulthood children grow into adolescents and young adults. Their inevitable progression through the developmental phases from childhood to adulthood affects every aspect of the parent's life. How parents facilitate their children's individuation and relate to them as young adults sets the stage for a new relationship based on equality and mutuality. The integration of in-laws and grandchildren into their lives can make the difference between a rich, full late adulthood or one characterized by rancor and emptiness.

LETTING GO Young-adult parental vigor and the control of young children go hand in hand, but so do middle-age awareness of physical decline and time limitation and the inevitable loss of control of adolescent and young-adult offspring. The shift in the balance of power between them is gradual, taking place over many years as both engage their separate but interlocking developmental tasks.

Facilitating the developing sexuality of adolescent children is difficult for the midlife parents because of the juxtaposition between their waning sexuality and the adolescent's sexual promise. The liberalization of sexual mores and attitudes since the parent's adolescence may also add to the discomfort by making the contrast between the parent's experience and the adolescent's opportunities quite distinct, particularly for women. Healthy parents struggle with their conscious and unconscious envy and concerns but gradually accept the fact that sons and daughters are likely to begin dating and become sexually active in mid- or late adolescence.

Conscious concerns about their children's sexual behavior and the reactivation of unresolved sexual conflicts from the childhood and adult past are frequent presenting themes in the treatment of middle-aged patients. Others find this area a source of great resistance because of excessive interest in, or undue restriction of, their children's sexual development and the arousal of unconscious incestuous feelings. A fundamental knowledge of child and adult development will help the clinician understand the interplay of the infantile, adolescent, and adult sexual issues that determines the patient's symptomatology and interaction with sons and daughters.

Each developmental transition brings with it the prospect of significant intrapsychic change and a shifting balance in relationships. In middle adulthood that transition is characterized by physical aging and disappearance of the parental function. Cross-cultural studies of older men and women indicate that normal midlife development and late-onset pathology are driven by the same forces, energies released in men and women in the course of the postparental transition toward androgeny. As the gender distinctions between middle-aged parents blur, postparental men become more nurturing and tender, and their wives adopt some of the ascendant, competitive qualities that their husbands have relinquished. As each postparental spouse becomes as the other used to be, the couple moves toward the normal androgeny of later life. Because of its linkage to the genetic requirements of parenthood, this contrasexual transition is, like paternity and maternity themselves, a quasi-universal event. As such, it usually precedes a developmental advance. After some period of psychic dislocation, most men and women accommodate to the changes in themselves and in their spouses and shape the energies liberated by the postparental reversal into new executive capacities of the personality without losing their identities as men or women, in an expanded sense of self.

But the relationship between grown children and their parents does not end here. The potential for further transformation remains as the young-adult child and the middle-aged parent work together to structure a new relationship that is in some ways more complex than the one that existed when they were younger.

ACHIEVING EQUALITY As parent and child move toward the latter stages of middle and young adulthood, respectively, all vestiges of the child disappear. The youthful appearance of adolescent and the early 20s is gone, replaced by the mature young adult who shows signs of aging. The dependent child has been replaced by the independent adult who lives away from home and is self-supporting and significantly involved with others, sexually and emotionally. These adult relationships and capabilities push the healthy parent-child relationship toward equality, but they are not in and of themselves evidence that equality has been achieved.

Ron, a 25-year-old man, complained bitterly in his therapy that his 57-year-old mother continued to treat him like a child. On a recent visit home mother insisted that Ron change his slacks and sport coat, considering them inappropriate for the occasion planned. When an argument ensued, Ron's father intervened (as he always did) and encouraged his son to change his clothes, which he did. Ron readily recognized his parent's need to infantalize him but was unaware of his own struggle between the wish to appease mother and so remain emotionally involved and dependent on her and the desire to be independent. Over the course of 2 years of psychotherapy, as he came to recognize his own contribution to the continuation of an unequal relationship, he began to make more-independent decisions. At first the changes in Ron's behavior were treated as provocations and intensified mother's attempts to control him. Gradually she worked through her feelings of rage, impotence, and loss of control and begrudgingly moved toward a more equal relationship.

In the more normative situation healthy parents not only accept their child's desire for independence and autonomy but also actively encourage moves in that direction whenever possible. The rationale for such behavior is not entirely altruistic, since it is based in part on the recognition of how involvement with this very special adult and his or her loved ones enhances the parent's mid- and late-life development.

INTEGRATING NEW MEMBERS INTO THE FAMILY Mother-in-law jokes are more than the sarcastic expression of some comic's humor. They also illustrate a universal tension between the newly married and their in-laws. The task for the in-laws is clear enough, if difficult to achieve: give up your claim to the position of primary love object in your child's life, then accept the new partner, initially experienced to some degree as an interloper, and work to cultivate his or her friendship. Once again the motivation for such behavior is not selfless. It is based on a desire to continue to occupy a central, although less important, position in the life of their child and to form a relationship with someone who may add a new dimension to life but who will also exercise some control over future involvement with one's child and grandchildren.

Because spouse and parent of the same sex love the same person a triangle is created, similar to the infantile oedipal one. Consequently, all three individuals are forced to reengage and rework their infantile experience in this new adult context. Like the infantile version, this current rendition is only resolved gradually and partially; the outcome is determined by the emotional capabilities of the participants. The solution for midlife parents may lie in the birth of grandchildren, those marvelous creatures who provide such a significant boost to mid- and late-life development by serving as partial replacements for lost children, connecting midlife development to childhood themes, and providing the only mastery of death that is available, the opportunity to continue living through genetic continuity.

For many midlife parents, particularly mothers, the attraction to grandchildren is not all-consuming, nor need it replace in importance or preference other, extrafamilial, interests. The failure of young adults to recognize that their parents have other interests than them and their children can be a source of conflict between the generations.

Accepting the Reversal of Roles With Elderly Parents At some point, as elderly parents become less able to care for themselves, a role reversal occurs. The child becomes the parent of the parent, increasingly fulfilling the functions of physical and mental caregiver.

A middle-aged patient described the change in her relationship with her 83-year-old mother. “It's sad. She used to be so vital. I remember her being so strong. When I was a child she worked from day to night. Now I have to help her when she walks. Yesterday I had to cut her meat. I felt like I was taking care of a 2-year-old. But every once in awhile she gets that spark back in her eyes, and I remember what she was like for so many years. My daughter was there at the time. Neither one of us said anything, but I knew we were seeing ourselves in the same situation, 20 or 30 years in the future.” For this woman the relationship with her mother was a central aspect of her psychotherapy, stimulating both a reengagement of issues from the childhood and adolescent past and the consideration of phase-specific midlife themes.

The acute reversal of roles that occurs when elderly parents cannot care for themselves forces the middle-aged child to anticipate the parent's demise, thus stimulating the ongoing process of psychological separation from them. Caring for aging parents is one of the most difficult and most frequently avoided developmental tasks of middle adulthood. In addition to presenting difficult financial and management problems, it forces a reworking of childhood themes; focuses attention on time limitation and personal death; and anticipates the inevitable role reversal that will occur with one's own children.

Avoidance of this developmental task has considerable psychological consequences, including the occurrence of late-onset depression. Clinicians who are aware of the enormous psychological power of this developmental process will pay close attention to their patients' experience in this area and will address the resistances to such material when it is absent.

When an elderly parent dies, no matter how expected or anticipated, a mourning process ensues. Long after the acute phase of this process is over intrapsychic relationships with dead parents remain dynamic, emotionally charged, and an important subject for psychotherapeutic exploration.

Developing Midlife Friendships Unlike friendships in latency and adolescence and, to some extent, in young adulthood, midlife friendships do not usually have the sense of urgency or the need for frequent or nearly constant physical presence of the friend. Midlife individuals have neither the need to build new psychic structure (as do latency-age children and adolescents) nor the pressing need to find new objects (as do young adults). They may have many sources of gratification available through relationships with spouse, children, and colleagues.

As their firstborn sons progressed through high school, two women in their mid-40s became fast friends. In addition to raising money for the school activities in which their sons were involved, thus maintaining a close involvement with the boys, they spent many hours talking about the boys' activities, girlfriends, and plans for college. Their husbands, who liked each other, became acquaintances, not friends. They directed their own feelings about their sons into other relationships. After the boys left for college the intensity of the friendship diminished, tending to peak again during vacation periods.

Because of their unique position in the life cycle, these individuals are easily able to initiate and sustain friendships with individuals of different ages as well as chronological peers. It need not be assumed that the unconscious motivation underlying these relationships is different from any other. However, the capacity for sublimation, particularly of aggressive impulses, may be considerable. Friendships with adolescents may be based in part on an identification with their youth and an envy of their abundant future in an attempt to bolster a sagging sexuality and painful feelings about aging. Friendship with young adults may serve the same psychic aims as well as provide an outlet for sexual and aggressive impulses related to parenthood and work. Friendships with older individuals may have multiple determinants, including longing for preoedipal parenting, oedipal sexual and aggressive gratification, or the passive gratifications of a mentee relating to an older mentor.

However, as at all other points in the life cycle, Freud's recognition that friends can rapidly become lovers or enemies remains completely valid. In the face of a disrupted marriage or intimacy or the pressure of other midlife developmental themes, friendships may quickly become vehicles for the direct expression of impulses.

In the face of his wife's aging, a man in his early 50s turned to a younger woman. In a spirit of locker room comaraderie, he spoke openly to his closest friends of the sexual details of the affair, bragging about sexual prowess and adventure. As it appeared to his therapist (and partly to the patient as well), the woman seemed more interested in the gifts and money that he lavished on her than his sexual prowess. He did not tell his friends of his occasional impotence with the girlfriend and with his wife.

At first, the friends listened to his war stories and vicariously enjoyed the affair. However, their feelings turned to concern when he expressed a desire to leave his wife and business and move away with his girlfriend. Concurrent therapeutic efforts to understand and temper the desire for abrupt action were stymied by the excitement of the affair and an urgent wish for a new life. Dynamically, the behavior was understood as a flight from fears of aging, loss of sexual prowess, impotence, and multiple difficulties in the marriage. These midlife conflicts also had many, readily apparent, infantile determinants that were being presented concurrently in the transference.

The therapist watched as the patient's best friend confronted the patient, telling him his behavior was stupid and inappropriate and that his girlfriend did not really love him and was taking him for a ride. He was told that he was acting like “an old fool” and had better stop before he threw away his life. After initial embarassment and rage, the patient analyzed his response and eventually came to admire his friend's courage and appreciate the depth of his concern. The confrontation produced a postponement of the move and greater willingness to use the therapeutic process. Eventually, after a miniscandal, the patient broke off the affair and began to approach the complicated and painful issues in his marriage and in himself.

PRESSURES ON THERAPIST'S FRIENDSHIPS The relationship between friends and between therapist and patient are alike in that both are primarily aim inhibited. Neither friend nor therapist is expected to use the relationship as an avenue for sexual or aggressive actions. Sometimes, the aim-inhibited nature of the relationship breaks down, and therapist and patient become lovers or enemies. Much more frequently the feelings generated in therapists by their work are displaced onto nontherapeutic relationships such as those with spouse and children or friends.

Although the family is a constant repository of such displacement, friendships may be unconsciously singled out even more because they do not have the central importance of relationships within the family and therefore can be disrupted with less realistic consequences. In many instances, disruption of a friendship causes less intrapsychic pain because it can be more easily rationalized and more easily replaced than a relationship with either a family member or a patient.

In addition, like all other human beings in the second half of life, therapists are subject to the normative conflicts engendered by the incessant pressures of the adult developmental process. If these conflicts become particularly severe or if therapists become subject to an unusual number of traumatic acts of fate such as severe personal illness or the premature loss of loved ones through death, both their work and their friendships may suffer even more.

Becoming a Generative Mentor and Planning for Retirement Work is a psychic organizer of major importance: organizing the use of time, providing meaning and purpose, enhancing relationships, and ensuring financial well-being. Midlife is the time of achievement and exercise of power, the result of years of effort during young and middle adulthood when skills were mastered and seniority acquired.

The narcissistic gratifications related to work may be considerable, compensating for the painful realities of everyday life. Sometimes the imbalance is such that work becomes the main source of emotional gratification, resulting in a relative failure to engage more-difficult developmental issues of midlife and neglect of relationships with spouse and children. As a result the eventual loss of work as a central organizing function and source of gratification may be ignored. The recognition of the juxtaposition of maximum achievement and power in the workplace and the acceptance of eventual displacement by the next generation is at the core of the midlife worker's intrapsychic experience.

Recognition of the conflict may be facilitated by plateauing (lateral movement in the workplace instead of promotion), indicating that the highest level of achievement possible has been attained, or by relationships with subordinates.

As one company president put it, “My toughest job is not running the company and making tough decisions, it's finding and training somebody to succeed me. I know whomever I choose will be grateful and appreciative, but they'll also be anxious to get me the hell out of there.”

The conflict of the midlife mentor is to pass on knowledge and power to the next generation while recognizing that this behavior will lead to eventual displacement. The healthy individual does not act on the anger and envy generated by such understanding to any significant degree and instead sublimates these feelings into generativity. Others, however, may display cruel, sadistic verbal attacks or actions intended to impede the development and progression of the mentee.

Midlife attitudes toward money are closely related to success or failure in the workplace. For almost all individuals except the very wealthy the issue is the same: how to earn enough money to meet the simultaneous demands to cover daily expenses, provide children with the opportunity for higher education or the transition to independent status, care for aging parents, and enjoy life in the present while providing for a secure old age.

In the treatment process money may be a therapeutic preoccupation or be defensively ignored. In either circumstance, the developmentally oriented therapist will help the middle-aged patient deal with the powerful thoughts and feelings about finances and develop realistic plans regarding money management.

Giving Play New Meanings and Purposes Play is a lifelong human activity, an amalgam of physical abilities and limitations and mental capabilities and preoccupations. Thus the unique features of midlife play, not suprisingly, reflect the phase-specific preoccupation with the acceptance of time limitation and personal death. The structure of play changes little beyond adolescence. The games that most adults and children prefer are learned before adulthood begins.

By midlife, aging forces the abandonment of most contact sports and the modification of other physically demanding ones. Individuals who refuse to modify their physical expectations of themselves often present themselves in therapy with pathological responses to physical injuries or an exaggerated preoccupation with physical activity.

The psychological meaning of play also changes. Instead of being a joyous expression of mental and physical capability as it was in childhood and young adulthood, physical play is increasingly associated with the maintenance of physical integrity and the enhancement of the aging body.

All forms of play are increasingly used (consciously and unconsciously) to master the developmental tasks of accepting time limitation and personal death. Golf and gin rummy are examples. Golf is a game full of brief intervals with numerous beginnings and endings; in other words, opportunities to conquer time and imperfection by beginning over and over. There is always another shot, an approaching hole, tomorrow's match; unlike one's life, which has one beginning and, more to the midlife point, an approaching end. Gin rummy and similar mental games eliminate the necessity to use the increasingly imperfect body at all and offer the same concept of inexhaustable rhythmic beginnings.

> The musing of an avid golfer patient who was analyzing his game with great seriousness eventually led to the following insight. “I got so upset on the course yesterday, I considered quitting for good. Then I thought to myself this is ridiculous. This isn't life or death, it's just a game. A month from now I won't even remember what I shot today. I don't want to stop; I love the game. All I have to do is accept a higher handicap as I get older. On second thought, no I don't, when I'm eighty, I want to shoot my age.”

Becoming a Grandparent In the mid twilight of their lives and because of their position in the life cycle, grandparents tend to idealize their grandchildren. The grandparental tendency to engage their grandchildren with intense love and devotion is similar to the toddler's undeterrable need for mother during the rapprochement crisis. The similarity exists because both toddler and grandparent have an intense developmental need for fusion with the objects of their attention as they face an immense developmental challenge. The toddler needs to be refueled before venturing out into the ever-expanding world beckoning beyond the symbiotic membrane, and the grandparent faces the collapse of the world and the great unknown void beyond the end of mortal existence. Thus, the intense investment in, and idealization of, grandchildren serves several defensive and developmental purposes: (1) a narcissistic buffer against the stings of old age and the inevitability of death, (2) a chance for magical repair of one's own life through genetic immortality, and (3) a denial of unalterable imperfections in the self through selective identification with particular qualities in the grandchild. The healthy grandparent sees the falseness in this idealization but deeply enjoys the intensity of the rapprochement that accompanies it.

MIDLIFE TRANSITION AND CRISIS

Although the terms “midlife transition” and “midlife crisis” have become part of the pop culture, they are definable syndromes that have considerable clinical relevance (Table 50-5). The midlife transition is a quasi-universal, normative developmental phenomenon. The midlife crisis, on the other hand, is a pathological state experienced by only a few.

Midlife transition—A searing intrapsychic appraisal of all aspects of life
Midlife crisis—A major pressured upheaval in which long-standing relationships and achievements are abandoned impulsively, without insight

Table 50-5 Definitions

The midlife transition has been defined as an intense reappraisal of all aspects of life precipitated by the growing recognition that life is finite and approaching an end. It is characterized by mental turmoil, not action. For 80 percent of those studied, the examination of relationships, achievements, failures, and future plans was preoccupying, painful, and searing. For the others, this midlife critique was less conscious and much less painful. The common denominator was the need to reappraise all aspects of life and make decisions about them—while there was still time to change. For most people the reappraisal results in decisions to keep most life structures, such as marriages and careers, which have been painstakingly built over time. When major changes are made they are thoughtful and considered, even when they include such major shifts as divorce or a job change. The developmentally aware clinician recognizes that every patient in this age group is engaged in a midlife transition (whether the patient is talking about it or not) and facilitates the process by making it conscious and verbal.

A true midlife crisis is a major, revolutionary turning point in life, involving changes in commitments to career or spouse or both and accompanied by significant, ongoing emotional turmoil for both the individual and others. It is an upheaval of major proportions. A period of internal agitation is followed by a flurry of impulsive actions; for example, leaving spouse and children, becoming involved with a new sexual partner, and quitting a job, all within days or weeks of each other. Although there may have been unrecognized warning signs, those who are left behind are often shocked by the suddenness and abruptness of the change.

Efforts by family members or therapists to get the individual to stop and reconsider usually fall on deaf ears. The overwhelming need is to avoid anyone who counsels restraint and to ignore therapists who recommend examining motivations and feelings before making such major decisions. Usually, in the midst of the crisis, the therapist is left with the painful job of helping those who have been left deal with their shock and grief.

Dr. C., a prominent, 45-year-old surgeon, had been married for 22 years and was the father of three adolescent children. One Saturday he left home for the golf course and did not return. Although he had been somewhat bored by his wife for some time, he did not have any conscious plans to leave her. As he reconstructed his thoughts, he was standing on the tenth tee, after making a par on the ninth, when the thought occurred to him “I'm never going home again.” After showering and lingering over a drink with his friends, he drove for several hours and checked into a motel. The next day was spent in thought “about my life, its meaning and purpose. I suddenly knew it wasn't right for me and I had to change it.” On Monday morning he returned home, left his wife a note in the mailbox telling her, without any explanation, that he was leaving, and drove to his office. There he saw his patients, went to the bank and cashed in a $100,000 certificate of deposit from his pension plan, and got on a plane for a distant city. Upon arriving he left a message for one of his partners asking him to take over his practice. For the next 2 months he did nothing but exercise and think. Eventually he wrote his wife a letter informing her of his whereabouts and of his decision to remain away.

When he came for treatment 16 months later he was working in an emergency room and had begun a relationship with a 43-year-old divorcee with two teenage sons, “not so very different from the family I left,” he said.

Therapeutic efforts to reconstruct the patient's thinking during the acute phase of the crisis were limited by his inability to remember. He just knew he had to change, now.

Therapeutic exploration of the probable dynamics behind the crisis—the recent death of his father, occasional impotence and dissatisfaction with his wife—were illuminating but did not change Dr. C.'s determination to avoid his former life. He refused to meet with his wife and eventually agreed through a lawyer to a divorce settlement that gave her almost all of their assets. He did agree to see his children when they sought him out but did not initiate contacts with them. All of his energies were directed toward “doing what I want to do, meeting new people, and finding myself.”

The therapy seemed to meet the patient's need to understand himself and build a new life. He eventually remarried and supported his new family by continuing to work in emergency rooms, making far less money than he had in his surgery practice. He even took up golf again.

ADULT DEVELOPMENTAL DIAGNOSTIC EVALUATION

The purpose of doing an adult developmental diagnostic evaluation is to collect relevant data about the patient that will allow the clinician to formulate a clear understanding of the normal and deviant developmental influences from childhood and adulthood that underlie the patient's healthy growth and symptomatology and to formulate a treatment plan (Table 50-6).

Traces the patient's life experience from birth to the adult present
Provides the information necessary to understand the meaning of presenting symptoms
Describes the influence of important figures such as parents, siblings, and grandparents in adulthood

Table 50-6 The Adult Developmental History

The components of the evaluation are the same as those in any standard psychiatric evaluation; however, added emphasis is placed on obtaining a developmental history that extends beyond childhood and adolescence to the chronological present. The child and adult developmental histories provide the information necessary to understand the meaning of the presenting symptoms and appreciate their effect. Without detailed knowledge of the patient's life experiences, the diagnostician is reduced to making educated guesses in an impersonal context. Relying on knowledge of child and adult development, the clinician traces the individual's life experience from conception to the present, relating the findings to the information obtained in the history of the present illness.

The influence of important figures such as parents, siblings, and grandparents does not end with adolescence. Consequently, the course of these interactions may be traced throughout life, focusing on such critical issues as the interactions between newly married children and their middle-aged parents. Even after death, parents remain important intrapsychic objects and may be the subject of meaningful therapeutic dialogue when the clinician recognizes their importance to the older patient and inquires about them.

In gathering information about adult developmental processes the historian inquires systematically about all major areas of adult development. Thinking in terms of the adult developmental tasks described earlier in the chapter is one way to organize the process. For example, in covering the young-adult years, the clinician would inquire about how patients feel about the aging process in their body. Is the body being cared for or neglected? In another area questions would be asked to determine whether gradually increasing sexual experience had led to a sense of comfort with the body as a sexual instrument and to the emergence of the capacity for intimacy. Other developmental tasks of young adulthood are addressed in similar ways.

If patients are in middle adulthood, ages 40 to 60, examples of the questions to be asked are as follows: Has an adult-to-adult relationship been forged with grown children and their spouses? Have grandchildren been recognized and enjoyed? Has generativity become a central aspect of relationships with young individuals, particularly in the workplace? Have intimacy and an active sexual life been maintained in the face of diminished sexual drive, menopause, and the environmental

pressures of midlife?

CASE OF JOHN L.

The following detailed case report and discussion illustrate the use of adult developmental concepts in the diagnosis and treatment of a young-adult man, on the cusp of middle age.

John L. entered therapy at age 38, a trim, well-dressed man with streaks of gray in his hair. He was self-referred because despite a happy marriage and a successful law practice, he was increasingly anxious to the point of panic and had been experiencing fleeting thoughts of running away. John L. had little idea what was upsetting him but knew it was “time to talk to somebody.”

John L. was married for the second time 5 years earlier to a woman who had two sons, currently aged 12 and 14. He had a 15-year-old son of his own from his first marriage who lived with his mother in a nearby city. John L.'s own mother was dead, but his father was alive and well.

Initially John L. attributed his symptoms primarily to work. His solo practice, in a city overflowing with lawyers, was very successful but demanded 80+ hours a week of his time. Good help was difficult to find and keep, and his entire existence seemed to revolve around his law practice. His wife thought he worked entirely too hard but had demanded little of his time or energy until recently, when her 14-year-old son began to manifest behavioral problems at home and in school. John L. did what he could to help but felt increasingly guilty as he spent more and more time with his stepson and even less with his natural son, whom he saw only sporadically at best.

The mention of his natural son was accompanied by a striking increase in free-floating anxiety and an unrecognized revelation of important conflictual material. John L.'s girlfriend had become pregnant with his son when they were college students. Both of them had been virgins prior to dating each other and had only engaged in intercourse three or four times when the pregnancy occurred. His parents were dismayed by the pregnancy since they did not like his girlfriend and wanted John L. to complete his education before marrying.

When John L.'s father announced that he would no longer pay for his son's college education, John L. said one word (“Oh?”) and left. The two men never discussed the matter again. John L. married his girlfriend and was cut off financially. He in turn withdrew emotionally. In the past 20 years, contact with his parents had consisted of four or five frosty phone conversations initiated by his mother and a false display of family togetherness at her funeral 5 years ago.

The marriage was difficult from the start, beginning as it did with a pregnancy and an absence of family blessing or financial resources. John L. managed to stay in college—his wife dropped out to care for the baby—but within a short time he knew that the marriage was a mistake. He loved his young son desperately but was increasingly distant from his wife who seemed “superficial, boring, and fat.” After graduation and a brief trial of marriage counseling, he took off, feeling “exhilarated and free. I finally had all of it off my back.”

After working for a while, John L. put himself through law school. His former wife followed him, hoping for a reconciliation, but to no avail. She eventually married a man who made little money but was a decent stepfather. John L. was painfully aware of the difference between the very comfortable lifestyle that he provided for his two stepchildren and the rather meager circumstances under which his natural son lived.

When John L. met his second wife, he felt exhilarated and happy for the first time in many years. She was outgoing, uninhibited sexually, and “made me the center of her life.” They were married within 6 months. His new stepsons, quiet and unassuming latency-aged boys, “seemed like nice kids, I didn't give them much thought.”

John L. did not remember much about his early years, but gradually a picture emerged of a quiet, somewhat shy child who was physically healthy and who did not manifest any obvious psychological problems or developmental delays or deviations. His mother was at home on a full-time basis and seemed to enjoy raising her son.

John L.'s memories of latency were clear and not particularly happy. Although an excellent student, he was short and frequently teased. He had a few friends but felt “on the outside looking in.” His father pushed him into sports where he did not excel and seemed disappointed in him.

Puberty occurred late, in tenth grade. “I remember erections, wet dreams, and thoughts about girls.” When I commented on the absence of masturbation from his list, John L. blushed and said, “that was so good I knew it must be terrible in some way.”

College was a time of greater acceptance socially, a sense of “liberation” from his father, and the beginning of dating and a sexual life. Unfortunately, this heady sense of exhilaration and freedom was short-lived, quickly replaced by premature work, marriage, and parenthood.

The clinician made a diagnosis of anxiety neurosis and presented a recommendation for therapy. After a discussion about schedule and finances, John L. agreed to begin twice-weekly psychotherapy.

John L.'s sexual inhibitions emerged as a central theme in the treatment fairly early on. When his masturbation was analyzed, strongly repressed phallic and exhibitionistic fantasies emerged. For example, he pictured himself as an Arab sheik lounging on silk pillows in a richly decorated palace, choosing his sexual companion for the night from his harem girls, who paraded suggestively before him. As he anticipated the sexual adventure ahead, his erection began to grow, and grow, and grow, breaking through the ceiling and continuing skyward, not unlike Jack's beanstalk. The gradual disappearance of John L.'s sexual inhibitions led to a return of his masturbation and an enhanced sex life with his wife.

The analysis of the transference, specifically the interpretation of John L.'s great concern about the therapist's reaction to his phallic aggressiveness, led to many associations about his father. Gradually he tested the therapist's ability to accept his rage at the father/therapist, eventually spewing forth blast after blast at his father for his coldness and insensitivity, particularly in regard to the pregnancy. Signs of softening and wishes for reconciliation followed, stimulated by the therapeutic work, to be sure, but also propelled by the patient's position on the threshold of midlife. As he approached the age of 40 and his father, 70, he became increasingly aware that if a reconciliation were to take place, it better occur soon, and it did. John L. called his father, who was mildly receptive, and eventually went, along with his son, to visit him. John L. was surprised at the pleasure and inner comfort that he experienced during the visit but was totally unprepared for—and consciously jealous of—the warmth of the rapport that developed almost instantly between grandfather and grandson, strangers just getting to know each other. John L. and his father continued to develop their relationship, which took the form of a reversal of generations as John increasingly cared for his aging father—not without a sense of superiority for being there for his father in his time of need.

In the months following the rapprochement between son and father, John L.'s associations increasingly turned to his relationship with his own son. Following the acceptance of the painful interpretation that he had abandoned his son just as his father had abandoned him, John L. increased their contact and eventually invited his son to come and live with him, “during the few years that are left before he becomes a man.” The transition took place after several months of patient negotiation with both wives.

Watching John L.'s guilt diminish and self-esteem grow as he incorporated the role of full-time father was a rewarding experience for patient and therapist alike. Although personally satisfying, detailed contact with his son also led to the realization that the teenager was struggling, primarily with social relationships. In a bittersweet burst of newly found similarity, John L. recognized that “he looks like me, is beginning to talk like me, and seems to have the same problems I did. At least he'll get help when he's 15, not 40.”

His wife's kindness to his son suprised him and precipitated more guilt since John L. had accepted her children but not the role of their stepfather. Gradually he came to accept the realization that he had three teen-aged sons to raise and support.

The development of his relationship with the three boys and his father as well as the more intimate, less inhibited relationship with his wife gave John L. a sense of integrity and competence that he had never experienced before. “For the first time in life I'm doing what I ought to be doing—I'm being a good husband, father, and son. I wish my Mom were alive to see this. I think she'd be very proud of me.”

he came to accept the realization that he had three teen-aged sons to raise and support.

The development of his relationship with the three boys and his father as well as the more intimate, less inhibited relationship with his wife gave John L. a sense of integrity and competence that he had never experienced before. “For the first time in life I'm doing what I ought to be doing—I'm being a good husband, father, and son. I wish my Mom were alive to see this. I think she'd be very proud of me.”

But the joy and pleasure in these relationships, the shift from a life almost devoid of closeness to one overflowing with intensity, led to the realization that John L. was responsible for his loved ones. Increasingly, he began to recognize and accept that as an involved midlife husband, father, and son, he had assumed the “burden” of caring for his father as he aged and eventually died, of raising his sons, including the probability of putting all three of them through college, and of remaining emotionally and sexually intimate with his wife in a sustained relationship. “It's tough,” he said, “but it's great. Life does begin at 40!”

Consideration of the Clinical Material From a Developmental Standpoint

The Third Individuation The transition from the second to the third individuation is a young-adult experience, stimulated by the growing capacity for intrapsychic separation from the parents and engagement of the phase-specific developmental tasks of young adulthood. John L. had been individuating rather easily—as evidenced by the growing sense of emotional self-sufficiency at college, academic success, and the beginning of an adult sexual pattern—until the unexpected pregnancy and his parents' reaction to it arrested the process. Although John L. appeared to have mastered the third individuation (he married, became a father, had a successful career, and moved to another state), in reality he repressed his primarily neurotic conflicts around sexuality and aggression and ran away from his wife, son, and parents. This state of affairs continued until the death of his mother, the approaching old age of his father, and the adolescence of his son upset the tenuous emotional equilibrium that had existed through much of his young adulthood and resulted in the outbreak of intense anxiety. The unconscious command was do something about these relationships before time runs out.

Developing the Capacity for Intimacy John L. married his first wife out of need and spite. As their relationship was compromised by pregnancy, parenthood, and near poverty, he emotionally withdrew from her. It took more than 10 years before he allowed himself to become emotionally involved with another woman. For a second time, he began to fuse sexual and loving feelings, this time in an environment far removed from parental influence and with a woman much more advanced than he along the developmental line of the capacity for intimacy. In fact, some of the anxiety that precipitated the search for treatment was related to a growing conscious awareness that he could not match his wife's level of sexual freedom and comfort or her desire for emotional closeness. The removal of many of his sexual inhibitions through treatment made it possible for him to sustain an intimate relationship with a woman for the first time in his life. To quote him, “life does begin at forty.”

Becoming a Father The experience of impregnating a woman adds a new dimension to a young man's sexual identity by confirming that his penis and testicles can perform the primary function for which they are intended. For most males in their teens and early 20s, the goal is avoiding this state. When an active, purposeful attempt is made to become a father, a powerful psychological process is begun. One newly married man described the conscious aspect of the process as follows: “I've always enjoyed sex, but now that my wife and I are trying to have a baby it's totally different. I hope we can do it. It will be pretty awful if we can't.”

John L. became a biological father in his early 20s but avoided a psychological commitment to his son for over 10 years. His failure to become a committed psychological parent was based on his conflicted identification with his father. He attempted to master the devastating psychological abandonment by his father when his girlfriend became pregnant by doing to his son what was done to him. A strong positive aspect in this relationship with his father facilitated his masculine development during childhood and became internalized in his superego and ego ideal. Thus, he could not rid himself of the internalized father or the internalized son. Eventually, without conscious awareness, he had to seek help to rid himself of his guilt by analyzing his conflicts about the roles of father and son relationships and then reestablish his ties with the two most important men in his life while there was still time to affect their adolescent and late-life development.

Developing a Relationship of Mutuality and Equality With Parents While Facilitating Their Mid- and Late-Life Development As John L. neared 40, he was deeply engaged in this process with his father. His reward was a deep inner sense of integrity and authority and, for the first time in many years, the absence of guilt.

When their normal development is not significantly impeded, adolescent males enter young adulthood (that marvelous time of life when masculinity reaches mature fruition), and in the process they become independent adults, loving husbands, and last but not least, fathers to their sons and eventually fathers to their fathers.

WISDOM, MATURITY, AND FULFILLMENT

Success and happiness in adulthood are made possible by achieving a modicum of maturity—a mental state, not an age. However, the capacity for maturity is a direct outgrowth of the engagement and mastery of the developmental tasks of young and middle adulthood. From a developmental perspective, *maturity* may be defined as a mental state found in healthy adults that is characterized by a detailed knowledge of the parameters of human existence, a sophisticated level of self-awareness based on an honest appraisal of one's own experience within those basic parameters, and the ability to use this intellectual and emotional knowledge and insight caringly in relation to one's self and others.

The achievement of maturity in midlife leads to the emergence of the capacity for wisdom. Those who possess wisdom have learned from the past and are fully engaged in life in the present. Just as important, they anticipate the future and make the necessary decisions to enhance prospects for health and happiness. In other words, a philosophy of life has been developed that includes an understanding and acceptance of the person's place in the order of human existence. That worldview, which varies widely from individual to individual, produces fulfillment when the following aspects of the human condition are accepted and integrated.

1. The body must be cared for—in health through regular checkups, exercise, and a proper diet, and in sickness through prompt treatment and proper care. Caring for the body is not an end in itself, but it is critically important because sentience, the essence of human experience, springs from a healthy brain and body.
2. Human beings are individuals alone with themselves, separated and individuated from all others.
3. Paradoxically, human beings cannot survive or develop on their own. Helpless at birth and relatively dependent throughout childhood, even the most self-sufficient individuals require the sustaining presence of others. We exist in a framework of interdependence, a basic characteristic of all human relationships, be it the parental view of the child as a confirmation of his or her sexuality, the need of the child for the parents' loving care and protection, or the reversal of these roles between adult child and aging progenitor. The mature adult (unlike the child who takes, uses, controls, and dominates) mutes the grandiose expectations of childhood and propels the self toward interactions characterized by caring and mutuality, thus striking a balance between personal needs and those of others.
4. Change is a constant in life. A basic aspect of this change is the shifting nature of significant relationships. Adult involvement with loved ones such as children, parents, colleagues, and friends is in constant realignment. Healthy marriages deepen in significance while others break up on the shoals of midlife development. Parents die. Children grow, leave, and return with new family members. As opposed to old age and in some respects childhood as well, the task for the mature person is to sort out, categorize, and set priorities among relationships, in the process balancing emotional needs and realistic demands and responsibilities. The shifting nature of relationships stimulates the achievement of greater maturity by forcing a constant redefinition of who one is in relationship to others. Mature individuals mourn lost relationships but can remain focused on current and future ones.
5. All human beings—regardless of wealth, position, power, achievement, appearance, or cultural background—are on the same developmental course. All are born and will die. All have a body with the same functions. All have the same emotional needs for closeness and love and the same vulnerability to loss and deprivation.
6. Few individuals have an exaggerated importance. The wish for such grandiose prominence is universal, the result of the untempered narcissism of infancy and childhood. In reality most individuals are important to themselves and a relatively limited number of others who know and love them. The mature individual accepts this fact without despair and uses the knowledge to set realistic goals and priorities that will increase the chances for personal happiness and fulfillment.
7. Personal time is limited. Everyone will die. Young children do not have the cognitive capacity to understand the notion of personal death. Spurred on by the thrust of physical growth and a seemingly endless future, adolescents and young adults think and act as though they are immortal. The true acceptance of time limitation and personal death occurs in midlife. Then the mature individual, religious or not, stimulated by an awareness of the aging process in the body, the maturation of children, the death of parents and friends, and the arrival of grandchildren, accepts the inevitability of a personal end. As with the realization of the limited importance of each individual, this painful recognition, which precipitates midlife crises in some, stimulates the mature individual to seek fulfillment in each moment, to define what is truly important, and to plan the future to actualize those priorities.
8. Money and possessions have limited intrinsic value. They are a means to an end, tools for enriching life and improving the human condition of loved ones and the broader community. Ownership of tangible objects is temporary; sooner of later they will be lost, left behind, or given to others.
9. Work occupies a central position in adult life. Considered a drudgery by some, the wise person recognizes its extraordinary value. In addition to the obvious function of earning a living, work is organizing, an activity that provides purpose and direction, a meaningful way to manage time, and an environment in which to form sustaining relationships. Satisfied midlife workers, at the peak of power and position in the workplace, facilitate the development of the skills and capabilities of younger colleagues while fully realizing that these individuals will, sooner or later, replace them and assume control of the levers of power. Wishes to hold down and attack younger workers are sublimated into generativity, Erikson's term for enhancing the development of the next generation.
10. Midlife is the phase of life in which the experience of being human can be realized and enjoyed most fully. It is when the combination of physical health and

vigor, power and prestige in the workplace, accumulation of wealth and possessions, and meaningful relationships from within the midst of three or four generations provide the potential for a life overflowing with richness and complexity. The mature life is one in which the triumvirate of human experience—love, work, and play—are successfully balanced to bring true fulfillment.

11. Unfortunately, the joys of midlife do not last forever. Old age lies ahead. Although the hope and statistical expectation is for many years of mental competence and independence, physical and mental decline, increased dependence, and eventually death must be anticipated. Late adulthood has its own great pleasure when there is a focus on continued mental and physical activity, a dominant preoccupation with the present and the future, and involvement with and facilitation of the young. Then death can be met with feelings of satisfaction and acceptance, the natural endpoint of human existence that follows a life lived and well loved.

CHAPTER 51. GERIATRIC PSYCHIATRY

51.1 OVERVIEW

51.1A GERIATRIC PSYCHIATRY: INTRODUCTION

LISSY F. JARVIK, M.D., PH.D. AND GARY W. SMALL, M.D.

The number of individuals over age 65 is rapidly expanding. In 1900, for example, 4 percent of the U.S. population was older than 65 years. By 1990 it was 12.5 percent, and by 2030 it is projected to be 20 percent. That increase far exceeds the general population growth—10-fold compared to just over 3-fold between 1900 and 1990—and is projected to continue (e.g., 2½ times vs. just over 1½ times between 1990 and 2050) (Table 51.1a-1).

Year	Median Age	Mean Age	Population, in Millions and as a Percentage of Total Population: All Ages (N)	65 and over (N)	65 and over (%)	85 and over (N)	85 and over (%)
1900			76.0	3.1	4.1%	0.1	0.1%
1950			150.1	12.3	8.2%	0.6	0.4%
1990			248.7	31.1	12.5%	3.0	1.2%
2000	35.7	36.5	276.2	35.3	12.8%	4.3	1.6%
2010	37.2	37.8	300.4	40.1	13.3%	6.0	2.0%
2030	38.5	39.9	350.0	70.2	20.1%	8.8	2.5%
2050	38.1	40.3	392.0	80.1	20.4%	18.9	4.8%

Population: U.S. Bureau of the Census: *Current Population Reports, Special Studies, P23-190, 65+ in the United States.* U.S. Government Printing Office, Washington, DC, 1996.
Mean/Median Age, 2000–2050: Day JC: Population projections of the United States by age, sex, race and hispanic origin: 1995 to 2050. In *U.S. Bureau of the Census, Current Population Reports, P25-1130.* U.S. Government Printing Office, Washington, DC, 1996.

Table 51.1a-1 Aging Population of the United States: 1900–2050

Survival curves illustrate the trend: in 1900 to 1902, for example, about 50 percent survived to age 55; by 1991, about 50 percent survived to age 80 (Fig. 51.1a-1). It is notable that life expectancy at age 85 has consistently been longer for blacks than for whites, both men and women (Table 51.1a-2).

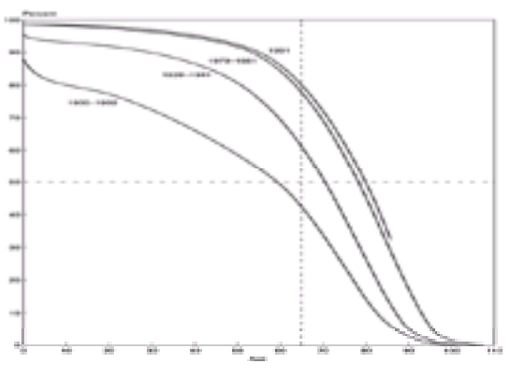

FIGURE 51.1a-1 Percentage of persons surviving to each exact age according to life tables: 1900–1902 to 1991. (U.S. Bureau of the Census. Current Population Reports, Special Studies, P23–190, 65+ in the United States. U.S. Government Printing Office, Washington, DC, 1996. Source: Data for 1901–1902 from U.S. Bureau of the Census, United States Life Tables 1890, 1901, 1910, and 1901–1910, 1921, table 1; 1979–1981 data are from National Center for Health Statistics: United States Life Tables, U.S. Decennial Life Tables for 1979–1981, vol 1, no 1, DHHS Pub. No. (PHS) 85-1150-1, Public Health Service, 1985, table 1, U.S. Government Printing Office, Washington, DC; data for 1991 are from Public Health Service, National Center for Health Statistics, unpublished data from Interpolated Abridged Life Table, 1991.)

Year	Male: White	Male: Black	Female: White	Female: Black
1900–1902	3.8	4.0	4.1	5.1
1909–1911	3.9	4.5	4.1	5.1

Table 51.1a-2 Life Expectancy at 85 Years by Sex and Race: 1900–1902 to 1991 (Average Number of Additional Years of Life Remaining)

The most rapidly growing segment of the population is the age group 85 years and older, the group with the highest morbidity and the highest rate of psychiatric and medical comorbidities. This age group grew 30-fold, from 100,000 in 1900 to 3 million in 1990, and is projected to reach 18.9 million by 2050—an increase of over 600 percent (Table 51.1a-1).

The accuracy of the above projections depends on the accuracy of predictions concerning birth rates, immigration, and emigration—all of which are more difficult to gauge for the future than the remaining variables, death rates or life expectancies. Projections concerning life expectancy, for example, can change substantially within a single decade. Thus, on the basis of the 1980 census, the life expectancy for women at birth was projected to continue to exceed that for men by 6.9 years until the year 2050. After the 1990 census, however, new projections show the gap in life expectancy gradually diminishing to only 4.6 years by 2050 (Table 51.1a-3). The corresponding difference in life expectancy in 2050 at age 65 declined from 5.0 years to 2.1 years between the two projections (Table 51.1a-3). By 2050, therefore, the composition of the U.S. population by age and sex is estimated to differ markedly from that of 1990. Such changes are bound to influence income and marital statistics, the percentage of elderly persons living alone or in long-term care facilities, and other aspects of the social network. The social structure of different

ethnic groups will also be affected by changes in the percentage of elderly persons in the population (Fig. 51.1a-2).

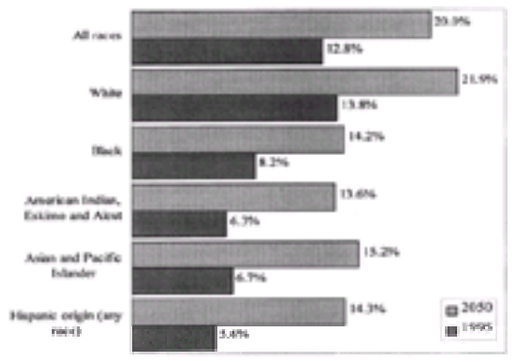

FIGURE 51.1a-2 Percentage of elderly persons, by race and Hispanic origin: 1995 and 2050. (From Day JC: Population Projections of the United States by Age, Sex, Race and Hispanic Origin: 1995 to 2050. U.S. Bureau of the Census, Current Population Reports. U.S. Government Printing Office, Washington, DC, 1996.)

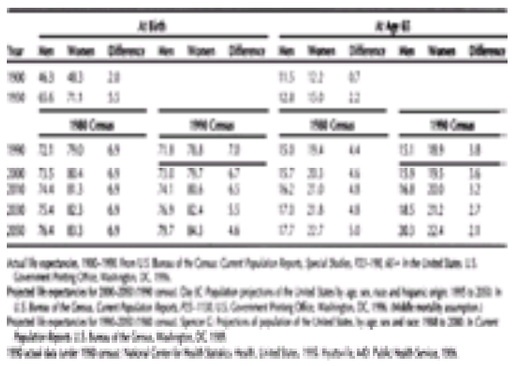

Table 51.1a-3 Life Expectancies at Birth and at Age 65 According to Two Census Reports

Prevalence data for mental disorders in elderly persons vary widely, but a conservatively estimated 25 percent of that population have significant psychiatric symptoms. Thus, the number of elderly mentally ill individuals will total about 9 million by the year 2000 and 20 million by 2050. In recognition of this trend, in April 1991 the first examination was offered for added qualifications in geriatric psychiatry, the first area of specialization recognized within psychiatry in three decades.

In 1988 it was estimated that the geriatric psychiatrist of the twenty-first century will have, at best, about 20 minutes to spend with each patient each year. That prediction assumed that 34 geriatric psychiatrists would complete training annually. Although some new positions have been funded by the Department of Veterans Affairs (beginning with 12 in 1991 and doubling in 1992) and some hospitals are funding their own fellowships, that is still not enough to fulfill the prediction of even the inadequate 20 minutes for each patient each year.

When considering how variations in the geographic distribution of the older population (Fig. 51.1a-3) influence the availability of geriatric psychiatrists, one must remember that the states in which elderly persons constitute a higher percentage of the population are not necessarily the states with the largest numbers of persons over the age of 65. For example, California, with the largest number of elderly individuals (over the age of 65—3.1 million in 1990—ranked only 46th among the 50 states in terms of the percentage of the population that is elderly (10.5 percent). The leader, Florida (18.2 percent), had only 2.4 million elderly individuals in 1990. Nonetheless, clearly, there will be so few geriatric psychiatrists that most will be needed as clinical consultants and academic teachers, leaving the major burden of providing mental health care for elderly persons to their professional colleagues. Consequently, every psychiatrist needs to know the basics of geriatric psychiatry.

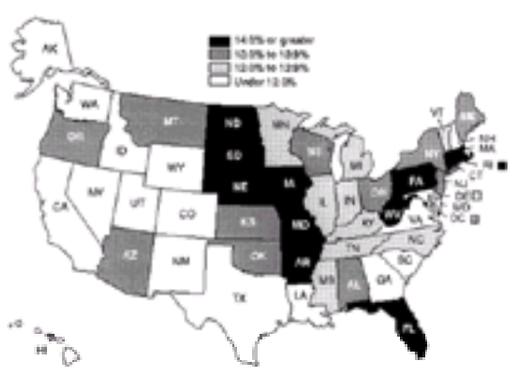

FIGURE 51.1a-3 Percentage of the population that is aged 65 years and over, by state: 1993. (From U.S. Bureau of the Census: *Current Population Reports, Special Studies, P23–190, 65+ in the United States*. U.S. Government Printing Office, Washington, DC, 1996.)

Why is specialized training in geriatric psychiatry emphasized? After all, is not geriatric psychiatry just general adult psychiatry applied to people who are elderly? True, many patients grow old with their psychoses and neuroses. Others remain well until their years and life circumstances create stresses that eventually exceed their ability to cope. It is, perhaps, the frequency and severity of the stressors associated with aging that make geriatric psychiatry unique.

STRESSORS

High-ranking stresses of aging include acute and chronic medical illnesses (Table 51.1a-4), the concomitant use of therapeutic drugs, and the complicating drug-drug and drug-disease interactions. Thus, geriatric psychiatrists must be able to recognize both the physical and mental ills of their patients, as well as having skills in the social sciences, knowledge of the health care delivery system, and information about the availability of financial and social supports, especially nursing homes (Table 51.1a-5). Medical illness connotes physical loss and changes in body image, but the loss of one's job, including voluntary and involuntary retirement, carries with it the loss of financial resources, social status, and much of the social network (Fig. 51.1a-4, Fig. 51.1a-5, Fig. 51.1a-6 and 51.1a-7). The loss of contemporaries through death, illness, and migration brings not only psychological deprivation of an intimate love object but also a void that usually remains unfilled; forming new friendships is difficult in old age. Physical limitations and the loss of friends are frequently associated with restricted mobility, which leads to further social isolation and increased difficulty in pursuing the tasks of daily living, such as procuring food and clothing and maintaining one's shelter. Often, homes are lost because of financial strains and the inability to perform home upkeep. Many widows, for example, have had to move from the 5- to 10-room family homes which they occupied for most of their lives to half a room in a residential extended-care facility for the elderly. In addition to losing most of their wordly possessions and social support, they also lose their privacy and their sense of self-worth.

Condition	Age				Race (65+)		
	65+	65 to 64	65 to 74	75+	White	Black	Black as % of White
Arthritis	480.0	253.8	437.3	554.5	483.2	522.6	108

HETEROGENEITY

Generalizations concerning the stresses of aging must be viewed in light of the heterogeneity of the aged as a group as well as the uniqueness of each older person. Individual variability characterizes the geriatric age group not only in terms of chronological age, physical and mental vigor, socioeconomic resources, educational background, ethnocultural heritage, spirituality, and life experience, but also in terms of physiological, anatomical, genetic, and psychodynamic elements. At one end of the spectrum is the healthy, active, involved person, usually under age 85, whose lifestyle differs imperceptibly from that of the middle-aged adult despite changed responsibilities (e.g., grandchildren, management of increased assets and estate planning). Many in this group are retirees who are busier now than they were before retirement. At the other end of the spectrum is the frail octogenarian, nonagenarian, or centenarian plagued by chronic illness, sensory loss, and debility, who has difficulty in processing information and performing the essential activities of daily living. Age alone is not the sole determining factor, as illustrated by the space flight of Senator John Glenn while in his mid-70s.

The geriatric psychiatrist must be aware of the vast individual variability in this age group and must be sensitive to the possibility that medical comorbidity as well as atypical presentation of psychiatric illness may complicate diagnosis and treatment of frail elderly persons. Subtle cues may have to be pursued in detecting such diverse disorders as major depression, subdural hematoma, or infectious or hematological disease.

Attention to psychiatric symptoms among medically ill patients has just begun to become a focus for geriatric psychiatrists. Traditionally, these patients were excluded not only from clinical trials but from other research targeting uncomplicated patients with a single disorder (i.e., the disorder under study). Psychiatric comorbidities are emerging as important factors in increasing length of acute inpatient stays and frequency of medical complications as well as mortality. Therefore, it is expected that geriatric psychiatrists will participate much more in the care of these patients. Further, the geriatric psychiatrist must recognize that the impaired functioning produced by psychiatric or medical illness may be only temporary or may persist for prolonged periods. In either case, the goal is to maintain the individual in the least restrictive environment. Many older individuals are embedded in a system: family members, friends, or neighbors are closely involved in activities of daily living. The psychiatrist must be skilled in assessing caregivers: is the caregiver at risk for medical or psychiatric illness or for substance abuse? Do caregivers need respite, or are they unable to continue caring for the older individual for other reasons? Are there appropriate resources in the community such as day programs, assistance in the home, or group living situations? Does the community have accessible and affordable options for transportation for older individuals? Is elder abuse present, whether physical abuse, neglect by self or others, or fiduciary abuse? Ethical and legal dilemmas that arise as people age mandate additional expertise in assessment and the ability to make appropriate referrals.

The psychiatrist who treats older adults must be comfortable collaborating with primary care physicians and various subspecialty physicians. The ability to work with a multidisciplinary team is essential. Education of physicians, nonphysicians, and older individuals and their families is an important role for the geriatric psychiatrist. The older adult must be able to access psychiatric care. Barriers to care include such beliefs on the part of health providers and individuals in the community as “I'd feel depressed too, if I were old and sick,” “Medicines won't do any good, they'll only make her sicker,” and “That person is too old for therapy.” Older individuals themselves may fear being labeled “crazy” if they seek psychiatric help. Knowledge of beliefs of different cultures regarding aging and psychiatric illness will contribute to improved access to evaluation and treatment.

Advocacy for the older adult by the psychiatrist and members of other disciplines will become increasingly important as guidelines for care, reimbursement policies, and measurement of outcomes are developed in both the public and the private sectors. Organizations such as the National Alliance for the Mentally Ill (NAMI), the American Association of Retired Persons (AARP), the American Association for Geriatric Psychiatry, and the Alzheimer's Association will have input in many areas, including care of aging chronically mentally ill patients. As managed care organizations enroll increasing numbers of older adults, the need for adequate access to psychiatric care will emerge as will the need for collaboration between psychiatrists and other physicians in the diagnosis and treatment of psychiatric disorders.

The quiet apathetic 86-year-old individual brought to the office by relatives convinced that “something is wrong” is readily dismissed as demented, probably suffering from Alzheimer's disease and best left undisturbed. In collaboration with the geriatric psychiatrist who makes the diagnosis of coexisting myocardial infarction and depressed mood, this type of patient can receive appropriate treatment for both conditions. All psychiatrists, all physicians, all mental health specialists, and all health care professionals should bear in mind that most elderly patients are neither demented nor suffering from any other psychiatric disorder; and, they must carry out their professional mandate to assess each patient carefully, regardless of age, before arriving at a diagnosis. This means giving thoughtful consideration to the differential diagnosis, including the diagnosis of no mental disorder.

BURDEN OF CARE

As the cost for extended-care facilities continues to skyrocket, fewer and fewer persons will be able to afford them; thus the burden of care is likely to increase for the adult children of mentally ill and physically frail elderly parents. Both society and psychiatry are ill prepared. As the “sandwich” generation—the adult children sandwiched between the needs of their parents and the needs of their children—becomes more prominent and more squeezed, more facilities at affordable rates will be needed to treat the major mental disorders of old age, such as Alzheimer's disease (called dementia of the Alzheimer's type in the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* [DSM-IV]), depression, and anxiety. Those disorders are frequently reasons for the dependence of elderly persons.

Most dependence needs of elderly parents are being fulfilled by adult children, especially daughters (Fig. 51.1a-8). Caring for elderly parents raises numerous psychological issues for the adult children. Geriatric psychiatrists may often be the most appropriate professionals to work with those caregivers—either directly or in conjunction with other mental health professionals—because their expertise encompasses the psychological, medical, and sociological databases required for truly informed decision making.

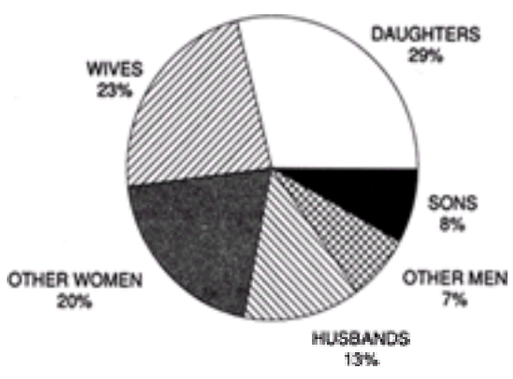

FIGURE 51.1a-8 Caregivers and their relationship to the elderly care recipient: 1982. (From Select Committee on Aging, U.S. House of Representatives: *Exploding the Myths: Caregiving in America*. U.S. Government Printing Office, Washington, DC, 1987.) (Caregiver population includes primary and secondary caregivers.)

TREATMENT

Psychiatrists are familiar with diverse treatment approaches and can use pharmacotherapy, psychotherapy, or both, as well as other somatic therapies. Elderly persons require special techniques in all forms of therapy. The psychiatrist of an 87-year-old patient suffering from heart disease, arthritis, and depression must ask a number of questions: What is the best treatment? Pharmacotherapy? Psychotherapy? Electroconvulsive therapy? If pharmacotherapy, what is the most appropriate drug? Balancing adverse effects and efficacy, what is the best dosage? How soon will the patient's symptoms decrease? If the drug is effective, how long will the improvement last? If the drug seems ineffective, how long should the wait be before changing the treatment? Will the psychiatrist and patient have to settle for improvement without remission?

Currently, psychopharmacology is the mainstay of treatment in geriatric psychiatry. Advantages include acceptability to this cohort of patients accustomed to medication treatment of other disorders, ability of nonpsychiatrists to prescribe psychotropics, and ability to obtain reimbursement. Disadvantages include adverse effects (even with new medications), drug-drug interactions, and interaction of medication with existing disease processes.

Psychosocial treatments have not yet gained acceptance for several reasons: results become evident later than with pharmacotherapy; it is difficult to quantify evaluations of treatment effectiveness; existing data specifically addressing older adults are very limited; treatments tend to be more expensive than pharmacotherapy, even if administered in group settings; and reimbursement is often problematic.

Electroconvulsive therapy (ECT) is an effective treatment for depression in elderly patients. However, its effectiveness and safety have not been widely recognized because of politically charged issues. ECT should be considered especially in frail elderly individuals whose nutritional status and activity level have deteriorated significantly, since it may result in rapid improvement. The risk of memory loss must be weighed against the adverse effects and drug interactions of psychotropic medication.

FUTURE DIRECTIONS

Little is known about the needs of elderly patients in the twenty-first century. What will happen to the Vietnam-era and Gulf War veterans who suffer from posttraumatic stress disorder and to similarly afflicted victims of crime and survivors of genocide in Africa, Asia, and Eastern Europe? Substance abuse and its long-term effects will undoubtedly assume increased importance as the youths of the 1960s reach geriatric age. Will the trend toward decreasing alcohol and nicotine abuse continue among elderly persons? (Fig. 51.1a-9). Clearly, psychiatrists of the twenty-first century will have to be alert to acquired immune deficiency syndrome (AIDS) dementia among elderly persons (Fig. 51.1a-10) as improved treatments prolong the lives of those testing positive for the human immunodeficiency virus. Further, genetic factors will probably assume increasing importance in elucidating susceptibility and resistance not only to AIDS but also to Creutzfeldt-Jakob disease, bovine spongiform encephalopathy (mad cow disease), and other transmissible diseases. Expertise in molecular genetics will help geriatric psychiatrists participate actively in exploring the causes and cures of other dementing (e.g., Alzheimer's disease) and nondementing (e.g., mood disorders) illnesses afflicting the elderly population.

(Data from U.S. Bureau of the Census: *Current Population Reports, Special Studies, P23–190, 65+ in the United States*. U.S. Government Printing Office, Washington, DC, 1996.)

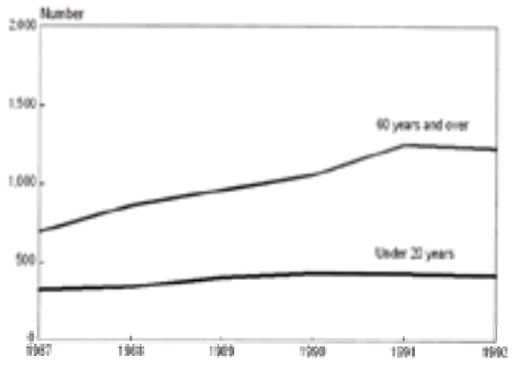

FIGURE 51.1a-10 AIDS deaths under 20 years and 60 years and over: 1987 to 1992. (From U.S. Bureau of the Census. *Current Population Reports, Special Studies. 65+ in the United States*. U.S. Government Printing Office, Washington, DC, 1996.)

Although psychiatrists delight in the advances made in neuroimaging, brain mapping, and other technological approaches to the neurocognitive aspects of Alzheimer's disease and look forward to the discovery of additional genes for the major psychiatric illnesses, progress has been slow in converting the knowledge gained in these areas into effective treatments or prevention. Geriatric psychiatrists entering the twenty-first century will not only increase their collaboration with primary care physicians as increasing numbers of frail elderly persons are maintained in the community, but they will find themselves in new settings as aged individuals increasingly become part of the penal system. Regardless of how diverse the area of geriatric psychiatry, when it comes to treating the individual patient, it will still be the psychiatrist's clinical skills—grounded in scientific knowledge—that will ensure that the patient receives the best care medicine can offer, and it is likely that the psychiatrist will still assume the roles of family doctor, friend, parent, and child to the geriatric patient. It is an awesome responsibility for which psychiatrists must be prepared.

SUGGESTED CROSS-REFERENCES

Normal aging is discussed in Section 51.2c, neuroimaging in Section 51.2e, Alzheimer's disease and other dementing disorders in Section 51.3e, psychiatric problems in medically ill geriatric patients in Section 51.3a, sociocultural and minority issues in Section 51.6d and Section 51.6e, financial issues in Section 51.5a,

AIDS in Section 2.8, health care delivery systems in Section 51.5, and posttraumatic stress disorder in Section 51.3c.

CHAPTER 51. GERIATRIC PSYCHIATRY

51.1 OVERVIEW

51.1B EPIDEMIOLOGY OF PSYCHIATRIC DISORDERS

A. SCOTT HENDERSON, M.D., D.SC., F.R.A.C.P., F.R.A.N.Z.C.P., F.R.C.P., F.R.C.PSYCH.

Epidemiology is concerned with the mass aspects of health and disease. For elderly persons as for other age groups, it has eight purposes: to identify changing patterns of disease; to estimate the prevalence and incidence of specific categories of morbidity; to study the operation of health services and their impact; to estimate the risk for individuals of developing a disorder according to the exposures they have experienced; to complete the clinical picture by determining all the presentations of a disorder and its course at the general population level; to identify syndromes from the distribution of clinical phenomena in the population; to search for causes or risk factors; and finally, prevention, which Ernest Gruenberg said was its ultimate service.

A clinician who deliberately develops an epidemiological style of thinking can gain an appreciation of what contribution is being made, or not made, by a given environmental exposure. Here, the key concept is the population at risk. For example, a patient may attribute mental symptoms to a disturbing experience, recent or past. In ideographic terms, this may be plausible, and the clinician may accept the explanation as at least one causal factor. But the epidemiological thinker must know how many persons have had the same experience but not developed the symptoms and how many had the exposure, developed symptoms, but did not reach professional services and thus were not subsequently referred to a specialist. Only in this way can one determine the probability that the experience in question is indeed causally related to the onset of a disorder.

Global Demographic Changes The need for epidemiological information about elderly persons has taken on some urgency because of an unprecedented change in the world population. Not only is the global population increasing rapidly, but many more people are living into old age, and that change applies particularly to the very old. The change is due to a shift from high fertility and high mortality to low fertility and low mortality. Many more people than in the past live to an age when the likelihood of dementia greatly increases, so that the absolute number of persons with dementia is now expanding rapidly throughout the world. The predicted situation in six economically and culturally diverse countries in shown in Figure 51.1b-1, which is based on data published by the United Nations. It illustrates the growth in the total population, in the elderly population, and in persons with dementia in each country. In some countries, the proportion with a dementia is increasing much faster than the size of the elderly population. This is because of the greater increase in the very old. For some countries, the public health consequences are considerable. According to predictions published by the United Nations, the United States population aged 60 years and older will rise from 43.3 million in 1995 to 92.4 million in 2050, an increase of 213 percent. Even more significant for health services is the projected increase in persons 80 years and older from 8.0 million in 1995 to 24.9 million in 2050, an increase of 311 percent. The social, economic, and public health consequences are profound. Cost-containment alone will not restrain the projected increase in health service use. The prevention and effective treatment of age-dependent disease has become a compelling need. One contribution to this comes from epidemiology.

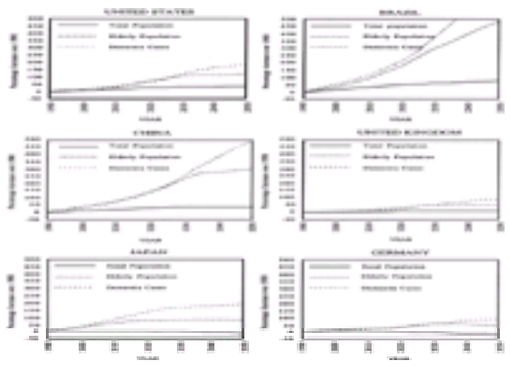

FIGURE 51.1b-1 Dementia cases predicted in six countries. (Adapted from Jorm AF: *The Epidemiology of Alzheimers Disease and Related Disorders*. Chapman & Hall, London, 1990.)

P>**Levels of Inquiry** Psychiatric epidemiology conducts its inquiries at one of three levels: morbidity as it occurs in the community or general population; morbidity as it occurs in primary health care (including family physicians); and morbidity as it occurs in psychiatric or medical services. Research on etiology may be carried out with advantage at the community level rather than on treated series because bias is less likely in a community sample, particularly in relation to the likelihood of exposure to putative risk factors. This can be important in avoiding Berkson's bias, whereby some other variable, unrelated etiologically, may influence the chances of a person's reaching services. The unaware researcher might then mistakenly conclude that the unrelated variable contributed causally. Such biases are usually absent in community samples, which also provide a wider range of severity, whereas hospital or clinic series will, for example, only have depressive disorder of the severe type. But community samples have their own problems. They are laborious and costly, requiring trained personnel to contact and interview hundreds and commonly thousands of persons in their own homes. Invariably refusals and persons who cannot be contacted lead to significant sample bias. Another important but unavoidable bias applies in prospective longitudinal studies in which the focus of interest is the course and outcome of morbidity. When a sample of elderly persons is followed over several years, those who subsequently refuse, are not available, or have died during the study are often more likely to have had the condition in question, such as a dementia, or to have developed it during the course of the inquiry. This means that those who are successfully reexamined are a survival elite who may differ in important ways from the original cohort. These distortions could lead to mistaken conclusions if the nonrandom losses are not allowed for.

Instruments Case ascertainment might be assumed to be the sine qua non for any progress in the epidemiology of mental disorders, namely to identify individuals who have the disorder. But using the traditional expression “case ascertainment” nicely illustrates a problem that has to be overcome: it implies a categorical structure in the morbidity being studied. In a population, there are traditionally cases and noncases, but some have recently argued that many neuropsychiatric conditions have dimensional properties and that there are advantages for some research purposes in not only identifying persons with cases by criteria in the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) or the 10th revision of *International Statistical Classification of Diseases and Related Health Problems* (ICD-10), but also determining the score on relevant scales for all members of the sample. The resulting frequency distribution of symptoms such as depression or cognitive impairment is usually highly skewed, with most people having none or only a few symptoms and progressively fewer persons having higher counts. The same applies to measures of disability in the activities of daily living (ADLs), which are an important part of the assessment of older persons. For research on etiology or on the effect of interventions, the inclusion of continuous measures is to be recommended because they lose less information in statistical analyses.

Epidemiological research on mental disorders in late life calls for specially built instruments to detect what is clinically important in this age group: cognitive impairment, cognitive decline, dementia, anxiety and mood disorders, psychotic states, and functional capacity in ADLs. There are two main types of instrument: scales and standardized interviews. The Geriatric Depression Scale is specifically designed for elderly persons.

The standardized research interviews in current use typically have a section for assessing the elderly person and a separate section for an informant, who is usually a relative or close friend. The Geriatric Mental State Examination has been used extensively in diverse countries, allowing comparisons on the prevalence of dementia and depression. The CAMDEX was originally intended as a clinician's instrument but can be used by lay persons after some training. The Consortum to Establish a Registry for Alzheimer's Disease (CERAD) battery is a standardized clinical assessment of persons likely to have dementia of the Alzheimer's type. It is principally a research instrument for use by clinicians. The Canberra Interview for the Elderly was designed for use by lay interviewers and was developed by constructing items to tap each element in the revised third edition of DSM (DSM-III-R), DSM-IV, and ICD-10 criteria for dementia and depressive disorders. The coverage of cognitive function is wide and includes the Mini-Mental State Examination. It also has a depression scale derived from all the depressive symptoms in DSM-IV and ICD-10. Subsequently, using latent trait analyses, the Psychogeriatric Assessment Scales were developed as an optimally parsimonious screening instrument for both clinicians and nonclinicians to detect individuals likely to have depression, cognitive decline, or stroke. These scales are now in wide use for both routine assessment and research.

Matrix for Organizing Epidemiological Knowledge To organize what is known about the epidemiology of mental disorders in the elderly population, it is useful to use a matrix in which the columns consist of the main categories of mental disorders and the rows are made up of the variables that may contribute to the onset or course of morbidity. This matrix helps to organize the information already available, and as inspection will show, it also acts heuristically by proposing associations that otherwise might not have been considered. Table 51.1b-1 sets out such a matrix for the main psychiatric disorders of later life.

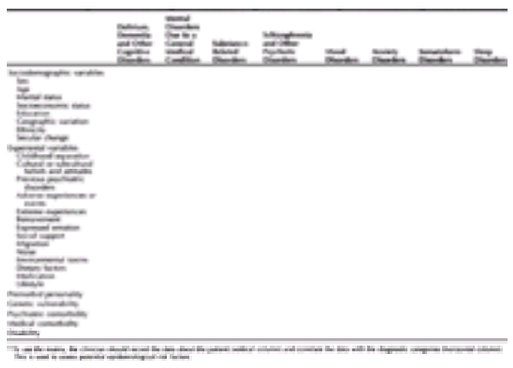

Table 51.1b-1 A Matrix for Organizing Epidemiological Knowledge on Psychiatric Disorders in the Elderly*

DEMENTIA

Incidence Studies There are many fewer studies of the incidence than of the prevalence of dementia, but enough exist to allow some estimate of age-specific rates in the community. As an approximate guide, for dementia of all types the incidence is about one new case per year for every hundred persons aged 65 years and over. What is clear is that the age-specific incidence of both dementia of the Alzheimer's type and vascular dementia rises steeply from the 60s. It is uncertain whether this continues to extreme old age, reaches a plateau, or even decreases in those who survive until then. Data from the Framingham study suggest that the annual incidence of dementia of the Alzheimer's type is about 1.0 percent for men and women aged 75 years and over.

Prevalence There are published reports on the prevalence of dementia in diverse areas of the world including North America, Europe, Scandinavia, Russia, Japan, China, Singapore, India, Africa, and Australasia. Prevalence studies are currently under way in several Latin American countries. As in the incidence studies, only a proportion refer to the prevalence of specific dementias; the remainder are estimates for the dementia syndrome. An integrative analysis of 47 surveys across 17 countries has suggested approximate rates under 1 percent for dementia from any cause in persons aged 60 to 69 years, rising to about 39 percent in persons 90 to 95 years old. The prevalence doubles with every 5 years of age within that range. For both cognitive impairment and all the psychiatric disorders of the elderly considered here, the findings of the large National Institute of Mental Health Epidemiologic Catchment Area (ECA) studies in the United States are summarized in Table 51.1b-2. In the studies in five centers, 4.9 percent of persons aged 65 years and older were found to have severe cognitive impairment, as evidenced by a score of 17 or less on the Mini-Mental State Examination. That test was used instead of the much more demanding task of making a diagnosis of dementia, let alone a specific dementia. The annual prevalence of cognitive disorder in the ECA studies was 4.6 percent in persons 65 years or older but only 0.4 percent in young adults. For the prevalence of dementia of the Alzheimer's type specifically, a pooled analysis from six European surveys suggests rates of 0.02 percent, 0.3 percent, 3.1 percent, and 10.8 percent for the age groups 30 to 59, 60 to 69, 70 to 79, and 80 to 89 years, respectively. Age-specific prevalence rates rising to 47.2 percent in those over 85 years have been reported in an East Boston study. For vascular dementia the prevalence in the United States has been estimated at 3.5 percent for men and 0.8 percent for women 65 years and older.

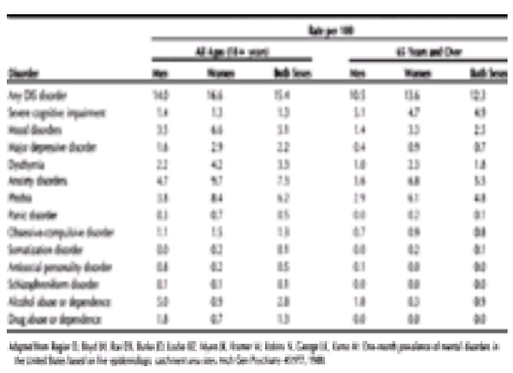

Table 51.1b-2 One-Month Prevalence Rates of Diagnostic Interview Schedule (DIS)/DSM-III Disorders in Five Sites in the United States

Secular Change Is there more dementia now than some decades ago? Because there are larger numbers of elderly persons now than there were only a few decades ago and more of the very elderly in particular, the number of persons suffering from a dementia has inevitably increased. Furthermore, an elderly person with a dementia is now likely to survive longer because of the greater availability of medical and nursing care—what has been called the failure of success. Even with no change in incidence, this would tend to increase prevalence. Studies in Sweden and across Western Europe have found no change in incidence, but it is intuitively plausible that vascular dementia may be decreasing in many countries in parallel with a general decrease in vascular disease.

Age and Sex The incidence of dementia increases steeply with age from the 60s. Some have suggested that the age-specific incidence may plateau or even fall by the ninth decade, so that persons reaching late old age without a dementia may have a reduced risk. But to answer this requires longitudinal data on a representative sample of very elderly persons assessed cognitively on at least two occasions a few years apart. Because the numbers dwindle so markedly, the estimates of incidence tend to be very unstable. As a consequence, the possibility of a late decline in incidence remains uncertain. The overall prevalence of dementia is the same in men and in women, but the prevalence of dementia of the Alzheimer's type is higher in women. This may be partly explained by the fact that those with dementia of the Alzheimer's type are more likely to survive if they are women.

Education A recurrent finding in field surveys is that rates for dementia and cognitive impairment are higher in elderly persons who have had little education. This may be partly due to bias in ascertainment, whereby the tests are done better by persons who are more literate. While such bias may be present in the detection of mild impairment in surveys, it is much less likely to influence the diagnosis of a fully developed dementia. There may indeed be a true gradient in the incidence of dementia, including dementia of the Alzheimer's type, across educational levels. In this way, lack of education could be seen as an exposure that may confer increased risk. One interpretation is that education may delay the point at which a developing dementia becomes clinically manifest. In interpreting results of a large

survey in Shanghai, the authors raised the possibility that having no education may lower brain reserve, allowing the earlier appearance of symptoms of dementia. It is also possible that education is a proxy for other beneficial factors, as in diet or lifestyle. But a recent longitudinal study of American nuns suggests that education and intelligence may actually protect against the neuropathological processes in dementia of the Alzheimer's type. This means that exposure to education in childhood may conceivably have a protective effect many decades later. If such a protective effect does apply, the implications for public health could be appreciable, because education has become much more widely available to young persons during the twentieth century. The incidence of dementia may therefore show a modest decrease in the future.

Geographic and Ethnic Comparisons Dementia of the Alzheimer's type and vascular dementia may occur at different rates in different parts of the world and in different ethnic groups. But it is not easy to be certain what factors are operating. There may be different patterns of mortality for dementia patients with different living conditions, different genetic vulnerabilities, or different environmental exposures. A general population study in Mississippi and North Carolina found more dementia of the Alzheimer's type in blacks than in whites. A study in Israel suggests that dementia of the Alzheimer's type is more common in Ashkenazi than Sephardic Jews. A fairly consistent finding is that the ratio of dementia of the Alzheimer's type to vascular dementia is well below 1.0 in Japan and elsewhere in the Far East, but significantly above 1.0 in white populations. Although the overall prevalence of dementia in elderly Cree Indians is the same as in whites, dementia of the Alzheimer's type is very rare in that group. No explanation has yet been found. In an attempt to disentangle possible genetic, dietary, and lifestyle factors, dementia was studied in Japan and in ethnic Japanese in Hawaii. This study showed that when Japanese men migrate to Hawaii, they acquire a higher risk of developing dementia of the Alzheimer's type. They also acquire a slightly lower risk for vascular dementia. Although these different rates for dementia could have other explanations, this study has yielded some of the best data yet available on the hypothesis that significant environmental factors are involved in the causation of dementia of the Alzheimer's type. A further finding of potentially great significance comes from a comparison of prevalence rates for dementia and specifically for dementia of the Alzheimer's type in 2494 Nigerian Africans and 2212 African-Americans in Indianapolis, both aged 65 and over, examined by the same methods. The prevalence was 2.3 percent and 1.4 percent for dementia and dementia of the Alzheimer's type, respectively, in the Nigerians, but 8.2 percent and 6.2 percent in the combined community and nursing home sample of African-Americans in Indianapolis. This demonstration of significant differences in rates in two different communities with similar ethnic origins again points to the possibility that some unknown environmental factors promote the neuropathological processes in dementia of the Alzheimer's type.

Prevalence of Dementia in Institutional Settings A matter of considerable importance for health economics and services is the proportion of persons with a dementia who are retained in the community, as opposed to being in nursing homes or sheltered accommodation for the elderly. This proportion is likely to vary considerably, since it is dictated by cultural and socioeconomic conditions. In a large prevalence study in Beijing, all persons with dementia lived in the community. This is in marked contrast to the pattern in most Western countries, where as many as two thirds of all patients typically live in institutional settings. In a Cambridge, U.K., study for example, 41 percent of those with moderate or severe dementia were in residential care, while one third of the severely demented were being cared for at home. A related matter is the proportion of nursing home residents who have a dementia. In the United States, a remarkably consistent average prevalence of 52 percent for nursing homes has been found. This estimate agrees closely with the U.S. Department of Health and Human Services' finding of a total of 696,800 persons with organic brain syndrome in U.S. nursing homes, representing 47 percent of all residents. In marked contrast, only 9000 persons with organic disorders were inpatients in psychiatric hospitals. This represents a ratio of 77 to 1 for numbers of persons with dementia in nursing homes compared with numbers in psychiatric hospitals.

Risk Factors For over two decades, there has been intensive epidemiological research to identify risk or protective factors for the most common dementias, so that preventive action can be taken against this serious social, health, and economic problem for many countries.

Vascular Dementia Risk factors are assumed to be similar to those for stroke. These are age, being male, a family history of stroke or dementia, hypertension, diabetes mellitus, transient ischemic attacks, elevated cholesterol or lipid concentrations, cigarette smoking, heavy alcohol use, oral contraceptives, physical inactivity, obesity, and ethnicity.

Dementia of the Alzheimer's Type The power of individual case-control studies of dementia of the Alzheimer's type has been greatly enhanced by an initiative undertaken by the European Consortium on Dementia (EURODEM) established by the European community. They carried out a collaborative reanalysis of 11 case-controlled studies, six from the United States and one each from Australia, Finland, Italy, Japan, and the Netherlands. That analysis revealed risk factors that had hitherto been only speculative. From this and other sources, only four risk factors can now be regarded as confirmed.

AGE As for dementia in general, the incidence rises steeply with age, making it the strongest of all risk factors.

FAMILY HISTORY Having a parent or sibling with dementia of the Alzheimer's type increases the risk of developing the disease about 3.5 times. The risk is greater for relatives of early-onset patients than later-onset patients. In interpreting the epidemiological data for individual patients though, the clinician needs to emphasize that the risk conferred by a positive family history depends on how long that person lives. Those who do not reach old age have a low risk. Even for relatives who live to age 90, the probability that they themselves will develop the disease is only about 50 percent.

APOLIPOPROTEIN E GENOTYPE The much rarer, early-onset dementia of the Alzheimer's type is caused by single genes such as a mutation of the amyloid precursor gene on chromosome 21 or the presenilin genes on chromosomes 1 and 14. But in most cases of dementia of the Alzheimer's type, onset is not until the 70s or 80s. In this group, of much greater public health importance, there are multiple genetic and environmental influences. One of the most exciting discoveries is that the apolipoprotein E e4 allele on chromosome 19 affects the risk of developing the disease. The e4 allele of this gene increases risk and the e2 allele may reduce it. Although early research with clinical samples showed a very strong relationship between apolipoprotein E e4 genotype and dementia of the Alzheimer's type, more-recent studies with general population samples show a weaker relationship. Currently much interest exists in preliminary findings that a combination of having the e4 allele and being infected with the herpes simplex type 1 virus confers a very high risk. It is now clear that although all individuals with the e4 allele are at increased risk, even homozygotes can live to age 90 with only a 50 percent chance of developing a dementia. An interesting proposal is that the apolipoprotein E genotype predicts when (not whether) a person is predisposed to develop this dementia. These epidemiological findings may in time lead to the development of pharmacological methods to slow the deposition of b-amyloid.

DOWN SYNDROME Persons with Down syndrome develop the brain changes of dementia of the Alzheimer's type before age 40. This is believed to be related to their having an extra copy of the amyloid precursor gene on chromosome 21. Interestingly, they do not usually develop dementia until much older, which may mean that accumulation of amyloid is necessary but not sufficient for the development of dementia of the Alzheimer's type.

POSSIBLE RISK FACTORS A number of possible risk factors exist for which the evidence is presently not conclusive. The importance of ethnicity and geographical region is described above.

Head Injury An integrative analysis of early studies showed that a history of head injury increased the risk of developing dementia of the Alzheimer's type by 80 percent. However, most of these studies assessed history of head injury through reports from relatives rather than from medical records, which could lead to biased reporting. A recent study suggests that head injury may be a risk factor only in individuals who carry the apolipoprotein E e4 allele.

Aluminum Because aluminum, known to be neurotoxic, occurs in neuritic plaques, evidence has been sought for an association between exposure to this metal and the development of dementia of the Alzheimer's type. Aluminum is ingested in food, drinking water, antacids, and toothpaste. It is used in kitchen utensils, and it is applied to the body in antiperspirants. The widespread use of aluminum as a flocculant in water supplies has led to public concern, although drinking water provides only a tiny percentage of dietary aluminum. The amount absorbed depends on its bioavailability, and considerable uncertainty exists about its subsequent deposition in the brain. From the epidemiological evidence, involvement of aluminum from drinking water or other sources in causing dementia of the Alzheimer's type remains unproven.

a2-Macroglobulin Inheritance of a polymorphism in the a2-macroglobulin (A2M) gene has been found to confer increased risk of Alzheimer's disease, but this has yet to be confirmed in other studies.

Previous Depression Interest has been shown in a possible link between previous psychiatric disorders or their treatment and the development of dementia of the Alzheimer's type. Examination of such an association requires clear determination of the time of onset of the previous disorder, because disorders such as depression could be early manifestations or prodromata of dementia of the Alzheimer's type itself. In the EURODEM reanalysis based on four studies in which depression had been assessed before the onset of dementia, a relative risk of 1.8 (95 percent confidence intervals, 1.2 to 2.9) was found for a previous depressive episode. This held for episodes more than 10 years before onset of dementia of the Alzheimer's type, but the effect was confined to late-onset cases. No association was found with

exposure to antidepressant treatment or to adverse life events such as death of a spouse, death of a child, or divorce.

Other Possible Risk Factors Three of the unconfirmed risk factors are possibly linked to the association with having Down syndrome: a history of Down syndrome in a first-degree relative, advanced maternal age at one's birth, and an excess of ulnar loops in fingerprints. Lastly, hypothyroidism and a long-standing history of physical inactivity have been reported in some case-controlled studies. Importantly, no evidence links dementia of the Alzheimer's type and antidepressants or electroconvulsive therapy (ECT), neurotropic viruses, allergic disorders, or general anesthetics or blood transfusions. The EURODEM reanalysis found that risk was not increased by any level of alcohol consumption or by occupational exposure to solvents or lead.

Possible Protective Factors Some factors may confer protection against dementia, specifically that of the Alzheimer's type. For the latter, four have been proposed, all identified through epidemiological research: education, anti-inflammatory drugs, estrogen replacement therapy, and moderate amounts of red wine. Each of these suggests the possibility of prevention; prevention can precede an understanding of etiology. The contribution of education is described above.

Anti-Inflammatory Drugs Since an inverse association between rheumatoid arthritis and dementia of the Alzheimer's type was first observed, over 20 publications have examined the possibility that persons who have taken steroids, aspirin, or other nonsteroidal anti-inflammatory drugs (NSAIDs) over long periods have a lower risk of dementia or have slower cognitive decline in late life. Some of these studies have reported a protective effect, but many have deficient designs, and there may be publication bias (i.e., papers with negative evidence for such an effect are less likely to be submitted and accepted for publication). Yet comprehensive and balanced information on the topic is needed. The most recent information is that anti-inflammatory drugs probably do prevent or attenuate the symptoms of dementia of the Alzheimer's type. This effect is biologically plausible in terms of the action of these drugs to inhibit the immune and chronic inflammatory pathology suspected to apply in dementia of the Alzheimer's type. But it is premature for physicians to prescribe anti-inflammatory drugs for dementia of the Alzheimer's type before their effect is established in a randomized controlled trial and the findings balanced with their risks.

Estrogen Replacement Therapy Case-controlled studies suggest possible protection against dementia of the Alzheimer's type afforded to women who take estrogen. But since these women also tend to be better educated and to differ in other lifestyle factors, this finding could be misleading. Again, only randomized controlled trials will establish whether a protective effect exists.

Red Wine A large population-based prospective study in France has found evidence that moderate consumption of red wine protects against the onset of dementia. The work was conducted in Bordeaux, France.

Other Causes of Dementia A third type of dementia has recently been recognized for which the name dementia with Lewy bodies has been proposed. Epidemiological data are not yet available, but it has been claimed to account for 15 to 25 percent of cases of dementia at autopsy, making it possibly the most common pathological group after dementia of the Alzheimer's type. The dementia is diagnosed neuropathologically by the presence of concentric hyaline inclusion bodies in the cytoplasm of neurons in the brainstem and subcortical nuclei. The clinical presentation has the following main features: progressive cognitive impairment often with deficits in tests of attention, problem solving, and visuospatial tasks; fluctuating cognition; persistent well-formed visual hallucinations; sensitivity to antipsychotic drugs; and motor features of parkinsonism. No community-based surveys have yet been able to estimate the prevalence of or the risk factors for this common dementia of unknown etiology.

Three other causes of dementia are Pick's disease, Huntington's disease, and Creutzfeldt-Jakob disease. Because Pick's disease cannot be accurately differentiated from Alzheimer's disease without a neuropathological study and because only a small proportion of all patients come to brain autopsy, little is known about the age-specific prevalence of Pick's disease. In a comprehensive autopsy series in Minnesota, 5 percent of dementia cases in the elderly were due to Pick's disease and 70 percent were due to the Alzheimer's type.

A large Maryland survey established a minimum prevalence estimate for Huntington's disease of 5.9 per 100,000 persons over 10 years old. The disorder can start in persons in their 60s, and one case is known to have begun at the age of 80.

The annual incidence of Creutzfeldt-Jakob disease is 0.1 to 0.2 per 100,000 population. Men and women are equally affected. The age of onset ranges from the late teens to the 80s, with a peak in the 50-to-59 age group. Because the incidence drops sharply in the eighth and ninth decades, the disorder is not related to aging.

Age-Related Cognitive Decline There seems to be a need to describe a state of mild cognitive decline associated with aging but short of dementia in both clinical features and severity. Terms include age-related cognitive decline in DSM-IV and age-associated memory impairment and mild cognitive disorder in ICD-10. The epidemiological evidence indicates that considerable caution is needed before new diagnostic entities such as these are established and their treatment then proposed. In a cohort study of a community sample of elderly persons, those diagnosed as having mild cognitive disorder by ICD-10 criteria were reassessed 3 to 4 years later. The diagnosis proved to depend on the presence of subjective complaints about memory and thinking, to be associated with anxiety and depression, and to have no prognostic value. From this and other studies, the epidemiological evidence is that subjective complaints of memory problems are more highly associated with mood state than with objective decline in cognitive function.

DELIRIUM

Delirium, a term introduced by Celsus 2000 years ago, is derived from the Latin *de* (from, away) and *lira* (track, furrow). Despite its long-established place in nosology, delirium must number among the most underdiagnosed conditions in medicine. Indeed, the most notable feature in the epidemiology of delirium is the marked discrepancy between its true prevalence and the frequency of its recognition. The point prevalence of delirium in elderly persons in general hospitals is conservatively estimated as about 5 percent. In community surveys of the elderly, delirium is rarely reported, presumably because it is a transient disorder with a high mortality and because many cases may be missed because the person was too ill to be seen by survey interviewers.

A classic report of 106 hospital cases of delirium collected in Baltimore, New York, and London noted the variability of both the causes and the clinical features of the disorder; yet no specific relationship was found between the clinical features and exposure to particular noxious agents. Delirium occurs most commonly at the extremes of life. Its highest incidence is in elderly persons, in whom it indicates the presence of systemic or cerebral disease or drug toxicity.

Despite its grave clinical significance, the marked disruptive effects of delirious behavior, and the high mortality attending it, delirium often goes unrecognized in medical and surgical wards. A study of considerable significance found that nurses had often recorded the signs of delirium in patients' notes, but those notes had been overlooked by physicians who tended either not to consider the diagnosis or to misdiagnose it. This is a nice example of how clinical epidemiology can contribute to areas of need in medical education.

MOOD DISORDERS

Elderly persons might be expected to have higher rates of depressive disorders than younger adults because of their social, economic, intrapsychic, and medical circumstances. Information based only on service use or treated prevalence of depression could be misleading: on the one hand, elderly persons may underconsult physicians; and on the other, comorbidity with physical disorders could distort the estimates. Only data from field surveys of all adult age groups can determine whether elderly persons have more or fewer depressive disorders than younger adults. Here a puzzle emerges. For all five centers in the ECA studies, both the lifetime and the 1-month prevalence of major depressive episode was appreciably lower in the elderly than in other age groups (Table 51.1b-2). The 1-month prevalence for major depressive episode was 2.2 percent for adults aged 18 to 64 but less than 1 percent in those aged 65 years or more. For dysthymia, the rates were 3.3 and 1.8 percent, respectively. A large Australian survey has also found that symptoms of depression and symptoms of anxiety become less prevalent as people age. And so do many risk factors for depression such as adverse life events and neuroticism. Some think these findings may be attributable to an error in ascertainment, namely, inappropriately discounting symptoms that could also be due to physical illness or to age itself. Alternatively, a cohort effect has been proposed, in which those aged 65 to 85 years in the ECA studies may have been protected against depression. Selective mortality could also contribute. It seems likely that the risk of cancer and cardiovascular disease increases in persons who have had a depressive disorder.

This raises a further intriguing possibility that is at first counterintuitive, namely that aging protects against depression and indeed against a range of other mental disorders. In the ECA studies, the 1-month prevalence rates for all disorders except cognitive impairment were lower in elderly persons than in any other age group. It has been suggested that exposure to adverse experience over a lifetime may induce increased resistance to depression and anxiety through psychological immunization. Whether the incidence of depression does decrease with age must be further tested, and if it does, the basis needs to be elucidated.

Geographical Distribution The prevalence rates of depression determined by exactly the same methods in elderly persons in New York and London were compared as part of the United States-United Kingdom Cross-National Diagnostic Project. The rates for pervasive depression were remarkably similar in New York (13.0 percent) and London (12.4 percent), despite the arguably different social environments for elderly persons in the two cities. Evidence from Japanese surveys of depression in elderly persons points to strikingly low rates of below 2 percent. That difference is attributed by some to the different social conditions for elderly persons in Japan. For example, even in urban Tokyo, three-generation families constitute 42 percent of the population (versus 3.3 percent in the United States), and the elderly are accorded much respect in Japan. But the existence of truly different incidence or prevalence rates of depression in elderly persons, free of artifact in diagnostic practice, remains to be demonstrated. Explanations that invoke factors in the social environment are premature.

Etiology When elderly persons have a depressive disorder, one may reasonably ask whether or not it is a recurrence. A study in London found that 37 percent of patients in a hospital series had had a previous episode. Several studies have noted that severe life events precede the onset of depression in at least half of all patients; conversely, depressive disorder may emerge in elderly persons with relatively untrammeled lives. Risk factors for depression in late life are a past history of such a disorder, physical illness or chronic pain, recent adverse experiences, and the absence of a confiding relationship. Contrary to expectation, elderly persons who live alone have not been found to be at risk for depressive disorder. A consistent finding in community surveys is that the complaint of loneliness is associated more with depression than with actual social isolation. A recent study of risk factors in a community sample of nearly 4000 elderly Americans found that on simple bivariate analysis, depressive symptoms were associated with increased age, being female, having a low income, physical disease, disability, and poor social support. But when these other variables were controlled in a multiple regression analysis, the association between depression and age reversed: the oldest old had fewer depressive symptoms than the younger old after allowing for confounding by these other factors. In a prospective longitudinal survey of 1045 elderly Australians assessed twice over 3 to 4 years, the best predictors for the onset of depressive symptoms were having had such symptoms at the start, followed by deterioration in health and ADL function, high neuroticism, poor social support, inactivity, and high use of health services. Depressive symptoms were associated with a higher mortality but did not predict subsequent cognitive decline or dementia.

Bipolar Disorders Although bipolar disorders continue into late life, no cases of mania were observed in the ECA 1-month prevalence estimates. Epidemiological information is limited to clinical series assembled at major hospitals, which show that manic episodes can emerge for the first time in elderly persons, usually those who have had previous episodes of depression.

SUICIDE

Elderly men have consistently higher rates for suicide than those in other age groups, in marked contrast to attempted suicide, which has its highest rates in young women. In the United States in 1993, the suicide rate for all ages was 12.1 per 100,000; but it was 22.3 per 100,000 in those 75 to 84 years. Elderly white men had markedly higher suicide rates than elderly black men: 52.1 and 16.3 per 100,000, respectively, in 1993 for persons 75 to 84 years. By contrast, the rates for elderly white and elderly black women were only 6.1 and less than 1 per 100,000. Factors associated with death by suicide in the elderly include depressive disorder, disabling physical illness, chronic pain, and social isolation.

ANXIETY DISORDERS

Anxiety disorders in late life have been more overlooked than depression as a significant cause of morbidity. In the ECA studies the 1-month prevalence for anxiety disorders in persons aged 65 years and older was 5.5 percent (Table 51.1b-2), which is broadly similar to the prevalence in young adults and to estimates from other industrialized countries. By far the most common syndrome was phobia (4.8 percent); the rate for panic disorder was only 0.1 percent. Elderly women had somewhat higher rates than elderly men and those in all other age groups. In an integrative review of eight community-based surveys of persons aged 60 years and above, anxiety disorders had a lower prevalence than in younger adults. The explanation is unknown. Agoraphobia often occurred for the first time in late life, whereas most other anxiety disorders had either persisted from earlier years or had arisen alongside another psychiatric or medical disorder. Depression frequently accompanied generalized anxiety disorder or phobias, and the depression was usually inappropriately treated with a benzodiazepine. Anxiety symptoms may also occur in the early stages of dementia and in association with depressive disorders. Little information is available on the prevalence of posttraumatic stress disorder, risk factors for it, or its natural history in older persons. Obsessive-compulsive disorder is infrequent in elderly persons, as shown in the ECA data (Table 51.1b-2).

SOMATIZATION DISORDER AND ANTISOCIAL PERSONALITY DISORDER

In the ECA studies, all the observed cases of somatization disorder in any age group were in women. Antisocial personality disorder was strikingly rare in elderly persons and was not observed at all in elderly women. The rate for elderly men was one fifteenth of that for men aged 18 to 24 years. That difference could be attributed to a maturation effect, a cohort effect, or differential survival.

SCHIZOPHRENIA AND SCHIZOPHRENIFORM DISORDER

DSM-IV and ICD-10 recognize that schizophrenia can begin in later life and that a number of distinguishing features may be present: a higher ratio of women, a better occupational history, and a higher frequency of marriage than in younger patients, with sensory loss being more common in those with onset at a more advanced age. DSM-IV recognizes that delusional disorder generally has its onset in middle or late adult life. When both affective and schizophrenic symptoms are present, schizoaffective disorder may be diagnosed in both DSM-IV and ICD-10, but this disorder in elderly persons has not attracted much attention. DSM-IV provides a subcategory of dementia of the Alzheimer's type for presentations with delusions as the predominant feature. In the Scandinavian classification, emphasis is placed on paranoid states as a reaction to life events and interpersonal difficulties.

Information about the epidemiology of schizophrenia and schizophreniform disorder in late life comes from two sources: studies of persons who have reached psychiatric services and surveys of elderly persons sampled from the general population. A review of published data from both sources leads to a number of conclusions.

1. Functional psychotic disorders in elderly persons living in the community have lower base rates than the dementias.
2. The prevalence of schizophrenia in late life may be lower than the approximate value of 1 percent generally accepted for the general adult population. In the ECA studies the 1-month prevalence of schizophreniform disorder in elderly persons was 0 (Table 51.1b-2) as were estimates of lifetime prevalence. The latter observation is particularly puzzling, since the lifetime risk of schizophrenia is about 1 percent. One interpretation is that schizophrenia, including paranoid states, does occur in elderly persons (as every clinician knows), but it may often fall short of the third edition of DSM (DSM-III) and DSM-III-R criteria that were used in the epidemiological surveys. Selective mortality, remission of symptoms, or nonavailability of respondents could also explain this result. If there is indeed a lower prevalence in late life, the reasons need to be sought.
3. Among elderly persons, the prevalence of schizophrenia and delusional disorder probably increases with age.
4. Psychotic symptoms are appreciably more common than formal diagnostic categories.
5. In studies that provide separate rates, women have higher rates than men.
6. The reported prevalence rates are likely to be an underestimate due to underreporting and the possible overrepresentation of psychotic persons among those not interviewed.
7. In those studies that inquired about it, impaired hearing and vision were both associated with psychotic symptoms.
8. Where it has been assessed, social isolation is a further associated factor, but it is not known whether this is a premorbid characteristic, a causal factor, or a consequence.
9. Self-report of poor physical health is more common in the psychotic group.
10. Few studies have determined the proportion of persons with psychotic symptoms who were receiving health or social services. Although one might intuitively expect paranoid or deluded individuals to be less likely to come to the attention of or accept professional services, the findings suggest that such persons do not differ from others in their contact with services, at least in some communities.
11. Population-based surveys that assessed both psychotic symptoms and cognitive function consistently found paranoid or delusional symptoms to be more frequent in persons with cognitive impairment. Further, the well-established association between functional psychotic syndromes and dementia in clinical series may be the same association now reported in community samples, that is, paranoid symptoms and cognitive impairment occur together.
12. Field studies have not often implicated variables found to be relevant in clinical series. These include gender, marital status, number of offspring, social relationships, premorbid personality, physical health, impaired hearing or sight, stressful life events and long-standing difficulties, and a family history of mental disorders and mortality.

ALCOHOL AND OTHER SUBSTANCE-RELATED DISORDERS

The drinking habits and associated psychiatric diagnoses of elderly persons are only part of the overall picture. The ECA studies showed that alcohol abuse or dependence was clearly lower in the elderly than in any other age group and that the rate in elderly women was one sixth that in elderly men. Heavy alcohol intake can contribute to cognitive decline and dementia, possibly because of its effects on key forebrain nuclei. An epidemiological study in Liverpool, England, found a clear association between a past history of heavy drinking and the development of either dementia or a depressive disorder in late life. Insofar as alcohol abuse in early adulthood is a potentially modifiable risk factor, the implications for prevention are considerable.

Substance abuse occurs only rarely among elderly persons; indeed, it was absent in the ECA elderly sample. Such data do not include elderly persons who are dependent on prescribed medications, a group that is likely to be far from negligible in size.

SLEEP DISORDERS

Elderly persons are commonly believed to have more sleep problems than younger adults. Data to confirm or refute this are scanty. In a recent community survey of 1485 persons aged 50 to 93 years in the Netherlands, more women had subjective complaints of sleep difficulties, but more men complained of excessive daytime sleepiness. With increasing age, only two variables changed: more had difficulty getting to sleep and more time was spent in bed. The most commonly reported cause of initial insomnia was worrying and nocturia was the main cause of broken sleep. In the National Institute on Aging's Publication “Established Populations for Epidemiologic Studies of the Elderly” covering over 9000 persons aged 65 and over, less than one fifth had sleep problems only rarely, while over half had some regular difficulty. Sleep complaints were linked to respiratory symptoms, physical disabilities, use of nonprescription medication, symptoms of depression, and poor self-rated health. An Australian survey found a prevalence of persistent insomnia of 16 percent in an elderly community sample and 12 percent in nursing home residents. In the community sample, 14 percent were regularly taking a hypnotic drug, compared with 40 percent in the nursing homes. Of those without the complaint of insomnia, 10 percent in the community but over a third in institutions were using a hypnotic agent. Insomnia was again found to be associated with depression, pain, and poor physical health. These findings lead to two conclusions. First, persistent insomnia in the elderly population, as in other age groups, is strongly associated with depressed mood and physical disease. Because of this, insomnia should not be dismissed as a normal accompaniment of aging and thus be ignored as a significant symptom. Second, continued surveillance is needed in family practice, geriatric services, and nursing homes of the routine use of hypnotic drugs by elderly persons.

SERVICES FOR ELDERLY PERSONS

The extent to which elderly persons with mental disorders receive services can itself be examined epidemiologically. The notion of filters proposed by David Goldberg and Peter Huxley proves useful. The first filter determines which persons with mental disorders reach a physician, whether they initiate the consultation themselves or have it initiated by their families or the physician. The second filter determines whether the physician recognizes the significant mental disturbance. The third filter determines referral to a specialist or to specific services for the elderly population. Although family physicians recognize early dementia quite efficiently, they often require further training in the diagnosis of depressive disorders in elderly persons, in whom tiredness, poor appetite, insomnia, and apathy may be mistakenly ascribed to old age. The benefits of correct diagnosis for both the patient and the community are self-evident.

DISABILITY

From a public health perspective, information about elderly persons and the services they require must include an assessment of disability; impaired functioning in daily life, rather than symptoms or diagnosis, largely indicates the need for services. Dementia is second only to arthritis as a cause of disability in this population. Less is known about impaired functioning caused by depressive disorders and depressive symptoms, but since they often occur with physical disease, their interactive effect is considerable. A community-based study conducted by an experienced geriatrician found that neuropsychiatric disorders of cognition, behavior, and mood together with extrapyramidal gait disorders are major predictors of disability in late life. Somatic disorders have less impact.

SUGGESTED CROSS-REFERENCES

A general discussion of epidemiology appears in Section 5.1, of normal aging in Section 51.2c, of sociocultural sciences in Chapter 4.1, of dementia and delirium in Chapter 10, of mood disorders in Chapter 14, of suicide in Section 29.1, of anxiety disorders in Chapter 15, of personality disorders in Chapter 24, of schizophrenia in Chapter 12, of schizophreniform disorder in Section 13.1, of substance-related disorders in Chapter 11, and of sleep disorders in Chapter 21. Psychiatric disorders of late life are discussed in Section 51.3. Psychiatric Rating Scales are discussed in Section 7.8.

51.2 ASSESSMENT

51.2A PSYCHIATRIC EXAMINATION OF THE OLDER PATIENT

ELEANOR P. LAVRETSKY, M.D., PH.D. AND LISSY F. JARVIK, M.D., PH.D.

In general, the psychiatric evaluation of the elderly patient, whether in residential settings, institutions, or in the community, is similar to that of younger adults. The major principles remain the same, that is, establishing rapport, minimizing discomfort, maximizing privacy and confidentiality, and yet eliciting the information necessary to assess the patient's mental and physical status as well as pertinent psychosocial influences. The psychiatrist must go beyond the diagnostic assessment and consider the patient and the setting as a whole, evaluating the influence of internal and external destabilizing factors and assisting in the development of treatment plans as well as maintenance strategies.

When approaching the examination of the older patient, one must remember that older adults differ markedly from one another. Just as the approach to examining a child will take into account whether the child is 3 years old or 12 years old, so the approach to examining the older patient must take into account whether the person is a healthy 75-year-old who recently retired from a second career or a frail 96-year-old who just lost the only surviving relative with the death of the 75-year-old caregiving daughter.

METHODOLOGICAL ASPECTS OF INTERVIEWING OLDER PATIENTS

Assessment of the geriatric patient differs from that of younger adults primarily in regard to greater use of ancillary sources of information and greater attention to concomitant medical problems; prescription and over-the-counter medications; external destabilizing factors such as loss of family and friends (whether through death or relocation), socioeconomic losses, and recent changes in environment; cultural and religious influences; and sensory impairments, especially vision and hearing.

The psychiatrist needs to take a more active stance with geriatric patients than with younger patients, involving interaction with family and other caregivers, referral sources, social services, cultural and religious agencies, and outside hospitals and physicians. Also, the psychiatrist needs to schedule extra time for geriatric patients, since they have longer life histories, may be slower, may fatigue easily, and may be distracted by reminiscing. It is usually not possible, therefore, to complete the psychiatric evaluation of the geriatric patient in a single session; two or three sessions are often needed. Even that may not be sufficient in a slowly progressing disorder. For example, a patient with dementia of the Alzheimer's type may require several visits over a period of months to gauge progress before a diagnosis can be made.

While gathering information from informants other than the patient is always desirable, it may be mandatory with cognitively impaired patients. Often, one must consult more than one informant, and every effort should be made to get in touch with persons in close contact with the patient, be they family members, friends, or neighbors. Information from one or more independent sources intimately acquainted and in close contact with the patient is often vital not only when cognitive impairment is suspected, but also to corroborate changes in personality, mood, and activities of daily living. The reliability and validity of the information obtained from third parties should always be carefully assessed. Psychiatrists need to consider how well informed third parties are and what biases they may have that either favorably or unfavorably distort the information about the patient.

The psychiatrist must see the patient alone, even if there is clear evidence of cognitive impairment. Our recommendation is that the psychiatrist divide the first visit into the following four segments.

Interview With the Patient Alone Interviewing the patient alone shows clearly that the patient is the key individual, that the psychiatrist attaches importance to the doctor-patient relationship, and that the psychiatrist wants to hear what the patient has to say, and it provides the privacy necessary for patients to express opinions freely and provide data that they are not ready to share with family members or other third parties. Information concerning undesirable behavior of significant others may not be elicited in their presence or the presence of someone who might communicate it to them, especially if the patient depends upon them and fears reprisal. Patients may also minimize depressive symptoms and suicidal thoughts in the presence of others because of shame, embarrassment, or fear of burdening the family. The same applies to paranoid ideation, especially if it involves family members or others significant in the patient's daily life.

When interviewing elderly patients one must determine whether they understand the nature and purpose of the examination. One can make sure that perceptual changes are not severe enough to preclude the patient's understanding, for example, by sitting close, selecting the side of the patient's good ear, talking slowly and loudly without shouting, procuring hearing aid devices, providing ample time for responses, and, if there is any doubt, having the patient repeat the question. Writing key words in large print and showing them to the hearing-impaired patient may be valuable.

As with middle-aged and younger adults, one must pay attention to culturally derived attitudes toward psychiatry and toward symptoms of mental illness and their expression. Many elderly patients are reluctant to see a psychiatrist because they fear they will be labeled “crazy.” Stress interviews are rarely indicated in the geriatric patient, and the same is true of direct confrontation. Geriatric patients tend to withdraw and discontinue treatment rather than being stimulated to explore feelings aroused by a challenging or probing confrontation. For example, cognitively impaired patients, aware of their deficits, may refuse to cooperate and thus prevent full evaluation if their deficits are clearly exposed, especially in the presence of others. Indirect assessment may yield far richer data.

Family or Significant Others Without the Patient The psychiatrist then tells the patient that the others will now be seen in private and then the patient will be called back in. The absence of the patient makes it easier to explore subtle signs of cognitive impairment and paranoid ideation as well as course of illness. The psychiatrist must not reveal information received from the patient to the family or others unless authorized by the patient to do so, but without revealing any particulars, information obtained from the patient can be verified or refuted by the family. However, the psychiatrist must always bear in mind that even the cognitively impaired patient's account may be the correct one, not the relatives' account. Talking with the family members will help the psychiatrist ascertain if the patient is being scapegoated, neglected, or abused, or became the identified patient for reasons of family dynamics rather than patient psychopathology. The frail elderly patient often depends on the family, just as the frail young child does and the psychiatrist needs to be as alert to elder abuse as to child abuse.

Growing numbers of elderly adults are residing in retirement hotels, board and care homes, or nursing care facilities, depending on their level of functioning and type of impairment. The transition from independent living in their own apartments or homes or living with family members to such other facilities is a significant source of stress and tends to create intrafamily conflicts. Sometimes adult children decide on the move without the patient's full involvement or even awareness. Subsequently, a wide range of negative emotional reactions can be seen in both the patient and the family. Patients feel rejected, abandoned, manipulated, and taken advantage of by the family, become angry, and blame the family for their declining health and depression. Even if there were no other options, family members frequently feel guilty, helpless, frustrated, or angry for having made this decision, and they can turn their anger and frustration against the patient as well as against treating physicians and facility administrators, demanding better care no matter how good the care is. Many of these processes tend to be revealed in separate sessions with the patient and family.

Patient With the Family or Significant Others The patient returns for the third portion of the session, and the psychiatrist gets an opportunity to gauge both the interaction between family members in the presence of the patient and the interaction between the patient and the others. Further, the psychiatrist can discuss issues about which contradictory information was given, always respecting confidentiality. Thus, for example, disagreement over driving (e.g., patient insists on driving

despite poor eyesight or tendency to get lost) can be elicited, and the psychiatrist can get an idea of the family dynamics and approach a realistic estimate of the disputed facts.

Patient Alone Again During the fourth and last portion of the session, the patient is again seen alone. The psychiatrist can now reevaluate the patient in light of the additional information obtained, and the patient has another opportunity to bring up matters of concern and to clarify interactions that took place with the others. Also, both patient and family can see that the attention has been focused on the patient. (Depending on the particular family situation, subsequent visits may have to focus on one or more family members or the family as a unit; however, this should not be done in a way that excludes or neglects the patient.)

Many geriatric patients are plagued by the fear of going crazy and will ask the psychiatrist at the end of the visit, “Am I losing my mind?” or some variant thereof. Instead of bland denial (which the psychiatrist may mistakenly consider reassurance), these patients need an opportunity to describe what they mean by going crazy and what leads them to believe that it may happening to them. Although the geriatric patient may not always find consolation in the distinction, “It is not your age, it is your hypertension that's slowing you down,” there are clear differences in potential treatment strategies. Treatment of hypertension or diabetes may indeed improve mental functioning. Symptomatic treatment can restore the individual to a prior level of functioning—physiological, psychomotor, social, and occupational. If the psychiatrist adopts an optimistic stance, it will encourage the patient and the family and will help maintain rapport and further the therapeutic relationship. At the same time, one must consider the patient's mood and outlook and be realistic in treatment outcome expectations. A profoundly depressed 85-year-old person with feelings of hopelessness and helplessness is likely to perceive exuberant optimism and anticipation of a quick cure as a lack of understanding and professional skill. Regardless of the patient's age, the skilled psychiatrist treads a thin line between reasonable expectations based on realistic assessment and the detrimental effects of dashing the patient's hopes in the mistaken belief that brutal bluntness is the only honest way.

HISTORY

The psychiatric history includes the identifying data (i.e., name, age, sex, marital status); chief complaint; history of present illness; past psychiatric problems; family, medical, and psychosocial history; and information about the patient's habits, particularly any substance abuse or medication misuse.

History of Present Illness The history of present illness usually includes a description of the temporal sequence of symptom development, the relation to daily activities, medication usage, and treatment outcome. The accepted teaching that the history is the most important element in the diagnosis and that “unless you think of it first, you won't get the information” is as true in elderly patients as in younger ones. One should know about differences in presenting symptoms between old and young patients; for example in depression, somatization tends to be more common in older patients and expressed feelings of guilt and self-reproach more frequent in the young.

The psychiatrist must also realize that many older patients may have adjusted to a variety of symptoms, learned to tolerate them, and even accept them as part of ordinary existence, so that they may not consider them important enough to mention. This applies to both psychiatric and somatic symptoms. They may also dismiss somatic symptoms, such as insomnia, anorexia, and general malaise as part of normal aging. Finally, medications may have become so routine that they are not mentioned (e.g., thyroid preparations that patients have taken for decades).

The contribution of life events to disease development needs to be carefully examined. At a time when the body's adaptive physiology, immune system, and other host defenses are compromised by the ravages of old age, life stresses such as loss of family and friends, loss of income, and loss of status and social supports tend to mount. Death of a spouse is considered one of the highest stressors, and clinical experience suggests that death of an adult child is among the most stressful events for older patients; parents do not expect to outlive their children. Minor stresses (e.g., a change in daily routine) may contribute to the decompensation of the fragile stability of geriatric patients.

The older patient is clearly more vulnerable than the younger adult to the stress of hospital admission. Thus, delirium is a frequent complication in elderly individuals but not in younger adults. In a prospective study of the adverse consequences of hospitalization, 30 percent of those over age 70 (vs. 3.6 percent of those under age 70) exhibited confusion within 6 weeks of their admission to general medical wards. Reports from psychiatric wards have given frequencies of delirium between 10 and 40 percent. The mnemonic *sundowners* summarizes the risk factors for delirium: *s*ick, *u*rinary retention/fecal impaction, *n*ew environment, *d*emented, *o*ld, *w*rithing in pain, *n*ot adequately evaluated, *e*yes and ears, *r*x–therapeutic drug intoxication, *s*leep deprived.

In frail elderly individuals, transition from home to an institution may become life's last tragedy. Careful interview reveals what kind of losses and stresses this change of environment brings to the older patient: loss of independence (the most frequent complaint); feeling unnatural among only old and sick people; being constantly reminded about upcoming death; humiliation of being treated by staff as a kid or a demented person; and giving up driving.

In some institutions elderly persons with different levels of functioning reside in close proximity to each other. For example, when board and care and nursing homes (usually owned by the same agency) are located on the same premises and use the same dining and activities rooms, multiple daily contacts are the rule. In this situation, many high-functioning individuals feel depressed, frightened, and overwhelmed by constant interaction with those who are severely impaired mentally or physically, moribund, or bemoaning their fate. Understanding such stresses may help one uncover the source of depressive symptoms and lead to improved treatment.

Past Psychiatric History Psychiatric history should include careful documentation of dates as well as description of specific psychiatric symptoms, details of treatment modalities (e.g., names and dosages of drugs; bilateral or unilateral, as well as number of electroconvulsive treatments [ECTs]), treatment outcomes, remissions, and exacerbations. Often, documentation is unavailable because old records have been destroyed or lost, and the psychiatrist may have to resort to best guesses.

Personal and Psychosocial History As in the middle-aged and younger adult, the personal history indicates the level of premorbid functioning and provides clues to the patient's coping strategies. Knowing premorbid personality characteristics may clarify current psychopathological symptoms. The stability of personality throughout life remains controversial. Some assert that personality does not change with age, although certain traits may become exaggerated. Thus, the well-adjusted, assertive, liberal 30-year-old is likely to turn into the well-adjusted, assertive, radical, 80-year-old, with Benjamin Spock the prototypical example. The hostile, unfriendly 30-year-old may become the even more hostile, crotchety, misanthropic 80-year-old. Above all, the psychiatrist needs to appreciate the range of individual differences, which generally increases in old age.

The personal history may also indicate how the patient is likely to adapt to certain losses. For example, energetic, independent, ambitious individuals may find it more difficult to accept physical limitation and dependency than their dependent, relaxed, leisure-oriented, age-matched peers. Early life history and developmental data may shed light on the patient's interpersonal relations when they must depend upon others, particularly at a time of life when dependence upon others looms large again. Religion is often of major importance to older patients, and religious beliefs may contribute to the patient's ongoing problems or ameliorate them.

Sexual History The geriatric patient usually has been married and, if a man, likely is married. Psychiatrists are often reluctant to take a sexual history from a geriatric patient because they identify the patient with a parent or a grandparent or they subscribe to the popular stereotype of old persons as asexual. The geriatric patient, however, may be eager to discuss sexual dysfunctions (e.g., increased time needed to achieve erection or ability to achieve only partial erection in the man, physical discomfort due to vaginitis in the woman, performance anxiety in the newly remarried man, inability to satisfy sexual urges in the widow without a sexual partner, extramarital activity in the spouse of a demented or physically incapacitated patient). At times new onset of neurosis in old age may result. Even though sexual history needs to be taken in the privacy of the doctor-patient dyad, information from significant others is also needed, not only for corroboration of the patient's report but also because they reveal, for example, extramarital affairs or aberrant sexual interests and activities (e.g., paraphilias) that the patient failed to mention. The inquiry may also open subjects for discussion by family members who were reluctant to bring them up, whether in the realm of physiological, psychological, or social functioning. Many children, for example, find it unacceptable when their parent has affairs or when the 83-year-old mother decides to move in with her male friend of many years' standing—without benefit of marriage. A decision to get married may carry equal disapproval!

Family History The older the patient, the more difficult it is to verify the family history unless such documents as family bibles, diaries, and other vital records are available. Patients are usually the oldest surviving family members, so there is no one in their own or preceding generations who can contribute. Succeeding generations are generally not well informed about their ancestors, unless someone has taken a special interest in the family history. Clearly, family history is important in genetic disorders such as Alzheimer's, Creutzfeldt-Jakob, Gerstmann-Straussler-Scheinker, Huntington's, and Pick's diseases. Elderly persons are at high risk for suicide, especially white men, but information is inadequate to assess the importance of prior suicides in the family.

Medical History Elderly patients have more concomitant chronic and multiple medical problems and take more medications than younger adults; many of these medications can influence their mental status. The past medical history includes all major illnesses, traumata, hospitalizations, and treatment interventions. The psychiatrist should also be alert to underlying medical illness. Infections, metabolic and electrolyte disturbances, and myocardial infarction and stroke may first be manifested by psychiatric symptoms. Depressed mood, delusions, and hallucinations may precede other symptoms of Parkinson's disease by many months. On the other hand, psychiatric disorder can also be the cause of such somatic symptoms as weight loss, malnutrition, and inanition of severe depression.

Careful review of medications (including over-the-counter medications, laxatives, vitamins, tonics, and lotions) and even substances recently discontinued is extremely important. Drug effects may be long lasting and may induce depression (e.g., antihypertensives), cognitive impairment (e.g., sedatives), delirium (e.g., anticholinergics), or seizures (e.g., neuroleptics). Review of medications must include sufficient detail to identify misuse (overuse, underuse) and relate medication use to special diets. A dietary history is also important; deficiencies and excesses (e.g., protein, vitamins) may influence physiological function and mental status.

History of Alcohol and Substance Use and Abuse One must inquire into alcohol and substance use and abuse. Geriatric patients—even women in their 70s and 80s who only used alcohol socially throughout life—may develop serious alcohol problems in old age. Lifelong alcohol abusers and those who stopped or markedly decreased their alcohol intake before age 65 may exhibit residual physical complications from their past alcoholism. Data on substances other than alcohol are notably absent. Some prescription medications (e.g., benzodiazepines, other sedatives and hypnotics) are often misused and overused by geriatric patients who come to clinical attention.

MENTAL STATUS EXAMINATION

The goal of the mental status examination is to obtain precise, detailed information about the patient's functioning—how the patient behaves, feels, and thinks. Geriatric patients may require serial mental status examinations to evaluate fluctuating and changing behavior, mood, and ideation.

General Description General observations of the geriatric patient are those used with patients of any age, that is, appearance, behavior, functioning, motor activity, speech, and attitude toward the examination and the examiner.

Appearance Caution is indicated with regard to appearance. The disheveled, cachectic, unkempt patient, smelling of urine, is readily diagnosed as demented, while the well-groomed, poised, quiet patient is readily categorized as depressed. In actuality, the situation is often the reverse, the appearance of the demented patient being the product of loving care bestowed by a relative or other concerned caregiver. One must also note the presence and absence of hearing aids and corrective lenses to ascertain to what extent the patient suffers from one or more of the sensory deficits so common in old age.

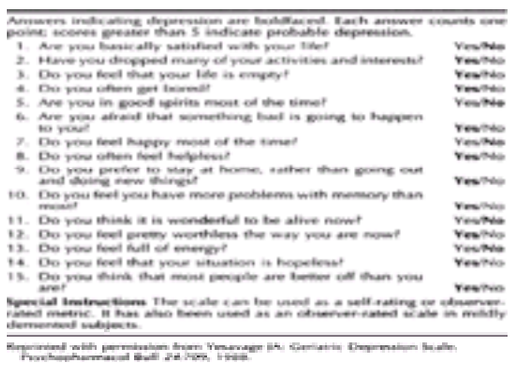
Behavior The patient's attitude toward the examiner (e.g., cooperative, attentive, interested, guarded, suspicious, defensive, apathetic, withdrawn) needs to be documented. Disturbances of motor activity should be described (e.g., body asymmetry, unsteady gait, retarded movements, stooped posture, hyperactivity, mannerisms, combativeness, tremor, involuntary movements of the mouth and tongue). Many depressed, apathetic, and demented patients may exhibit slow movements and speech. Masklike facies, resting tremor, and pill-rolling movements may indicate Parkinson's disease or adverse effects of neuroleptics.

Speech and Language Quality, quantity, and fluency of speech need to be recorded. Speech may be described as normally responsive, rapid, pressured, loud, or emotional; it can be slow, monotonous, unspontaneous, slurred, or mumbled. Mutism, excessive latency of response, paucity of speech, anomia, agrammatism, and paraphasic errors are all important symptoms for diagnostic assessment.

A patient's language reflects thought processes and may reveal verbal perseveration, circumstantiality, loosening of associations, and other disturbances. Different types of aphasia, often seen in elderly patients with a history of strokes, may lead to the mistaken classification of the aphasic patient as demented and should always be taken into consideration.

Mood and Affect Elderly patients are generally less psychologically minded than younger adults and experience greater difficulty in describing their mood and affect. Repeated inquiries about mood are often appropriate, since denial and suppression of affect are prevalent in geriatric depressed patients, who may say, “I don't feel sad, I'm not down” as they cry. Some patients who deny experiencing sadness and depressed mood do describe the somatic and vegetative symptoms of depression (i.e., significant changes in appetite and weight, insomnia or hypersomnia, fatigue, and diurnal variations in general well-being) and lack interest in family affairs and wordly events. Somatization is common, for example, in the patient who attributes to abdominal pain all somatic and dysphoric symptoms: “If only you could help me with my abdominal pain, or my back pain, or... I would be perfectly well and have no problems.”

Some standardized scales may be helpful in documenting the symptoms of depression and estimating severity (e.g., Hamilton Depression Scale or Geriatric Depression Scale [Table 51.2a-1]). The psychiatrist should ask the patient directly about suicidal ideas—passive death wishes—and then about intent, plans, and definite methods. Past suicide attempts increase the risk of a new and successful suicide attempt.



Answers indicating depression are boldfaced. Each answer counts one point; scores greater than 5 indicate probable depression.

1. Are you basically satisfied with your life? **Yes**/**No**
2. Have you dropped many of your activities and interests? **Yes**/**No**
3. Do you feel that your life is empty? **Yes**/**No**
4. Do you often get bored? **Yes**/**No**
5. Are you in good spirits most of the time? **Yes**/**No**
6. Are you afraid that something bad is going to happen to you? **Yes**/**No**
7. Do you feel happy most of the time? **Yes**/**No**
8. Do you often feel helpless? **Yes**/**No**
9. Do you prefer to stay at home, rather than going out and doing new things? **Yes**/**No**
10. Do you feel you have more problems with memory than most? **Yes**/**No**
11. Do you think it is wonderful to be alive now? **Yes**/**No**
12. Do you feel pretty worthless the way you are now? **Yes**/**No**
13. Do you feel full of energy? **Yes**/**No**
14. Do you feel that your situation is hopeless? **Yes**/**No**
15. Do you think that most people are better off than you are? **Yes**/**No**

Special Instructions The scale can be used as a self-rating or observer-rated metric. It has also been used as an observer-rated scale in mildly demented subjects.

Table 51.2a-1 Geriatric Depression Scale (Short Version)

The examiner must record the predominant affect during the interview. An incongruous, labile affect that changes readily from laughing to crying may indicate cerebrovascular disease, vascular dementia, or other brain damage.

Perception Hallucinations vary from simple and unformed to highly complex and organized. They may be transitory and associated with vision and hearing impairment in the elderly patient. They also often occur in patients with organic mental disorder and may be associated with alterations of consciousness, disorientation, or confusion. Some hallucinations indicate focal brain or peripheral perceptual organ pathology, and their appropriate description may lead to an accurate diagnosis. For example, focal lesions in the visual pathway are often associated with release visual hallucinations, complex formed images that tend to occur in the area of field deficit.

Other types of perceptual impairment that may be found in older patients with organic brain disorders include visual agnosia (inability to recognize visible objects); prosopagnosia (inability to recognize familiar faces); astereognosis (inability to recognize objects by touch); autotopagnosia (inability to recognize parts of one's own body); micropsia (objects seem smaller than their real size), or macropsia (objects seem larger than their real size).

Thought Process and Content As with younger patients, this section of the examination deals with the logic and coherence of thought processes. Can the patient understand and answer questions appropriately? Is thinking concrete and literal? What are the patient's preoccupations or obsessions? In depressed elderly patients preoccupation with health problems often replaces the complaint of depressed mood.

The content of any delusions should be described in detail, and whenever possible, in the patient's own words. Are they persecutory, guilty, nihilistic, somatic, erotic,

grandiose? Are they bizarre and diffuse or focused on the immediate environment? Are they stable or transient? What is their impact on the patient's life?

Elderly individuals often display significant suspiciousness. They become concerned about external forces or individuals controlling their lives. These concerns may be diffuse or (more often) focus upon a limited number of targets, usually persons in the patient's closest environment—children, other relatives, neighbors, landlords. Ideas that things are being stolen are very common and are generally interpreted as a response to the losses accompanying old age, when beauty, youth, health, and vigor are indeed being stolen. Sometimes, however, these ideas reflect reality rather than delusional thinking, and clothing, jewelry, or cash have actually been stolen.

Hypochondrial delusions often center around the functions of the bowel or brain. Patients may believe that their bowels are paralyzed or completely destroyed so they cannot digest any food. Use of rating scales (e.g., University of Washington Paranoia Scale) may help define the range and severity of the delusional disorder.

Sensorium and Cognition Because of the wide prevalence of memory and cognitive impairment, this part of the mental status examination is specially important with geriatric patients. The psychiatrist can learn a lot about the patient's cognitive functioning throughout the entire interview. Careful listening and asking specific questions should enable the psychiatrist to comment on level of alertness and consciousness, attention and concentration, orientation, memory (recent, remote), language (spontaneous, naming, comprehension), constructional abilities and praxis, and frontal lobe tasks.

Impaired consciousness needs to be assessed first, since it may preclude obtaining other information. Alterations of consciousness are characteristic of organic mental disorder in elderly persons; patients are not alert, display fluctuations in level of awareness, and are somnolent or lethargic. Disorientation to time, place, person, and situation may be present in patients with impairment of consciousness but also may occur in those with cognitive deficits without impaired consciousness.

Memory—immediate, recent, and remote—is evaluated by asking the patient about recent and past life events and by administering special tests. A popular way to test immediate recall is to give the patient three items or six digits to repeat forward and backward. Errors can reflect attentional or memory deficits. Impaired performance may occur with depression, anxiety, and agitation. Patients with attentional disorders also perform poorly in tests of verbal fluency. For example, they enumerate only a few items when asked to name everything that can be found in a supermarket or as many words as they can think of beginning with the letter ‘K'.

Recent memory, the ability to learn and recall new information; may be elicited in various ways. One might ask patients to repeat the three items they were told to remember 5 minutes earlier or to repeat a short story told 5 to 10 minutes earlier. Orientation to time and place and questions about events of that morning or the day before help to explore recent memory; it tends to deteriorate early in Alzheimer's disease and other dementing processes. Confabulations may also be revealed during such testing. Remote memory can be tested by asking about significant events in the patient's life (e.g., birthdates of children, years of graduation from school, date of retirement) or well-known historical events (e.g., wars, holidays). One must keep in mind the premorbid state of this individual's memory, and cross-checking information is advised. Age-related changes may also impair memory, but cross-sectional and longitudinal studies have shown that such decline in memory, learning, and problem solving is not substantial for groups of normal individuals until they are well past their 70s.

When testing intellectual functioning and general knowledge, educational level and social status are considered. Vocabulary, complexity of concepts that the patient uses, knowledge of current political, sporting, and cultural events, as well as names of the president, vice president, and governor may provide a preliminary estimate of cognitive functions. Testing reading and writing abilities and clock drawing may also reveal memory and speech deficits.

Constructional ability can be tested by asking the patient to draw or copy a circle, a cross, a cube, a clock, or other two- or three-dimensional figures. Praxis is tested by asking the patient to perform volitional actions on command; for example, “with your right hand show me how you would comb your hair,” “drink through a straw,” “hammer a nail,” “stand as a boxer.”

The Mini-Mental State Examination (MMSE) is a simple tool for general assessment of cognitive functions. Other standardized scales currently used in evaluating geriatric patients include the Blessed Dementia Index, the Progressive Deterioration Scale (PDS), and the Alzheimer's Disease Assessment Scale (ADAS) (Table 51.2a-2).

Table 51.2a-2 The Alzheimer's Disease Assessment Scale (ADAS)

Frontal system tasks are used to reveal frontal lobe dysfunction. The frontal lobes are involved in recruiting and engaging attention, inhibiting inappropriate behavior, and initiating, sequencing, and planning complex behaviors. Disturbance of attention and initiation and apathy and withdrawal may be found in patients with lesions of the frontal lobe. Disinhibition of aggression and sexuality, impairment of planning functions, and concreteness are characteristic of patients with lesions in orbital areas of the frontal lobe. Tests for perseveration (the pathological repetition of speech, actions) and concrete thinking (e.g., similarities, metaphorical speech, proverbs) are often used to reveal frontal lobe dysfunction.

Insight and Judgment The ability of patients to understand the situation (e.g., their own disease, its causes and symptoms, and reasons for examination) can clarify their level of insight. Judgment includes the ability to act appropriately, in accordance with a given situation. It can be assessed by asking about the patient's proposed action in a specific hypothetical situation.

Functional Assessment Functional status is an important part of assessment in geriatric psychiatry. It includes characteristics of everyday behavior and activities in the community and at home. Assessing how well an elderly person maintains independence and performs activities such as dressing, grooming, eating, toileting, and preparing food, enhances the psychiatrist's knowledge of the patient's competence in dealing with the tasks of daily life.

Table 51.2a-3 lists characteristics of physical and instrumental activities of daily living. This scale typifies those now widely used in geriatric psychiatry for functional assessment of the elderly patient. It may be completed by caregivers even before the formal interview, to give important information about the level of the patient's functioning. Later corroborative evidence from the patient, and if indicated, from others, then allows psychiatrists to form their own judgment.

Table 51.2a-3 Functional Assessment

Competence The assessment of competence stands in close relationship to the mental status examination. Can the patient give consent for medical treatment, give power of attorney, sign or change a will, manage personal finances? Information gained throughout the interview should help the psychiatrist to answer these questions. Is the patient aware of the illness and the need for treatment? How much does the patient's memory impairment interfere with the ability to remember financial transactions? Is judgment so impaired that the patient's finances are in jeopardy? Such issues may assume substantial legal importance and may be why a psychiatric evaluation of the older person was requested.

SUMMARY, DIAGNOSIS, RECOMMENDATIONS

The psychiatric examination concludes with a short summary of the major findings and differential diagnostic considerations. These data yield the rationale for the initial diagnosis and recommended treatment strategies.

Mr. S. is an 89-year-old white, retired businessman, married, living with his 90-year-old wife in a board and care home located in a well-designed and well-equipped retirement complex that holds several board and care and nursing homes on the same park territory. Mr. S. was referred for psychiatric evaluation for symptoms of depression, social isolation, disinterest in his usual activities, and poor sleep and appetite.

Mr. S. has no previous psychiatric history. He is described by his family as an active, enthusiastic, and warm person. He moved to this retirement complex approximately 7 months prior to his first clinic appointment from his own condominium, where he and his wife had been residing for 20 years. Serious damage to the condominium building from the 1994 Northridge earthquake had necessitated having all residents move elsewhere for 1 to 2 years during reconstruction. The couple's four children decided that placement in a comfortable retirement setting with medical and nursing care available would be better for their parents than relocation to a new rented apartment. Their decision was based on their parent's advanced age, their mother's declining physical health and memory, and their father's inability to take care of his wife and household. The patient initially resisted his children's recommendation, but his wife agreed, and finally he too decided to accept it. Mr. S. and his wife moved into separate rooms on the same floor, at the patient's request. They had always had different interests; his wife would spend many hours a day watching TV or talking on the phone to her friends, and he preferred to work on his computer or write notes for his autobiography, which he has been planning for many years. He felt they both would be most comfortable to be next to each other but in separate rooms.

One month after they moved to the complex, Mr. S. became depressed. He ruminated about the “mistake I made by moving to an institution,” which entailed loss of his condominium, financial independence, car, activities in clubs and volunteer organizations, and daily meetings with friends. More important, he lost self-respect; he felt that from now on he would be treated as an “institutionalized,” potentially demented person, dependent on the board and care staff for care and decision making. He felt “unnatural” being among only elderly people, many of whom were ill, with impaired mobility and cognition. This forced him to acknowledge his own age and the possibility of similar impairments and death in the near future. He was angry with his children who, he felt, had used his wife's declining intellectual capacity to force him to move here. His children were unwilling to discuss an alternative living situation, such as an apartment with a 24-hour caregiver for his wife.

Mr. S. described the situation: “I stayed in my room, trying to work on my computer and write, but I could not concentrate or enjoy it. I no longer was interested in doing volunteer work. I couldn't sleep and began losing weight (18 pounds by the time of his first appointment, from an initial weight of 168 pounds). Finally, I decided to kill myself. It was a difficult decision. I have a big family: 4 children, 13 grandchildren, and 12 great-grandchildren. I knew that my suicide would be a tragic blow to my family. I struggled with this decision, constantly reviewing in my mind all the pros and cons. I decided that I had only two options: death or long-lasting suffering.”

Mr. S. worked out a plan. He invited all his family for a four-day cruise. He would see and hug them all for the last time and, upon return, would obtain a gun and shoot himself. He made necessary preparations, paid all the family's cruise expenses, and wrote letters or called his grandchildren living out of state to invite them for this “good-bye trip.” Everybody came. He almost revealed his plan to one of his grandsons who always was close to him and seemed to understand him better than others. This grandson shared his concern about his grandfather's depression and possible suicidal thoughts with two of Mr. S.'s children. However, it was not taken seriously.

After the trip the patient became even more depressed, isolating himself in his room and avoiding any activities. During his regular meeting with the social worker he was tearful, unable to discuss any issues. At this time he was referred for psychiatric consultation.

Mr. S. had never before visited a psychiatrist. He always was very active, enthusiastic, productive in his business, warm with his family and friends. In the last 15 to 20 years he had had difficulty sleeping but refused to take any medications and preferred to work on his computer several hours every night until he felt tired and able to fall asleep.

History of psychiatric disorder in the family included reports of depression in one of the patient's brothers and some emotional instability and increased level of anxiety in two of his grandsons.

Prior surgical history included an appendectomy at age 21 and hernia repair at age 29. Medical history included pneumonia at age 65 and a recent diagnosis of degenerative disease of the lower spine. The patient has partial vision loss. He takes aspirin (81 mg once a day) for cardiovascular prophylaxis. He takes Tylenol (65 mg once or twice a day as needed) for back pain and headaches. The patient denied any history of substance abuse. He drinks wine socially, one to two drinks every 2 or 3 weeks. He never smoked.

Mr. S. was born and raised in Chicago, the youngest of three brothers. His father died of heart disease at age 78 and his mother of cancer at age 83. One brother died of brain tumor at age 69, and one brother is still alive. After graduating from high school, Mr. S. worked for a management company in Chicago. He married his current wife at age 27 and moved to Los Angeles, where he started his own business managing office buildings. He was relatively successful and financially independent. The couple had two sons and two daughters, all college educated. According to Mr. S. and his children, the marriage was not a very happy one, but the couple never considered divorce. They had close relationships with their children, grandchildren, and great-grandchildren, many of whom they supported financially, even recently. Mr. S. enjoyed his club memberships, activities in charitable organizations, and his many friends.

MENTAL STATUS EXAMINATION

Appearance. The patient was an 89-year-old man, neatly and casually dressed, with a sad facial expression and minimal body movements.

Behavior. Eye contact was poor, as patient primarily stared at his hands or shoes. Although he initially resisted discussing his “private and difficult situation which nobody can understand or change,” he became more open and talkative as the interview progressed, seeking understanding of his position and decision.

Speech. Was soft and slow initially, but toward the end it reached almost normal volume and speed.

Mood. Mr. S. was depressed and stated “I've lived enough.” He did not want to become demented and sick before dying of natural causes; he wanted to make his own decisions. He felt that his life had become meaningless and his days “long and empty” since moving to his current residence. He had lost his interests and had no energy to get up in the morning or eat. He showed his “good-bye” note: “Last year has been too hard for me. I had enough. I love you all.” He revealed his suicide plan. Hamilton Rating Scale for Depression score was 33, which indicates serious depression.

Affect. Had decreased range.

Neurovegetative symptoms. Mr. S. had no energy to get up in the morning or to eat. He complained of slowed thinking and poor concentration. His movements were slowed.

Perceptual disturbances. Mr. S. denied auditory, visual, and other hallucinations. He said he felt detached from his environment, which had become less bright and real for him.

Thought processes. Were logical and goal directed. He complained that his thoughts were slow and that it was “hard to think.”

Thought content. Mr. S. had active suicidal ideation, with a specific plan for killing himself. He denied delusions or homicidal ideation. He was focused on the change in his living situation, his current dependence on other people's decisions, and control by the “institution's rules and regulations.” He was distressed by changes in his sleeping and eating routines imposed by the retirement home—such as rising at 6 AM to be ready for breakfast at 7—as well as by his association at mealtimes with other residents whom he did not know, many of whom were cognitively impaired. “It is what I am going to be soon, if I survive.”

Sensorium. The patient was alert and oriented to time, place, and person.

Attention. He repeated five of six digits forward and four backward and performed serial 7's with one error.

Memory. The patient's memory was not significantly impaired. He had some difficulties with concentration and learning new material. However, he did remember most important dates of his life; names of his grandchildren and great-grandchildren; their education, occupations, and achievements; names of his recent doctors; and his family's visits. He recalled all three objects after 1 and 5 minutes.

Abstract thinking. He had good abstract thinking. He had no difficulty explaining similarities or proverbs.

Knowledge and intelligence. The patient had a good fund of knowledge. His Mini-Mental State Examination score was 29/30; he made one mistake in serial 7s.

Learning. The patient was able to learn 4 of 10 words after the first and second trials, 6 words after three trials, and 7 after four trials.

Insight and judgment. Were fair. The patient believed he had no mental problems that could be treated and that he had reason to be depressed secondary to multiple losses and complete change in his life. He did not realize his growing limitations and stated that he could still drive a car (even with his impaired vision), live with his wife in an apartment, and take care of her with help of a part-time housekeeper (which was not realistic in light of his physical limitations). However, he was interested in finding out if there was something that could help him with his depressed mood and constant thinking about suicide (note the contradiction with his statement that he had no mental problems to be treated).

Impulse control. Was preserved despite intrusive suicidal thoughts. He could continuously control them, trying to find solutions, talking to his children, and viewing different perspectives.

FUNCTIONAL ASSESSMENT

The patient remained independent in most activities of daily living. His limitations in driving and reading were related to declining vision. Difficulties lifting were due to frequent back pain. Loss of interests and energy were due to depression. There was no change in physical self-maintenance scale (Table 51.2a-3).

Physical examination and laboratory tests revealed only mild benign prostate hypertrophy, degenerative joint disease in the lower spine; impaired vision; and increased concentrations of cholesterol (248), low-density lipoprotein (LDL, 212) and high-density lipoprotein (HDL, 33).

Discussion This 89-year-old patient with no prior psychiatric history meets fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) criteria for major depressive disorder with approximately 5-month history of increasingly depressed mood; loss of interest and pleasure in usual activities; feelings of hopelessness and helplessness; and serious suicidal ideation and plans; as well as low energy, insomnia, poor appetite, and weight loss. An interesting feature of this depression is that it developed late in life and was precipitated by placement at a board and care facility, which the patient considered a dramatic loss of the major values of his life—independence, control, self-respect, and the ability to be productive and give help rather than to get it from others.

This patient did not have significant cognitive deficits or medical problems, which ruled out such diagnoses as dementia with mood disorder or mood disorder due to medical condition. Differential diagnosis includes adjustment disorder with depressed mood.

WORKING DIAGNOSIS

Axis I Major depressive disorder, single episode, severe, without psychotic features

Axis II None

Axis III Medical; benign prostatic hypertrophy, degenerative spine disease

Axis IV Severe psychosocial and environmental problems; change of environment due to institutional placement

Axis V Global assessment of functioning, 23; last year, 75

TREATMENT AND OUTCOME

The patient was initially seen daily to ensure his safety. A combination of medication and psychotherapy (individual and family therapy) was used to treat this patient, with the patient confirming that he would not attempt suicide. Treatment was started with paroxetine (Paxil) for depression (10 mg a day; after 3 days the dosage was increased to 20 mg a day) and zolpidem (Ambien) 5 mg at bedtime for insomnia with difficulty initiating sleep. Sessions with the patient alone, family alone, and patient with family helped to educate them about depressive disorders, suicide, current concepts, and treatments and to clarify family behavior that made Mr. S. believe that he was “forced, placed” without consulting with him.

As a result, the patient was given the right to reconsider his current living situation, see other places, including separate apartments with assisted living, and make his own choice. The patient's children took him to these places, discussed with him all pros and cons, and explained their reasons for believing that the current living arrangement was the best for both him and his wife. He was given time and responsibility for making the final decision. The patient finally concluded that he could not find a better choice and decided to stay with the current arrangement. His depression gradually resolved; he became more active and joined volunteer organizations in his retirement complex. He remained on maintenance treatment with paroxetine (20 mg a day) for approximately 6 months, then he was weaned from this medication. At 5-months follow-up he remained stable.

SUGGESTED CROSS-REFERENCES

The psychiatric examination is discussed in Chapter 7. Dementia and Alzheimer's disease are discussed in Chapter 10 and Section 51.3e, substance-related disorders in Chapter 11 and Section 51.3h, and psychiatric problems in the medically ill in Section 51.3a.

51.2 ASSESSMENT

51.2B CENTRAL NERVOUS SYSTEM CHANGES WITH NORMAL AGING

JEFF VICTOROFF, M.D.

An understanding of the expected impact of aging on the central nervous system (CNS) is important to geriatric psychiatry. Such an understanding alerts psychiatrists to typical changes in neurological and neurochemical function that may impose or alter senescent vulnerability to psychiatric disorders and response to medications and leads them to consider the role of sensory and signal-processing decrements in psychiatric disease. Ultimately, an understanding of the neurobiology of normal aging may provide insight into the etiology of mental illness among aged individuals, not only by determining the changing neural substrate of mental life but also by explaining how altered capacity and strategies for adapting to the environment may change the impact of psychological stresses on these individuals.

Aging is often conceptualized as a final stage of life, marked by deterioration from a prior level of functioning. However, several alternate concepts may be much more useful in considering the changes in the CNS associated with normal aging. First, although many aspects of neurobiology clearly change over the life span, there is no simple dichotomy of age versus youth, since a continuum exists for most structures and functions across the age spectrum. Second, there are great individual differences in the impact of aging and cross-sectional studies of the aging nervous system show a large variance in values at any given age. Third, aging of the nervous system can be seen not as a late stage or a critical threshold, but as a feature of development that begins with conception and unfolds throughout the life span. Fourth, many age-related aspects of physiology (e.g., oxidative stress, excitatory neurotoxicity, or glucocorticoid-induced neurotoxicity) might be considered both causes and effects of aging. Fifth, some age-related changes in the nervous system may result from evolutionary processes with neutral or even healthfully adaptive significance for human interaction with the environment. Finally and most critical to the goal of examining the evidence of normal aging of the CNS, neuroscientists are seriously reexamining the boundaries between normal and abnormal aging. At the extremes of the spectrum of neuropathologic findings and behavioral functions it is easy to say that major macroscopic, microscopic, and physiological changes have or have not occurred in a nervous system between sexual maturation and senescence or that, behaviorally, an individual has or has not lost the ability to carry out the activities of daily life. The most difficult single task in discussing the normal aging of the human CNS is specifying a point on any of the multiple continua of age-related changes where it is biologically or philosophically meaningful to say normal ends and abnormal begins. In particular, with regard to the significantly overlapping diseases called neurodegenerative (e.g., Alzheimer's disease and related disorders), despite remarkable progress in untangling their molecular genetics, neurobiology, treatment, and even prevention, arbitrary operational definitions are still widely used to distinguish the effects of aging per se from those of mild disease.

It is currently unknown whether everyone would experience some or all of the cerebral changes that are currently called Alzheimer's disease were they to live long enough, but evidence suggests they would. Thus one must carefully avoid equating age-related normal CNS changes with whatever changes may be typically found among the aged or assuming that age-related neurodegeneration differs from precocious presentation of a nearly universal combination of genetically programed human nervous system change and common environmental influences. Instead, as neuroscientists study the rich evidence of age-related changes in the CNS, they must attempt to critically examine the validity of apparent dichotomies between normal and abnormal neurodegeneration. Overall, three exciting themes have emerged at the very end of the twentieth century: (1) age-related neuronal loss may be less than was formerly thought; (2) typical aging and neurodegeneration blend imperceptibly into one another, such that, for instance, so-called nonfamilial Alzheimer's disease is probably on a continuum with the universal changes expected with aging; and (3) that the no-new-neurons dogma may be incorrect, and perhaps, multipotential stem cells and some capacity for continued division and differentiation of neurons may persist in the adult human brain. Table 51.2b-1 outlines age-related CNS changes with aging.

Gross brain atrophy
Ventricular enlargement
Selective regional neuronal loss
Remodeling of dendrites, axons, and synapses
Appearance of intraneuronal lipofuscin
Selective regional decrease in neurotransmitters and neuropeptides
Selective modification of neurotransmitter metabolism
Possible dysregulation of gaseous neurotransmitters
Glucocorticoid neurotoxicity
Changes in receptors
Changes in neurotrophins
Changes in signal transduction
Impairment of calcium homeostasis
Possible changes in cell cycle regulators (e.g., cyclins)
Possible changes in extracellular matrix proteins (e.g., laminins, proteoglycans)
Probable regional decline in cerebral blood flow
Probable regional decline in cerebral metabolic rate
Appearance of senile plaques and neurofibrillary tangles

Table 51.2b-1 Summary of Age-Related Changes in the CNS

GROSS CHANGES IN THE BRAIN

Brain atrophy is often reported to accompany aging. Neuropathological examination usually reveals loss of cortical tissue and white matter and enlargement of the ventricles. However, as reviewers of this subject have pointed out, there are five problems with interpreting the results of pathological studies of normal aging and brain atrophy. First, since many such studies do not prospectively determine the cognitive status of the subjects, a large pathology series may include a significant number of subjects with dementia or other neurological disorders. Second, because of changes in general health and total body weight, persons born earlier in the century may have had a lower average brain weight than those born later, which might confound age-related measurements of atrophy. Third, normal brain weight varies widely, which may obscure specific effects of aging. Fourth, most large neuropathology series do not measure the brain weight in a standardized way. Finally, and possibly most interesting, currently available estimates reflect average brain changes derived from cohorts born before the discovery of environmental factors that may accelerate or decelerate brain aging. Some brains show no evidence of atrophy. As more is learned about the factors that alter the pace of atrophy and this knowledge is applied earlier in the life course, later cohorts may better reflect the maturation of the normally aging human CNS.

Despite these caveats, several findings have held up consistently. Robert Boyd reported in 1860 that brain weight in males increases from 493 grams at 3 months of age to a peak 1374 grams between 14 and 20 years. By age 80, the brain has lost 90 grams. Subsequent studies have shown a mean loss of 100 grams in both sexes between ages 25 and 70. This represents about 7 percent loss of weight over the life span or a mean loss of about 3 grams a year for both sexes from age 40 to 90. This weight loss may not be linear, since brain atrophy appears to accelerate after age 60. In addition, there may be a sex difference in brain atrophy, with women showing loss by the sixth decade and men showing loss beginning in the seventh decade. There is typically some regional variation in lobar loss, with greater average loss in the frontal lobes and less in the occipitoparietal region. Furthermore, atrophy progresses differently in different types of brain tissue. Some evidence suggests that cortex is lost more rapidly than white matter between ages 20 and 50 and that white matter atrophies more than cortex between ages 70 and 90. Still, this loss of gray and white matter has recently come under new scrutiny. Recent evidence suggests that age-related brain atrophy may be due to much less cortical loss and much more white matter loss than previously thought.

Neuroimaging of Age-Related CNS Atrophy The gross atrophy of the brain can be visualized in the living patient by neuroimaging techniques. Both lobar shrinkage and increase in ventricular size are apparent on computed tomography (CT) scans, although quantifying the changes in the ventricles is much easier than measuring the multiple convolutions of expanded sulci. Changes in ventricular size with age have been demonstrated by linear measurements, planimetric area measurements, and volumetric measurements. Linear measures have shown an 11 to 220 percent difference in the width of the lateral ventricles from the third to the eighth decade. Planimetry results are usually reported as ventricular area divided by brain area at a single CT scan level (ventricular brain ratio [VBR]). The VBR is reported to increase from 2.2 to 14.2 percent over the life span, and in several studies, increased VBR has been inversely correlated with cognitive function. Volumetric measurements are made either by outlining ventricular area and taking into account the thickness of the CT slice or by counting pixels with cerebrospinal fluid density. Studies using these methods have consistently reported an age-related, progressive increase in ventricular volume. These changes with age may not occur in a linear progression; most studies report a relatively stable ventricular volume during young adulthood, followed by a rapid increase that has been variously reported to occur in the 40s, 50s, or 60s. Evidence from both CT and magnetic resonance imaging (MRI) studies suggests that men undergo more age-related brain atrophy than women. One investigator reported that men experience this increase in ventricular volume at a younger age than women. Studies of the relation of cognitive status to ventricular volume do not permit definite conclusions, and again, recent MRI studies suggest that most of the age-related atrophy of the cerebrum occurs in white matter, not in cortex.

NEURONAL LOSS

Since the publication of a classic paper by Harold Brody in 1955, it has been widely assumed that loss of cortical neurons was a striking and inevitable feature of aging. Brody reported neuronal loss in human cerebral cortex most marked in the superior temporal gyrus and—among the cortical layers—most apparent in the small neurons of the external and internal granular cell layers. Since then, many studies have reported up to a 40 percent loss of cortical neurons, even among subjects selected for antemortem normal mental status. However, this widely held assumption of significant cortical neuronal loss with age has recently come into question.

Humans probably possess their full complement of neurons at birth. After this point, it has been generally thought that neurons, which are postmitotic cells, can no longer divide and that lost neurons cannot be replaced. However, this traditional belief has recently come under question. It was shown in 1997 that multipotential stem cells could be identified in the brains of adult mice and—perhaps most interesting because of the implications for eventual therapies—that such cells can be transplanted to various brain regions where they differentiate to become mature, working components of neuronal systems. A report published in 1998 indicates that adult marmoset monkeys generate new hippocampal neurons. Although a previous comparable study had failed to find similar evidence of adult neurogenesis in rhesus monkeys (a species more closely related to humans), another 1998 report suggested that, in fact, adult rhesus brains do exhibit new neurons. Neuronal progenitor cells have been cultured from the subependymal zones of temporal lobes obtained from adult human epileptics, suggesting a possible lifelong capacity for differentiation. Finally, in 1998 Peter Eriksson of Goteborg, Sweden, and Fred Gage of the Salk Institute in San Diego reported evidence of adult neurogenesis in the dentate gyrus of the hippocampus in humans.

Estimates of the rate of neurogenesis in adult mammalian brains vary greatly, and some theorists suggest that thousands of new neurons are created weekly. One interesting possibility is that adult neurons may enter the cell division cycle, but ordinarily this process is arrested before the G2 phase. In advanced age or in Alzheimer's disease, perhaps regulatory control is lost, and cells proceed further but maladaptively into the cell division cycle and then become targets of apoptosis. Thus, adult human neurogenesis has created a wave of excitement in the neuroscience community, both because it could explain some aspects of age-related neurodegeneration and because it suggests some previously unsought therapeutic options, but it remains unclear how widespread this phenomenon may be in humans and how it relates to or is altered in typical aging or neurodegeneration.

The greatest loss of cortical neurons occurs in the perinatal period, when pruning via genetic programs of cell death—apoptosis—interacts with environmental cues to sculpt a working CNS. After the perinatal period and proceeding through maturation there may be a much slower decrease in neuron counts and neuronal densities. Even if age-related neuronal loss is assumed, it cannot necessarily be concluded that these losses lead to dysfunction; apoptosis may be a common feature of normal adult aging and conceivably serves an adaptive role, paring neuronal populations in a way that optimizes cerebral function for the needs of mature life.

Table 51.2b-2 lists the brain regions that have been reported to undergo or not undergo age-related neuronal loss. Table 51.2b-3 compares the loss reported in normal aging with that reported in persons in Alzheimer's disease; the considerable overlap found in comparable studies suggests that aging and Alzheimer's disease, may, in important respects, be on a continuum. Although the likelihood of age-related neuronal loss probably differs in different brain regions and between those with greater or lesser degrees of neurodegenerative change, one should be very cautious about accepting these reports uncritically. Many studies that survey age-related brain changes fail to screen adequately for subclinical disease, including early neurodegenerative processes that lack a good biological marker and conditions such as diabetes or hypertension that might have produced chronic cerebrovascular compromise without overt stroke. Perhaps more importantly, most surveys of normal brain aging have failed to take into account genetic diversity and pool results, for instance, from subjects with different apolipoprotein E genotypes. There is no easy way to bypass this problem. When one asks what is normal age-related brain change in a human population, one is by necessity attempting to describe norms in a highly heterogeneous group. For similar reasons, one must be wary of studies contrasting normal aging with Alzheimer's disease. Too much uncertainty about a coherent strategy remains to dichotomize these two, and indeed, a dichotomy between late onset nonfamilial Alzheimer's and typical aging may be more a difference of degree than of kind.

Regions that may undergo neuronal loss with normal aging
Cortical
Frontal cortex: superior and middle frontal gyri, precentral gyrus, gyrus rectus
Temporal cortex: superior, middle, and inferior temporal gyri
Parietal cortex: postcentral gyrus, inferior parietal cortex
Occipital cortex: striate and peristriate cortex
Limbic lobe: subiculum, hippocampus, amygdala, cingulate gyrus
Cerebellum: Purkinje cells
Subcortical
Hypothalamus: suprachiasmatic and sexually dimorphic nuclei
Locus ceruleus
Substantia nigra
Nucleus basalis of Meynert (possible)
Putamen (possible)
Inferior olive (possible)
Regions that may not undergo neuronal loss with normal aging
Cortical: none reported
Subcortical
Hypothalamus: supraoptic and paraventricular nuclei
Ventral cochlear nucleus
Motor nucleus of facial nerve
Dorsal tegmental nucleus
Abducens nucleus
Trochlear nucleus
Mammillary bodies

Table 51.2b-2 Locations of Neuronal Loss

Brain Region	Age Range (years)	Percentage Decrease	
		Normal Aging	AD
Frontal lobe			
Precentral gyrus	18–95	22–44	19–37
Association areas	19–95	15–51	22–40
Anterior cingulate gyrus	68–95	15–16	22
Temporal lobe			
Superior gyrus	18–95	34–57	33–53
Middle gyrus	19–97	23–50	25–67
Inferior gyrus	18–95	18–36	11–63
Parietal lobe			
Inferior parietal cortex	19–NA	15	9–37
Occipital lobe			
Area 17	18–95	31–54	17–22
Area 18	19–NA	14	14–30
Hippocampal cortex	45–90	27–80	47
Cerebellum			
Purkinje cells	60–100	25	NA
Subcortical areas			
Locus ceruleus	60–80	43	60–70
Substantia nigra	20–65	35	35–40
Nucleus basalis of Meynert	50–66	Unchanged?	75–80

AD, Alzheimer's disease; NA, not available.

Table 51.2b-3 Neuronal Loss in Selected Regions of the Human Brain During Normal Aging and in Alzheimer's Disease

Cortical Regions In multiple studies of human cerebral cortex, a 10 to 60 percent loss of neuronal density has been reported from young adulthood to advanced age in the superior, middle, and inferior temporal gyri; superior and middle frontal gyri; pre- and postcentral gyri; cingulate gyrus; gyrus rectus; striate and peristriate

cortex; subiculum; and inferior parietal cortex. Such losses would amount to roughly a 1 percent decrease per annum in the neocortex between ages 69 and 95. In contrast to Brody's early report, subsequent studies find the greatest age-related loss among the larger neurons. The hippocampus of the temporal lobe was reported to lose 3.6 to 6.2 percent of pyramidal cells per decade; these hippocampal losses may be most prominent in specific regions such as the subiculum and dentate gyrus and have been speculated to be the basis of memory loss with aging. Several nuclei of the amygdala have also been reported to lose cell density, and about 2.5 percent of cerebellar Purkinje cells are reportedly lost per decade.

The question currently under debate is how much, if any, of this cortical neuronal loss is truly normal, that is, an inevitable, universal feature of human aging absent disease. The usual methods of brain tissue examination may confound the measurement of cortical loss. Several investigators have suggested that less shrinkage of older than younger brains in postmortem processing leads to an apparent, rather than a real loss of neuronal density. One careful study at the University of California at San Diego indicated that neuronal density does not actually decrease with age; decreased average neuron size creates the appearance of reduced density. Others proposed that since the cortex shrinks as a whole, which would tend to increase cell density, reports of decreased neuronal density may actually underestimate the neuronal loss that occurs with aging. Another issue is whether sufficient care has always been taken to exclude persons with mild dementia from populations described as normal. Collaborators from Harvard University and Washington University in St. Louis reported that among 10 subjects carefully selected to rule out even very subtle cognitive deficits, there was no neuronal loss in the entorhinal cortex (a part of the temporal lobe important for memory functions) between ages 60 and 90. Similarly, Danish investigators, using a new method that determines total neuron counts rather than neuron density, found no neuronal loss in the memory-associated Ammon's horn pyramidal cell regions of the temporal lobe in cognitively normal elderly humans but found significant losses in the subiculum. A third issue is that white matter loss may be greater than previously thought and may account for much of the observed age-related cerebral atrophy. While most animal studies have reported an increase in glial cells with age, several recent studies in rhesus monkeys suggest that cortical neurons are preserved with age, but that myelin loss is significant, suggesting decreases in the oligodendroglia that envelope axons, which would be consistent with recent MRI observations of disproportionate white matter loss. Taken together, these recent findings call into question the long-accepted assumption of normal age-related cortical neuronal loss; improved methodology may be required to clarify this issue.

If there is neuronal loss with aging, when does it begin? The decrease in cell density observed before the middle teen years probably reflects growth of the cerebrum. However, reports differ regarding whether true adult-era neuronal loss begins as early as age 20, not until age 50, or much later in life. This wide variation may represent either substantial individual variation in maturation of the CNS or considerable variation in the impact of subclinical neurodegeneration.

Subcortical Regions Of particular interest to psychiatry may be the apparent cell losses with aging among subcortical nuclei. In general, the sensory and motor nuclei of the brainstem are unchanged with age, as are the mammillary bodies. However, several nuclei associated with the production of neurotransmitters have been reported to lose neurons. The locus ceruleus (norepinephrine) may lose 40 percent of its pigmented cells after age 63. The substantia nigra (dopamine) may lose 35 percent of pigmented cells after age 65. Data regarding cell density in normal aging of the nucleus basalis (acetylcholine) are less consistent; some studies report losses and others report no significant change with age. Further, several hypothalamic nuclei with potential behavioral significance exhibit cell loss: the suprachiasmatic nucleus (implicated in biological rhythms) and the sexually dimorphic nucleus both reportedly lose neurons with age.

CHANGES IN NEURONAL STRUCTURE

Dendrites form the receptive network of interneuronal communication. Like neuronal cell bodies, the dendritic tree exhibits changes with age. The loss and replacement of dendrites takes place throughout life, a process of neural network remodeling that may underlie the ongoing adaptation of the CNS to the environment. Golgi studies show a net age-related loss of dendritic branching and regularity in several regions of the aged human cortex, including superior frontal and superior temporal gyri, hippocampus, and entorhinal cortex. This loss is most apparent in the pyramidal cells of the third and fifth layers of cortex, which may play an important role in the processing of information within association cortex. Dendritic regression is most common among the oldest of the old in both rodents and primates, and dendritic loss appears to follow a centripetal sequence, with the first losses at the extremes of branching. The number of dendritic spines per unit length of the dendritic branches may also decrease. Axons, which carry signals from the cell body to the target cell, may undergo demyelination, swelling, and changes in cytoskeletal components such as neurofilaments and neurotubules. Synapses, the points of interneuronal contact, are also altered with age, which may reflect the loss of dendritic spines or be an independent process. A 13 percent loss of synapses in the frontal cortex was reported among elderly persons compared with a younger group.

Despite these findings, there is an intriguing variability regarding the reports of age-related dendritic atrophy. Investigators have reported an increase in the number and length of terminal dendritic segments in layer II of the parahippocampal gyrus with advanced age at the same time as a decrease was found in the middle frontal gyrus. It was thus proposed that some neurons are dying and losing their dendrites while others are actually growing with age, expanding dendritic arborization and neuronal connectivity to compensate for losses of neighboring neurons or even that individual neurons may both lose and gain dendrites in the lifelong process of adaptive neural remodeling. This may be one aspect of the potential for plasticity in the aging human brain. Research in macaques suggests that the ability to repair dendritic loss, like the loss itself, is probably both regional and age dependent. Therefore, rather than an inevitable decrease in a neuron's arborization with time, the apparent overall loss of dendrites and dendritic spines with age may represent a slower rate of replacement relative to the rate of loss.

Further evidence of plasticity in the aging CNS comes from animal studies of axon sprouting and reactive synaptogenesis. *Axon sprouting* is the phenomenon in which, when nerve fibers are damaged or lost, fibers from undamaged neurons sprout to form new connections with the target. This process was first noted in the peripheral nervous system and is now recognized to occur in the CNS as well. *Reactive synaptogenesis* is the process by which synapses are replaced by new synapses. This can occur in response to damage, chemical stimulus, or behavioral changes. Both axon sprouting and reactive synaptogenesis occur in the aged rodent brain, although reinnervation is slower in the aged animal. Conceivably, the preservation of these mechanisms with aging permits continued adaptability to novel circumstances, although that adaptability may be lower in aged individuals than in those younger.

Other Structural Changes One of the most consistent findings in the biology of aging is the increase in *lipofuscin*, or aging pigment, in cells. Lipofuscin, which contains lipid, carbohydrate, and protein, is found in granules distributed through the cytoplasm or clustered near the nucleus. It accumulates not only in neurons and glia but also in the cells of multiple organs and multiple species, so that its appearance has been proposed to be a basic function of cellular aging. Although it has been proposed that lipofuscin is produced during cellular self-digestion, it remains unknown whether lipofuscin in neurons merely marks aging or is causally related to neuronal deterioration. To date, there is little evidence that neuronal lipofuscin is deleterious to neuronal function.

Other age-related structural changes include granulovacuolar degeneration and Hirano bodies. *Granulovacuolar degeneration* refers to small granules that stain with silver; *Hirano bodies* are larger and stain with eosin. Both are found in hippocampal pyramidal cells in aging and neurodegenerative disorders. Both are of unknown significance.

NEUROCHEMICAL CHANGES

Neurotransmitters The neurochemistry of aging has been extensively investigated and evidence indicates that several established neurotransmitters undergo significant changes in production, metabolism, or both with age. Some of the observed decrease in neurotransmitter concentrations may be due to loss of the pigmented cells of the locus ceruleus and substantia nigra (which respectively produce norepinephrine and dopamine) and possibly in the nucleus basalis (which produces acetylcholine). However, aging also affects specific points in the metabolic pathways for neurotransmitters.

Monoamines There is an age-related decline in tyrosine hydroxylase activity, the enzyme that converts tyrosine to dopa, although much of this decline may occur before young adulthood. There are inconsistent changes in different brain regions for dopa decarboxylase activity, the enzyme that converts dopa to dopamine. Still, dopamine content of the midbrain and basal ganglia may be 50 percent lower by age 75. Aging may have different effects on the two classes of dopamine receptors, the type 1 (D_1) receptors linked to adenylate cyclase, and the D_2 receptors, which appear to be the binding site associated with clinical efficacy of neuroleptics. Autopsy studies suggest that D_1 receptors may be unchanged, while D_2 receptors in the striatum are progressively lost with aging. However, one noninvasive study using positron emission tomography (PET) scanning with a selective D_1 ligand found an age-related decrease in D_1 binding in both frontal cortex and striatum. In addition, evidence suggests that the concentration of messenger ribonucleic acid (mRNA) for the dopamine transporter (a cell-specific protein that regulates dopamine reuptake into presynaptic terminals) decreases significantly with age, suggesting that age-related decreases in dopaminergic transmission could be due to altered gene expression.

Enzymes that degrade catecholamines are altered regionally. Monoamine oxidase activity increases with age in the frontal cortex, basal ganglia, and substantia nigra, leading to increased catabolism of dopamine and norepinephrine. Catechol-O-methyltransferase activity increases in the hippocampus, again suggesting localized

acceleration of monoamine catabolism.

Acetylcholine Since acetylcholine degrades rapidly in postmortem tissue, inferences about the impact of aging on cholinergic activity come primarily from measurements of the synthetic enzyme cholineacetyltransferase. Cholineacetyltransferase activity reportedly declines in the human cortex with age but appears to remain unchanged in the striatum. There is an age-related decrease in cortical uptake of choline, the precursor that combines with acetylcoenzyme A (acetyl-CoA) to form acetylcholine. Both changes suggest decreased cholinergic function with normal aging, although not of the magnitude seen in Alzheimer's disease. The activity of the degradative enzyme acetylcholinesterase also decreases with age.

GABA Glutamate functions as an excitatory neurotransmitter. However, glutamate is converted to the inhibitory neurotransmitter g-aminobutyric acid (GABA) by the action of the enzyme glutamic acid decarboxylase. GABA is widely distributed in the brain and may act at as many as one third of all synapses. Both GABA concentration and its glutamic acid decarboxylase activity have been reported to decline with age in human cortex. On the other hand, based on inconsistent observations of increased GABA concentration in the brains of aged rats and Alzheimer's patients, a GABAergic theory of aging and Alzheimer's disease postulates that adenosine triphosphate (ATP)-mediated negative control of GABA synthesis declines with age, unleashing GABA production and leading to excessive concentrations of this inhibitory transmitter. Better assays of age-related changes in GABA synthesis will be needed to resolve these inconsistencies.

Neuropeptides and Amino Acids An emerging area of research in neurobiology involves the presence in brain of neuropeptides that function as neurotransmitters. With several exceptions, little is known about the specific role of these neuropeptides in human behavior. For example, beta endorphin may mediate and modify responses to pain and stress, and cholecystokinin may be colocalized with dopamine in limbic dopaminergic neurons that may play a role in psychosis. As with other neurotransmitters, some regional declines in neuropeptide activity have been reported with age. Somatostatin concentrations are reportedly unchanged with normal aging in the frontal cortex, basal ganglia, or substantia nigra, while diminished somatostatin immunoreactivity has been found in the cortex and hippocampus of Alzheimer's patients. Brain corticotrophin-releasing hormone concentration may decrease in neurodegenerative disease. Substance P concentration is reportedly lower with normal aging in the putamen and hippocampus but not in frontal cortex. Neurotensin concentrations have been reported to decline by 40 percent in the human substantia nigra but remain stable in frontal cortex and basal ganglia. Cholecystokinin concentration appears to be unchanged. Vasoactive intestinal polypeptide (VIP) concentration in the temporal lobe increases with old age. More must be learned about the biological role of these neuropeptides to assess the impact of these changes on function in elderly adults.

Perhaps most pertinent to aging and cognition is the apparent functional decline in the excitatory glutaminergic amino acid neurotransmitter system. Glutaminergic activity decreases with age, and more so with Alzheimer's disease. Multiple reports exist of decreased activity of the *N*-methyl-D-aspartate (NMDA) subtype of glutamate receptors, which are important to hippocampal memory function; how much of this decline is presynaptic—decreased production of glutamate—and how much is due to the loss of postsynaptic receptors remains uncertain. A well-established association exists between excess glutaminergic stimulation and cell death. One theory attempts to reconcile the apparent paradox of decreased glutaminergic function with age and increased excitotoxic neuronal injury as follows: aging causes a loss of inhibitory neurons bearing NMDA receptors, which results in a relative increase in excitatory neurons bearing such receptors and unleashes chronic, low-level excitotoxic cell damage.

Gaseous Transmitters Nitric oxide (NO) and carbon monoxide, both soluble gases, were recently reported to function as neurotransmitters in the CNS. NO in particular is emerging as an important new component of the neuronal signaling system. NO is produced when stimulation of the NMDA receptor leads to calcium influx that activates nitric oxide synthase. NO and its congeners have been associated with (1) NMDA-mediated long-term potentiation, thought to be important in learning; (2) NMDA-mediated neurotoxicity, thought to play a role in neurodegenerative disorders including Alzheimer's disease and amyotrophic lateral sclerosis; (3) generation of potentially toxic free radicals; and paradoxically (4) neural protection against excitatory neurotoxicity. The relation between normal aging and gaseous transmitters is being investigated. Aging may be associated with dysregulation of the NO system, which might both lead to neuronal loss due to increased excitatory neurotoxicity and induction of apoptosis and specifically impair the plasticity of neuronal electrophysiology that underlies memory.

Glucocorticoids and CNS Aging A glucocorticoid hypothesis of brain aging was proposed in the late 1970s as a unifying explanation for neuronal loss with advancing age. While the sequence of molecular events culminating in neuronal loss cannot be attributed to this single factor, much evidence supports a role for glucocorticoids in age-related CNS change. The hippocampus is particularly rich in glucocorticoid receptors and particularly vulnerable in aging. Even normal physiological concentrations of corticosteroids are associated with age-related hippocampal pyramidal cell loss and reactive astrocytosis. Stress increases both glucocorticoid concentrations and glucocorticoid-induced neuronal loss. These losses are reportedly mediated by dysregulation of calcium homeostasis. While the evidence is mixed regarding age-related changes in brain glucocorticoid receptors, it is currently hypothesized that aging produces increased neuronal vulnerability to corticosteroids, perhaps because loss of a protective downregulatory mechanism leads to excessive calcium influx. Like certain other aspects of age-related CNS physiology (e.g., oxidative stress, excitatory neurotoxicity, and impaired calcium homeostasis), the effect of glucocorticoids on neurons may be regarded as both a physiological and a pathological occurrence and both an effect of the organism's age and a cause of CNS aging.

Receptors Complicating the issue of neurotransmitter loss is the question of changes in neuronal responsiveness due to age-related changes in receptors. Only a few studies determine receptor number, an anatomical issue; most studies measure receptor binding, a physiological process that could be affected by multiple factors. Receptors may be divided into (1) those that have enzymatic activity, (2) those that couple to G-proteins, (3) those that act as transcription factors, and (4) those whose action is unknown. Depending on type, both increased and decreased receptor function with age have been reported. Many animal studies confirm a loss of hippocampal receptor binding associated with age, stress, or both. One study reported a 30 percent age-related loss of NMDA receptors in the hippocampus. Since this excitatory neurotransmitter facilitates memory storage, changes in its cellular reception might account for memory dysfunction even without cell loss. Neocortical serotonin (5-hydroxytryptamine [5-HT] type 2A (5-HT_{2A}) receptor binding, studied in vivo with PET, also reportedly decreases with age. Another study reports increased GABA receptor sensitivity in aged rats, possibly compensating for the loss of presynaptic production of this inhibitory transmitter.

This again raises the issue of age-related changes in plasticity. Up- or downregulation of receptors modifies neuronal responsiveness. In addition to the apparent decline in reactive synaptogenesis—a question of receptor structure—age-related changes have also been reported in the postsynaptic neuron's capacity to up- or downregulate receptivity—a question of function. It is extremely difficult to study this issue in humans, so one must attempt to extrapolate from the available animal literature. One of the best-established findings is that aged rats show impaired muscarinic receptor regulatory capacity. Different neurotransmitter receptor systems may exhibit different degrees of change, so the net affect on signaling is unclear. Overall, these data suggest that the final impact of normal aging on neurotransmission may be a complex result of simultaneous processes that may in fact have opposing effects.

Synapsins A related issue is the question of the effects of aging on the terminal membrane–associated vesicle proteins, the synapsins. The four synapsins, of which the best studied are synapsin I and synaptophysin, are associated with the regulation of neurotransmitter release. Synapsin concentrations appear to be associated with the ability of axons to form synaptic vesicle clusters in response to contact with neighboring neurons; hence, synapsin production indicates the capacity for intercellular signaling. Several studies in rats have demonstrated an age-related decline in synapsin concentrations.

Neurotrophins Neurotrophins play a critical part in the growth, differentiation, and maintenance of neurons. These substances include nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), glial-cell-line-derived neurotrophic factor (GDNF), and neurotrophins 1,2,3, 4/5, and 6 (NT-1, NT-2, NT-3, NT-4/5, NT-6). Neurotrophins bind to a number of specific membrane receptors; for example, BDNF and NT-3 bind to tyrosine kinase A and B receptors (trkA, trkB). Another neurotrophin receptor, the $p75^{NTR}$, was recently shown to bind many neurotrophins, including NGF, BDNF, NT-3, NT-4/5, and NT-6. Since neurotrophins control nerve growth and may protect against neuronal injury, they are being actively investigated both as factors in aging and neurodegeneration and as potential pharmaceutical agents.

Studies have revealed multiple aging effects on the neurotrophin system. Aging is reportedly associated with decreased trkA, trkC, and p75 immunoreactivity and decreased concentrations of mRNA for trkA, trkB, trkC, and p75 in various parts of the rat CNS. Aging has also been associated with reduced neuronal response to neurotrophins and (possibly pertinent to the neurochemistry of Alzheimer's disease) with reduced transport of NGF in basal forebrain cholinergic neurons. One study reports that the neuroprotective effect of BDNF against ischemic damage is markedly lower in adult rats than in developing rats, although whether this protective capacity continues to decline into senescence is not known. Perhaps most intriguing for understanding programmed cell death, stimulation of the $p75^{NTR}$ by NGF, BDNF, or NT-3 reportedly increases conversion of sphingomyelin to ceramide and may cause apoptotic neuronal death.

Transducers and Second-Messenger Systems Regulation of the transmission of messages from the cell surface to intracellular elements permitting control of transcription is known as *signal transduction*. Some membrane signals may be carried to the nucleus of neurons by a sequence of events that begins with binding of the first messenger (the neurotransmitter) to membrane receptors, which activates a family of transducer molecules known as guanine nucleotide binding (G) proteins. These in turn activate enzymes such as phospholipases that produce molecules that serve as second messengers and activate the phosphorylation and

dephosphorylation events that finally control deoxyribonucleic acid (DNA) transcription and gene expression. In one such cascade, extracellular events trigger activation of phospholipases C and D that hydrolyze glycerophospholipids such as phosphotidylinositol to produce diacylglycerol, a second messenger that activates protein kinase C. Both the G proteins and the enzymes involved in transduction, such as cyclic-adenosine monophosphate (AMP)-dependent protein kinase and protein kinase C, may be altered with aging. Recently (at least in replicating cells) cellular senescence has been specifically associated with decreased diacylglycerol concentration (and hence, protein kinase C activation) in response to external stimuli. Such changes in kinases would perhaps hinder phosphorylation of hippocampal membrane proteins, considered possibly an important step in the consolidation of new memories. Although the extent to which these age-related changes occur in postmitotic neurons is still being investigated, it is thought that these changes may alter gene expression and lead to lasting changes with age in the structure or function of neurons or both.

Calcium Homeostasis Many neuronal functions of behavioral significance—including the regulation of neurotransmission and the production of growth cones that may be one structural basis of long-term memory—depend on careful regulation of calcium ion (Ca^{2+}) concentrations in different compartments. Normal Ca^{2+} influx is controlled by voltage-gated calcium channels, the NMDA receptor channel complex, and the sodium ion (Na^{+})/Ca^{2+} exchanger. Ca^{2+} efflux is controlled by Ca^{2+}–adenosine triphosphate (ATP) pumps and the Na^{+}/Ca^{2+} exchanger. Ca^{2+} may also be released within the neuron by the Ca^{2+}-binding proteins calmodulin, calbindin, calretinin, and parvalbumin. In healthy neurons, after Ca^{2+} influx (e.g., through voltage-gated channels following depolarization), it is expected that Ca^{2+} homeostasis will be restored by Ca^{2+}-dependent outward potassium currents that produce feedback inhibition of the Ca^{2+} influx.

Evidence is emerging that dysregulation of Ca^{2+} influx, perhaps causing excessive intracellular free Ca^{2+}, is a feature of aging in the CNS. Aged rats reportedly exhibit excess Ca^{2+} influx through L-type calcium channels in hippocampal neurons, leading to prolonged afterhyperpolarization and decreased neuronal responsiveness. Concentrations of calbindin and calretinin, two of the Ca^{2+}-binding proteins that would buffer free Ca^{2+}, are reportedly decreased in the hippocampus of aged rats. Uptake of free Ca^{2+} into synaptosomes also decreases with age. However, controversy remains regarding intraneuronal calcium and aging. On one hand, John Disterhoft and colleagues at Northwestern University Medical School reported that aged rabbits have decreased excitability of CA1 hippocampal neurons (neurons in Ammon's horn known to be important for memory consolidation), a likely cause of impaired learning, and they attribute this change to excessive Ca^{2+} influx causing enhanced afterhyperpolarization of the membrane. On the other hand, Hans Forstl's group in Mannheim, Germany, reported both decreased basal intracellular Ca^{2+} and decreased poststimulation Ca^{2+} concentrations in aged rats' brains. Perhaps Ca^{2+} influx may both increase or decrease with aging, depending on regional factors and which receptor system is activated. Further, Ca^{2+} sensitivity may perhaps be enhanced or diminished, depending on other circumstances of aging, such as the co-occurrence of ischemic or glucocorticoid stress. Nonetheless, substantial evidence indicates that excessive Ca^{2+} influx acts in neuronal death by (1) mediating glutamate excitatory neurotoxicity; (2) activating calpain, a protease that can damage neuronal proteins; (3) activating phospholipase C, which activates protein kinase C, which can both amplify Ca^{2+} influx and alter DNA transcription; (4) activating NO synthase, generating NO as part of the excitatory neurotoxic cascade, and (5) activating endonucleases that degrade DNA. Moreover, there may be a tendency toward a self-perpetuating cycle in which excessive Ca^{2+} influx leads to loss of normal feedback controls and further excess influx. In this way, even small aging changes in Ca^{2+} homeostasis may effect age-related changes in the CNS that are pertinent to cognition. The finding that b-amyloid deposition may increase Ca^{2+} influx provides a potential link between altered calcium homeostasis and Alzheimer's-type neuropathology.

METABOLIC CHANGES

The human brain undergoes a variety of changes in chemical constituents and metabolic functions with aging. There are regional decreases in protein content and synthesis. Although total DNA content appears to be preserved, there are regional changes in RNA concentration, which declines in cortex but may actually increase with advanced age in the subicular region of the hippocampus. Brain glucose metabolism may be altered in part by decreased sensitivity of neuronal insulin receptors. Total brain lipid decreases after age 50, although the significance of this is unclear, since decreased brain weight and changes in the proportion of gray and white matter may keep relative lipid content unchanged. Lipid synthesis also decreases, including membrane phospholipids and specific lipids important to the myelin sheath.

Noninvasive neuroimaging methods have recently revealed metabolic changes in the human brain in vivo. The effect of age on cerebral metabolic rate for glucose was measured by the [^{18}F]fluorodeoxyglucose method using PET. One early report found a mean 26 percent decrease in global cerebral metabolic rate for glucose when comparing human volunteers without evidence of dementia over the age range of 18 to 78 years. Several subsequent PET scan studies have failed to confirm this global decline in cerebral metabolism with age, especially after the metabolic measurements have been corrected for ventriculomegaly. While global metabolic rates may remain stable through the life span, regional metabolism may be altered; a relative hypofrontality of glucose metabolism with increasing age has been reported. One factor that complicates these PET measurements is that atrophy may cause underestimation of regional metabolism, although metabolic decline has been reported in brain regions that should be little affected by atrophy or ventricular enlargement. Further, the sensory deficits of the aged may lower their basal level of stimulation and reduce the cerebral metabolic rate. Determining the impact of normal aging on global or regional brain metabolism requires further study.

Magnetic resonance spectroscopy (MRS) is another noninvasive way to measure certain aspects of cerebral metabolism. Proton MRS has been used to measure *N*-acetylaspartate (NAA) concentrations, regarded as a neuronal marker, and ^{31}P-MRS has been used to measure high-energy phosphate concentrations in aged controls and subjects with dementia. Preliminary results suggest a possible decline in NAA concentrations with age or dementia, but this research is still in an early stage.

Oxidative Stress At the molecular level, much recent research suggests that one cost of normal human aerobic metabolism may be oxidative stress-induced neurodegeneration. As with many aspects of age-related change, it is quite difficult to determine how much of this oxidative injury should be considered an inevitable physiological consequence of aging and how much should be considered pathological. It appears that physiological oxidative phosphorylation—the mitochondrial process of reducing O_2 to H_2O—produces free radicals including superoxide anion, hydrogen peroxide, and hydroxyl radicals that cause age-related damage to DNA (especially mitochondrial DNA), proteins, and lipids. Perhaps because free radical production is maximal near the mitochondrial inner membrane or because of a lack of protective histones, mitochondrial DNA is especially sensitive to oxidative injury; several studies report strongly age-related deletional mutations in mitochondrial DNA at about ten times the mutation rate in nuclear DNA. One study of human brain tissue found a marked age-related increase in 8-hydroxy-2-deoxyguanosine concentration (a marker of oxidative DNA damage), which was also much higher in mitochondrial DNA than in nuclear DNA. Most of the protein complexes involved in oxidative phosphorylation are coded by mitochondrial DNA, and these proteins also seem to be particularly vulnerable to oxidative stress, with several studies reporting increased damage to these proteins with age. Lipid peroxidation generates potentially mutagenic free radicals such as peroxyl radicals and singlet oxygen and may also damage neighboring membrane proteins; lipid peroxidation reportedly also increases with age.

Endogenous defense mechanisms exist for all these types of oxidative stress. Superoxide dismutase detoxifies the superoxide radical. Repair-glycolases excise damaged DNA. However, in aging, the rate of repair seems to fall behind the rate of oxidative injury. Perhaps the best specific demonstration of the connection between age-related neurodegeneration and oxidative injury is the finding that familial amyotrophic lateral sclerosis is associated with mutation of the Cu/Zn-superoxide dismutase gene, with decreased enzyme production leading to loss of defense against superoxide radical damage. This may be a model for the more general process by which age-related deficiency in repair processes (especially in mitochondrial DNA, proteins, and lipids) leads to neuronal loss.

VASCULAR CHANGES

As with other aspects of age-related change in the CNS, it is very difficult to dissect the consequences of aging from the consequences of vascular pathologies. However, independent of atherosclerosis, intracerebral arterioles may undergo hyaline arteriosclerotic changes, and become increasingly tortuous and probably stiffer with aging. Possibly, changes occur in laminins in vascular basement membranes. Capillary diameter and length per unit volume also reportedly increases in aged persons. Vascular amyloid, identical to the amyloid found in Alzheimer's disease, has been found in the walls of arteries and arterioles of the aging human brain, although in smaller amounts than seen in Alzheimer's patients. The effect of these microvascular changes on cerebral circulation and brain function in aged persons remains uncertain.

Under normal circumstances, cerebral blood flow directly reflects cerebral metabolism and responds to the metabolic demands of perfused brain tissue. Therefore, cerebral blood flow should be a good measure of neuronal activity. Relative cerebral blood flow has been measured noninvasively using the tracer ^{99m}Tc-*d*,*1*-hexamethylpropylenamineoxime (HMPAO) monitored with single photon emission computed tomography (SPECT) scanning and absolute regional cerebral blood flow has been measured using the xenon-133 inhalation technique in subjects of different ages. Results of these studies are highly variable; some investigators report significant decline in global cerebral blood flow with age and others report no correlation between age and cerebral blood flow. PET scanning has also been used to assess changes in cerebral blood flow with age using such tracers as ^{15}O-labeled water, also with varying results. While a few PET studies report no age-related change, most report that regional cerebral blood flow decreases with age bilaterally, especially in cingulate gyri, parahippocampal, superior temporal,

medial frontal, and posterior parietal cortices. Thus, selective decline in cerebral blood flow probably occurs, especially in limbic and associated areas of cortex and periventricular regions of white matter. Aging may also decrease the capacity for cerebral blood flow autoregulation, perhaps in part because of reduced endothelium-dependent relaxation in response to b-adrenergic stimulation.

It is unclear whether age-related changes in cerebral blood flow may be a factor causing the cognitive changes of normal aging or may result from decreased cognitive activity. However, emerging evidence indicates that CNS vascular changes may contribute to neurodegeneration of the Alzheimer type. Further, recent evidence from PET and functional MRI studies suggests age-related reductions in cortical cerebral blood flow responsiveness to perceptual and memory challenges.

Periventricular White Matter Changes *Leukoaraiosis* refers to rarefaction of the periventricular white matter. This change is visible on head CT scans as a periventricular halo of hypodensity, and visible on both proton density or T2-weighted brain MRI scans as periventricular white matter hyperintensities (PVWMHs). In one study, leukoaraiosis on CT was reported in 22 percent of normal volunteers, 52 percent of patients with vascular dementia, and 61 percent of patients with Alzheimer's disease. In a study of nondemented elderly volunteers, those with leukoaraiosis exhibited slightly lower scores on psychometric testing. PVWMHs have been reported in as many as 93.5 percent of unselected MRI scans and appear on 20 to 60 percent of scans of cognitively normal adults over age 65. The pathophysiological changes underlying PVWMHs comprise a spectrum, including mild ependymal disruption, subependymal gliosis, and myelin loss. However, changes that extend further from the ventricles into the deep white matter probably involve more extensive ischemic microangiopathy. It has been proposed that many of these pathological changes are due to acute or chronic white matter ischemia, and some evidence suggests a correlation between the extent of PVWMHs and (1) cerebrovascular risk factors and (2) degree of dementia among patients with vascular dementia. Still, PVWMHs are so common among nondemented elderly adults that they cannot be taken to indicate the presence or cause of a cognitive disorder. A threshold effect has been reported by several investigators in which PVWMHs and cognitive loss are associated only in the most severe stages. However, the vascular pathophysiology and cognitive significance of PVWMHs remain uncertain.

NORMAL AGING, NEURODEGENERATION, AND ALZHEIMER'S DISEASE

The most difficult problem in characterizing the normal aging of the human CNS is identifying a meaningful boundary between normal aging and abnormal neurodegeneration.

Plaques and Tangles Senile plaques and neurofibrillary tangles are associated with Alzheimer's disease, Down syndrome, and other neurodegenerative diseases. Tangles are fibrous bands of intracytoplasmic inclusions consisting of paired helical filaments that seem to result from abnormal hyperphosphorylation and perhaps glycosylation of the microtubule-associated protein tau. Plaques consist of an b-amyloid core surrounded by microglial processes, dendritic processes, and sometimes neurites that may also contain paired helical filaments. While they are often called “lesions,” implying pathology, both plaques and tangles occur in the brains of normal aged persons. Plaques may be found, in lower average numbers than in Alzheimer's disease, throughout the neocortex and in the hippocampus. Tangles accumulate with age first in layer II of the entorhinal cortex, later in the hippocampus and nearby temporal lobe areas, and later still in neocortex. There is a rough correlation between plaque counts (especially the neuritic type) and cognitive loss, but there is so much overlap between the counts in elderly adults without cognitive loss and in Alzheimer's patients that conventional neuropathological criteria for Alzheimer's disease require age-adjusted plaque counts. There is a better correlation between tangle counts and cognitive loss. Nonetheless, as Arnold Scheibel of the University of California, Los Angeles has noted, “It is not possible to provide parametric limits to the ‘allowable number' of plaques and tangles in the healthy aging brain.” While the number of plaques, the proportion of plaques containing neurites, the presence of hyperphosphorylated tau, and the number of tangles are greater, on average, in individuals with impaired cognition, there is no absolute structural or biochemical difference in these entities when they are found in the brains of apparently normal individuals and in those considered to have Alzheimer's disease, suggesting that plaques and tangles are not specific disease markers but are probably a consequence of multiple age-related processes.

A subgroup of aged individuals has been reported with no evidence of dementia despite numerous neocortical plaques. Since this group also had greater brain weight and neuronal density than controls, possibly individuals with a greater brain reserve are more resistant to age-related neurodegeneration. This phenomenon may be important to the conceptualization of Alzheimer's disease, because it suggests that the same pathological process may have significantly different effects on cognition and that the appearance of dementing disorder is not an all-or-none occurrence but may depend upon crossing a critical threshold of cerebral dysfunction.

Synapsins Synapsin concentrations may decline in normal aging. Robert Terry and colleagues at the University of California at San Diego have also reported that human synaptophysin concentrations are the best correlate of cognitive loss in Alzheimer's disease. Possibly aging leads to deterioration in the neuron's capacity to establish and maintain transmitter-dependent connectivity with other neurons—a form of diminished plasticity—and beyond a certain point, such loss of connectivity impairs cognition enough to be clinically apparent. Again, this model might imply that another aspect of what is currently called Alzheimer's disease may differ from normal aging in degree and timing rather than in kind.

Apolipoprotein E There is a definite association between the number of e4 alleles (zero, one, or two) of the cholesterol transport protein apolipoprotein E and the risk of developing sporadic Alzheimer's disease. e4 is associated with increased b-amyloid in brains of patients diagnosed with Alzheimer's disease; pathophysiologically, e4 may be associated with enhanced production or decreased degradation of neurotoxic amyloid fibrils. Gary Small of the University of California, Los Angeles reported that cerebral metabolism may decrease in a pattern suggesting Alzheimer's disease in people with the e4 allele, even prior to cognitive decline. Recently, a group from the University of Barcelona showed that among elderly patients complaining of memory loss without dementia (age-associated memory decline), the presence of e4 alleles was associated with slightly lower cognitive scores and subsequent progression to dementia. These findings do not resolve the question of whether normal aging and Alzheimer's disease are on a continuum, but they suggest that a genetic risk factor strongly associated with eventual development of Alzheimer's disease can influence the cerebral function of people who appear to be aging normally.

Cerebrovascular Contributions Another problematic area is the relation between age-related cerebrovascular changes, CNS aging, and Alzheimer's disease. The convention is to distinguish between vascular dementias and neurodegenerative dementias such as Alzheimer's disease. However, blood vessels serving the CNS may change throughout life with no overt clinical effect but with an unknown—but probably accelerant—effect on the rate of many aspects of CNS aging. Recent evidence suggests that distinguishing vascular and neurodegenerative dementias may be difficult, since cerebrovascular change may significantly influence the expression of Alzheimer's disease, b-amyloid deposition on cerebral vessels is associated with stroke, and ultrastructural studies show angioarchitectural distortions in cerebral capillaries in brains of persons with Alzheimer's disease. Perhaps the most persuasive evidence comes from the Nun Study, in which David Snowdon and colleagues at the University of Kentucky showed that dementia was more likely to occur in subjects with the neuropathology of Alzheimer's disease if they also exhibited subcortical lacunar infarcts, suggesting an interaction between vascular and Alzheimer's pathologies. Alzheimer's disease may in many ways be likened to atherosclerosis, a pathological process that (1) is more or less universal, (2) becomes clinically apparent only after significant progression, and (3) may be accelerated by and exhibit phenotypic heterogeneity due to many genetic and environmental factors. Recent studies suggest that age-related changes in the CNS, as well as Alzheimer's disease, are not only analogous to vascular disease but are in part due to it.

Clearly, Alzheimer's disease is not just accelerated normal aging of the entire human organism, because little evidence suggests that it is associated with accelerated degeneration of systems outside the CNS. Further, there are familial forms of this disorder in which the outstanding pathophysiology is a mutation in the amyloid precursor protein leading to increased production of neurotoxic b-amyloid. This suggests that in at least some cases, dysregulation of a specific single neurobiological system initiates a cascade of events that causes the phenotype, as might be expected for a true genetic disease. This raises the question of the relation between the genetics of aging and the occurrence of neuronal loss and Alzheimer's disease.

MOLECULAR GENETICS OF CNS AGING

Study of the genetics of CNS aging is just beginning, so any conclusions based on the current data must be considered highly tentative. In addition, many of the phenomena currently under study have been observed in yeast, nematodes, or rodents but not yet in humans. For example, a well-established age-related genetic change in rodent brain is the increase in the transcription and expression of the gene for glial fibrillary acidic protein (GFAP), which is conceivably related to increased astrocytic activity in aged humans. Perhaps most pertinent to both aging and Alzheimer's disease is the fact that across species, neurons possess the cellular machinery of apoptosis.

Apoptosis is a microscopic morphological pattern of a dying neuron that exhibits blebbing of the membrane, clustering of nuclear chromatin, and finally DNA fragmentation without membrane dissolution or the inflammatory features associated with necrosis. This pattern, usually attributed to genetically programed cell death, serves important physiological purposes such as deleting self-recognizing thymocytes and probably the developmental pruning of neurons. However, apoptosis followed by secondary necrosis may be the principal mechanism for loss of neurons with normal aging and Alzheimer's disease. Apoptosis apparently requires the presence of certain death domains in cell receptors and transcription factors, and multiple stimuli may act on cells with these domains to initiate the cascade of apoptosis. For example, NGF appears to induce terminal differentiation of the neuron to its postmitotic state in part by activating sphingomyelinase, which then

generates ceramide, a second messenger probably involved in growth arrest. NGF may also activate the cascade leading to apoptosis, and it is likely that ceramide is a transducer in this process. Hence, the effects of NGF appear to be rather complex, potentially facilitating both the terminal differentiation of the neuron into its mature functional role and the apoptotic death of the neuron. Several other mechanisms may link aging or Alzheimer's disease (or both) to genetically programed neuronal death: age-associated dysfunction of cytochrome c oxidase (complex IV of the oxidative phosphorylation pathway) may enhance apoptosis; b-amyloid may also initiate the apoptotic cascade—a potential explanation for the toxicity of amyloid in neurodegeneration; cyclins (cell cycle regulators) may participate in excitatory neurotoxicity and apoptosis; impaired energy metabolism may lead to production of 4-hydoxynonenal, which mediates apoptosis related to oxidative stress; and caspases may cleave presenilin to produce fragements that enhance vulnerability to apoptosis. Furthermore, ceramide production in aging neurons may be involved not only in the intracellular cascade leading to apoptosis, but also in the loss of neuronal capacity to deal with DNA damage; by activating caspases, ceramide may cause the inactivation of poly-adenosine diphosphate-(ADP)-ribose-polymerase, an enzyme thought to be valuable in DNA repair. This might diminish the neuron's capacity to recover from age-related DNA damage.

However, as Kalluri Subba Rao of the University of Hyderabad in India has pointed out, evidence is mixed regarding age-related decline in DNA repair processes in neurons. Several syndromes thought to be associated with elevated genomic damage or failed repair, such as Down syndrome, ataxia telangiectasia, and Cockayne's syndrome, are also associated with both premature aging and neurodegeneration. Others, such as Werner's syndrome or Hutchinson-Gilford's syndrome, are associated with striking premature aging, or *progeria*, of multiple organ systems but do not exhibit early neurodegeneration, which suggests that the features of aging may be dissociable. The gene for Werner's syndrome, called *WRN*, was recently located on chromosome 8 by positional cloning. *WRN* encodes a protein that is very similar to the helicases involved in DNA unwinding, which may explain why DNA repair capacity is altered in this syndrome. Yet, even though Werner's syndrome is associated with both diminished DNA repair and increased production of oxidized proteins, patients with Werner's syndrome do not typically develop either Alzheimer's disease or hypertension. Down syndrome, on the other hand, is associated with both diminished DNA repair and premature Alzheimer's changes, which hints relation between the genetics of failed DNA repair and the occurrence of neurodegeneration. Williams syndrome, another hereditary condition associated with cognitive deficits and early death (though not thought of as a progeria), has also been associated with premature Alzheimer's-type changes in the brain of a 35-year-old patient. The examples of Werner's, Down, and Williams syndromes suggest that different genes control different aspects of aging or the same mechanisms of aging in different organ systems; hence genes influencing the rate of neurodegeneration may act independently of genes that influence other features of aging.

One recent line of research suggests that even in the adult mammalian CNS, multipotential stem cells exist that retain the capacity to differentiate into neurons. This, combined with the recent report that new neurons arise in the adult marmoset hippocampus, might represent another aspect of adult plasticity and raises the possibility that even in aging, the CNS has some potential to compensate for lost neurons by the differentiation of new neurons from neuroepithelial tissue in response to currently unknown extracellular stimuli. Again, rather than thinking of CNS aging as a one-way street, this finding strengthens the concept of CNS aging as a dynamic to-and-fro of generation and degeneration.

CLASSIFICATION OF AGE-RELATED NEURODEGENERATION

Whether the neurobiological and neuropsychological changes associated with so-called normal CNS aging are best regarded as a later, slower, or less severe presentation of the changes currently called sporadic Alzheimer's disease or to what extent both reflect the same underlying processes is currently unknown. However, excluding the small proportion of familial Alzheimer's cases with mutations in the genes for presenilins 1 or 2 or amyloid precursor protein or other as-yet-unidentified mutations, no evidence currently exists for a pathophysiological process that occurs in Alzheimer's disease but not in aging with normal cognition. Aging is associated with neurodegeneration, but how much is normal? One way to conceptualize the difference between normal and abnormal neurodegeneration might be as follows. There are two categories of age-related neurodegeneration: (1) changes clearly related to a single gene mutation, such as familial Alzheimer's disease, familial Parkinson's disease, familial amyotrophic lateral sclerosis, and perhaps the chromosome 17–linked dementias, and (2) the heterogeneous, overlapping, multidetermined changes of CNS aging affected by interdigitating genetic and environmental factors that may accelerate the process, including apolipoprotein e4 alleles, excitatory neurotoxicity, oxidative stress, abnormal processing of amyloid precursor protein, altered production and function of neuronal proteins (e.g., b-amyloid alpha-synuclein, and ubiquitin), calcium dysmetabolism, enhanced apoptosis, cerebrovascular disease, stress-related glucocorticoid neurotoxicity, and head trauma, or decelerate the process, such as endogenous antioxidation mechanisms and DNA repair processes, cerebral reserve possibly related to developmental stimulation and educational and occupational challenge, and possibly interventions such as postmenopausal estrogen replacement therapy, vitamin E supplementation, and antiinflammatory agents. Should they live long enough to experience these problems, all humans will develop neurodegenerative changes and cognitive loss with age due to cumulative neuronal apoptosis and necrosis reflecting the sum of these factors and ultimately leading to a critical loss of neuronal connectivity that becomes clinically apparent. Some aspects of these interrelated processes may involve vicious cycles, such as mutations of mitochondrial DNA that compromise oxidative phosphorylation, and thus generate reactive oxygen species that further damage DNA. Due to lost regulation of feedback-inhibited control systems, this process might be somewhat analogous to the self-directed criticality of chaos theory, like a gradually fraying of a rope, in which initial fraying accelerates subsequent fraying until the rope inevitably breaks. A subgroup of people will experience a disproportionate acceleration in the aging of the CNS relative to other organ systems—a kind of segmental progeria which is currently called “Alzheimer's disease” but difficult to separate from the universal processes of aging except in arbitrary quantitative terms. Thus, pending the discovery of a definitive genetic or physiological discriminator between aging and sporadic so-called Alzheimer's disease, it might be conceptually and semantically useful to make the following distinction: the term *Alzheimer's disease* should perhaps be reserved for cases of age-related neurodegeneration due to a specific cause such as a heritable mutation. On the other hand, when similar segmental CNS progeria with plaques and tangles that instead results from an interaction between multiple genetic and environmental accelerants and decelerants of aging, and produces a spectrum of overlapping pathophysiologies and phenomenologies with no neurobiologically clear-cut differentiation from aging might be more appropriately labeled *typical, sporadic, age-related neurodegeneration*. In the near future, specific molecular pathophysiologies may be discovered that will enable better isolation of parts of this spectrum, leading to both a better understanding of aging and an expanded causal system of classification of neurodegeneration.

CONCEPTUAL SUMMARY AND UNRESOLVED QUESTIONS

A review of the evidence that the human CNS exhibits significant structural and functional changes with age that tend to have a selective impact on different regions, systems, and molecular processes in the brain reveals a recurrent theme, namely, CNS aging and neurodegeneration may be associated with both an increase in neurotoxic processes and a decline in molecular repair mechanisms. Rather than thinking of brain aging as separate from brain development, one might regard it as a variation on a theme. Over the course of the life span, certain aspects of brain physiology shift in purpose and degree. For instance, in fetal life, apoptosis vigorously selects neurons with favorable connectivity, whereas in postmaturational life, apoptosis is less active and may primarily remove damaged neurons. Neurotrophin activity, cellular surveillance, DNA repair, neurotransmitter production and receptor modification, activity of transducer systems, and many other processes that change over the life span similarly may serve somewhat different purposes at different stages of life. Aging of neurons ultimately might be thought of as reflecting the results of a number of self-reinforcing cycles. For instance, mitochondrial DNA is particularly vulnerable to age-related mutations, which decrease the efficiency of oxidative phosphorylation. This not only deprives cells of energy in the form of high-energy phosphates, but also increases the relative production of reactive oxygen species—free radicals. Reactive oxygen species are notoriously hard on phospholipid components of neuronal membranes, peroxidating them. Lipid peroxidation of neuronal membranes threatens neurotransmission by damaging receptor/transducer integrity, a direct threat to cell-to-cell signaling, and also specifically reduces their capacity to bring in glucose, a form of insulin resistance that some have referred to as diabetes of the brain. Neuronal insulin resistance compromises delivery of glucose, the substrate for oxidative phosphorylation, which then reinforces the cycle by further decreasing the efficiency of energy production. The resulting excessive production of reactive oxygen species may very well increase the rate of mutation of mitochondrial DNA—completing the cycle. The consequences are manifold, since all of the ATP-dependent processes of the neuron might be compromised by this loss of efficiency, from intracellular signaling to transcription and translation of new proteins to DNA repair to alterations in NMDA receptors that increase vulnerability to excitotoxic injury. It is even conceivable that another consequence of excessive reactive oxygen species activity and lipid peroxidation is the upregulation of b-amyloid production, a protein best known as a marker for Alzheimer's disease which might have a physiological function of cellular repair. As an intermediate stage, the neuron is floundering somewhat in its many tasks. The final result would be the evocation of apoptosis and neuronal death, as the injured neuron is removed from the system by setting off the signals for self-destruction. While some aspects of this scenario remain to be confirmed as universal, if this is a fair representation of age-related neuronal change, it is easy to see how it blends into the condition currently referred to as Alzheimer's disease.

Questions that remain to be answered include why do neurons die? Or, more specifically, what is the chain of genetic and environmental causality that leads to the age-related neurodegeneration that seems to involve excitatory neurotoxicity, oxidative damage, calcium dysmetabolism, apoptosis, and necrosis? What makes particular neurons more susceptible? Is it location, vascular supply, connectivity, neurotransmitter type, metabolic rate, DNA repair capacity, free radical detoxification mechanisms, or some combination of these factors? To what extent are neuronal losses due to pathological events as opposed to universal genetically programed effects of aging? To what extent are CNS changes such as dendritic atrophy reversible once they have begun? How does the recent discovery of a potential master genetic clock for aging relate to human brain aging? To what extent are the age-related changes in the CNS deleterious as opposed to adaptations that crystallize the learning of a lifetime? How do the changes reported in cerebral structure, physiology, and chemistry relate to the epidemiology of psychiatric disorders among elderly adults? What role do life events and their psychological impact play in accelerating or decelerating the normal changes of age? What preventive interventions are

most likely to delay age-related neurodegeneration? These and other questions will be the focus of the next generation of research on the neurobiology of human aging.

SUGGESTED ROSS-REFERENCES

Sections in the neural sciences chapter relevant to the discussion of changes in the aging brain include Section 1.3, which discusses specific functional systems that may be altered with age, Section 1.4 on the monoamine neurotransmitters, Section 1.5 on amino acid neurotransmitters, Section 1.6 on neuropeptide biology and regulation, and Section 1.8 on intraneuronal signaling pathways. Section 1.15 and Section 1.16 introduce the basic concepts and psychiatric significance of CT, MRI, SPECT, and PET scanning. Most pertinent for correlation of brain aging with clinical psychiatry are other sections in the geriatric psychiatry chapter, including the introduction and overview in Section 51.1, and Section 51.2b and Section 51.2c on normal aging and physiological aspects. Section 51.3e on Alzheimer's disease and other dementing disorders discusses the important clinical consequences of neurodegeneration of the CNS.

51.2 ASSESSMENT

51.2C PSYCHOLOGICAL CHANGES WITH NORMAL AGING

JENNIFER J. DUNKIN, PH.D. AND JULIA E. KASL-GODLEY, PH.D.

The demographics of aging are by now well known. Advances in medicine and improvements in living conditions over the past century have resulted in greater and greater numbers of persons reaching old age. This graying of the population is expected to reach its peak over the next 60 years, as the baby-boom cohort reaches old age. By the year 2050 79 million persons are expected to be over the age of 65 (20.6 percent of the population), versus 31 million persons (12.5 percent of the population) over the age of 65 in 1990. Furthermore, the oldest-old population—those 85 years of age and older—is expected to grow at an even faster rate and will comprise 4.6 percent of the population (18 million persons) in 2050, versus 1.3 percent (3.1 million) in 1990.

While on the surface these demographic trends reflect favorably on society's attempts to eradicate disease, reduce infant mortality, and improve standards of living, recent debates (especially in political arenas) have focused on the hidden costs of these changes. For example, aging is associated with increased risks of physical illness, personal losses, and cognitive impairment, among other factors. If these risks translate into significant impairment for most older people, costs to society will increase as more people reach old age. While many view a future with many aging individuals as a contingent of happy, well-adjusted retirees on the golf course, others picture a bleak future with millions of debilitated elderly adults in overflowing nursing homes or living in poverty and isolation. Which picture will predominate in the future? It may be wise to make such predictions with caution; possibly the younger one is, the more susceptible one is to aging stereotypes and the less favorable the process of aging appears. While unique life challenges face the elderly, it may surprise many that most research suggests that most elderly people have high levels of life satisfaction, cope well with the challenges presented them in late life, and demonstrate considerable resilience in the face of functional and personal losses. This chapter reviews these studies and discusses their implications for those working with older adults.

RESEARCH ISSUES

The study of psychological issues and aging is relatively young, with most theoretical developments taking place after World War II. Nevertheless, by now a growing body of literature addresses life span development, mental health issues, cognitive aging, and coping and adjustment in old age. However, these studies vary considerably in design and sample used, which often limits the study's overall impact. A brief review of design and sampling issues provides a context in which to view studies of psychology and aging.

Design The design of a study markedly determines how its results can be interpreted, and erroneous conclusions can be drawn based on misinterpretations of a study's design and its limitations. For example, most studies in the field of aging are cross-sectional, that is, groups of individuals of different ages are sampled at one point in time. While meaningful conclusions about differences between age groups may be drawn from cross-sectional studies, it is inappropriate to draw inferences about change over time from such studies, since individuals are not studied prospectively and cohort differences can be mistaken for longitudinal change. For example, there are vast differences between the average 30-year-old and the average 70-year-old besides age, including average number of years of education, exposure to historical events such as the Great Depression and World War II, and comfort with revealing personal information. Thus, what may resemble change over time may instead be baseline cohort differences in the variable of interest. Because of these issues, it is likely that different trajectories of change will be necessary for each individual age cohort.

Sampling Until recently, most studies of psychological issues in aging have used predominantly white, well-educated, healthy, and financially comfortable samples of older adults. Studies have primarily used samples of subjects in the so-called young-old age group (65 to 75 years of age) or, less frequently, the old-old age group (75 to 85) but rarely the oldest-old group (85 and older). Furthermore, many longitudinal studies of personality development and adjustment have used only male samples. The result is that comparatively little is known about minority elderly adults, elderly women, inner-city and lower-income elderly adults, and the oldest-old population. Many psychometric and neuropsychological tests that measure cognitive functioning do not have adequate normative data for the oldest age groups. Attrition rates are also important phenomena; studies rarely compare individuals who drop out of studies with those who remain in the study. This may overestimate the amount of stability and underestimate the amount of decline in psychological functions, as those who decline in functioning tend to have higher attrition rates than those who do not. In terms of cognitive aging, studies have varied considerably in whether individuals with medical conditions known to affect brain function were included in the sample. While such individuals may be typical of their age cohort, their inclusion in studies makes it difficult to determine which cognitive changes can be expected as a function of the aging process itself and which may be a function of epiphenomena associated with aging such as medical conditions.

MENTAL HEALTH AND PERSONALITY

Mental Health Over the Life Span With the exception of dementing disorders and delirium, mental disorders are no more common in elderly adults than in younger age groups. Epidemiological studies have found that prevalence estimates of common disorders such as major depression, anxiety disorders, substance abuse, and psychotic disorders are generally lower for those over the age of 65 than for younger age cohorts. Furthermore, recent longitudinal studies that have followed individuals for up to 25 years found no evidence that rates of emotional distress increase with age.

Age differences in the experience and expression of both positive and negative emotions have also been studied to determine if older adults report more negative emotional experiences than younger adults. In a recent study using a series of large ethnically diverse samples, older adults reported experiencing fewer negative emotions such as sadness, anger, and fear but more positive emotions such as happiness than those in the younger age cohorts. In addition, older adults reported a greater sense of emotional control over negative internal emotional states than younger subjects. To explain their data, the authors proposed an emotional control model suggesting that aging is associated with an increased ability to inhibit negative emotional states and maintain positive emotional ones.

Stage Theories of Personality Development Early personality theorists proposed that development was completed by the end of childhood or adolescence. One of the first development theorists to propose that personality continues to develop and grow over the course of the life span was Erik Erikson. Erikson believed that development proceeded through a series of psychosocial stages, each with its own conflict that is resolved by the individual with greater or lesser success. Erikson termed the crisis of the last epoch of life *integrity versus despair* and believed that successful resolution of this crisis involved a process of life review and achieving a sense of peace and wisdom through coming to terms with how one's life was lived. For example, Erikson proposed that successful resolution of this crisis would be characterized by a sense of having lived one's life well, while a less successful resolution would be characterized by feeling that life was too short, that one did not choose wisely, and bitterness that one will not have a chance to live life over.

Several studies have attempted to validate aspects of Erikson's theory. In one study, a sample of over 400 men was studied prospectively, and the highest Eriksonian life stage each achieved was rated according to data gathered on the circumstances of his life. For example, if a man had achieved independence from his family of origin and was self-sufficient but was unable to develop an intimate relationship, the highest life stage achieved would be the identity stage, not the intimacy stage. This study found that Eriksonian stages are passed through in sequential order, although often not at the same age for different individuals, and that the stages are surprisingly universal in populations that are ethnically and socioeconomically diverse. However, in another study of approximately 150 elderly subjects that included both men and women in the sample, important gender differences emerged. For elderly women, scores on a self-report measure of identity appeared to bear the strongest relationship to a measure of self-realization, while for elderly men, scores on a measure of trust bore the strongest relationship to self-realization. In addition, a recent longitudinal study of approximately 500 subjects from two age cohorts found not only that the earlier age cohort scored significantly higher on a measure of integrity than the later age cohort, but also that scores for both age cohorts on this measure had declined significantly by the final time of testing. These

data suggest that the conflict of integrity versus despair may have a more favorable outcome in earlier age cohorts than in later ones, raising the possibility that changing societal values have had a negative impact on the struggle for integrity. Furthermore, a recent study found that *wisdom*, a construct related to integrity, bore a stronger relation to life satisfaction in elderly adults than other variables, including finances, health, and living situation.

Personality Over the Life Span: Stability or Change? While Erikson and other stage theorists focused on unique developmental tasks and stages central to each phase of life, other theorists have focused on defining core personality traits within the individual and determining their course over the life span. For example, do those who are gregarious or extraverted during early childhood and adolescence remain extraverted through midlife and old age? Several well-designed longitudinal studies that have followed individuals over periods ranging from 10 to 50 years have found strong evidence for stability in five basic personality traits: extraversion, neuroticism, agreeableness, openness to experience, and conscientiousness. Some studies found slight decreases in extraversion and slight increases in agreeableness as individuals move into the oldest-old category, which contrasts with early theories that proposed that personality rigidifies as individuals age.

Is the fact that personality appears to have considerable stability over time inconsistent with the basic tenets of stage theories? Perhaps not. It may be that while individuals are consistent over time in their basic personality structure, the themes and conflicts with which they struggle change considerably over the life span, from concerns about developing identity and a stable sense of self, to finding a life partner, to issues related to life review, as hypothesized by the stage theories. In addition, in developing theories about personality change, few studies have examined the impact of significant historical events on personality; thus the ways in which these events may result in personality change has not been systematically studied.

ADJUSTMENT AND COPING IN ELDERLY ADULTS

Individuals can expect to experience periods of change, disruption, and even crisis throughout the life span. Older adults experience significant challenges as they enter and negotiate the last phase of life, including bereavement, loss of socially valued roles (e.g., worker), and chronic, accumulating health problems. Younger individuals, when viewing the life circumstances of many elderly adults, often wonder how older individuals maintain self-esteem and joy of living in the face of deteriorating health, cognition, and functioning. Questions have been raised about how age affects the process of managing change and discontinuity, with some authors proposing that people become less effective as they age, because of depleted resources, while others have hypothesized that people become better at managing stressful life events over time, having learned more-effective strategies. These questions have been investigated from a wide range of theoretical perspectives; a discussion of several such perspectives follows.

Defensive Processes and Aging Much of the early work in adaptation and coping was generated by theorists working within a psychoanalytic framework. This model is exemplified by George Vaillant's now classic study in which he outlined a hierarchy of defensive processes and assessed age-related changes in them. Using small samples of men studied over 25 years, Vaillant measured the level of defense by blind ratings of numerous vignettes that described a particular conflict or stressor from several different periods in each man's life. Independent overall life-adjustment scores were made on the basis of history, including occupational and interpersonal functioning. Vaillant found that individuals who received the highest life-adjustment ratings were those who used primarily mature defenses (e.g., humor), and corresponding decreases in life adjustment scores were correlated with the use of neurotic defenses (e.g., intellectualization) and immature defenses (e.g., projection). For example, individuals receiving the highest life-adjustment score showed an average of 7.3 (±2.6) vignettes illustrating use of mature defenses, 7.8 (±3.3) using neurotic defenses, and only 0.6 (±0.6) vignettes using immature defenses. In contrast, individuals with only fair life-adjustment scores had an average of 5.2 (±2.6) vignettes using immature defenses, 12.3 (±2.3) using neurotic defenses, and 4.6 (±2.8) using mature defenses. Vaillant also found increased use of mature defensive processes as individuals age, as well as increased use of mature defenses as psychopathology decreased. Although Vaillant's work can be criticized on the basis of possible selection bias, it was one of the first to use prospective methodology in the study of coping and adaptation and the first study to suggest that coping abilities become more adaptive (rather than more regressive) over the life span.

Age Differences in Coping Strategies and Coping Effectiveness A cognitive conceptualization of adaptation is provided by the more recent stress and coping literature. *Coping* is a general term that refers to the actual strategies individuals use to manage stressful life situations that involve perceived or actual threats. It includes strategies designed to reduce emotional distress (e.g., distraction, passive-avoidance, and positive reappraisal) and strategies designed to solve the problem (e.g., direct action, confrontation, and information seeking). Cross-sectional studies of age differences in coping strategies have yielded somewhat mixed results; some studies find no differences between age groups in their use of coping strategies and other studies find that older adults preferentially use strategies designed to reduce emotional distress, while younger adults use more problem-focused coping, although the effect sizes are relatively small. This finding has often led to the conclusion that older adults are more passive in their coping style, yet when the type of stressor is controlled for, these differences are often eliminated or reduced. In addition, older adults are often attempting to cope with situations that are less changeable than those faced by younger individuals, and therefore using coping techniques that attempt to reduce emotional distress rather than solve the problem may be a more effective approach.

Coping effectiveness across the life span is also of interest to gerontologists. The effectiveness of a coping strategy is not defined a priori, but rather by its outcome, usually measured by level of distress, depression, or health symptomatology. Clearly, if individuals become less effective at coping with the demands of life as they age, this has considerable implications for clinical practice and the kinds of interventions that might be used with older adults. However, studies of coping effectiveness have generally not revealed age differences; that is, the old appear to cope as well as the young, and their outcome, in terms of depression and other stress-related symptomatology, is just as favorable. For example, a recent study investigating age differences in coping across a broad range of stressors using a sample of over 2000 men ranging in age from the late 40s to over 90 found no significant age differences in the reporting of negative emotional states in response to stressors or perceived efficacy in coping.

Role Transitions Role transitions are important in the aging process, and in no domain is it more important to understand issues of coping and adaptation than during transitional phases of life. Many transitions are experienced by elderly adults but two major role transitions are especially likely: retirement, or the transition from worker to nonworker, and bereavement, or the transition from spouse to widow. These major transitions challenge the individual to redefine identity and create new roles to replace those that have been lost.

Retirement Retirement is an age-graded event; that is, individuals in our society are expected to retire at a particular age, regardless of health status or personal preference. This is almost entirely a phenomenon of Western, industrialized, and postindustrialized societies; prior to the late nineteenth century, it was largely a personal decision. The transition and adjustment to retirement has been characterized by social gerontologists as a psychosocial crisis, and the image of the successful executive deteriorating or dying soon after retirement has been popularized in the press. However, recent studies have suggested that most recent retirees rank retirement quite low on a list of psychosocial stressors, with 17 percent of men and 11 percent of women reporting dissatisfaction with retirement. Nevertheless, some heterogeneity exists among retirees, and the factors that predict a poor adjustment to retirement include an involuntary or unexpected retirement, low socioeconomic status, health problems, a competitive and highly achievement-oriented personality (the so-called type A behavior pattern), inability to set future goals, and general difficulty adjusting to change. Further, despite early data suggesting that an increased risk of death in the first 2 years after retirement, recent studies controlling for health status at retirement have failed to reveal any associations between retirement and mortality. In addition, when preretirement mental and physical health is controlled for, there are no clear associations between retirement and subsequent physical or mental health consequences. Thus, retirement must be considered in the context of an individual's life and other changes that may be occurring rather than in isolation.

Spousal Bereavement Demographic data suggest that 51 percent of women and 14 percent of men over the age of 65 will be widowed at least once. Bereaved spouses consistently rank spousal loss as among the most stressful of all life experiences. Early work on bereavement and elderly adults hypothesized that older adults might be less able to cope with the loss of a spouse than younger adults, because of declining physical capabilities and subsequent decrements in the ability to manage stress. Subsequent research has revealed age differences in coping with bereavement but in the opposite direction; younger bereaved spouses report greater symptomatology on measures of physical and mental health following bereavement than older spouses. Several factors might account for this difference, including cohort effects, with younger cohorts more comfortable with acknowledging symptoms, or whether the death was expected or unexpected, with unexpected deaths causing greater symptomatology and occurring with greater frequency in younger age groups.

Other recent data are consistent with the idea that as a group, older adults appear to have a more favorable outcome than expected following the death of a spouse. A recent longitudinal study comparing over 120 older bereaved spouses with age-matched nonbereaved controls found that depressive symptoms peak within the first few months after a death but decline significantly within a year, and after 2 or 3 years of follow-up, while bereaved groups still report significantly higher levels of depressive symptoms than age-matched controls, these differences are very small. For example, at 30 months following the death, female bereaved subjects obtained an average score of 7.22 (±6.31) on the Beck Depression Inventory (BDI), a commonly used self-report scale to measure depressive symptoms, compared with an average score of 6.62 (±5.83) for age-matched female control subjects. Both scores are in the nonclinical range. Even during the first few months following bereavement, few older adult widows (between 5 and 17 percent) score in the severely depressed range on depression rating scales. While elderly bereaved spouses report that loneliness and performing activities of daily living complicate adjustment, many older spouses also report positive feelings following a death, such as relief, in contrast to younger samples. Further, the relationship between spousal loss and subsequent mortality has only been found to be significant in younger samples.

Nevertheless, important exceptions exist; studies suggest that elderly survivors of spouses who committed suicide, who have low social support, and who report greater psychopathology at the time of death are all at higher risk of poorer long-term adjustment.

Resilience of the Aging Self Older adults by and large cope well with adversities and challenges, despite often facing more-chronic and accumulating risks. The concept of *resilience*, offered by several theorists to explain this phenomenon, is defined as the process of both maintaining adaptive behavior in the face of stress and recovering from adversity. Rather than viewing the last epoch of life as a period of multiple losses that deplete the individual, resilience theory suggests that maintenance of adaptive behavior despite these losses is a example of the resilience of the aging self. Resilience may involve a process of *selective optimization*, an accommodative process of rescaling goals to match one's limitations and the demands of the environment, and investing the fewer resources available in personally salient activities that maintain self-esteem.

SOCIAL FUNCTIONING IN LATE LIFE

Research over several decades has consistently validated the importance of social support in buffering the effects of stress; given equivalent stressors, individuals with strong social ties appear to have better outcomes than those who are isolated or who perceive that support is unavailable or unhelpful from those in their network. In fact, a recent study of over 1000 elderly adults found that the anticipation of family support in case of financial hardship was effective in reducing depressive symptoms. Yet, elderly adults appear to have reduced social networks and fewer social contacts than younger adults, which may be especially true for the oldest-old individuals, whose social networks are one-half the size of those in the young-old group. This finding was previously thought to be evidence for the *disengagement* hypothesis of aging (i.e., aging involves a process of withdrawal from society and others) and the development of a more inward focus. However, for many older adults, the reduction in social contact is not voluntary and may be more related to disability and reduced mobility than preference. The disengagement hypothesis has been recently reframed as *socioemotional selectivity*, based on the finding that while overall social contacts do decrease in late life, only contact with acquaintances and other peripheral individuals decreases; social contacts with close friends and family remain stable, and older adults' satisfaction with these close relationships remains high. It may be that as individuals age and resources become fewer, those resources are adaptively invested in maintaining close relationships rather than in maintaining acquaintanceships. However, this phenomenon may depend at least partially on the external circumstances of older people's lives. For example, in a recent study of over 500 elderly individuals over the age of 70, the size of social networks and the feelings of connectedness to that social milieu were related to the presence and availability of nuclear family. Older adults with nuclear family members tended to have social networks that were both larger and more emotionally close than those of older adults without nuclear family. On the other hand, those without nuclear family reported greater feelings of closeness to friends than those with nuclear family, suggesting that older adults can adapt to the absence of family by creating satisfying relationships with others.

The social structure of oldest-old individuals has recently been studied, and data suggest that this group may be particularly vulnerable to social isolation because of multiple losses. In a recent study, most individuals over the age of 85 had at least one surviving relative, but approximately one-quarter had little or no contact with that relative. Most social contact was derived from children, and for those individuals without children, social contact and support was not provided by more-distant relatives, except within the African-American community, where other relatives and friends were available to provide help and support. For the oldest-old group then, the family (especially adult children) appears to play a crucial role in providing social support.

COGNITIVE AGING

The study of cognition and aging has been extraordinarily productive over the past several decades. Nevertheless, the existing literature is difficult to interpret, with confusion or disagreement about the inclusion or exclusion of subjects with medical problems and multiple medications and the inadvertent inclusion of subjects with early dementia, which tends to overestimate the effects of age by lowering the overall mean of elderly groups. Furthermore, before magnetic resonance imaging (MRI) scanning was widely used, studies unknowingly included subjects with subcortical ischemic disease, confounding the effects of age with those of disease. In addition, design issues are important; cross-sectional studies that compare individuals of different age groups at one point in time almost always show broader and sharper age effects than longitudinal studies, because of possible confounding of age effects with cohort effects.

Summary of Age Effects on the Major Cognitive Domains The broad domain of cognition has been divided into subdomains that include attentional processes, language functions, visuoperceptual abilities, learning and memory, processing speed, and the executive functions. Age effects on each domain are reviewed below.

Attentional Processes Attentional processes are a complex group of behaviors by which individuals select information for cognitive processing while ignoring competing information, concentrate on information over a sustained period of time, divide attentional focus between two or more aspects of a task at a time, and shift attentional focus from one set of stimuli to another and back again. Basic attention span (the amount of information that can be apprehended at one time) demonstrates little or no relationship to age. Similarly, sustained concentration or vigilance is not affected by the aging process. However, complex attentional tasks that place more demand on cognitive capabilities (e.g., divided attention) show significant declines with advancing age.

Language Functions and Verbal Abilities Language functions remain remarkably stable with age, with few exceptions. Vocabulary and expressive word knowledge may even increase over the life span. Verbal expression and verbal reasoning skills may demonstrate subtle changes with age; some studies have shown that spontaneous language may become less precise and more repetitious over time, although most of these conclusions were drawn from cross-sectional studies and may be confounded with cohort effects. Finally, the ability to retrieve names of objects from the lexicon spontaneously appears to show reliable but small decreases with age, although these effects are heavily influenced by educational achievement.

Visuoperceptual and Visuoconstructive Abilities Visuoperceptual abilities are those functions that involve the recognition and appraisal of nonverbal relationships, specifically those involving shapes, patterns, and objects that are spatially related. Visuoconstructive abilities are those involving the reproduction of nonverbal material, such as the direct copy of simple and complex designs. Visuoperceptual abilities demonstrate relatively consistent age effects across studies, with older adults generally performing as well as younger adults on tests of simple object and pattern recognition but less well on measures of visual closure and spatial orientation. Similarly, in terms of visuoconstructive functions, older adults perform about as well as younger adults when copying simple two-dimensional designs but less well when copying three-dimensional complex designs and when planning and strategy are necessary for good performance. Age effects are largest on visuoconstructive tasks that are timed, and removing the speed component of the task often considerably reduces (but does not remove) the age difference.

Learning and Memory Effects of age on learning and memory are among the best-documented and best-studied effects in the neuropsychological literature. However, memory is an extremely complex set of functions and systems, and the aging process affects some components of memory more than others. Sensory memory (the extremely brief sensory record of a stimulus), primary memory (exemplified by the ability to recall a string of digits long enough to repeat them), and tertiary memory (memories from childhood) show no significant age effects or mild and subtle effects that can be detected in the laboratory. Studies have consistently shown that secondary memory exemplified by the ability to learn information and recall it after a time delay is most strongly affected by age. Nevertheless, the age-related effects on secondary memory are relatively small; studies suggest that performance declines at a rate of 10 percent per decade of life beginning in midlife. However, once older adults learn information, it is retained well; studies suggest that older adults retain information at rates only slightly below that of younger adults. In addition, available data suggest considerably stronger age effects in spontaneous recall than in recognition memory, which is the ability to recognize information previously presented.

Processing Speed Speed of information processing and pure motor speed demonstrate the most reliable age differences and decrements with age, whether measured cross-sectionally or longitudinally. Indeed, reduced processing speed in aging may be a crucial component of many age-related effects on cognition; a recent study found that age effects on a number of neuropsychological tests were considerably diminished after processing speed was partialled out, even on tests where speed of performance was not measured. Nevertheless, it is doubtful that processing speed accounts for all age effects on cognition, as age effects on memory performance appear to be relatively independent of processing speed.

Executive Functions The term “executive functions” refers to those cognitive skills involved in abstract reasoning, problem solving, planning, response inhibition, and the ability to shift cognitive set. Early studies suggested that executive functions decline with age. However, recent studies that use carefully selected samples and exclude subjects with histories of chronic medical conditions known to affect central nervous system (CNS) functioning or documented evidence of subcortical white or gray matter lesions on MRI scanning reveal very few age differences on executive tasks. Because of the relation of performance on tests of executive functioning to the presence of medical conditions, especially diseases of the cardiovascular system, these studies suggest that some of these age effects may be preventable.

Models of Cognitive Aging Taken together, studies suggest a profile of cognitive changes with old age that includes significantly reduced information processing speed and pure motor speed and mild decrements in spontaneous recall, executive skills, complex attentional processes, and complex visuoperceptual and visuoconstructive abilities. While age-related changes in cognition are statistically significant, most elderly persons still perform within normal limits on cognitive

testing. The extent to which these observed changes are related to the process of aging itself, the effects of particular medical conditions on the brain and CNS functioning, or cohort differences in education and experience is not well understood at present, although a recent longitudinal study with a 10-year follow-up interval revealed significant decline in cognitive functions (excluding psychomotor speed) only in individuals suffering from poor health. A number of models proposed to account for these changes include both psychosocial and biological interpretations. First, it is unlikely that all age-related effects on cognition are secondary to cohort differences, as cohort-sequential studies, in which individuals from different age cohorts are followed prospectively, reveal clear longitudinal decline across age cohorts. Unfortunately, few studies have specifically addressed this important question, and they have only investigated intellectual abilities, not functions such as memory or other neuropsychological variables. Cohort effects probably exert the strongest influence on those abilities most dependent on formal education, but this hypothesis has not been formally tested. It is also unlikely that simple disuse accounts for significant aspects of age-related cognitive decline.

The Cattell-Horn model of intellectual changes over the life span proposed that age affects different cognitive processes differently. The model proposes that general intelligence can be subdivided into *crystallized intelligence* (referring to abilities and information learned through exposure to education and life experience) and *fluid intelligence* (referring to abilities involved in novel problem-solving). The model proposes that crystallized intelligence remains stable or increases over the life span, and may even increase into old age, because of continuing exposure to information. In contrast, fluid intelligence, thought to depend on the integrity of brain function, was hypothesized to decline with advanced age. Available data have generally supported this model, with studies showing little evidence of decline on measures of such crystallized abilities as word knowledge or general fund of information, while measures of fluid abilities such as novel problem-solving generally reveal some decline. However, the model as originally proposed is limited in that it only discusses changes in intellectual functions, while excluding other cognitive functions, such as learning and memory. Furthermore, the limitations of studies of executive functions discussed above apply to the fluid intelligence concept.

Neuropsychological models of age-related decline have attempted to integrate findings from cognitive testing with findings from brain imaging and neuropathological studies to suggest possible causes of cognitive changes. The most promising of these is a model called the frontal deficit hypothesis or the frontal subcortical hypothesis, based on the finding that the pattern of cognitive performance in normal aging, although less pronounced, is similar to that seen in many dementing processes affecting primarily subcortical-frontal circuitry. In addition, neuropathological data suggest that frontal-subcortical structures are the most vulnerable to aging, and many studies reveal that neuronal loss and degeneration of dendritic arborization is most prominent in the frontal cortex and in some subcortical areas. Further, definite changes in the vasculature of the brain with age result in ischemic white and subcortical gray matter disease that predominantly affects cognitive processes mediated by frontal-subcortical circuits. Finally, a recent study found that age-related changes in the dopamine system, particularly declines in dopamine type 2 (D_2)-receptor availability in some basal ganglia structures, were related to age-related declines in performance on both motor and executive systems tasks.

The line between a “normal” process of cognitive aging and a pathological process is not well drawn at present. For example, there is considerable disagreement in the field about the inclusion or exclusion of elderly subjects with medical conditions known to affect brain function or individuals with white matter lesions in studies of normal aging and cognition. Since these conditions affect such a high proportion of functional elderly persons, their exclusion may lead to erroneously high estimates of normal expectations of performance and subsequent classification of many individuals as impaired. In addition, many older individuals without known cerebrovascular risk factors or other medical conditions have periventricular white matter lesions on MRI scanning, confusing further the line between disease processes and normal aging. Until this demarcation is better defined, the study of typical aging, which attempts to characterize most elderly people, as well as the study of optimal aging, which attempts to characterize the ideal outcome of both the aging process and changes that are a function of aging itself and not epiphenomena of other conditions, are both important, as long as the appropriate sample is used.

IMPLICATIONS FOR CLINICAL PRACTICE

One of the major points of this chapter is that with the exception of cognitive processes, age per se is rarely an important predictor of outcome. Studies of mental health over the life span, coping and adjustment, and personality often fail to reveal any significant age effects when other factors are controlled. In addition, research has revealed often surprising resilience in older adults. Therefore, the clinician working with older adults should not expect age to be a risk factor for poor outcome. Unfortunately, this notion has probably been partially responsible for the underidentification of depression in many elderly cohorts; many clinicians used to believe that depression was a normal response to aging. Clearly, the life themes older adults struggle with differ from those of younger adults, and the clinician should be prepared to deal with issues of loss, increasing dependency, and the struggle to come to terms with the past. In addition, the concept of resilience may be useful in psychotherapeutic work with older adults; clinicians can encourage patients to selectively invest resources in activities they find especially gratifying.

The important exception to some of these conclusions may be individuals in the oldest-old category (those over the age of 85). Research has shown that these individuals may be at higher risk of social isolation than younger age groups, especially those without living children. Clinicians should be alert to the unique life situations faced by individuals in this age group, who may be especially vulnerable not only to isolation but also to increasing frailty and the cumulative deleterious effects of chronic medical conditions. Interventions that both provide social support and encourage alternative sources of social support such as senior centers may be especially helpful for individuals in this age group without living family.

In terms of cognitive processes, clear decrements exist in some, but not all, cognitive processes over the life span. However, with the exception of processing speed, these changes are generally small. The typical changes in cognition should not have a significant impact on the clinical situation, either the psychotherapeutic encounter or the psychiatric consultation. Some older adults may require more repetition and explanation of material, especially novel and highly abstract material, but this can easily be managed with modified psychotherapeutic approaches. The pattern of cognitive decline seen in normal aging discussed in this chapter should alert the clinician to changes that deviate from this pattern that might be cause for concern, especially such things as difficulties with recalling information even after cueing, problems with basic attentional processes, problems with constructing basic two-dimensional designs, or language impairment.

Finally, since research findings are based on the central or average tendencies of groups of individuals, the conclusions drawn often mask underlying heterogeneity. This may be especially true with elderly adults, as research has shown that the variability of almost every construct studied (e.g., personality, cognition, health status, and income) increases over the life span. This increased heterogeneity is probably a complex interactive process of increasingly individualized expressions of genetic predispositions in response to accumulating demands from the environment over the life span. Thus, the clinician working with older adults may have less precise guidelines or standards for normative expectations for elderly patients, since they can display a much wider range of behavior, personality, and life experience than younger adults.

SUGGESTED CROSS-REFERENCES

Section 51.2d describes neuropsychological evaluation in the older adult. Section 51.1 is a useful overview of many relevant issues in geriatric psychiatry. Section 51.6e contains more information on ethnic and cultural issues relevant to working with older adults. Section 51.1b contains more information on the epidemiology of psychiatric disorders in late life. Section 51.2b and Section 51.2e describe basic physiological and CNS changes with age. Psychotherapy with the older adult is described in more detail in Section 51.4i. Life span development is discussed in Chapter 50 on adulthood, and in Section 6.2, which describes the work of Erik Erikson in greater detail. Section 3.1 contains detailed information on perceptual and cognitive processes in humans.

51.2 ASSESSMENT

51.2D NEUROPSYCHOLOGICAL EVALUATION

KYLE BRAUER BOONE, PH.D.

Elderly individuals comprise an ever larger percentage of the general population. Older individuals are particularly at risk for the development of diseases that compromise cognitive function, leading to substantial declines in quality of life and an economic burden to families and society at large. Thus, for each geriatric patient, one must ascertain whether the observed cognitive abnormalities are treatable. A neuropsychological evaluation is a cost-effective and efficient means of determining if a significant cognitive abnormality is present, and if so its impact on activities of daily living and whether the pattern of cognitive scores points to a specific disease process.

EVALUATION AND DIAGNOSIS

The field of neuropsychological testing initially developed from the observation that different brain areas are associated with specific types of thinking skills and that measuring various cognitive abilities can yield information regarding possible areas of cerebral dysfunction. A neuropsychological evaluation involves standardized paper-and-pencil testing of a broad range of cognitive functions, including memory and learning, language, visuospatial skills, executive/problem-solving skills, motor dexterity, attention, information-processing speed, and overall intelligence.

Basic attention is typically assessed by having patients repeat spoken numbers in both forward and reverse order; significantly lowered attentional ability often signals a delirium or confusional state. Information-processing speed can be measured by having patients rapidly complete rote tasks such as drawing lines between numbers in sequential order, copying codes from a template, reading words, or naming colors. Mild-to-moderate losses in mental speed are found in depressed patients, but marked abnormalities in information-processing speed are prominent in patients with Parkinson's disease and other subcortical dementias.

In most individuals, language skills are tied to left hemisphere functioning. The typical language skills assessed in a neuropsychological evaluation include word-retrieval, word generation, and vocabulary range. Word-retrieval is measured by having patients provide precise names for pictured objects, and word generation is quantified by having them generate words beginning with particular letters (e.g., *F*, *A*, *S*) or in specific categories (e.g., animals) within a circumscribed time period. Measurement of vocabulary range usually involves having patients define various words. Mild declines in word-retrieval and word-generation are often observed in early Alzheimer's disease, multi-infarct dementia, and subcortical dementias, although a marked loss in word generation, a skill associated with left frontal lobe functioning, may signify frontotemporal dementia. For example, while Alzheimer's patients in the early stages of the disease may be able to generate only 20 words beginning with the letters *f*, *a*, and *s* within 3 minutes, a performance 50 percent below that of normal individuals, patients with frontotemporal dementia often generate fewer than 10 words.

Visual perceptual and constructional ability are skills primarily associated with right posterior cerebral functioning. Visual perception can be sampled by having patients identify missing parts of pictured objects. Visual spatial/constructional ability has traditionally been assessed by having patients copy line drawings with paper and pencil or reproduce designs with colored blocks. Low scores on visual perceptual/spatial tasks often suggest Alzheimer's disease or other conditions (e.g., right hemisphere stroke) that interfere with right parietal lobe functioning.

Memory testing usually involves measuring the ability to learn both verbal and nonverbal information. Verbal memory, an ability primarily tied to the left temporal lobe, is typically measured by reading patients a list of words, and then having them repeat the words recalled. Four to five learning trials are generally administered to assess the presence of a learning curve. After a delay of 15 to 30 minutes, patients are requested to recite again the words recalled. The use of an 8- or 10-word list (rather than the more standard 15- or 16-item list used in younger populations) appears adequate to detect the memory difficulties exhibited by older patients. Verbal memory can also be assessed by reading patients a short story and having them recall story gist and details, both immediately and after a delay. Visual memory, a skill that may be primarily related to right temporal lobe function, is typically measured by having patients reproduce or recognize pencil-and-paper designs viewed or copied previously.

The ability to retain newly learned information over a delay is especially correlated with medial temporal lobe functioning, and marked impairment in memory scores is found in patients with prominent hippocampal dysfunction (e.g., those with Alzheimer's disease). For example, many patients with Alzheimer's disease cannot recall any word list items, story details, or components of a geometric design after a short delay.

Executive/problem-solving ability is used to describe higher-level organizational skills requiring planning and monitoring of behavior. These abilities are assessed by (1) divided-attention tests in which patients must keep track of two streams of information simultaneously (e.g., Trails B of the Trailmaking Test, in which patients draw lines alternately between numbers and letters in sequential order), (2) tests involving inhibition of overlearned responses (e.g., the Stroop Test, which contains names of colors printed in an incongruous color ink; patients are to name the ink color rather than read the word), and (3) tests requiring behavioral change in response to environmental feedback (e.g., the Wisconsin Card Sorting Test in which patients must deduce the correct strategy for matching cards by listening to feedback to initial sorting attempts). Executive abilities tend to be particularly sensitive to frontal lobe functioning, and while most patients with Alzheimer's disease, vascular dementia, and subcortical dementia show declines in this sphere, pronounced deficits are seen in patients with frontotemporal dementia. For example, many patients with frontotemporal dementia are completely unable to stop themselves from reading the color names on the Stroop Test.

Table 51.2d-1 lists the general cognitive domains assessed in a neuropsychological evaluation with the tests used to measure that skill and a description of the specific behaviors measured by each test. The tests listed in the table constitute a comprehensive test battery generally appropriate for use with a geriatric population. Use of a comprehensive battery is preferable for confident determination of presence and type of dementia or other cognitive disorder in elderly persons, but in some circumstances, administering a several-hour battery is not possible. Tests marked with an asterisk are the core tests that are most sensitive for detection of a dementia.

Table 51.2d-1 Cognitive Domains

Test score interpretation is a multi-step process. First, patient scores are compared with normative data from same-age peers. Second, an attempt is made to compare the patient's scores with estimates of premorbid levels of function based on educational level, grades in school, and occupational attainment. Cognition is generally judged to be impaired when scores fall 1½ to 2 standard deviations below normative means. However, more minor losses warrant longitudinal monitoring because they may signal the earliest stages of a disease process. In addition, in some cases, current scores may be technically within the normal range but still be judged abnormal if evidence indicates the patient functioned at an above-average level premorbidly. Alternatively, although a patient's scores may be significantly depressed, they have less clinical relevance if the patient functioned at a relatively low level premorbidly.

Finally, the pattern of observed deficits is analyzed to determine whether the lowered scores reflect a viable pattern of cognitive decline or a more random pattern associated with diversity in normal functioning. Recent research has revealed that three fourths of healthy, normal individuals aged 50 and older earn a borderline or impaired score on at least one measure in a comprehensive neuropsychological test battery, while 20 percent of normal older individuals display at least two scores in the impaired range in separate cognitive domains. However, the number of persons showing multiple lowered scores within a cognitive domain is much lower. These findings indicate that isolated lowered scores may simply reflect normal variability.

Periodic neuropsychological reevaluations, typically at yearly intervals, can be used to track disease course and document efficacy of treatment. In addition, sequential testing can help determine when conservatorship or durable power of attorney become necessary and when independent living is no longer a viable choice. Prominent memory difficulties can be expected to compromise effective management of safety and financial matters; for example, the patient may forget to lock doors, take medications, turn off the stove, pay bills.

DIFFERENTIAL DIAGNOSIS

Various neurological, psychiatric, and medical diseases have relatively distinct patterns of cognitive deficits, thus neuropsychological testing can aid in differential diagnosis. However, detecting cognitive abnormalities in elderly persons first requires understanding the cognitive decline associated with normal aging.

Normal Aging Many early studies on cognitive losses associated with aging presented a rather dismal picture of marked deficits in most cognitive domains. However, more recent studies that have appreciated the importance of controlling for substance abuse, psychiatric illness, and medical disease have shown that cognitive losses with advancing age are much more circumscribed than previously observed.

Short-term memory, mental speed, and visual perceptual and spatial skills do appear to decline gradually with advancing age. However, verbal intelligence, most language skills (e.g., vocabulary range, reading, spelling), calculation ability, and basic attention appear to be generally well maintained across the life span of healthy individuals. Even executive abilities, which initially were thought to be the cognitive skills most disrupted by aging, are generally found to be spared in healthy persons. For example, several recent studies found no significant declines in word generation and ability to shift set or increases in perseverative responses in healthy, older individuals.

Men and women display subtle differences in cognitive skills, which may become more pronounced with advanced age. Men appear to have a slight advantage in math calculations, fund of general information, and select visual-perceptual-spatial tasks, while women may show a minor advantage on rote verbal memory tasks, select executive skills, and speeded eye–hand coordination. The superiority of women in rote verbal memory and select executive skills appears to be either confined to or more pronounced in elderly women versus elderly men. Biological environmental factors may play a role in the greater gender differences in cognition observed in advanced age. For example, estrogen enhances and protects verbal skills, and verbal fluency and verbal memory skills are higher in older women on estrogen replacement than in older women without hormonal supplements and older men. In addition, comparison of studies conducted since the 1970s with data collected in prior decades has suggested that gender differences in cognition have declined over the last 30 years, perhaps due to changes in parental socialization practices or more equitable school environments. As a result, measurement of cognitive skills in older cohorts could be expected to reveal larger gender differences than those observed in younger generations.

Medical Illness Chronic cardiovascular illness in particular appears to be related to disruption in select cognitive abilities. Hypertensive patients have shown declines primarily on executive, attentional, mental speed, and memory tests. Similarly, patients with mild-to-moderate cardiovascular disease show lowered scores on speed and executive tasks. One recent study found that cardiovascular health status was a potent predictor of performance on an executive categorization measure, accounting for 28 percent of test score variance.

Factors that positively influence the cardiovascular system, such as regular exercise, low cholesterol and triglyceride levels, and antihypertensive medications, may improve cognition, especially executive abilities. For example, vigorous exercise is associated with superior reasoning, concept formation, and abstraction, as well as rapid information processing. Similarly, decreases in serum cholesterol concentration and hypertriglyceridemia, obtained either through diet or medication, improve cognition, particularly problem-solving ability and concept formation. While most studies have failed to detect any neuropsychological differences between patients treated with antihypertensive medications and those who fail to take medications, a few investigations have shown some evidence of improvement in executive skills after medication treatment.

Diabetes and chronic obstructive pulmonary disease also appear to have a negative impact on cognitive ability. Diabetic patients reportedly perform particularly poorly on tests requiring such executive abilities as complex problem-solving, abstract reasoning, categorization, and divided attention. Similarly, chronic obstructive pulmonary disease has been reported to be associated with decrements in perceptual-motor learning, problem-solving, and motor speed and strength in the context of intact verbal intellectual abilities, alertness, and psychomotor speed.

Taken as a whole, the available literature suggests that executive skills may be particularly sensitive to chronic systemic illness. The physiological mechanism underlying this sensitivity is not known, but in some patients it may be related to decreased cerebral blood flow in anterior brain regions. For example, the relative impairment in executive skills in hypertension is consistent with reported declines in regional cerebral blood flow (rCBF) in the frontal and temporal regions of hypertensive patients. Cognitive declines associated with hypertension and diabetes may also be due to “silent” cerebrovascular lesions in brain white matter. Hypertension and diabetes are risk factors for these so-called white matter hyperintensities observed on brain magnetic resonance imaging (MRI) in older individuals, and recent research has suggested that once a threshold of white matter abnormalities is exceeded, significant deficits in attention and executive abilities are observed.

Depression Depressive symptoms, the most common psychiatric symptoms observed in the elderly population, are estimated to occur in over one fourth of community-residing older individuals, with 1 to 2 percent actually meeting criteria for a major depression.

The term “pseudodementia” has been used to refer to cognitive changes that occur during a depressive episode. The incorporation of *dementia* in the name “pseudodementia” implies that advanced age and depression interact to cause cognitive decline that mimicks that observed in a frank dementia such as Alzheimer's disease. The use of *pseudo* reflects the belief that the cognitive abnormalities are not permanent cognitive impairments and that they normalize when the depression remits. While *pseudodementia* has been useful in alerting mental health professionals to the cognitive sequelae of depression, the underlying assumptions embodied in its name have no empirical support.

Examination of neuropsychological functions of older depressed patients with major depression has revealed evidence for subtle declines in *right hemisphere skills* (e.g., performance I.Q., visual constructional skill, visual nonverbal memory). In addition, increasing severity of depression is associated with additional decrements in mental speed and executive skills. The pattern of cognitive scores, suggesting right hemispheric and anterior cerebral dysfunction, matches evidence from some studies of reduced right hemisphere and bilateral frontal lobe rCBF in depression.

While discrete cognitive difficulties are detectable in depression, the abnormalities are mild and do not approximate the deficits in short-term memory, speed, executive skills, and I.Q. found in degenerative or vascular dementias. In addition, advanced age does not appear to potentiate the effect of depression on cognition; in fact, while subtle differences are documented between depressed and nondepressed subjects under age 70, the cognitive abilities of depressed patients age 70 and older actually appear to converge with those of nondepressed elderly persons. Of interest, the cognitive abnormalities in depression appear to be confined to patients with primarily vegetative symptoms; patients with primarily psychological symptoms (e.g., dysphoria, feelings of guilt, suicidal ideation, worry) appear to be cognitively intact. The abnormalities in mental speed and executive skills appear to be “state” cognitive characteristics limited to acute depressive episodes, and the executive deficits in particular have been found to be predictive of treatment response; recent research suggests that the more severe the executive deficits at baseline, the worse the prognosis for recovery from depression. In contrast, the deficits in visual memory, visual spatial skills, and nonverbal intelligence may be “trait”

cognitive characteristics of depression, remaining after recovery from depression and possibly signaling a chronic underlying abnormality in the right hemisphere.

The above research was limited to patients with major depression of mild-to-moderate severity, and very severe depression may be associated with more marked cognitive impairment. However, if pseudodementia exists, it is rare. It is more likely that if significant cognitive impairment is seen in older depressed patients, it is due to the independent effects of concurrent dementia or some collateral factor such as chronic or acute medical illness or white matter hyperintensities, or to an interaction between depression and medical or neurological illness.

Dementia Diagnosis of dementia requires that the patient meet the criteria outlined in the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV). Specifically, the patient must show evidence of a significant short-term memory impairment, as well as evidence of at least one of the following: (1) language impairment, (2) apraxia, (3) agnosia, and (4) executive dysfunction. Several types of dementia exist; the cognitive characteristics of some of the most common forms are discussed below.

Alzheimer's Disease Alzheimer's disease is a progressive degenerative disorder characterized by accumulation of neurofibrillary plaques and neuritic tangles in the hippocampus, amygdala, and temporoparietal and frontal cortex. Neuroimaging studies in the initial stage of Alzheimer's disease reveal prominent hypometabolism and hypoperfusion of bilateral temporal and parietal lobes. The associated cognitive findings are significant loss in short-term memory for both verbal and nonverbal information and mild-to-moderate losses in visual spatial/constructional skill, word-retrieval, mathematical calculations, mental speed, executive skills, and overall intelligence. While recognition memory is generally superior to free recall, it is still below normal. In contrast, basic attention (as measured by forward digit span), motor dexterity, remote memory, and vocabulary range are generally intact.

The middle stage of Alzheimer's disease is marked by diffuse cerebral hypometabolism and hypoperfusion, with associated marked declines in most standardized test scores. In the final stage of the illness, profound cognitive changes render patients essentially untestable.

The various neuropsychological test scores vary in their utility for diagnosis versus disease staging. Learning and recall scores are the best measures for initial diagnosis of dementia of the Alzheimer's type, since they decline precipitously early in the disease but then plateau. In contrast, because word-retrieval, word-generation, visual spatial skills, and recognition memory decline gradually from onset to the middle stage of the illness, these abilities are better for staging the disease.

Vascular Dementia Vascular dementia is typically associated with multiple infarcts in cerebral gray matter that are readily observed on brain imaging. Given the different etiologies for Alzheimer's disease and vascular dementia, one might expect the two diseases to have distinct neuropsychological profiles. However, empirical comparisons of cognitive scores of the two groups generally have revealed no significant differences, although there are a few exceptions. Some studies have suggested that patients with Alzheimer's disease tend to have intact motor dexterity, while patients with vascular dementia display motor dexterity impairment comparable to their cognitive impairment. This occurs because the infarctions in vascular dementia impinge on motor areas, whereas in Alzheimer's disease, motor function is spared until late in the disease. In addition, Alzheimer's patients may have lower memory scores, especially in visual memory, and show more scatter across I.Q. subtest scores than patients with vascular dementia. Finally, some reports indicate that patients with vascular dementia may exhibit more depression and also more insight into their impairments in activities of daily living, more focal motor and sensory abnormalities and gait disturbance, and more pronounced frontal system impairment (e.g., worse performance on Wisconsin Card Sorting Test, initiate less on unstructured cognitive tasks) than patients with Alzheimer's disease.

Frontotemporal Dementia Postmortem examination of patients with frontotemporal dementia reveals neuronal loss, gliosis, and sometimes spongiosis and Pick bodies but an absence of the neurofibrillary tangles and amyloid plaques seen in Alzheimer's disease. Frontotemporal dementia has traditionally been considered a rare degenerative dementia; however, it is often misdiagnosed as Alzheimer's disease. In fact, recent research has suggested that it may represent up to 25 percent of primary progressive dementia cases.

In contrast to the relative preservation of social skills observed in the early stages of Alzheimer's disease, frontotemporal dementia is characterized by prominent behavioral changes including loss of personal awareness, hyperorality and changes in eating habits, stereotyped and perseverative behavior, progressive reduction of speech, and aggressive and antisocial actions.

Neuroimaging studies reveal distinct cerebral abnormalities in the early stage of the disease involving atrophy and hypoperfusion of frontal lobe or anterior temporal areas. Cognitive performance reflects the underlying cerebral dysfunction and is characterized by significant declines in executive function, with more variable difficulties in memory, word-retrieval, and overall intelligence. As the disease progresses, the cerebral dysfunction spreads posteriorly, and a diffuse cognitive disturbance emerges that is indistinguishable from moderate-to-severe Alzheimer's disease.

Despite the unique neuroimaging findings that distinguish Alzheimer's disease from frontotemporal dementia early in the disease course, empirical studies have suggested that the cognitive differences between the two are relatively subtle. Both groups perform significantly below controls on verbal and nonverbal memory, executive skills, and complex constructional skills, with Alzheimer's patients showing more widespread memory deficits. The two patient groups do not differ significantly from each other except that Alzheimer's patients score lower on select memory variables and frontotemporal dementia patients may exhibit more perseverative behavior and poorer judgment regarding social dilemmas. Thus, examination of absolute scores is of limited use for distinguishing between the two disorders. However, analysis of the relative pattern of scores across cognitive domains appears to show more promise in differential diagnosis. Specifically, Alzheimer patients demonstrate relatively better performance on executive than memory tasks, while frontotemporal dementia patients typically show the opposite pattern. For example, in a recent study, 100 percent of Alzheimer's patients obtained word generation (FAS test) *z*-scores that were superior to Rey-Osterrieth delay *z*-scores, while only 25 percent of frontotemporal dementia patients showed this pattern.

In addition, while both groups demonstrate low scores on pencil-and-paper copy of complex line drawings, they appear to fail for different reasons; Alzheimer patients score poorly because of frank constructional apraxia, while frontotemporal dementia patients obtain substandard scores because of poor organization rather than any actual constructional impairment. This author has also observed that in copying simpler designs, the performance of frontotemporal dementia patients closely approximates that of normal individuals, while Alzheimer's disease patients continue to demonstrate evidence of a constructional disability even on this easier material.

Emerging research is suggesting that cerebral dysfunction in frontotemporal dementia is often asymmetrical, with unique cognitive and behavioral profiles associated with primarily right anterior hypoperfusion and primarily left anterior hypoperfusion. Left frontotemporal dementia involves prominent language abnormalities including anomia and reduced word generation, losses in expressive vocabulary, inability to sequence verbal material, and lowered verbal I.Q., in the context of intact social behavior. In contrast, patients with right frontotemporal dementia frequently display bizarre and socially disinhibited behavior, flat affect and a remote and distant demeanor, lack of facial expression, and intrusive staring. In addition, the cognitive profile is characterized by lowered performance I.Q., word generation superior to design generation, verbal sequencing superior to pictorial sequencing, more-pronounced perseverative behavior, and relatively intact word-retrieval. A frontotemporal dementia subtype has recently been identified, the *temporal lobe variant*, in which degeneration targets anterior temporal and basal frontal lobes, leaving dorsolateral areas intact. The left temporal lobe variant is characterized by pronounced aphasia, while patients with the right temporal lobe variant display marked behavioral aberrations including impulsiveness, bizarre alterations in dress, decreased facial expression, and increased visual alertness. While dementia is typically viewed as leading to global cognitive devastation, a particularly fascinating finding in patients with frontotemporal dementia, especially those with the temporal lobe variant, has been the observation of development of visual artistic skill after disease onset. It is hypothesized that emergence of artistic talent in a subset of patients with frontotemporal dementia is due to (1) sparing of the posterior brain regions tied to visual-spatial and constructional ability and (2) interruption of the inhibitory control of the degenerated anterior brain regions on posterior visual systems. Table 51.2d-2 summarizes the cognitive patterns of the various clinical disorders.

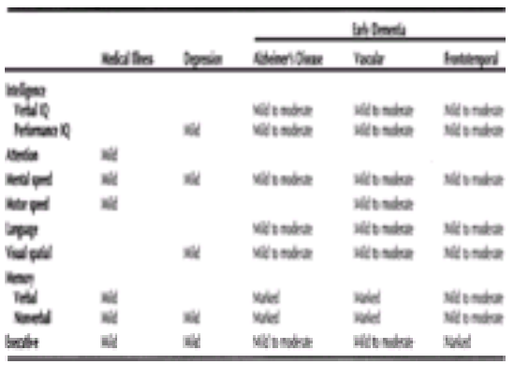

Table 51.2d-2 Summary of Cognitive Deficits for Various Clinical Disorders

SUGGESTED CROSS-REFERENCES

Chapter 3 contains discussions of the biological underpinnings of memory and other thinking processes. For another perspective on neuropsychological assessment, cognitive testing of adults is described in Section 7.4. Neuroimaging findings as they relate to neuropsychiatry and behavioral neurology and geriatric psychiatry are addressed in Section 2.13, Section 51.2e, and Section 51.2f. An overview of normal aging, mood disorder in the elderly, and Alzheimer's disease and other dementing disorders is provided in Chapter 51. For a discussion of cognitive disorders including dementia caused by medical conditions, refer to Chapter 10.

51.2 ASSESSMENT

51.2E NEUROIMAGING: OVERVIEW

ERIC M. REIMAN, M.D.

Neuroimaging techniques provide a window through which clinicians and researchers can peer into the head and study the structure and functions of the living human brain. Structural imaging techniques include X-ray, computed tomography (CT), and magnetic resonance imaging (MRI). Functional imaging techniques include positron emission tomography (PET), single photon emission computed tomography (SPECT), functional magnetic resonance imaging (fMRI), and magnetic resonance spectroscopy (MRS).

As clinical tools in geriatric neuropsychiatry, structural imaging techniques are commonly used to rule out potentially treatable space-occupying lesions in patients with dementia and those who develop behavioral disorders in conjunction with the onset of focal neurological signs. Functional imaging techniques are sometimes used to support the diagnosis of Alzheimer's dementia, frontotemporal dementia, and vascular dementia. As research tools in the behavioral neurosciences, imaging techniques have begun to help characterize the alterations in brain structure and function that are associated with normal aging and those that are involved in the predisposition to, clinical course, behavioral features, treatment, and possible prevention of age-related disorders.

STRUCTURAL IMAGING TECHNIQUES

Computed Tomography CT provides images of tissue density. This technique uses a rotating source of radiation to transmit X-rays through the head, scintillation detectors to characterize the attenuation of radiation as it passes through tissues in the head at different trajectories, and a computer algorithm to transform attenuation values into horizontal sections that reflect the electron and physical density of tissues. (A recently developed technique known as spiral CT can provide an image consisting of volumetric sections in about 10 seconds.) Conventionally, cerebrospinal fluid (CSF), which has low radiation-attenuation values, is black; bone, which has high radiation-attenuation values, is white; and the brain, which has intermediate radiation-attenuation values, is gray. In addition, an image can be acquired following the intravenous administration of an iodinated or noniodinated contrast agent. The intravascular contrast agent can help visualize vascular abnormalities, such as arteriovascular malformations and aneurysms, and it can enhance abnormalities associated with a breakdown in the blood-brain barrier, including tumors, abscesses, recent hemorrhage, and inflammation. Advantages of CT include its affordability, its ability to produce an image quickly (an important consideration in detecting lesions that require acute surgical intervention, such as a subarachnoid hemorrhage, and in studying patients who have difficulty remaining still during the imaging procedure), its ability to detect bony abnormalities and calcified tumors, its safety in patients with pacemakers and certain ferromagnetic foreign bodies, and its freedom from small spatial distortions (not usually a consideration in clinical psychiatry). Disadvantages of CT include “beam-hardening artifacts,” which make it difficult to characterize tissues in close proximity to bone (such as inferior frontal and anterior temporal cortex), relatively poor sensitivity in detecting white matter lesions, relatively poor contrast between white matter and gray matter, the inability to acquire sagittal or coronal sections (an advantage for certain lesions), and relatively uncommon but potentially dangerous allergic reactions to the iodinated contrast agent.

Magnetic Resonance Imaging MRI provides information about the response of hydrogen protons in water to perturbations in an externally applied magnetic field. This technique uses a strong magnet (typically 0.5 to 1.5 Tesla), causing protons in water to precess in the same frequency along the axis of a strong magnetic field; brief radio-frequency pulses to tip these protons away from this axis; and radio-frequency receivers to measure one of the three following parameters: T1-relaxation, which reflects the rate at which the protons in water return to the axis of the magnetic field; proton density; and T2-relaxation, which reflects the rate at which the protons decline to precess at the same frequency because of nonuniformities in surrounding protons. Using different radio-frequency pulse sequences, MRI can provide different kinds of images. T1-weighted images are commonly used to characterize normal anatomy: conventionally, gray matter is gray, white matter is white, and CSF is black. T2-weighted images are commonly used to detect brain pathology because cerebrospinal fluid (CSF) and brain lesions (which typically are associated with increased water) are white. Proton density images are intermediate in density. In addition, an MRI image can be acquired following intravenous administration of a paramagnetic contrast agent (most commonly gadolinium diethylenetriamine pentaacetic acid [GdDTPA]). As in CT, the intravascular contrast agent can help visualize vascular abnormalities, such as an arteriovascular malformation or aneurysm, and it can enhance abnormalities associated with a breakdown in the blood-brain barrier, including certain tumors and abscesses, a recent hemorrhage, and inflammation. Its advantages include the ability to characterize potentially complementary tissue parameters, its sensitivity to detect white matter (T2 hyperintensity) lesions, excellent contrast between gray matter, white matter, and CSF, the ability to study brain tissues in close proximity to bone (which is not visualized), the ability to acquire images in any orientation, the ability to acquire volumetric images containing contiguous sections with extremely high spatial resolution, the absence of allergic reactions to the paramagnetic contrast agent, and the absence of ionizing radiation. Disadvantages of MRI include its expense, the inability to detect bony abnormalities and calcified tumors, the duration of the imaging procedure (an important consideration in detecting lesions that require acute surgical intervention and in studying patients who are unable to remain still), claustrophobic anxiety, contraindications to the magnet (e.g., a pacemaker and certain ferromagnetic foreign bodies), and small spatial distortions and signal losses due to inhomogeneities in the magnetic field (a consideration in quantitative, morphometric studies that seek to measure the volume of different brain regions). With only a few exceptions, MRI is the structural imaging technique of choice in clinical psychiatry and the behavioral neurosciences.

FUNCTIONAL IMAGING TECHNIQUES

Positron Emission Tomography PET is an imaging technique that provides information about physiological and biochemical processes. This technique capitalizes on the synthesis and administration of a positron-emitting radiotracer; an imaging system to record PET counts; attenuation-correction and image-reconstruction algorithms to transform PET count records into horizontal images of tissue activity; tracer-kinetic models (mathematical equations that account for the behavior in the body) to convert tissue activity data into quantitative measurements of biochemical or physiological processes; and increasingly sophisticated image-analysis techniques. These still-developing techniques can be used to coregister the blurry images of brain function onto each subjects' volumetric MRI; define anatomical regions of interest; segment the brain into gray matter, white matter, and CSF tissues; correct PET images for the combined effects of atrophy and partial-volume averaging (i.e., contributions from neighboring CSF and white matter regions to measurements in a gray matter region of interest, which are expected to be greater in subjects with brain atrophy); deform brain images into the spatial dimensions of a standard brain atlas; and compute statistical maps that compare PET data acquired in different subjects.

PET measurements of cerebral blood flow and the cerebral metabolic rate for glucose are markers of local neuronal activity; these commonly used measurements have the potential to characterize regions of the brain that are preferentially involved in normal human behaviors, those that are preferentially affected during normal human aging, and those that are involved in the pathophysiology, clinical course, possible diagnosis, and possible treatment of age-related disorders. Because of the unusually short radioactive half-life of the cerebral blood flow tracer [^{15}O] water, cerebral blood flow measurements are usually used in studies that involve multiple scans during a single imaging sessions (e.g., scans acquired during memory and control tasks); because of the quality of images acquired over a 30- to 60-minute period following the uptake of the cerebral metabolic rate for glucose tracer [^{18}F]-fluorodeoxyglucose, these measurements are usually used in studies that involve comparisons across imaging sessions (e.g., clinical studies, comparison of patients with controls, and longitudinal studies performed during the resting state or a single, psychophysiologically stable behavioral task). In addition to these measurements, PET measurements of cerebral blood volume, the cerebral metabolic rate for oxygen, and the oxygen extraction ratio have been used to investigate the viability of ischemic brain regions in patients with cerebrovascular disease. While PET measurements of the cerebral metabolic rate for glucose have the potential to grade tumors and predict survival time with greater accuracy than the histological grade of sampled tissues, PET measurements of amino acid uptake are increasingly used to define the spatial extent of these tumors. PET measurements of dOPA decarboxylase activity (using [^{18}F]6-fluoro-dOPA) and the density of dopamine transporter sites provide information about the functional integrity of dopaminergic

neuronal terminals in the striatum, which is reduced in patients with Parkinson's disease. PET has the potential to characterize a wide range of neuroreceptor and neurotransmitter processes. Techniques have been developed for estimating the density of dopamine D_1, D_2, D_3, D_4, and transporter receptors, serotonin 1A, 2A, and transporter receptors, glutamate *N*-methyl-D-aspartate (NMDA) receptors, acetylcholine muscarinic and nicotinic receptors, μ-opioid and d-opioid receptors, benzodiazepine omega-1 and omega-2 receptors, and estradiol receptors; for characterizing how synaptic concentrations of neurotransmitters (including dopamine, serotonin, acetylcholine, and endorphins) are affected in relation to pharmacological challenges and behavioral tasks; for characterizing the synthesis of serotonin and dopamine and the activity of monamine oxidase types A and B. Techniques are now being developed to investigate second-messenger processes.

Compared with other functional imaging techniques, PET has several advantages. Compared with SPECT and MRS, PET is more sensitive in detecting processes that occur in minute concentrations (such as neurotransmitter and neuroreceptor processes). Compared with SPECT, PET also has the potential to measure a wider range of biochemical and physiological processes (partly because the positron-emitting radiosotopes ^{15}O, ^{11}C, ^{13}N, and ^{18}F can be incorporated into physiological and pharmacological compounds without affecting their behavior in the body) and has fewer artifacts from radiation scatter and attenuation (because of the current availability of attenuation-correction procedures). Compared with fMRI, advantages of PET include a better-established role in comparing images acquired in the resting state during different scanning sessions (e.g., in patients versus controls, before and after treatment, and in longitudinal studies of aging and age-related disorders); less-severe artifacts from head movement, claustrophobic anxiety, and ambient noise; the absence of signal dropout in brain regions in close proximity to sinuses (e.g., the hippocampus); the ease with which one can provide sensory stimuli and acquire ancillary measurements during the imaging session; and the ability to characterize a wide range of neurochemical processes. Disadvantages of PET include its relatively low spatial resolution (limiting its ability to characterize changes in extremely small regions, such as brainstem nuclei), the time required to acquire an image (requiring behavioral and baseline tasks to be studied in blocks), radiation exposure (limiting the number of scans that can be acquired in normal volunteers), expense (typically, about $1500 to $2000 per scan), and limited availability.

Single Photon Emission Computed Tomography Like PET, SPECT is an imaging technique that provides information about biochemical and physiological processes. This technique capitalizes on radiosotopes (e.g., ^{123}I, ^{99m}Tc, ^{133}Xe) with longer radioactive half-lives than those used in PET studies, permitting their manufacture at facilities far away from the imaging system; while more powerful systems continue to be developed, the most widely available systems use one to three gamma cameras that rotate around the head. SPECT is commonly used to provide measurements of cerebral blood flow (e.g., using the radiotracer ^{99m}Tc-hexamethylpropyleneamine oxime [HMPAO]). SPECT also has the potential to measure neuroreceptor processes. Techniques have been developed for estimating the density of acetylcholine presynaptic and muscarinic receptors and dopamine type 1 (D_1), D_2, and transporter receptors. Compared with PET, SPECT studies are less expensive and more widely available. However, SPECT provides a smaller range of biochemical and physiological measurements; current imaging systems have a slightly lower spatial resolution, have lower sensitivity for detecting processes that occur in minute concentrations, and cannot acquire transmission images for the correction of radiation attenuation. The longer-lived radioisotopes tend to be associated with slightly higher levels of radiation exposure.

Functional Magnetic Resonance Imaging First demonstrating its brain mapping potential in 1991, fMRI is a rapidly developing imaging technique that can provide information about regional cerebral blood volume and perfusion in the baseline state and state-dependent within-session changes in cerebral blood volume, cerebral blood flow, and blood oxygenation. fMRI techniques typically use conventional MRI systems (typically 1.5 to 4.7 Tesla) and either an echo planar imaging (EPI) platform (an ultrafast imaging technique usually requires specialized gradient coils for the whole body or head) or a spiral multishot imaging platform. These techniques capitalize on an exogenous or endogenous paramagnetic material to produce a measurable magnetic susceptibility contrast.

To measure cerebral blood volume, one technique capitalizes on an intravenous paramagnetic contrast agent, such as Gd(DTPA), and EPI to dynamically track its passage through small cerebral blood vessels. This technique has been used to map regions of the brain that are involved in normal human behaviors (though it is less commonly used for this purpose than techniques that do not require an exogenous contrast agent) and to identify reductions in temporoparietal cerebral blood volume in patients with Alzheimer's disease. To measure CBF, techniques generally capitalize on arterial spin labeling, in which arterial blood is magnetically tagged prior to its arrival in the imaging plane and EPI is used to track its passage dynamically through small blood vessels. Recently, researchers have begun to develop techniques to generate quantitative cerebral blood flow images, acquire data from a larger number of brain slices, and identify reductions in temporoparietal blood flow in patients with Alzheimer's dementia. Brain oxygen-level dependent (BOLD) contrast capitalizes on the observation that increased local neuronal activity is associated with increases in cerebral blood flow, cerebral blood volume, and oxygen delivery that exceed the cells' need for oxygen, leading to an increased concentration of oxygenated hemoglobin and a decreased concentration of the paramagnetic material deoxygenated hemoglobin in venules and veins. While BOLD is extremely well suited for investigating state-dependent changes in local neuronal activity (e.g., mapping regions of the brain that are involved in normal human behaviors) and has the potential to investigate how these state-dependent changes are affected by aging and age-related disorders, it cannot be used to characterize differences in baseline measurements of brain oxygenation (e.g., task-independent, between-session differences in patients versus normal control subjects, the treated versus nontreated state, and different stages of aging and age-related disorders).

Advantages of fMRI include its spatial resolution (although the spatial relationship between neuronal activity and the hemodynamic response is a limiting factor), its ability to acquire images quickly (although its ability to characterize the sequence of neuronal events may be limited by the lag time between neuronal activity and the hemodynamic event), and the absence of ionizing radiation. Disadvantages include the confounding effects of head movement, claustrophobia, practical challenges providing sensory stimuli or ancillary measurements during the scan, signal dropout and spatial distortions in certain brain regions (e.g., the anterior temporal lobe), and the inability to use BOLD contrast to compare data acquired in the baseline state in different subjects or during different scanning sessions. The last limitation may be addressed by further improvements in the application of fMRI to quantitative perfusion imaging.

Magnetic Resonance Spectroscopy MRS provides information about certain biochemical and physiological processes. This technique capitalizes on the extent to which the response of atoms with an odd number of protons and neutrons (e.g., ^{1}H, ^{7}Li, ^{13}C, ^{19}F, ^{23}Na, and ^{31}P) to perturbations in an externally applied magnetic field is affected by surrounding atoms. MRS uses highly homogeneous, high-field (e.g., 1.5 to 4.7 Tesla) MRI systems, radio-frequency pulses that selectively resonate a particular element, and a localized surface coil to provide information about the relative concentrations of compounds that incorporate that element. For instance, ^{1}H MRS can provide regional information about the relative concentration of *N*-acetyl-L-aspartate (NAA), which is thought to be localized in neurons and is thus a measure of viable neurons; inositol, which is involved in the inositol phospholipid second-messenger cascade; choline-containing compounds, some of which participate in the synthesis and degradation of membrane phospholipids. While patients with Alzheimer's dementia appear to have reduced concentrations of NAA in temporoparietal cortex and other brain regions, additional research is needed to determine the extent to which reduced NAA concentrations distinguish Alzheimer's disease from other forms of dementia, preferentially affect certain brain regions, are related to reductions in neuronal number or the combined effects of atrophy and partial volume averaging, and are related to the density of neuritic plaques, neurofibrillary tangles, and clinical course. ^{31}P MRS can provide information about the relative concentrations of phosphomonoesters and phosphodiesters, precursors and degradation products of membrane phospholipids, respectively; adenosine triphosphate (ATP), adenosine diphosphate (ADP), inorganic phosphate, and phosphocreatine, which are involved in high-energy-phosphate metabolism. Although findings from ^{31}P MRS in patients with Alzheimer's disease have not been entirely consistent, one study found that the phosphomonoester concentration increased in the early stage of the dementia and decreased in the later stages. Since MRS provides relatively unique information about brain chemistry, it has the potential to complement other neuroimaging and neuroscientific methods. Its limitations include poor sensitivity for detection of processes that occur in minute concentrations (e.g., neurotransmitters and neuroreceptors), poor spatial resolution, and an inability to compare measurements throughout the brain. Further research is needed to determine the role of MRS in the differential diagnosis of dementia and other age-related disorders.

NORMAL AGING

Understanding how alterations in brain structure and function are related to the pathophysiology, treatment, natural history, and diagnosis of age-related neuropsychiatric disorders requires understanding the alterations associated with normal aging. Studies of usual aging, which seek to characterize how the brain is affected in a representative sample of older subjects, must be distinguished from studies of “successful aging,” in which researchers attempt to characterize how the brain is affected independent of the potentially confounding effects of psychiatric, substance use, neurological and other medical disorders, and cardiovascular risk factors. It is also important to distinguish between cross-sectional studies of aging, which could be influenced by cohort effects (such as increases in brain volume, intracranial volume, or both in successive generations), and longitudinal studies, which are time-consuming, subject to potentially selective attrition effects, and vulnerable to the possibility that the study might outlive the usefulness of the original technology as improved image-acquisition techniques become available.

Postmortem studies suggest that normal aging is associated with reductions in brain volume and the number of large neurons (due more to cell shrinkage than to cell loss) and white matter changes (including a loss of myelin content and an increase in interstitial fluid). The reductions in brain volume and number of large neurons appear to be greatest in certain regions of prefrontal cortex. Imaging studies of the living human brain have supported some of these postmortem findings independent of the potentially confounding effects of selection bias (e.g., different preexisting illnesses and causes of death in younger and older age groups) and brain-fixation artifacts.

Atrophy Structural brain-imaging studies consistently find that aging is associated with reductions in whole brain volume; cortical thinning; enlargement of lateral ventricles, the third ventricles, and extraventricular cerebrospinal fluid spaces; and more-prominent sulci. These changes appear to begin at about 40 years of age, become more pronounced after age 60, and tend to be most pronounced in certain regions of prefrontal cortex (although other cortical and subcortical gray matter structures are also affected). In general, anatomical measurements become more variable with aging, and this variability is at least partly attributable to the presence of age-related disorders. So far, studies have not found a consistent relationship between age-related reductions in brain volume and neuropsychological test scores. While volumetric methods provide the most sensitive measure of brain atrophy, qualitative rating scales have been used to demonstrate that atrophy is not an inevitable consequence of aging (since the rating of mild atrophy is found in only half of persons by approximately age 70), that in the absence of age-related disorders the atrophy associated with normal aging is rarely rated more severely than mild, and conversely, that the identification of mild atrophy in a clinical study should not be used to confirm the diagnosis of an age-related disorder.

White Matter Lesions Aging is associated with an increased likelihood and severity of focal hyperintensity lesions on T_2-weighted MRIs. The lesions are found most commonly in deep white matter regions and less commonly in the pons, periventricular white matter regions, and the basal ganglia. It may be important to distinguish hyperintensity lesions that appear as periventricular caps or rims from those that appear as periventricular halos and those that extend more deeply into white matter regions or basal ganglia. Lesions in the form of periventricular caps or rims are commonly found in older persons independent of age-related neuropsychiatric disorders, diabetes, or cardiovascular risk factors, and are probably related to decreased myelin content, increased interstitial fluid, and other factors. The other lesions are more likely to be associated with age-related neuropsychiatric disorders (e.g., vascular dementia, dementia of the Alzheimer's type, late-onset depression, and bipolar I disorder), diabetes, or cardiovascular risk factors; these lesions could reflect a range of histopathological changes, including vascular ectasia, dilated perivascular spaces, edema, decreased myelin content, meningeal thickening, atherosclerosis, amyloid angiopathy, and lacunar infarcts.

Neurophysiological Changes When subjects with age-related disorders and cardiovascular risk factors were rigorously excluded from study, successful aging was not associated with significant reductions in whole brain cerebral blood flow or cerebral metabolic rates for oxygen or glucose in the resting, baseline state. When subjects with these disorders were not rigorously excluded from study, usual aging was associated with modest reductions in these measures in the resting baseline state, which could be at least partly related to the combined effects of atrophy and partial-volume averaging. Consistent with MRI and postmortem histological studies, PET studies suggest that normal aging preferentially affects regions in prefrontal cortex. After normalizing data for the variation in absolute measurements, successful and usual aging are associated with significant reductions in prefrontal cerebral blood flow and cerebral metabolic rates for oxygen and glucose in the resting baseline state. These reductions appear to be magnified during visual stimulation (though the use of standard tasks introduces the potentially confounding effects of differential task performance, such as age-dependent reductions in visual acuity). Although normal aging did not affect cerebral blood flow increases in the hippocampal formation during a memory retrieval task, it did affect the location of blood flow increases in prefrontal cortex, suggesting that aging alters some of the executive strategies that participate in tasks, such as memory retrieval. The finding that cognitively normal persons homozygous for the apolipoprotein E (APOE) type 4 allele have a reduced prefrontal cerebral metabolic rate for glucose in late middle age supports the possibility that this Alzheimer's disease susceptibility gene accelerates certain aging processes, and it illustrates the potential of imaging techniques to characterize the extent to which putative risk factors and therapeutic interventions might accelerate or retard aspects of neural aging.

Neurochemical Changes A few studies have investigated the effects of normal aging on neurotransmitter and neuroreceptor processes. While one PET study suggests that usual aging is associated with reduced uptake in the striatum of 6-fluoro-dopa (a marker of dopaminergic, nigrostriatal neuronal terminals), a PET study of more rigorously screened subjects suggests that successful aging is not associated with a significant decline in this measurement. Other PET studies find that normal aging is associated with reductions in the density of available presynaptic dopamine transporter sites, D_1 receptors, and D_2 receptors, muscarinic (M_1, M_2) receptors, and serotonergic (5-hydroxytryptamine [5-HT]) type 2 (5-HT_2) receptors. While these findings are consistent with data from postmortem studies, subjects with age-related neuropsychiatric disorders and cardiovascular risk factors were not routinely excluded, the validity of the radiotracer technique used to characterize D_1 receptors remains to be established, and reductions could be at least partly related to the combined effects of atrophy and partial-volume averaging.

DEMENTIA

Structural brain-imaging techniques are indicated in the diagnostic evaluation of dementia to rule out potentially treatable space-occupying lesions, including brain tumors, cerebrovascular lesions (e.g., subdural hematomas, other hemorrhages, infarcts, and pathological white matter lesions), abscesses, a chronic meningitic process, and normal pressure hydrocephalus and to provide evidence supporting several forms of dementia (such as vascular dementia, Pick's disease and other frontotemporal dementias, an asymmetric cortical degeneration syndrome, and a prior traumatic encephalomalacia). This section briefly considers characteristic brain imaging abnormalities in groups of patients with dementia of the Alzheimer's type, vascular dementia, and other forms of dementia; the promising but not fully established role that functional brain imaging techniques may play in the clinical diagnosis of patients with mild or atypical patterns of cognitive impairment and no known reversible causes; and the emerging use of brain imaging techniques to characterize abnormalities in cognitively normal persons at risk for Alzheimer's disease and to test the ability of treatments to prevent the onset of dementia.

Alzheimer's Disease Alzheimer's disease is the most common form of dementia, accounting for 50 to 75 percent of dementia cases. It is characterized clinically by a gradual but progressive decline in memory and other cognitive abilities and histopathologically by neuritic plaques, neurofibrillary tangles, and a loss of neurons and synapses. The clinical diagnosis of dementia of the Alzheimer's type (or probable Alzheimer's disease), which depends on the exclusion of other causes of dementia through a history, physical and neurological examinations, and laboratory tests, conforms to the histopathological diagnosis in about 70 to 90 percent of cases but is least reliable in the earliest stages of the illness.

Although brain-imaging studies are not routinely indicated to confirm the diagnosis of Alzheimer's disease, they have identified statistical differences between groups of patients with this disorder and normal control subjects. Further research is required before imaging techniques are routinely indicated to confirm the diagnosis of Alzheimer's dementia. Since these techniques cannot predict whether or when persons at risk for Alzheimer's disease will develop dementia, can cause false alarm or false reassurance, and provide no guidance about strategies to prevent the onset of dementia, they are not clinically indicated to predict a person's risk for this catastrophic disorder. Still, some of these techniques could be used scientifically to help test the ability of treatments to retard disease progression (rather than compensate for disease progression) in patients with Alzheimer's disease, persons with mild cognitive impairment (who are at increased risk for dementia of the Alzheimer's type), and cognitively normal persons at genetic risk for Alzheimer's disease.

Volumetric MRI studies find reductions in hippocampal volume and increased rates of cortical atrophy in patients with Alzheimer's disease, which are correlated with the severity of cognitive impairment. Although not clinically indicated, studies of persons at genetic risk for Alzheimer's disease suggest that hippocampal volume reduction tends to begin in conjunction with memory decline, shortly before the onset of Alzheimer's dementia. Techniques for the reliable measurement of hippocampal volumes are labor intensive. Characterizing increased rates of cortical atrophy requires sequential studies (typically, at least one annual follow-up study), some manual processing in addition to an automated image-subtraction algorithm, and confirmation of their predictive value. Additional research is required to establish the sensitivity, specificity, prognostic value, and therapeutic implications of structural brain-imaging techniques in the clinical diagnosis or prediction of Alzheimer's disease.

While some MRI studies fail to find an increased number of T2-hyperintensities in rigorously screened patients with Alzheimer's dementia, others find an increased number of hyperintensities in periventricular regions. One postmortem MRI study found that these hyperintensities were related to loss of myelin content, arterial changes, and a breakdown of the ventricular lining. Clinically, the presence of periventricular white matter changes should neither confirm nor exclude the diagnosis of dementia of the Alzheimer's type.

PET studies find characteristic abnormalities in cerebral blood flow and cerebral metabolic rates for oxygen and glucose in patients with Alzheimer's dementia, including reductions in posterior cingulate, posterior parietal, temporal, and prefrontal regions. Reduced measurements in posterior cingulate and cinguloparietal transitional cortex appear to provide the earliest index of Alzheimer's disease pathology, reductions in posterior parietal and temporal regions also appear relatively early, and reductions in prefrontal and whole brain measurements appear to develop in more advanced stages of the disorder. While the reductions in regional metabolic rates for glucose are typically bilateral, they are sometimes asymmetrical (especially in the earlier stages of the illness) and more-prominent reductions are sometimes found to correspond to salient clinical features (e.g., a reduction in left temporal metabolic rate for glucose in a patient with aphasic symptoms). The metabolic rate for glucose is relatively spared in primary visual and somatosensory cortex and may be least affected in the pons. While reduced metabolic rates for glucose in parietal and temporal regions have also been reported in Parkinson's dementia and dementia with Lewy bodies, the latter disorder may be distinguished from most cases of Alzheimer's disease by an additional reduction in occipital regions containing primary visual and visual association cortex. Additional studies are required to further differentiate these forms of dementia by the pattern of regional reductions in the metabolic rate for glucose throughout the brain. Although the reductions observed in heteromodal sensory association areas in patients with Alzheimer's dementia appear to be greater than those observed in the hippocampal

formation (which histopathological and structural brain-imaging studies find to be affected in the early stages of Alzheimer's dementia), relatively few studies have examined hippocampal measurements using coregisteredMRIs and reliable methods for characterizing the hippocampal region of interest. The observed PET abnormalities could reflect reduced density, viability, or metabolic function in the terminal neuronal fields that innervate the implicated regions (rather than the cell bodies that arise there), the combined effects of atrophy and partial-volume averaging, or a combination of these factors.

Automated algorithms to generate surface-projection three-dimensional maps appear to be more powerful than visual inspection in the detection of PET abnormalities. As research tools, these still-developing algorithms have been used to demonstrate that cognitively normal persons at risk for Alzheimer's disease have reduced cerebral metabolic rates for glucose in the same brain regions as patients with Alzheimer's disease. If the PET abnormalities prove to be progressive, PET could be used to test the ability of treatments to prevent Alzheimer's disease without having to wait many years to determine whether or when treated persons at risk go on to develop symptoms. Using the same algorithms, preliminary studies suggest that PET is about 94 percent sensitive and 99 percent specific for Alzheimer's disease in patients with questionable or mild dementia. While additional studies are required to confirm the ability of PET to distinguish Alzheimer's disease from other conditions (e.g., Parkinson's dementia and dementia with Lewy bodies) in the early stages of cognitive impairment, provide information about a patient's prognosis, and influence treatment decisions, some clinicians use this technique to confirm the diagnosis in patients who have mild or atypical cognitive impairment, no known reversible causes, and family members who are otherwise reluctant to accept the diagnosis. While PET scans are most commonly performed in the resting state, unconfirmed reports raise the possibility that scans acquired during the performance of visual, audiovisual, memory, or other behavioral tasks might enhance the ability to detect PET abnormalities in the earliest stages of Alzheimer's disease.

All patients with trisomy 21 (Down syndrome) have neuritic plaques by the age of 40, and about 75 percent have Alzheimer's disease by the age of 60. PET studies find that older patients with this disorder have a pattern of reductions in cerebral metabolic rate for glucose similar to that observed in Alzheimer's dementia (e.g., reductions in temporoparietal measurements). While one report suggests that abnormalities in preselected temporoparietal regions of interest are enhanced if the subjects are studied during the performance of an audiovisual task, it would be helpful to compare the sensitivity and specificity of PET to detect characteristic reductions when automated brain mapping algorithms are used to compare data acquired during the resting state, audiovisual tasks, and other behavioral tasks.

SPECT cerebral blood flow studies and still-developing fMRI cerebral blood flow and blood volume studies find that patients with Alzheimer's dementia have a pattern of regional abnormalities similar to that observed in PET studies in the resting state. Additional research is needed to refine MRI methods for the acquisition of quantitative cerebral blood flow images and directly compare the sensitivity and specificity of PET metabolic rate for glucose, SPECT cerebral blood flow, and fMRI cerebral blood flow imaging in the diagnosis of Alzheimer's disease. ^{1}H MRS studies find that patients with Alzheimer's dementia have reduced concentrations of NAA (a marker of intact neurons) in parahippocampal, parietal, temporal, and frontal regions, some of which appear to be correlated with the local density of neuritic plaques and neurofibrillary tangles. A ^{31}P MRS study suggests that patients with Alzheimer's disease have increased levels of phosphomonoesters (membrane phospholipid precursors), increased cerebral metabolic rate for oxygen, and reduced levels of phosphocreatinine and ADP (ATP precursors) during the early stages of dementia of the Alzheimer's type and reductions in each of these measures during the subsequent stages of the illness. A placebo-controlled study by the same group suggests that the compound acetyl-L-carnitine (a compound reported to normalize membrane and energy metabolism and increase the effects of nerve growth factor in animals) normalized phosphomonoester concentration and attenuated cognitive deterioration in a small group of patients with Alzheimer's disease. While this finding requires independent confirmation in larger subject groups, it illustrates the promise of MRS and other imaging techniques in the study of this disorder and its treatment. While MRS promises to complement other research methods, it is not yet clinically indicated in the diagnosis of Alzheimer's disease.

Dementia With Lewy Bodies Though well characterized only recently, dementia with Lewy bodies may be the second most common form of dementia. While this form of dementia shares several clinical features of Alzheimer's disease, it tends to begin at an earlier age, fluctuate in severity, and progress more rapidly, and it is associated with more prominent parkinsonian features, particular sensitivity to the extrapyramidal side effects of antipsychotic medications, and visual hallucinations. Histopathologically, the disorder is distinguished by the presence of Lewy bodies in the cerebral cortex; it also displays Lewy bodies in subcortical regions (as does Parkinson's disease) and neuritic plaques (as does Alzheimer's disease). With or without dementia, patients with diffuse Lewy body disease appear to have reductions in posterior cingulate, parietal, temporal, and prefrontal metabolic rates for glucose similar to those observed in patients with dementia of the Alzheimer's type. However, they appear to be distinguished from patients with Alzheimer's disease (except, perhaps, in those Alzheimer's disease cases associated with Balint's syndrome and other complex visual disturbances) by additional reductions in occipital areas containing primary visual and visual association cortex. Additional research is needed to determine the extent to which PET and SPECT can distinguish dementia of the Alzheimer's type from dementia with Lewy bodies in the earliest stages of the illness.

Dementia Due to Parkinson's Disease Some 20 to 60 percent of patients with Parkinson's disease develop dementia, usually late in the course of the illness. Analyzing preselected regions of interest, dementia due to Parkinson's disease is associated with reductions in parietal and temporal metabolic rates for glucose—indeed, this pattern was shown early in the course of one patient with histologically confirmed dementia due to Parkinson's disease (i.e., Lewy bodies confined to the substantia nigra and no neuritic plaques) prior to the onset of extrapyramidal features, suggesting that this pattern is not specific for Alzheimer's disease. Additional studies using automated brain-mapping algorithms and histopathological confirmation are needed to determine the extent to which PET and SPECT can distinguish Parkinson's disease from Alzheimer's disease and dementia with Lewy bodies in the earliest stages of the illness. PET studies of 6-fluoro-dopa uptake and PET and SPECT studies characterizing the density of dopamine transporter sites reveal abnormal reductions in the striatum of patients with Parkinson's disease. Additional studies are needed to confirm the extent to which these reductions distinguish dementia with Parkinson's disease from Alzheimer's disease and dementia with Lewy bodies and the extent to which these differences might predict outcome or influence treatment decisions.

Pick's Disease and Other Frontotemporal Dementias Whether or not patients have Pick bodies at autopsy, frontotemporal dementias are characterized by declines in executive function, personality, social skills, emotional expression, and language abilities in the early stages of the disorder. Other features of dementia become apparent as the illness progresses. Structural brain-imaging studies find atrophy preferentially affecting the frontal or temporal lobes. When used in conjunction with automated brain-mapping algorithms, PET and SPECT appear to be even more sensitive in the confirmation of frontotemporal dementias. The reductions in frontal and temporal measurements (which are relatively selective in the earlier stages of the illness) could reflect reductions in the density, viability, or metabolism of terminal neuronal fields that innervate these regions, the combined effects of atrophy and partial-volume averaging, or a combination of these factors.

Vascular Dementia Vascular dementia is typically characterized by an abrupt onset, stepwise progression, focal neurological signs and symptoms, imaging evidence of cerebrovascular disease with CT or MRI, risk factors for vascular disease (e.g., hypertension, diabetes, and hypercholesterolemia), and histopathological evidence of cerebrovascular disease obtained from biopsy or autopsy specimens. CT and MRI findings include evidence of multiple large vessel strokes; a single, strategically situated infarct (e.g., in the distribution of the carotid, anterior, middle, or posterior cerebral arteries and affecting certain regions, such as the thalamus and basal forebrain); CT lucencies or MRI T2-hyperintensities in deep white matter and basal ganglia; extensive periventricular white matter lessions (which are not unique to this disorder); or a combination of these features. Using CT, the probability of finding an infarction (i.e., one or more lucent areas) in patients with vascular dementia is highly variable (20 to 86 percent). Using MRI, patients with vascular dementia invariably have one or more T2-hyperintensities in periventricular regions, deep white matter (leukoaraiosis), the basal ganglia, or the thalamus. The clinical significance of the periventricular hyperintensities in the form of caps or rims is questionable; while extensive white matter hyperintensities are commonly found in patients with vascular dementia, some studies suggest that they are present in dementia of the Alzheimer's type, late-onset depressive and psychotic disorders, bipolar disorders, and other conditions. Indeed, the relationship between probable vascular dementia and probable Alzheimer's disease (i.e., diagnoses of exclusion made in the absence of histopathological confirmation) can be confounded by the observations that the disorders sometimes co-exist, that white matter lesions may be present in both disorders (though much more commonly in patients with vascular dementia), and that cerebrovascular disease may be a risk factor for dementia of the Alzheimer's type.

Vascular dementia is typically characterized by a seemingly random pattern of focal reductions in PET images of cerebral blood flow and metabolic rates for oxygen and glucose and in SPECT images of cerebral blood flow. This pattern, which differs from that typically observed in Alzheimer's dementia, might influence decisions about the treatment of cerebrovascular disease. Common treatments include hypertensive therapy, aspirin, and cessation of cigarette smoking. In uncommon cases, treatment may involve a surgical vascularization procedure or, in patients with signs of collagen-vascular disease, aggressive treatment of inflammatory vasculitis. Additional studies are needed to determine how well structural and functional brain-imaging studies correspond to histopathological diagnosis and histopathological characterization of the imaging abnormalities, influence treatment, and predicted outcome.

Other Neurodegenerative Disorders *Focal (asymmetrical) cortical degeneration* is characterized by gradually progressive symptoms such as apraxia, aphasia, agnosia, and cortical blindness. Histopathological features may be consistent with Alzheimer's disease, Pick's disease, or other conditions. Structural brain imaging studies typically find atrophy preferentially affecting the temporal or parietal region to which the symptoms are related. PET cerebral metabolic rate for glucose and SPECT studies find localized reductions in these areas. A study of identical twins who were clinically discordant for asymmetrical cortical degeneration suggests that imaging can detect localized reductions prior to the onset of symptoms and that the pattern can resemble that found in patients with Alzheimer's disease. In patients with *Huntington's disease*, CT and MRI studies find atrophy of the caudate nucleus and whole brain; PET studies find characteristic reductions in the metabolic rate for glucose in the caudate and putamen, which are apparent in genetically predisposed persons prior to the onset of motoric or cognitive symptoms. In later stages of

Huntington's dementia, the metabolic rate for glucose is also reduced in parietal, temporal, and frontal cortex. In patients with *Creutzfeldt-Jakob disease*, structural brain-imaging studies are either normal or show nonspecific atrophy; some PET studies find a patchy pattern of metabolic rate for glucose reductions, while others find asymmetrical reductions in the temporal lobe.

LATE-ONSET DEPRESSIVE DISORDERS

In about two thirds of cases, late-onset depressive disorders may be attributable to an identifiable neurological or medical condition. While structural and functional imaging studies have been used to investigate regions of the brain that are involved in the pathophysiology and treatment of major depressive disorder, they have been used in relatively unique ways to study primary and secondary depressive disorders that occur in late life.

Compared with elderly control subjects, patients with late-onset depressive disorders have an increased number of MRI T2-hyperintensity lesions in deep white matter (especially in the frontal lobe) and the basal ganglia (especially in the caudate nucleus). While this finding has also been reported in patients with bipolar I disorder irrespective of age, it has not been reported in patients with major depressive disorder who develop their first episode at an earlier age, raising the possibility of etiological and pathophysiological distinctions between early-onset and late-onset major depressive disorders. Additional studies are needed to confirm the suggestion that these abnormalities distinguish patients with major depressive disorder who develop their first episode in late life from those who develop their first episode at a younger age; to determine the extent to which patients with an excessive number of T2-hyperintensities differ from other patients with major depressive disorder in their clinical course or response to treatment; and to characterize the histopathological significance of these lesions.

In 20 to 50 percent of cases, patients develop depression following a stroke. Several structural brain-imaging studies find a significant association between poststroke depression and lesion location. Several studies find that poststroke depression is more likely to be associated with lesions in the left dorsolateral prefrontal cortex and left caudate nucleus. These regions have been implicated in functional imaging studies of major depressive disorder and have been postulated to participate in a circuit involved in the pathophysiology and treatment of depression. Several studies of poststroke depression also find a significant relation between the proximity of lesions to the frontal pole and the severity of depression. According to one theory, these lesions interfere with bioaminergic pathways that arise in the brainstem and pass through frontal regions on their way to more posterior regions of the brain.

LATE-ONSET PSYCHOTIC DISORDERS

Late-life psychosis can be attributable to a spectrum of disorders, including early-onset schizophrenia persisting into late-life, late-onset schizophrenia (sometimes called paraphrenia), late-onset delusional disorder (characterized by persistent paranoid delusions), dementias, delirium (from drug use and other causes), cerebrovascular disease in the absence of dementia, and other identifiable neurological disorders. Initial MRI studies of late-onset schizophrenia find an increased number of T2-hyperintensity lesions in deep white matter and basal ganglia regions that cannot be reduced to a specific histopathological lesion or location. Although findings are not entirely consistent, CT and MRI studies tend to find slightly enlarged ventricles in patients with late-onset psychotic disorders, more so for late-onset psychotic disorders other than schizophrenia. Initial SPECT studies find multiple areas of reduced cerebral blood flow in most patients with late-onset psychotic disorders. One PET study found that neuroleptic-naive patients with late-onset schizophrenia had an increased density of dopamine D_2 receptors in the striatum. While the researchers also found an increased density of D_2 receptors in patients with early-onset schizophrenia, this finding was not confirmed in an independent group of patients with early-onset schizophrenia when a different radiotracer technique was used.

Findings from T2-weighted MRI and SPECT studies raise the possibility that microvascular disease contributes to some of the late-onset psychotic disorders. Still, research is needed to further distinguish different late-life psychotic disorders using imaging techniques to identify distinctive structural and functional brain abnormalities in patients with these disorders and determine how these abnormalities are related to the patients' clinical course, response to treatment, and histopathology.

CLINICAL INDICATIONS

As part of the laboratory dementia workup, a structural brain image is routinely indicated to rule out potentially treatable, space-occupying lesions such as brain tumors (e.g., frontal lobe meningiomas and temporal lobe gliomas), cerebrovascular lesions (e.g., subdural hematomas, other hemorrhages, infarcts, and pathological white matter lesions), a chronic meningitic process (as suggested by meningeal enhancement), normal pressure hydrocephalus (suggested by pronounced ventriculomegaly without commensurate cortical atrophy), and a prior traumatic encephalomalacia. A structural brain image can also be used to identify clinically relevant patterns of focal atrophy, supporting the diagnosis of certain neurodegenerative disorders (e.g., frontotemporal dementia and asymmetric cortical degeneration syndromes), and it can be used to provide evidence for vascular dementia. While CT is less expensive and less confining, MRI offers several advantages including superior sensitivity in detecting lesions in white matter and meninges and the ability to study brain regions in the posterior fossa and brainstem without artifacts from bone.

Structural and functional brain-imaging studies find significant differences between groups of patients with dementia of the Alzheimer's type and normal controls, but these techniques are not routinely used to confirm this diagnosis. It remains to be established how well these techniques improve the clinician's ability to detect Alzheimer's disease in an individual patient with mild cognitive impairment (when the clinical diagnosis is least reliable), distinguish this disorder from normal aging and other forms of cognitive impairment (e.g., dementia with Lewy bodies), predict a patient's clinical course and postmortem histopathology, and make decisions about treatment.

While the sensitivity, specificity, and predictive value of imaging techniques in the diagnosis of Alzheimer's disease remain to be established, some groups have begun to use either PET cerebral metabolic rate for glucose or SPECT cerebral blood flow images in conjunction with automated brain-mapping algorithms with improved power to identify characteristic abnormalities in the diagnostic evaluation of patients with mild or unusual forms of cognitive impairment and no known reversible causes. To the extent that these techniques identify patterns that are consistent with the diagnosis of Alzheimer's disease, they may help family members who are reluctant to accept this catastrophic diagnosis take the proactive steps needed to maximize the patients' safety, address their financial and legal needs, and ensure future access to assisted living programs.

In addition, some clinicians use either PET metabolic rate with glucose or SPECT cerebral blood flow images to support the diagnosis of vascular dementia (e.g., identify a patchy pattern of focal reductions), which could affect decisions about risk factors for cerebrovascular disease. Some clinicians use PET metabolic rates for glucose and oxygen or SPECT cerebral blood flow images in conjunction with automated brain-mapping algorithms to support the diagnosis of certain neurodegenerative disorders other than Alzheimer's disease (e.g., frontotemporal dementia and asymmetrical cortical degeneration), which might benefit from unique behavioral management strategies. Although its ability to predict outcome, correspond to histopathology, or influence treatment decisions remains to be established, some clinicians recommend PET 6-fluoro-dopa, PET dopamine transporter site, or SPECT transporter site images to support the diagnosis of Parkinson's disease in its earliest stages.

While structural and functional brain-imaging studies find statistical differences between groups of patients with psychiatric disorders other than dementia (e.g., depression, schizophrenia) and normal controls, these techniques are not yet indicated in the clinical diagnosis of these disorders. It remains to be established how well these techniques distinguish the psychiatric disorder of interest from other disorders (e.g., distinguish depressive pseudodementia from other forms of dementia), predict clinical course, correspond to postmortem histopathology, or influence decisions about treatment.

FUTURE DIRECTIONS

Improvements in image-acquisition and image-analysis techniques promise to improve the ability of researchers to characterize the brain regions, pathways, and chemical processes that are affected during normal aging and those that are involved in pathophysiology of age-related disorders and to strengthen the role of imaging techniques in the diagnosis of dementia of the Alzheimer's type and other dementias. By providing surrogate markers of illness in intervention studies, imaging techniques promise to help distinguish treatments that slow the progression of Alzheimer's disease and other disorders in patients with dementia from those that compensate for these disorders and to help establish the efficacy of prevention treatments in healthy persons at genetic risk for these disorders. As a complement to other neuroscientific studies, imaging techniques can potentially help to clarify how identified brain abnormalities are related to specific behavioral features, clinical course, response to treatment, and histopathology in geriatric patients with psychiatric disorders.

SUGGESTED CROSS-REFERENCES

The basic principles of neuroimaging techniques, including CT, MRI, PET, SPECT, MRS, and fMRI, are described in Section 1.15 and Section 1.16. The application of neuroimaging techniques to the clinical evaluation of dementia, other degenerative disorders, vascular disease, head trauma, tumors, and epilepsy is discussed in Section 2.13. Electrophysiological recording techniques, including electroencephalography (EEG), quantitative EEG, event-related potentials (ERP), and magnetoencephalography (MEG) are discussed in Section 1.9. Functional neuroanatomy is discussed in Section 1.2. The use of CT and MRI is further discussed in Section 51.2f.

51.2 ASSESSMENT

51.2F NEUROIMAGING: SPECIAL ISSUES

ANAND KUMAR, M.D.

The development of sophisticated imaging techniques such as computerized tomography (CT) and magnetic resonance imaging (MRI) permit examination of the structural correlates of the major mental disorders in elderly adults. These techniques together with magnetic resonance spectroscopy (MRS) can provide meaningful information on neurochemistry and neurotransmitter functions as they relate to major psychiatric disturbances. In addition to cross-sectional information, they also provide an opportunity to study brain function longitudinally and to examine the relations between clinical phenomena and anatomical and biochemical perturbations. Neuroanatomical indexes may also serve as early preclinical markers of disease and thereby provide a more holistic picture of human neurobiology.

METHODOLOGY

CT provides an example of the early use of computers to reconstruct cross-sectional images of the body from information gathered by a narrow beam of X-rays. The X-ray beam enters the edge of the cross-section of the body being imaged. After traversing the body the emerging X-rays are counted, and the number lost during passage through the body is calculated. During a scan, the position of the beam is changed many times, so that any one cross-section of the body may be examined many times from several different directions. The computer then reconstructs the density of the tissue in the cross-section being examined. A CT image thus reflects tissue density, which can be quantified by the computer and obtained as CT attenuation numbers (also referred to as density numbers).

MRI uses the magnetic properties of living tissues to produce an image. Since hydrogen has the most magnetic nucleus and makes up two thirds of the atoms in living tissue, it is largely the hydrogen in tissue water that is imaged. The hydrogen nucleus has only one proton; consequently, imaging of hydrogen is often referred to as proton imaging. In clinical MRI, the protons are aligned by placing the subject in a strong magnetic field. Tissues are exposed to a single or multiple excitation pulses (radio waves), which causes the hydrogen atoms to absorb energy and precess (spin) around their common axes. The protons then release energy and return to their resting orientation. The released energy is the signal that forms the basis of an MR image. A standard MRI scan provides an image of hydrogen distribution in the organ being examined and it displays a slice of tissue as regions of varying brightness. Typically two or more pulses are used for better characterization of tissues. By varying the time interval between two successive pulse cycles (TR) and the interval from a pulse to the measurement of the MR signal (TE), one can obtain MR images with different tissue contrasts (T1- and T2-weighting and proton density). A T1-weighted image, in which cerebrospinal fluid (CSF) appears black, provides better gray:white parenchymal discrimination, while a T2-weighted image (in which CSF is bright) helps distinguish brain parenchyma from CSF. Proton density images provide tissue contrasts of intermediate brightness.

Early studies using CT to examine cerebral anatomy focused on indirect measures such as ventricular-brain ratios (a measure of CSF volume relative to brain parenchymal volume) and CT attenuation numbers as indicators of parenchymal damage. The increased spatial resolution and sensitivity of MRI permitted more-direct study of neuroanatomy. Quantitative estimates of total and hemispheric brain and CSF volumes provided global estimates of neuroanatomical integrity. Regional measures of neocortical and subcortical structures can be obtained by MRI, and these indexes facilitate the study of more anatomical aberrations in psychiatric disorders. The increased sensitivity of MRI also allows qualitative and quantitative examination of the high-intensity-signal lesions that are typically found in the periventricular, deep white matter, and subcortical regions of the brain. These lesions appear as bright spots on conventional T2-weighted MR brain images and were previously referred to as unidentified bright objects (UBOs). These measurements, together with segmentation techniques, make possible individual examination of the structural integrity of gray and white matter, thereby providing the clinical neuroscience disciplines with the necessary tools for more precise examination of the relation between anatomical perturbations and major mental disorders.

NEUROANATOMIC CHANGES WITH NORMAL AGING

Before considering changes in cerebral anatomy that may be associated with specific psychopathological states, one must first appreciate the neuroanatomical changes that occur in aging per se, unassociated with any mental disorder. Several studies have reported MRI-determined structural changes associated with normal aging. These studies demonstrate an increase in whole brain CSF and high-intensity-lesion volumes with increasing age. Aging is also associated with decreased volumes of cerebral hemispheres, frontal and temporal lobes, associated with increased ventricular volumes. Volumes of specific diencephalic structures and the caudate and lenticular nuclei have also been reported to decrease with age (Table 51.2f-1). Sex differences in brain structure have been reported by several (though not all) groups using volumetric MRI. A few studies have found that the brains of men age faster or earlier than those of women. Sex differences in aging may be apparent at both a hemispheric and a lobar level, with the frontal lobes showing more marked sex differences with aging (with men showing more atrophy) than the temporal lobe.

Condition	Observations	Caveats
Healthy aging	Increase in volume of CSF and high-intensity lesions Decrease in brain volumes	Gender differences present; structural changes amplified by superimposed disease
Mood disorders	Smaller brain volumes Larger lesion and CSF volumes than controls	Differences depend on health status of control group; lesion volume correlates with overall medical burden
Alzheimer's disease	Progressive atrophy; early changes detected in the hippocampus Atrophy widespread	Lesion volume increases with cerebrovascular risk factors; despite consistent group differences, diagnostic utility is minimal
Psychoses	Larger CSF and ventricular volumes together with lesion volumes	Atrophic changes more striking than those observed in younger patients with psychoses

Table 51.2f-1 Summary of Findings in Late-Life Mental Disorders

NEUROIMAGING IN LATE-LIFE DEPRESSION

Computerized Tomography Studies The application of CT to the study of brain disorders has permitted examination of neuroanatomical aberrations that occur with aging and those associated with specific psychiatric disorders. CT studies demonstrated relative abnormalities in CT attenuation numbers (suggesting altered parenchymal density and consequently brain pathology) in patients with late-life major depressive disorder, compared with controls. Some studies suggest that CT density counts in patients with major depressive disorder lie midway between nondepressed elderly controls and patients with probable dementia of the Alzheimer's type. A subgroup of depressive persons with cognitive impairment had CT counts that approached those of patients with dementia of the Alzheimer's type. Some investigators correlated abnormal CT numbers with poor prognosis and mortality in patients with major depressive disorder. Other groups examining semiquantitative measures, such as ventricular-brain ratios, demonstrated global abnormalities in subjects with late-life depression, compared with nondepressed controls. While CT provided an early tool for examining neuroanatomical abnormalities, MRI permits examination of neuroanatomy with much more precision than previously possible.

Superior resolution and increased sensitivity to brain changes have made MRI extremely useful for psychiatric research.

MRI Studies—High-Intensity Signals in Depression High-intensity lesions have received considerable scrutiny in psychiatric research. Earlier reports using MRI in late-life depression focused on the presence and severity of high-intensity signals in the brain in T2-weighted MR images. Elderly patients with major depression exhibited more frequent and more severe high-intensity signals in the periventricular, deep white matter, and subcortical regions of the brain than nondepressed controls. Some of these studies focused on depressed inpatients and those referred for electroconvulsive therapy (ECT) for failure to respond to antidepressant trials. Qualitative ratings were used to estimate high-intensity-lesion volumes in patients and controls in most of the early studies. Despite these caveats, the increased severity of these lesions in patients diagnosed with major depressive disorder (compared with controls) was widely interpreted as evidence supporting a “structural” basis for depression in late life.

Several investigators have examined the clinical and biological correlates of high-intensity signals in humans. Results from community-based studies, such as the Cardiovascular Health Study, indicate that the most frequent correlates of these lesions include increasing age, prior stroke, hypertension, and forced expiratory volume in 1 second (FEV_1). The prevalence of high-intensity signals in the brain has been consistently low in studies that screened subjects to exclude those with major vascular risk factors. However, not all studies find strong correlations between high-intensity signals and specific vascular risk factors such as hypertension and diabetes in depression. It therefore appears likely that other, yet unidentified, biological factors may also be responsible for these lesions. Pathologically, they reflect a spectrum of changes, including arteriolar ectasia and myelin pallor associated with arteriosclerosis of perforating arterioles, more pronounced in the subcortical white matter. The location of these lesions together with their frequent pathological correlates suggests that white matter compromise from medical or vascular disease may contribute to late-life mood disorders. Some investigators have argued that high-intensity signals represent silent infarcts of the brain in depression. The increased severity of high-intensity signals in major depressive disorder and their relation to cerebrovascular risk factors have led other investigators to suggest a vascular etiology for late-life depression. While a vascular component to major depressive disorder remains plausible, evidence supporting this claim remains largely indirect at the present time. These complexities should be seriously considered in designing and interpreting the results of neuroimaging studies in mental disorders in late life. Interpretations of data on specific psychopathologic states should always be tempered by comparisons with identical measures obtained from control subjects matched for age, gender, and appropriate medical comorbidity.

Volumetric studies of the brain in late-life depression have focused on both global and regional measures of brain and CSF volumes. Global measures examined include total brain volume, ventricular volume, and whole-brain CSF volume. Comparisons have typically been made between major depressive disorder patients with several comorbid medical disorders and relatively healthy elderly control subjects recruited from the community. An earlier study from the author's laboratory demonstrated that in a sample of patients with major depressive disorder and diverse medical comorbidity, whole-brain CSF volume and total ventricular volumes were significantly larger than those of healthy nondepressed controls recruited from the community. In that study, high whole-brain CSF volume (normalized to intracranial volume) and overall medical comorbidity (quantified using the cumulative illness rating scale) greatly increased the odds of patients developing major depressive disorder.

Other investigators have reported smaller frontal lobe volumes in samples of mixed-age depressive patients referred for ECT. Studies have also demonstrated smaller caudate volumes in a mixed-age sample of patients diagnosed with major depressive disorder, which has been interpreted as evidence of a disruption to the caudate-prefrontal pathway in depression. Y. I. Sheline and coworkers reported smaller hippocampal volumes in a small sample of medically healthy women in remission from major depressive disorder than in age- and sex-matched controls, but other investigators find no consistent neuroanatomical differences between depressed patients and controls. A recent study by the author's group, focusing on a group of elderly patients with major depressive disorder and nondepressed elderly controls better matched for overall medical comorbidity, demonstrated that smaller prefrontal lobe brain volumes and greater high-intensity-signal-lesion volumes independently increased the odds of developing depression. These findings suggest that atrophy and high-intensity lesions may represent complementary pathways to late-life depression. The group also reported on the neuroanatomical correlates of patients with late-onset minor depression diagnosed using modified research criteria from the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) for minor depressive disorder. Patients with minor depressive disorder were compared with an age-matched group of nondepressed controls with comparable medical comorbidity. The group with minor depressive disorder had smaller normalized prefrontal lobe volumes than the controls. In addition, prefrontal lobe volumes were linearly related to severity of illness (i.e., volumes decreased from the controls to patients with minor depressive disorder to those with major depressive disorder). While issues of nosology and clinical definitions of major versus minor depressive disorders complicate interpretation of these results, the data suggest a general neuroanatomical basis for mood disorders in late life that transcends traditional diagnostic boundaries. Collectively these results indicate that MRI detects structural correlates to most forms of mood disorders in late life. The pathways leading from neuroanatomical changes to mood disorders are likely to vary in different clinical populations and need better elucidation.

PSYCHOTIC DISORDERS OF LATE LIFE

There has been a resurgence of interest in examining the clinical and biological characteristics of psychosis occurring in late life. Nosologic disagreements and overlap between conditions such as late-onset schizophrenia, late paraphrenia, and other psychotic states in late life have limited the interpretation of results in certain instances. Several investigators have reported higher ventricular-brain ratios in patients with late-onset schizophrenia than in age-matched control subjects. More recently, a quantitative MRI study of patients with late-onset schizophrenia reported that these patients had larger ventricular volumes than controls. In this study, thalamic volumes were larger in the late-onset group than in elderly schizophrenia patients with an earlier onset. Other investigators have reported that patients with late paraphrenia have larger lateral ventricular volumes than both elderly patients with schizophrenia and nonpsychotic age-matched controls. They argue that paraphrenia may have a more striking neuroanatomical basis than other psychotic disorders in late-life. They additionally assert that part of the confusion regarding the neuroanatomical correlates of psychotic disorders in late life is an inability to distinguish clinically between late paraphrenia and schizophrenia in elderly patients. More recently, investigators using MRI to examine patients with all forms of late-onset psychoses reported an increased prevalence of high-intensity signals in neocortical, subcortical, and brainstem regions compared with age-matched controls without psychosis. In summary, patients with late-onset psychoses (both schizophrenia and other psychotic states) also display neuroanatomical abnormalities on CT and MRI (Table 51.2f-1). These abnormalities are also nonspecific, and the mechanisms by which they contribute to psychoses remain unclear.

NEUROIMAGING STUDIES IN DEMENTIA

Dementia of the Alzheimer's type has been studied quite extensively by both CT and MRI. The findings from neuroimaging studies in dementia closely parallel the more established pathological hallmarks of the disorder. Cross-sectional neuroimaging studies demonstrate smaller brain volumes and increased CSF volumes in these patients than in age-matched controls without dementia. Longitudinal studies using CT demonstrate progressive ventricular enlargement in patients with dementia, significantly greater than the minimal progressive dilatation seen in nondemented controls. Also, while ventricular enlargement was noted relatively early in the course of the illness (when memory impairment dominates the clinical picture), the rate of enlargement appears to increase substantially when other nonmemory cognitive aspects of the dementia become clinically apparent. In addition to the more global measures of atrophy, investigators have demonstrated focal volumetric reductions in both medial and lateral temporal lobe structures in patients with dementia (compared with controls). Even in patients with mild dementia, hippocampal volume reductions between patients and controls were striking. Other reports indicate that volumes of the left amygdala and the entorhinal cortex best discriminate patients with dementia of the Alzheimer's type from controls. In an effort to examine the neuroanatomical correlates of patients in the predementia stage, one study found that patients with minimal cognitive impairment and CT evidence of hippocampal atrophy progressed to clinical dementia on follow-up. Thus focal hippocampal atrophy may serve as a marker for dementia of the Alzheimer's type. Focal neuroanatomical perturbations captured by CT and MRI early in the course of the disease may reflect the early pathological changes that occur in circumscribed brain regions in the limbic/mesial temporal areas. Progression of Alzheimer's disease is clearly associated with progressive neuronal loss, and the neuroimaging evidenceclearly corroborates these changes.

High-Intensity Signal Changes MRI studies have demonstrated high-intensity signals in patients with dementia of the Alzheimer's type in the periventricular, subcortical, and other neocortical regions of the brain. The prevalence of high-intensity signals in dementia of the Alzheimer's type was found to be low and comparable to that in controls in selected samples of patients prescreened to exclude those with major cerebrovascular risk factors. Research also suggests that in certain patient groups, neuropsychological performance may be more impaired in patients with dementia of the Alzheimer's type who have these lesions than in those without them. High-intensity signals may attenuate the relation between neuropsychological functions and glucose metabolism that is typically seen in dementia of the Alzheimer's type. Other investigators found no difference in either cognitive or behavioral features in these patients with or without high-intensity signals. One recent study showed that reduced gray matter volume and an increase in abnormal white matter high-intensity signals independently compromised cognitive functioning in patients with dementia of the Alzheimer's type. Collectively, these data appear to suggest that the presence of high-intensity signals in patients with dementia of the Alzheimer's type indicates an additional pathophysiological process that is predominantly vascular. Some investigators assert that these lesions exert their effects by disrupting corticocortical connections in the brain.

Pathologic and Behavioral Correlates The frequent pathological correlates of MRI high-intensity signals are demyelination, white matter ischemia, and edema in deep white matter and periventricular regions of the brain. These pathological descriptors were obtained from studies of the brains of patients who died from a variety

of neurological and nonneurological illnesses. These findings suggest that a variety of neuropathological and biochemical processes can result in brain changes that are captured by MRI as high-intensity (bright) signals in different brain regions. While high-intensity signals in the periventricular regions may reflect the transudation of ventricular CSF into the surrounding white matter, vascular factors may be responsible for these signals in the deep white matter and subcortical regions. Though these signals do not necessarily provide any diagnostic specificity, they do provide information about possible underlying pathological changes that lead to their development. The neurochemical correlates of high-intensity signals are unknown and have not been investigated in a direct, reproducible manner. There is also some disagreement about the behavioral consequences of these signals in relatively healthy elderly subjects and patients with dementia of the Alzheimer's type. Some investigators have reported that large high-intensity lesions are associated with reduced frontal glucose metabolism and impaired frontal lobe–mediated neuropsychological functions in healthy elderly subjects. Others, however, find no specific cognitive compromise attributable to high-intensity signals in either healthy elderly populations or patients with dementia of the Alzheimer's type. Therefore, while high-intensity signals are consistently associated with certain risk factors in elderly subjects, their behavioral impact remains controversial.

FUTURE DIRECTIONS

High-resolution techniques such as MRI have made it possible to study the anatomical and functional integrity of specific brain structures believed to be responsible for regulating normal and abnormal human behavior, which has helped advance our understanding of the biological basis of certain mental disorders. Several neuroanatomical correlates have been identified in elderly patients with major mental disorders. Many of these abnormalities, however, are nonspecific and may reflect a spectrum of pathological changes not pathognomonic of any single clinical entity. Neuroimaging studies can potentially yield useful information on the mechanisms that lead to major mental disorders in elderly adults. Therefore these technologies are better conceptualized as powerful research tools for the clinical neurosciences than as diagnostic instruments in clinical psychiatry.

Newer techniques such as MRS and functional MRI (fMRI) have rendered historical distinctions between neuroanatomical and physiological imaging somewhat obsolete. MRS can potentially provide information on neurotransmitters and important neuronal markers such as *N*-acetylaspartate, choline, lecithin, creatine, and glutamate. Phosphorous spectroscopy can help us study the role of several metabolites such as adenosine triphosphate and diphosphate in focal brain regions. These tools should be used in carefully designed human studies with appropriate clinical and control groups. In vivo pharmacological challenges specifically designed to probe neurotransmitter systems may elucidate the relation between neuroanatomical abnormalities and dysfunction in individual neurochemical systems. Postmortem MRI together with neurochemical and neuroanatomical analysis of brain tissue in patients with well-characterized antemortem psychiatric and medical illness may further clarify some biological issues relevant to mental disorders in elderly patients. In conclusion, the early results are encouraging and certainly suggest a neuroanatomical basis for late-life mental disorders. The next generation of studies must be more focused and should further probe the role of specific neurochemical and neurobiological systems in depression.

CHAPTER 51. GERIATRIC PSYCHIATRY

51.3 PSYCHIATRIC DISORDERS OF LATE LIFE

51.3A Psychiatric Problems in the Medically Ill

SOO BORSON, M.D. AND JURGEN UNÜTZER, M.D., M.P.H.

Increases in life expectancy during the twentieth century have produced an aged population of unprecedented size and longevity and altered the scope of clinical practice in all medical specialties. Demographic forecasters predict that by 2030 one person in five will be over age 65, and reductions in mortality among the very old (persons over age 80) already exceed those in other age groups. In the United States the average 65-year-old will remain independent for another 10 years and will live an additional 6.5 years in need of assistance; the average 85-year-old is likely to be independent until age 88 and live to age 89 with help. Persons over 65 account for more than one third of the country's total personal health expenditures and use three times the national average hospital bed days, twice the average number of prescription drugs, and one and a half times the number of physician office contacts. Chronic diseases and disabilities account for most of this increased health service utilization in later life, as most persons over age 65 suffer from one or more conditions that significantly impair health or function. Degenerative arthritis, primarily osteoarthritis, affects 50 percent, hypertension 40 percent, hearing loss 30 percent, urinary incontinence up to 30 percent, heart disease 28 percent, diabetes mellitus 15 percent, and significant impairment of vision 13 percent. Medical comorbidities aggregate with aging; 40 percent of men and over 50 percent of women who live beyond the age of 70 have two or more chronic diseases, and most of those over 80 have multiple health problems requiring professional care. These profound changes in the demographics of chronic disease have significant implications for the practice of psychiatry. For the psychiatrist, medical comorbidity is the single most important factor that distinguishes older and younger patients. The impact of comorbidity has increased demand for psychiatric care of patients with complex mental, emotional, and behavioral complications of medical illness. New research has begun to quantify these effects and focused attention on an emerging need for models of practice based on collaboration with primary and specialty medical providers and for interventions that demonstrably improve quality of life.

Estimates of the prevalence of psychiatric problems in the medically ill and disabled elderly population vary widely with clinical setting, but reliable data on comorbidities are still sparse. For example, 30 percent of older adults in primary care have at least one active psychiatric diagnosis; 10 to 15 percent have clinically significant depressive syndromes such as major depressive, dysthymic, or minor depressive disorders; 5 percent have dementia; and 2 to 5 percent have alcohol use or psychotic disorders. As a rule, the lowest rates of psychiatric symptoms and disorders are found among persons living independently in the community, and prevalence increases with medical acuity and severity of functional dependency (Fig. 51.3a-1). The relation between functional health and psychiatric comorbidity has been most clearly established for depression, and emerging data suggest similar trends for anxiety disorders, sleep disorders, and psychoses.

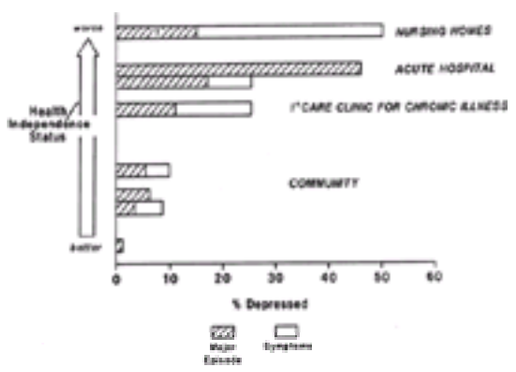

FIGURE 51.3a-1 Health, independence, and the prevalence of depression in late life.

Growing recognition of the association of chronic ill health and mental disorder among aged persons has spawned the development of specialized geropsychiatric services in many larger cities across the United States, but regular access to these services remains limited by financial, attitudinal, and organizational constraints. As a result, most treatment for comorbid psychiatric conditions in the elderly population in all medical settings is provided by primary care physicians and emphasizes the more acute, more severe, and more easily recognized disorders. Designing a full range of geropsychiatric health services, lowering barriers to their utilization, integrating primary care and specialty mental health care, and validating the role of the geropsychiatrist in optimal health care for the elderly are important priorities for the decades to come.

Clinical care of psychiatrically disturbed medical patients poses several special challenges for the psychiatrist. Diagnosis is frequently difficult, as clinical syndromes may vary in presentation from classical disorders with well-established treatment guidelines, and common disorders such as depression and anxiety may present in an atypical fashion. Key etiologic factors may become evident only as treatment unfolds, and physiological vulnerabilities arising from medical illness or its treatment may limit therapeutic choices or complicate therapy. Disparate explanatory models used by patients, their families, physicians, and other professionals must be reconciled before effective treatment can be implemented.

In most situations, psychiatrists initially become involved in the care of medically ill older patients as consultants to other physicians, but in a given episode of care, their role may be variously that of consultant, educator, advocate, mediator, counselor to caregivers, and traditional psychotherapist or pharmacotherapist. In some cases, psychiatrists find themselves becoming primary health care coordinators for complex elderly patients. These multiple tasks require a working familiarity with the common medical and functional problems of the elderly population as well as skill in the full range of psychotherapeutic and somatic treatment modalities unique to the profession of psychiatry. In spite of these inherent challenges, most psychiatrically disturbed older persons can be substantially helped when approached within a systematic framework.

APPROACH TO THE PATIENT

Mastery of a few central concepts helps to integrate the variety of clinical data critical for the successful evaluation and management of psychiatrically disturbed, medically ill geriatric patients (Table 51.3a-1). Aging is accompanied by a gradual diminution in adaptive reserve of all vital organs, including the brain, even in the absence of manifest disease. While the magnitude of these changes can be measured in aging populations, loss of physiological resilience in individual patients can generally be detected only after acute medical or psychosocial stress prompts a sudden, unexpected deterioration. Such age-related reductions in adaptive reserve underlie the commonly observed downward spiral and multiple organ failures of many sick elderly patients. They are responsible for the narrowed margin of safety observed for many drugs; they may also alter the presentation of disease and intensify the morbidity of medical and psychiatric disorders. For example, acute myocardial infarction in an octogenarian may present as painless delirium, while a mild chronic anxiety disorder may become fulminant panic in a patient with minor diverticular bleeding. Such complex patterns of causation are typical of psychiatric symptoms in very old persons and in those with multiple medical disorders. Sometimes causal factors emerge clearly only after successful intervention or not at all.

Diminished organ reserve alters response to illness, treatment, and social stressors
Comorbid medical illness may alter presentation and influence treatment choices
Nondrug treatments are preferable when effective
Combining treatment modalities optimizes gains
Comfort, function, and safety are the major goals of treatment
Coordinated care is better care

Table 51.3a-1 Key Concepts in Psychiatric Care of the Medically Ill Elderly

A 78-year-old man with bipolar I disorder since age 40 became manic while residing in a nursing home. His mental illness had been complicated by chronic dependence, and he was now mildly demented. He had no history of renal disease, and his serum creatinine was normal. After an initial period of typical manic grandiosity, when he was often seen near a local tavern, he soon deteriorated to crawling on his hands and knees, growling and barking like a dog, and striking out at all who approached. His lithium concentration was 1.2 mEq/L with a maintenance dosage of 750 mg a day. After reducing the lithium (Eskalith, Lithobid) dosage to achieve a concentration of 0.6 mEq/L, temporary addition of low-dose haloperidol (Haldol), and close attention to adequate fluid intake and preventing access to alcohol, both the manic episode, and the superimposed delirium cleared within 3 weeks without need for another psychiatric hospitalization.

Medical causes should be considered whenever an elderly patient develops a new psychiatric symptom or disorder. Whenever possible, major changes in management should be evaluated singly, especially when new drug treatments are added. When psychotropic medications are used, clinicians should remember to "start low and go slow," follow target symptoms, carefully monitor for the emergence of adverse effects, and allow sufficient time for medications to reach effective plasma and receptor site concentrations. Close collaboration with other clinicians and caregivers is essential at every stage of treatment to ensure its maximal safety and effectiveness. Combining psychotherapeutic, social, environmental, and somatic treatment modalities usually yields the greatest overall therapeutic gains at the smallest cost in treatment-related adverse events. Achieving therapeutic goals with elderly patients should be framed as an ongoing process that takes shape over time.

An 83-year-old woman with long-standing diabetes and ischemic and hypertensive cardiovascular disease had gradually become bedfast over several years in a nursing home. Two months before psychiatric consultation was requested, she developed a psychotic illness characterized by delusions of being beaten during the night, aggressive outbursts, and pervasive despondency, which led to frequent and disruptive nocturnal phone calls to her daughter and to the local fire station. Initial clinical assessment disclosed a moderately severe dementia in a personable but angry, frightened, and desperate woman eager for relief. Collateral history confirmed progressive cognitive deterioration over the course of her chronic medical illness, on a background of dysthymia of many years' duration. Trials of several antipsychotic and antidepressant medications had exacerbated both her symptoms and the problems of nursing staff in managing her care. A review of her medications showed that 4 of the 12 drugs she was taking on a regular basis were not essential for her medical management. A head computed tomographic (CT) scan showed mild cerebral cortical atrophy, moderate periventricular white matter hyperintensities, and numerous lacunar infarcts. A search for medical causes of her psychosis eventually associated its onset with the initiation of aggressive treatment of arterial leg ulcers, including round-the-clock debridement dressings, oral antibiotics, and narcotic analgesics. Control of her diabetes had deteriorated (as expected with this medical complication), and her insulin dose had been increased. Nursing staff members had provided excellent physical care, but neglected her emotional needs because they resented her ingratitude, racist attitudes, and physical aggressiveness, which exacerbated her loneliness and paranoia. Treatment of her psychiatric illness included the following interventions: discontinuation of nightime debridements (allowing elimination of narcotics for pain), simplification of her drug regimen, preventing nocturnal hypoglycemia (insulin reaction), installation of a nightlight in her room, problem-solving discussions with staff, and weekly psychotherapeutic conversations and wheelchair walks, which represented her first opportunity to go outdoors for several months. Her distressed phone calls ended within the first week. Her mood, sleep, and interactions with staff improved more gradually, and her delusions and racist remarks diminished and then disappeared altogether. Foci of psychotherapy were discovery of traumas she experienced in Cossack Russia (the origin of the delusional content), explanation of the delirium that led to her psychotic episode, and frank discussions of her desire to die rather than to continue to live in a physically deteriorated state. She developed a firm therapeutic alliance and regained the dignified, compassionate, and self-contained manner that had characterized her response to adversity before its erosion by her lengthy illness.

PSYCHIATRIC SYNDROMES IN MEDICALLY ILL PATIENTS

General Principles Almost any psychiatric syndrome may be mimicked by systemic medical illnesses with the capacity to affect central nervous system function. The fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) has simplified the classification of psychiatric disorders due to medical diseases (Table 51.3a-2). These syndromes are usually accompanied by some intellectual impairment, and a careful cognitive assessment provides valuable clues to their possible medical etiology. The cognitive component may be as subtle as confusional episodes in response to complex or changing environments or as obvious as syndromal delirium or dementia. Most serious medical disorders can cause psychiatric symptoms by more than one pathophysiological mechanism. Secondary psychiatric syndromes commonly lack some features of the typical primary disorders they resemble, particularly in patients with no history of psychiatric illness earlier in life. For example, in depressions due to central nervous system effects of medical disorders, guilty rumination is uncommon, and sleep disorder, when present, is often atypical. In patients with a history of psychiatric disorder, the onset or exacerbation of medical illness may precipitate relapse.

Cognitive disorders
Delirium
Dementia
Amnestic disorder
Psychotic disorders
With hallucinations, delusions, or mixed features
Mood disorders
With manic, major depressive, or mixed episode or features
Anxiety disorders
With generalized anxiety or panic attacks, or obsessive-compulsive, social phobic, or agoraphobic symptoms
Catatonic disorder
Personality change
Labile, disinhibited, aggressive, apathetic, paranoid, combined, other
Sexual dysfunction
Sleep disorder
Mental disorder not otherwise specified (e.g., dissociative symptoms due to complex partial seizures)

Table 51.3a-2 Psychiatric Disorders Due to a General Medical Condition

The interaction between psychiatric disorders and chronic medical conditions is complex. For example, a number of medical disorders cause significant depressive symptoms, but depression amplifies somatic symptoms of medical illnesses and can promote despair about the efficacy of treatment, leading to poor adherence and outcomes. On the other hand, comorbid medical illness partially explains why depression and other treatable psychiatric disorders are frequently unrecognized and untreated in primary care settings. Also, medical illness, polypharmacy, and changes in drug metabolism in older adults make adverse effects from psychotropic medications more likely.

A number of clues can alert the treating psychiatrist that an underlying physical disorder or a medication may be responsible for psychiatric symptoms: an abnormal level of alertness, new onset of psychiatric symptoms at a late age, lack of family history, psychiatric symptoms or personality changes that are more sudden or more severe than expected, coexisting physical illness, changes in medications, or poor response to usual psychiatric treatments.

Medications as a Cause of Psychiatric Symptoms Most drugs, in sufficient doses, can affect central nervous system function in a vulnerable host. Drugs affecting

the brain, either as their primary site of therapeutic action (e.g., all psychotropic drugs, opioids, antiparkinsonism agents, and many antihypertensive agents) or as a secondary site not essential to their therapeutic effect (e.g., digitalis [Lanoxin], cimetidine [Tagamet], glucocorticoids, and nonsteroidal anti-inflammatory drugs (NSAIDs) such as indomethacin [Indocin]), can cause psychiatric symptoms in medically ill elderly patients. When a pharmacological cause is suspected, a detailed search is indicated for associated systemic or neurological signs and symptoms, such as recent loss of appetite, reduced sense of well-being, blurred vision, slurred speech, dizziness, gait instability, or somnolence. A patient's complaint of being drugged, while often apparently delusional, should always prompt consideration of drug toxicity. A drug can be reasonably established as the primary cause in several ways. Some drugs produce classical symptoms in overdose, such as nausea and distorted color vision in digitalis overdose, or tinnitus and dizziness with aspirin. Certain clinical pictures with a common pathophysiology may be produced by drugs with different primary indications but similar pharmacological properties. An example is the central anticholinergic syndrome, characterized by tachycardia, pupillary dilation, visual hallucinations, and delirium in patients receiving tricyclic antidepressants, some antipsychotic agents, or antihistaminic drugs for sinusitis or gastric hypersecretion. For the relatively few drugs whose blood concentrations are readily determined and therapeutic ranges are well established, a markedly elevated concentration may be diagnostic. However, improvement when dosage of a suspect drug is decreased or discontinued is the most common and often most crucial test of its role in pathogenesis.

Drug and Disease Interactions Psychiatric symptoms arising from the interactive effects of medications and underlying disease may be severe enough to lead to psychiatric hospitalization. In a series of nearly 16,000 consecutive adult psychiatric admissions, about 1 percent were attributable to adverse drug reactions. Elderly patients were most often affected, particularly those with neurological disease or receiving multiple medications. Nearly 30 percent of elderly persons develop delirium after hospitalization for acute medical illness. Particularly at risk are those with cognitive impairment at the time of admission, the very old (over 80 years), patients with fractures or symptomatic infection, and those receiving antipsychotic drugs or opioids. Early detection of mental disorders arising from drug-disease interactions depends upon familiarity with the common medical illnesses of older people, the mechanisms by which they may affect brain function, and the pharmacological properties of drugs used in medical management and their special potential for interactive effects. Table 51.3a-3 gives examples of some drug-drug and drug-disease interactions that may be encountered in clinical practice.

Drug	Indication	Adverse Effect
Cimetidine	Gastroesophageal reflux	Delirium; elevated drug concentrations (e.g., tricyclic drugs, benzodiazepines, neuroleptic agents, propranolol [Inderal], theophylline [Theo-Dur]
Indomethacin (Indocin)	Cardioprotection	Parkinsonism, exaggerated reaction of levodopa
Tricyclic drugs	Depression, anxiety, insomnia, chronic pain	Confusion, constipation, tachycardia, cardiac conduction defect, hypotension, altered effect of antihypertensive agents (Lenox effect of digoxin, ↓ effect of α2-adrenergic receptor agonists, e.g., clonidine [Catapres])
SSRIs	Depression, anxiety, obsessive-compulsive symptoms	Agitation, insomnia, restlessness, agitation, ↑ acid hydrolysis, ↑ potential for diverse drug interactions, dysadaptation of workers (Lexapro), nausea, gastrointestinal distress, diarrhea
NSAIDs	Arthritis	Cognitive impairment, ↑ serum lithium concentration, ↑ blood pressure, ↓ hypertension control
Antipsychotic drugs	Dementia with psychosis	↑↑ cognitive impairment, extrapyramidal symptoms, falls, aspiration pneumonia
Alprazolam (high dose)	Insomnia	Delirium
Digoxin (Lanoxin)	Memory, arterial insufficiency	↑↑ falling time; restlessness (high dose)
Glucocorticoids	Inflammation, COPD	Depression, mania, psychosis (especially at high doses)

Table 51.3a-3 Examples of Drug-Drug Interactions in Elderly Persons

Differential Diagnosis Differential diagnosis begins with a psychiatric examination of the patient and interviews with competent informants, particularly about the timing of onset of the problem and its association with changes in medical or treatment status. This is followed by a thorough evaluation of the patient's current medical condition, emphasizing disease of major vital organs, painful conditions, and disorders that may leave few obvious clues (e.g., hip fracture or subdural hematoma in a patient who has fallen), a complete medication history; and a focused physical examination, including at a minimum a review of vital signs and a screening neurological examination to check for abnormal gait or movements, focal areas of weakness, or abnormal deep tendon reflexes. These data are used to derive a set of clinical probabilities and testable hypotheses. The judicious use of appropriate laboratory tests may clarify the possibilities in complex situations (Table 51.3a-4). For example, in a patient with blood pressure in the low normal range, pitting ankle edema, apathy, weakness, and depressed mood, who has been taking a high-potency diuretic for many years, an electrocardiogram (ECG) and echocardiogram may be needed to determine whether congestive heart failure or the diuretic is the most salient contributor to the depressive syndrome, whether it is safe to try discontinuing the diuretic, and what special precautions are required in prescribing an antidepressant. In doubtful cases, when the differential diagnosis includes a primary psychiatric disorder not caused by the physical effects of illness, an electroencephalogram (EEG) may be helpful. The EEG in patients with psychiatric syndromes due to metabolic, toxic, or circulatory causes typically shows diffuse slowing (although it cannot implicate specific diseases or drugs, and the interpretation may be confounded when an underlying dementing illness is present). An increase in dominant frequency accompanying recovery lends weight to the formulation.

Establish rapport quickly
Establish the reason for the consultation or visit
Learn and use a few rapid screening instruments
Cognition
Neuropsychiatric symptoms
Functional ability
Expect more than one psychiatric diagnosis (e.g., delirium and chronic depression)
Make a complete problem list
Medical
Psychiatric
Social
Functional
Identify all drugs in current use
Prescription drugs
Over-the-counter medications
Vitamins, minerals, botanicals, and "natural" remedies
Alcohol and tobacco
Include those used infrequently
Ask patients or caregivers to bring all medications from home in a paper bag for your inspection
Interview capable collateral sources
Family or other primary caregivers
Primary physician
Staff of residential facilities
For acute exacerbations of chronic problems, ask "why now?"
If problem unexplained, search for
Undiagnosed medical illness
Drug effect or interaction
Occult injury
Undetected social problem (abandonment, abuse)
Conduct a screening physical examination: vital signs, gait, neurological signs
Obtain appropriate corroborating laboratory studies; consider broad-spectrum tests to screen for subjacent disease (e.g., complete blood cell count [CBC], blood glucose, serum electrolytes, blood urea nitrogen and creatinine, liver enzymes, thyroid-stimulating hormone, syphilis serology, vitamin B_{12} and folate, urinalysis, electrocardiogram, chest X-ray, EEG for delirium, erythrocyte sedimentation rate [ESR] for occult systemic disorders, [sp] scans for a deficient patient who will not walk).

Table 51.3a-4 Practical Evaluation of Psychiatrically Disturbed Medically Ill Older Patients

When a drug is believed to cause or contribute to a psychiatric disorder, all drugs should be sorted into those clearly required for management of serious disease, and those that may be modified or stopped on a trial basis. Familiarity with drug adverse effects, interactions, and the pathways for their elimination may assist in the detection of otherwise occult medication toxicity syndromes. The authors estimate that assiduous adherence to the rule of maximal simplification of medication regimens will by itself lead to clinical improvement in perhaps half of all psychiatrically disturbed medically ill older persons.

A 68-year-old obese man with chronic obstructive lung disease and a history of alcohol dependence in remission came for treatment of an anergic depression with insomnia and daytime sleepiness following relinquishment of a long-standing extramarital affair. He responded initially to nortriptyline (Pamelor), but within 3 months began to deteriorate, with irritability, confusion, worsening depression, marked weight gain, edema, and eventual frank congestive heart failure. The plasma nortriptyline concentration was 75 ng/mL. Digitalis and diuretic treatment resulted in a 40-pound diuresis but no improvement in his psychiatric status. Measurement of (active) hydroxylated metabolites of nortriptyline showed concentrations above 300 ng/mL. His mental state cleared rapidly after discontinuation of the drug. Depression did not return, but he continued to require treatment for chronic congestive heart failure. The relative importance of psychological and medical factors in causing his initial depression was never clarified nor whether accumulation of nortriptyline metabolites (not measured in routine clinical assays) was the cause or consequence of his myocardial insufficiency.

Undiagnosed elderly patients who present with an undiagnosed dementia warrant aggressive assessment. In a review of 32 studies of causes of dementia, Alzheimer's disease accounted for 56 percent; vascular dementia, 13 percent; depression, 4.5 percent; alcoholic-induced persisting dementia, 4.2 percent; and substance-induced dementia, 1.6 percent. In 13.2 percent of cases, potentially reversible causes of cognitive impairment could be identified. In a subset of cases for which adequate follow-up information was provided, 11 percent of dementias resolved. Within this reversible group, drugs and depressive illnesses each accounted for approximately 25 percent of cases, and metabolic encephalopathies, 15 percent. These figures emphasize the value of psychiatric evaluation in detecting potentially reversible causes of cognitive impairment. In many cases, the initial evaluation may require more than one visit, particularly with frail elderly patients who

have difficulty providing relevant historical details.

PSYCHIATRIC SYMPTOMS ASSOCIATED WITH SPECIFIC MEDICAL DISORDERS

Cerebrovascular Disease Ischemic and hemorrhagic strokes cause a variety of disturbances of behavior and emotionality related both to effects of the lesion on brain function and to psychological problems in adaptation to disability. Significant depressions are common, occurring in up to 50 percent of all patients following an acute cerebrovascular accident. Depressive disorders after neocortical strokes resemble primary depressions in both clinical presentation and response to antidepressant pharmacotherapy, although the incidence of drug intolerance may be somewhat increased. Although depressions can occur after stroke anywhere in the brain, larger lesions in the anterior left hemisphere are associated with a high likelihood of depression in the early recovery period. Persistence of milder depressive syndromes after the acute phase has been associated with factors related to functional impairment, including impaired cognition, weak social supports, and inadequate living environment. Manic episodes (which may respond to lithium or antimanic anticonvulsants) and apathetic behavioral states without depressive affect or mood appear especially likely after right hemisphere strokes. *Subcortical dementia* is a clinically useful concept designating a syndrome of psychomotor slowing, depressed mood, inattentiveness, forgetfulness, motor impairment, and seemingly disproportionate functional dependency occurring in patients with diseases of the thalamus, basal ganglia, and upper brainstem. This syndrome commonly results from subcortical ischemic disease (vascular depression) as well as from classic neurological diseases such as parkinsonism. Its chief importance for psychiatrists is its frequent confusion with primary depressions in elderly persons, which leads to neglect of the associated intellectual deficits in formulating an overall management plan, and its contribution to depressive chronicity and poorer antidepressant treatment outcome. However, when depressive elements are prominent, antidepressant treatment may provide decisive benefits, and the apathetic state that frequently accompanies subcortical vascular brain disease can respond to pharmacotherapy with psychostimulants.

Acute confusional states frequently occur after stroke and may be the only presenting sign in a small minority of patients, particularly those with basal ganglia and other subcortical infarcts. Permanent cognitive impairment can result from strategically placed single strokes, and progressive dementia is associated with repeated events. Patients recovering from cerebrovascular accidents and those with vascular dementia may be extremely sensitive to substance induced delirium and to deterioration as a result of either uncontrolled hypertension or hypotensive episodes due to antihypertensive medications and drug interactions.

Psychotic symptoms with delusions, hallucinations, or a full schizophrenia-like syndrome may result from focal brain injury, particularly after lesions of limbic cortical and subcortical structures. Paranoid and persecutory delusions and ideas of reference are common and may be circumscribed or highly elaborate and pervasive. Personality changes, particularly those producing inappropriate aggressive or sexual behaviors, are encountered with regularity in patients with strokes, especially men with frank dementia, and frequently lead to psychiatric consultation and psychotropic drug treatment and sometimes to permanent psychiatric hospitalization. The relationship of these disorders to premorbid character pathology is uncertain, but families often report long-standing socially dysfunctional behavior in these patients before the onset of cerebrovascular disease further weakened the capacity to implement behavioral controls.

Parkinson's, Alzheimer's, and Other Neurological Diseases Depression occurs with disproportionate frequency in Parkinson's disease, affecting up to half of all patients. This depression is believed to be caused, in large part, by the neurodegenerative process itself; its presence is associated with evidence of damage to noradrenergic and serotonergic systems and is thought to predict more rapid overall neurological deterioration. Nevertheless, it typically responds to antidepressant drugs or electroconvulsive therapy. Selegiline (Eldepryl), an antiparkinson agent that selectively inhibits monamine oxidase type B, may be a useful addition to treatment in depressed Parkinson's patients, but its role in psychiatric management is not yet well characterized. Most depressed Parkinson's disease patients have cognitive deficits that also occur without mood disorder and influence learning, initiative, planning, and capacity for independent functioning, beyond the constraints imposed by the motor disability alone. These cognitive deficits tend to persist after successful treatment of mood disorder and are not substantially improved by treatment with levodopa (Larodopa) or other antiparkinsonian agents. Cognitively impaired Parkinson's disease patients are particularly vulnerable to delirium and psychosis induced by antiparkinsonian medications, including levodopa, other dopaminergic agonists, and anticholinergic agents. These syndromes may respond to lowered drug dosages. If not or if motor disability worsens to an unacceptable degree, low-potency dopamine receptor antagonists such as thioridazine (Mellaril) or serotonin-dopamine antagonists may be required. A large body of literature supports the use of clozapine (Clozaril) in relatively low dosages (up to 50 mg a day) for treatment of dopaminergic psychosis in Parkinson's disease, and may improve the motor disturbances as well. Olanzapine (Zyprexa), in dosages of 2.5 to 15 mg a day, is a useful alternative, but its onset of antipsychotic action is typically delayed by 2 to 3 weeks.

In Alzheimer's disease, depression affects up to one third of patients early in the course and may be the major presenting problem. Clear-cut major depressive episodes generally respond well to antidepressant pharmacotherapy with selective serotonin reuptake inhibitors (SSRIs) or secondary amino tricyclic antidepressants, but for apathetic states without prominent mood or sleep disorder, donepezil (Aricept), another cholinergic agonist, or a stimulant such as methylphenidate (Ritalin) may be more effective. As dementia worsens, classic depressions become less frequent, while agitation, psychosis, and aggressive behavior with or without dysphoria become more common. Assaultive or threatening behavior in Alzheimer's disease patients demands thorough medical and socioenvironmental assessment to identify factors that provoke or sustain these problems, but pharmacological interventions are usually required. Delirium induced by drugs or acute medical illness is a risk at all stages of the disease, as it is in other neurodegenerative disorders.

> A 70-year-old woman with moderately advanced Alzheimer's disease was brought for psychiatric treatment because of intolerable agitation and aggressive outbursts. Haloperidol, prescribed by the primary physician, seemed to worsen her behavior. During the interview, markedly impeded by the patient's severe aphasia, she acknowledged depression and tearfully expressed worry about her husband's drinking. After several visits and insistence on interviewing a son, it became obvious that her husband was severely alcoholic and was abusing benzodiazepines, that he had been emotionally and physically abusive throughout the marriage, and that the patient's agitation and aggression were defensive responses to his threats and assaults. Emergency nursing home placement solved her behavior problems, including her depression.

Posttraumatic and postanoxic encephalopathies, hydrocephalus, central nervous system (CNS) tumors and infections, multisystem atrophy (Shy-Drager syndrome), Huntington's disease, demyelinating diseases such as multiple sclerosis, idiopathic inflammatory diseases such as systemic lupus erythematosus, and temporal arteritis and occupational neurodegenerations such as chronic organic solvent encephalopathies may all be associated with depressive, manic, delirious, and psychotic syndromes. For depressions in patients with these brain diseases, antidepressant trials are generally warranted, though drug intolerance may be problematic and require the use of innovative strategies. The management of other psychiatric complications is less well established.

Cardiovascular Disease Acute myocardial infarction and chronic congestive heart failure may both be accompanied by psychiatric disturbances. Confusional states due to cerebral hypoperfusion or complications of treatment (e.g., cardiovascular drugs, electrolyte imbalances due to diuretics, or repeated resuscitations for ventricular arrhythmias) are best managed by primary efforts to improve compromised cardiac function and metabolic status. Brief use of benzodiazepines or low-dose neuroleptic agents is indicated for very fearful patients and to prevent injury to patients or professional staff when agitation poses a safety risk. About 10 percent of patients who undergo open heart surgery suffer lasting neuropsychological impairment as a result. Barring major intraoperative complications, most of these impairments are mild; most affected patients are elderly.

Depression and anxiety disorders following myocardial infarction or heart failure require attention to both possible medical causes and psychological factors, especially patients' concerns about risk of death and disability and the adequacy of supportive care. Untreated or inadequately treated major depression worsens prognosis in heart disease, and effective psychiatric treatment often requires both psychotherapeutic and pharmacological management. The safety and efficacy of antidepressant drugs in patients with chronic heart disease have been evaluated in several studies. SSRIs are usually the drugs of choice. These drugs occasionally cause bradycardia, by a central medullary mechanism, but lack primary cardiotoxicity. Patients who fail to respond to these agents and do not have serious cardiac conduction defects or severe chronic congestive heart failure can generally be safely treated with secondary amine tricyclic agents (nortriptyline or desipramine [Norpramine]) provided the potential for interaction with cardiovascular drugs is kept in mind. Conduction defects and chronic low-output states with hypotension increase the risk of tricyclic treatment; in these situations, bupropion (Wellbutrin) or psychostimulants are preferable. While electroconvulsive therapy is an undisputed myocardial stressor, treatment can usually be given without major complications if careful attention is given to anesthetic management and to individualizing the treatment schedule.

Chronic Diseases of the Lung, Kidneys, and Liver Obstructive lung disease, caused in large part by cigarette smoking, is the most prevalent of the chronic respiratory diseases of the second half of life. Psychiatric complications include acute and chronic encephalopathies related to acute infection or respiratory failure, to sustained hypoxemia and hypercapnia, or to the CNS effects of drugs used in management (oral or inhaled bronchodilators, high-dose prednisone, cough suppressants, or benzodiazepines). Depressions are common, as in other chronic medical illnesses, but tend to be characterized by prominent anxiety and paniclike episodes, accounting for frequent prescription of anxiolytics. Psychotic states may occur and are usually related to acute impairment of brain function. Psychological complications are frequent and include avoidance of therapeutic physical activity because of panic in response to dyspnea, fear of sudden death by asphyxiation, excessive self-blame in patients whose illness is related to smoking, and avoidance of appropriate social activities because of negative body image. Untreated

depression in chronic obstructive pulmonary disease increases functional disability. For milder dysphoric states not meeting criteria for a depressive diagnosis, a multidisciplinary rehabilitation and counseling approach improves mood in many patients. For patients with syndromal depressions who do not have severe left ventricular disease or hypercapnia, antidepressant pharmacotherapy with nortriptyline is effective and markedly improves anxiety and severity of somatic symptoms. Important nonpharmacological interventions for anxious depressed patients with chronic obstructive pulmonary disease provide individualized education about the disease and its management, demonstrate to patients how they can modify their own symptoms with appropriate techniques such as breathing retraining, and improve overall physical condition through supervised physical training. Patients with pulmonary disability and those who require home oxygen therapy may benefit from self-help groups available nationwide. Patients with lung cancer may develop psychiatric complications similar to those occurring in chronic obstructive pulmonary disease. Paraneoplastic psychiatric syndromes have also been reported.

Chronic renal and hepatic disease produce encephalopathic states through their effects on nutrition, metabolism, excretory clearance, and drug disposition. The prevalence of other psychiatric disorders in these conditions approximates those for chronic disease in general; treatment considerations include evaluating the effects of disease on effective plasma drug levels and half life. Chronic hemodialysis has been associated with dementia due to brain accumulation of aluminum present in dialysis solutions, a discovery that has led to its exclusion from the formula.

Arthritis The two major forms of arthritis in the elderly, osteoarthritis and rheumatoid arthritis, are important to the psychiatrist chiefly because together they constitute the leading cause of chronic disability in old age, affecting one of every two persons over 65. Mood disorders, the most prevalent psychiatric complications of degenerative arthritis, occur in up to 25 percent of patients and are primary determinants of the severity of functional disability. Because of the widespread comorbidity of arthritis and depression, recognition and treatment of mood disorder can contribute significantly to improving the functional health of the elderly population. Occasionally, psychiatric symptoms arise as a complication of treatment with NSAIDs, or prednisone.

Thyroid Disease, Malnutrition, and Anemia Thyroid disease, malnutrition, and anemia are relatively common, particularly in older adults with significant comorbid medical illness. They may be responsible for such psychiatric symptoms as lethargy, weakness, confusion, and behavioral changes and should be actively sought and treated.

SPECIAL ISSUES IN THE CARE OF ELDERLY PATIENTS

Impaired Sight and Hearing The importance of sensory impairments in patients who develop psychiatric disorders in later life justifies special attention to these issues during evaluation and treatment. Degenerative diseases of the eye and ear impair responsiveness to the interpersonal and social environment, increase feelings of vulnerability among older persons, and cause hallucinations in the affected sensory modality in some individuals. In addition, deafness originating in childhood disease but exacerbated by presbycusis appears to be a risk factor for late-onset paranoid illness, and hearing and visual loss both contribute to the onset and persistence of depressions. Treatment of eye disease, improvement in corrective lenses, appropriate prescription of hearing aids, and attention to environmental lighting and sound may enhance the efficacy of specific interventions for psychiatric disorder in sensory-impaired patients.

Falling Annually, falling and fall-related injuries occur in 30 percent of older adults living in the community and in more than 50 percent of those living in nursing homes. Complications of falling include hip fracture (25 per 1000 women over age 85), other fractures, lingering painful soft-tissue injury, and head injuries with behavioral complications. Such injuries are widely feared by the old as harbingers of death. Risk factors for falling include conditions that cause postural instability, slow response to unexpected circumstances, general muscular deconditioning, and environmental hazards. Visual, auditory, vestibular, proprioceptive, and central neurological impairments; musculoskeletal dysfunction arising from disease; a sedentary lifestyle; illness-related bed rest; painful or deforming foot conditions; systemic diseases; and medications all increase the risk of falls. Poor lighting, obstacles, slippery surfaces, too much or too little friction of shoe with ground, and inadequate ambulatory supports contribute. The use of sedative medications is the single most powerful predictor of falling in elderly persons, all other things being equal. These include drugs used to manage insomnia, anxiety, depression, and agitation (both prescribed and over-the-counter); alcohol; and drugs used in the treatment of many medical diseases that sedate by themselves or enhance the sedative effects of other drugs. The presence of cognitive disorders (dementia and delirium) and all causes of ambulatory disability substantially increase fall risk, and the presence of multiple risk factors geometrically increases the hazard. Psychiatric complications of falls include acute cognitive disturbance due to head injury, and a common but rarely recognized phobic anxiety state (fear of further falls, which leads to reduction in activity, curtailment of opportunities for social exchange, and sometimes permanent retirement to a wheelchair). Persistent fall phobias may become less common with aggressive rehabilitation after hip fracture and dissemination of exercise programs for frail elderly persons.

Urinary Incontinence Urinary incontinence affects up to one third of older adults living in the community and can cause significant suffering and functional impairment. Patients may not mention this problem to their physician unless specifically asked and may suffer silently, limiting their trips away from home and their opportunities for social activities. There are a number of causes for urinary incontinence, including urinary tract infections, altered mental status, restricted mobility, medications such as diuretics, or more chronic anatomical changes. Patients should be referred to their primary care physician or to an appropriate specialist for a thorough workup.

Over-Reliance on Drugs for Managing Mental Disorders Psychiatrists and other physicians tend to underuse psychotherapeutic modalities in the care of sick or frail older patients. While properly targeted biological interventions have an undisputed role, a psychotherapeutic orientation to care is an indispensable part of optimal diagnosis and clinical decision-making and enhances the efficacy of other treatment modalities regardless of clinical setting or the patient's diagnosis. Formal office-based individual psychotherapy is now, and will likely remain, a relative rarity for the medically ill and frail elderly population. Most psychiatric care for this population will continue to occur in the context of consultation to primary care physicians, psychiatric inpatient care, and liaison work with long-term care facilities. However, empirical studies have demonstrated the value of psychologically oriented, disease-focused, group treatment approaches to chronic heart, lung, and malignant diseases and of problem-solving group therapy for depression in elderly patients in the primary care setting. For all patients, the psychiatrist's capacity to develop a rapid and sustained emotional connection; the flexible use of techniques borrowed from psychodynamic, interpersonal, cognitive, and behavioral treatment paradigms; and empathic integration of the needs of patients, their families, and professional caregivers into a comprehensive and workable treatment plan are fundamental skills that make substantial contributions to both medical management and patients' comfort and capacity to persevere in the face of serious and ongoing illness.

HEALTH-SYSTEMS APPROACH TO THE CARE OF MEDICALLY ILL GERIATRIC PATIENTS

Most older adults receive care for mental and emotional problems exclusively in the general medical sector, and many who could benefit from treatment of psychiatric disorders do not get it. There is ample evidence, for example, that many if not most older adults with significant depression are not recognized and diagnosed in primary care. Even if they are recognized, only a minority of patients receive guideline-level treatment for their depression, despite good evidence for the efficacy of treatments such as antidepressant medications and psychotherapy in old age. Older adults are less likely than younger patients to seek and receive specialty mental health services on their own and, when referred by their primary care providers, are less likely than younger patients to follow through. Obstacles to effective treatment include the fact that older adults and their primary care physicians may misattribute treatable psychiatric symptoms to normal aging, stressful life events, grief, social isolation, caretaking responsibilities, dementia, or medical illness. These misattributions can entrench hopelessness and therapeutic nihilism in patients and providers. Older adults may also fear stigmatization associated with mental disorders or psychiatric treatments. Other barriers to cost-effective care include the fact that older adults may have difficulty accessing specialty mental health care, especially when provided only in off-site specialty clinics. Many mental health insurance plans frequently fragment care by restricting psychiatric services to providers who work in settings where patients do not receive their primary care. Further obstacles include higher copayments for outpatient mental health services under Medicare and limitations in medication coverage and restricted access to new and more expensive psychotropic medications that are often better tolerated by older adults.

In recent years a number of systematic approaches have been developed to improve the treatment of patients with mental disorders in primary care. Such nterventions have included systematic case finding using simple screening instruments such as the Primary Care Evaluation of Mental Disorders (Prime-MD), patient and family education and activation, clinician education and support, systematic assessment and treatment matching, proactive outcomes tracking, and most importantly the integration of primary care and specialty mental health services. These models may use a geriatric nurse specialist with special expertise in recognizing and treating common mental disorders or a mental health specialist such as a psychologist or psychiatrist working in a primary care clinic to provide consultation and treatment on site, thus reducing barriers to access and communication between primary and specialty providers. This kind of integration may be especially important for older adults who have multiple medical problems and who will not seek care in geographically separate psychiatric clinics. In a similar fashion, geriatric psychiatrists have also developed successful models for integrated care provided on site in nursing homes. Psychiatrists and other mental health specialists working in these general medical settings can also help refer patients to further specialty mental health care as needed or link them to helpful community services. Examples of such integrated systems of care have been shown to be cost-effective for mixed-aged populations and should now be formally evaluated for older adults.

51.3 PSYCHIATRIC DISORDERS OF LATE LIFE

51.3B SLEEP DISORDERS

PATRICIA N. PRINZ, PH.D., MICHAEL V. VITIELLO, PH.D. AND SOO BORSON, M.D.

Sleep and wake disturbances can result from physiological changes that are apparently part of normal aging or from poor sleep hygiene or one or more specific sleep disorders. Such rhythm disturbances are common in elderly adults and often lead to complaints of disturbed sleep that may baffle physicians. Specialized diagnostic aids are frequently helpful. A history of sleep problems, the patient's current sleep hygiene, and a comprehensive drug-use history should be sought. Spousal reports, sleep logs, and (where necessary) all-night polysomnograms from an accredited sleep disorder center can add further clues to help unravel the complex array of potential factors. Age-related physiological sleep changes, poor sleep hygiene, specific sleep disorders, and a variety of special medical, pharmacological, situational, and environmental factors can all affect sleep quality. A thorough diagnostic evaluation cannot be replaced by prescribing a hypnotic drug, and long-term use of a hypnotic agent is almost always contraindicated. Effective treatment, usually possible after thoughtful appraisal of the patient's needs, can range from patient education to surgical intervention.

SLEEP CHANGES IN NORMAL AGING

Age-related changes in the amount and pattern of the various stages of sleep and wakefulness are well described. Elderly people spend more time in bed and less time asleep and are more easily aroused from sleep than are young people. The most striking changes include a reduction in slow-wave sleep (particularly stage 4 sleep), increased nighttime wakefulness, and increased fragmentation of sleep by periods of wakefulness. Less striking age reductions in rapid eye movement (REM) sleep and total nighttime sleep also occur. The age-related impairments in sleep depth and maintenance seem to be accompanied by an age-related increase in sensitivity to environmental stimuli that disturb sleep; for example, elderly people are more easily aroused from nighttime sleep by auditory stimuli than are young people.

Many age-related changes in sleep patterns suggest that aging may disrupt the circadian sleep-wake rhythm. Increased nighttime wakefulness in elderly persons is mirrored by more daytime fatigue, more daytime napping, and a greater likelihood of falling asleep during the day. Advancing age has also been associated with a tendency to fall asleep and awaken earlier than in earlier years, and older people are less tolerant of phase shifts of the sleep-wake schedule, such as those caused by shift work and transmeridian flight (jet lag). Because these changes are also observed in healthy seniors, they are attributed to normal, age-related neuronal alterations in brain areas controlling sleep physiology rather than pathological processes.

SLEEP HYGIENE

Sleep disturbances may also derive from such treatable factors as poor sleep hygiene and specific sleep disorders. The clinician must fully evaluate an aged patient's sleep complaints, not simply attribute them to getting older. Poor sleep hygiene can reflect inappropriate expectations about sleep or sleep schedules (e.g., excessive expectations of sleep need that result in daytime napping and excessive time in bed or irregular bed and rise times), the bedroom environment (including acoustics, lighting, bed partner, and such inappropriate activities as worrying), dietary habits, lack of regular exercise, and inappropriate use of caffeine, alcohol, or medications in amounts or at times that affect sleep adversely. These factors should be evaluated and addressed when dealing with a sleep complaint, even when a specific disorder is suspected. Table 51.3b-1 contains a checklist of major issues to be explored when assessing sleep hygiene.

Table 51.3b-1 Sleep Hygiene Checklist

SLEEP DISORDERS

Sleep disturbances in the elderly can result not only from nonpathological age-related changes and poor sleep hygiene but also from specific sleep disorders.

Breathing-Related Sleep Disorder (Sleep Apnea) Sleep apnea is characterized by repeated episodes of breathing cessation and resultant hypoxemia, multiple brief awakenings from sleep, complaints of excessive daytime sleepiness, and impaired daytime functioning. Sleep apnea usually presents as a complaint of excessive sleepiness that interferes with normal daytime functioning. Apneic events occur more frequently in men as they age, particularly if they snore. The apneic episodes can be exacerbated by the use of depressant drugs and alcohol. A number of epidemiological studies have linked snoring with sleep apnea, hypertension, and cardiovascular disease. Untreated severe sleep apnea syndrome can compromise cardiac function and increase mortality.

The treatment of obstructive sleep apnea includes (from least to greatest risk of adverse effects) minimizing sleeping on the back, using a dental appliance, weight loss, avoiding respiratory depressant drugs (hypnotics and alcohol), using respiratory stimulants such as acetazolamide (Diamox), nasal continuous positive airway pressure, and upper airway surgery. Continuous positive airway pressure is initially well tolerated by most adult patients, and it almost immediately consolidates nighttime sleep, attenuates daytime sleepiness and fatigue, and improves cognitive function. Specific surgical procedures developed to modify the upper airway (e.g., uvulopalatopharyngeoplasty) have shown limited efficacy in follow-up studies. Tracheostomy has long been a viable treatment option for severe apnea. Both types of surgical procedures have obvious limitations including risk of morbidity and mortality.

The decision to treat and the choice of treatment depend on the relative morbidity of the sleep apnea and the treatment. Sleep apnea morbidity assessment includes the frequency and severity of the sleep disturbances, the degree of daytime sleepiness and cognitive impairment, and medical sequelae (cardiorespiratory abnormality). Little evidence supports the treatment of mild obstructive sleep apnea in the elderly in the absence of excessive daytime sleepiness, cognitive impairment, or associated cardiorespiratory abnormality.

Restless Leg Syndrome and Periodic Leg Movements Elderly persons can develop two sleep-related neuromuscular dysfunctions: *restless leg syndrome* (a very strong presleep urge to move one's legs repeatedly, resulting in sleep-onset insomnia) and *periodic leg movements* during sleep, commonly known as *nocturnal*

myoclonus (stereotypical and periodic rapid flexion of the leg and foot, associated with repeated awakenings throughout the night). The prevalence of these disorders appears to increase with age and may be related to metabolic, vascular, and neurological causes. Leg movements are often present in conjunction with sleep apnea.

Current treatments for these disorders are not ideal. Commonly used benzodiazepines (clonazepam [Klonopin] and temazepam [Restoril]) ameliorate repeated arousals from sleep but may have minimal effects on the leg movements and may cause daytime sedation. Opioids, levodopa (Larodopa), clonazepam, carbamazepine (Tegretol), and dopamine receptor antagonists have also been successful in some clinical trials.

Persistent Psychophysiological Insomnia Psychophysiological insomnia results from arousal or anxiety states that interfere with sleep. Also called learned or behavioral insomnia, this disorder is diagnosed when the insomnia is maintained by maladaptive learning or sleep-incompatible behaviors in the bedroom, such as excessive problem solving, worrying, and negative expectations about poor sleep and tiredness the next day. Among frail elderly patients living alone, fears and feelings of vulnerability may be exacerbated at night and lead to difficulty sleeping. Sometimes a move to some form of shared housing is the most effective intervention. Effective treatment includes behavioral therapies to curtail and regularize in-bed hours and to modify sleep-incompatible behaviors, biofeedback, and progressive muscle relaxation, always in conjunction with education about good sleep hygiene (Table 51.3b-1).

Circadian Rhythm Sleep Disorder Rest-activity rhythms and other circadian rhythms may diminish in amplitude with advancing age. Considerable circumstantial evidence indicates that shallow circadian rhythms are associated with impaired sleep. Increased nocturnal temperatures are common in those having disturbed sleep. Attenuation of the rest-activity cycle also occurs and adversely affects sleep in bedridden or sedentary adults, suggesting that the declining physical activity of old age may impair sleep. Possibly related to this attenuation is the tendency to both fall asleep and awaken earlier (i.e., a tendency for elderly people to be “larks” rather than “owls”). Numerous studies have suggested that sleep quality can be improved by interventions that foster a more robust rest activity rhythm by synchronizing or enhancing endogenous circadian rhythms. Interventions such as optimally timed social or physical activity, regularized sleep schedules, and optimally timed bright light, melatonin, or passive heating treatments have successfully improved sleep quality. Use of such interventions to treat age-related circadian sleep-wake disturbances is a new field receiving much attention.

Sleep Disorder Due to a General Medical Condition Sleep is often disturbed because of a medical illness, including arthritic and other pain syndromes, respiratory and cardiac diseases, and neurological diseases. Appropriate treatment can help ameliorate the sleep disturbance (e.g., analgesics for pain). Elderly persons are likely to have progressive cardiac, pulmonary, and neurological disorders that can affect respiration during sleep. Poorly controlled congestive heart failure may be associated with orthopnea and frequent awakenings, and sleep may also be disrupted by nocturnal diuresis. Some patients with irritable airways and gastroesophageal reflux develop acute bronchospasm that disturbs sleep; this nocturnal asthma can often be largely prevented by bedtime doses of histamine type 2 (H_2)-receptor blockers, such as cimetidine (Tagamet). Patients with chronic obstructive pulmonary disease are at greater risk for sleep apnea than healthy older adults. Patients with chronic obstructive pulmonary disease and sleep complaints should generally be considered candidates for sleep apnea screening. A Cheyne-Stokes pattern of breathing associated with fluctuations in blood oxygen saturation due to cardiac, pulmonary, or cerebral disorders can be detected by simple portable oximetry, polysomnography, or other investigative means and can lead to treatment by respiratory stimulants or nocturnal oxygen therapy. Sleep disorder affects most patients with Parkinson's disease and appears to be a function of disease severity. Disrupted sleep in Parkinson's disease is associated with nocturia, pain, stiffness, and difficulty turning over in bed and may also be caused by levodopa therapy. Substitution of sustained-release levodopa preparations, use of nasal vasopressin to control nocturia, temperate use of benzodiazepines, and antidepressants for depressed patients with parkinsonism have been suggested. Nonpharmacological approaches to managing sleep disorder in medically ill patients have not been experimentally investigated.

Recent large epidemiological studies concur that insomnia or daytime sleepiness in elderly persons is associated with impaired health, rated by both subjective and objective measures. In one study, incident self-reported insomnias that developed over a 3-year period were associated with incident medical and psychosocial burden, while the converse also held true: improved health over the 3-year study interval was associated with resolution of the original insomnia complaint. This ongoing study illustrates the secondary nature of many insomnia complaints.

Sleep Disorder Related to Another Mental Disorder Depression and Anxiety Disorders Complaints of insomnia in elderly persons should prompt diagnostic screening and appropriate therapies for depression and anxiety disorders, which are well-known causes of poor sleep. Attention to good sleep hygiene is an important part of any therapeutic regimen. Subjective complaints of sleep disturbance were shown to be a robust predictor of future depression in a large sample of nondepressed older persons.

Dementing Conditions and Delirium Sleep is also disturbed in dementing disorders. Episodes of nocturnal wandering and delirium can occur despite normal daytime functioning. The sleep of patients with Alzheimer's disease is marked by the increased duration and frequency of awakenings, decreased slow-wave and REM sleep, and (in more advanced stages) daytime napping. Similar changes also occur in other dementing disorders. Currently, no single, predictably effective treatment for these dementia-related sleep disturbances is available, but a search for contributing causes is an essential part of the clinical evaluation. In individual cases, frightening environmental stimuli, psychiatric complications of dementia, and associated medical disorders may impair sleep and respond well to specific interventions. Attention to good sleep hygiene in an effort to consolidate nighttime sleep (including discouraging napping, encouraging daytime exercise, and light therapy) and making the patient's environment as safe as possible for nighttime forays may help.

Sundowning Sundowning, defined as worsening of agitation and cognitive impairment in demented patients during the late afternoon and evening, is commonly observed by caregivers for patients with Alzheimer's disease and is associated with significant caregiver distress. The prevalence of sundowning in Alzheimer's disease is uncertain, but it seems to occur in about one-quarter of severely demented inpatients. Investigators have recently developed a valid and reliable method of quantifying sundowning and have shown an increased incidence during the winter months of low illumination in demented residents of nursing homes. Sundowning is commonly associated with nocturnal sleep disturbance.

Vulnerability to sundowning is believed to result from damage to the function of circadian systems by the neuropathologic process, responsible for the underlying dementia but some data suggest that caregiver factors may be important. Lowered tolerance for agitation because of caregiver fatigue and involvement in necessary tasks that reduce interaction with demented persons late in the day may increase agitation or bias reporting of diurnal behavioral rhythms. A decreased capacity of the impaired patient to adapt to normal rhythms of light, ambient activity, and sensory stimulation may play a role.

Numerous uncontrolled reports recommend the use of medications, particularly antipsychotic medications, for the management of sundowning, particularly when it is associated with fearfulness, hallucinations, delusions, and disruptive behavior. Low-dose haloperidol (Haldol) or serotonin-dopamine antagonists such as risperidone (Risperdal), which are less likely to increase cognitive impairment or cause extrapyramidal adverse effects, are often helpful when given before the patient's typical time of onset of sundowning behavior. However, systematic trials suggest that cholinesterase inhibitors (e.g., donepezil [Aricept]), selective serotonin reuptake inhibitors (e.g., sertraline [Zoloft]), and other nonneuroleptic drugs deserve consideration. In clinical care, approaches combining environmental modification (increased light late in the day, pleasurable distractions and activities, and increased attention from caregivers), more support for caregivers during vulnerable periods of the day, and serial trials of medications are frequently required to achieve satisfactory improvement. Bright light therapy is a promising but still experimental approach.

Substance-Induced Sleep Disorder Elderly patients may be taking a variety of prescribed medications (often from a number of physicians), herbal remedies, and over-the-counter medications. Some of these medications may cause secondary insomnia or may exacerbate sleep apnea. Inquiries about fatigue and daytime sleepiness can help detect underlying drug-induced sleep apnea, and physicians should make liberal use of the “brown bag” drug history, asking patients to bring all medications with them to their next appointment. This time-honored technique in geriatric medicine provides clues to potential adverse drug effects and is a useful tool in educating patients. The long-term use of centrally acting agents (e.g., antianxiety agents, antidepressants, sleeping medications, and alcohol) can induce a drug-related insomnia. In elderly persons, drug metabolism may be slowed, and long-term use of hypnotic drugs may result in excessive daytime sleepiness, impaired memory, and impaired psychomotor functioning. These effects may be subtle and must be specifically sought. Although both use and the abuse of alcohol decline with age, unsuspected alcohol abuse or even self-medication with alcohol as a sleep aid can impair sleep. The clinician must educate elderly insomniacs about the sleep-impairing effects of long-term sedative and alcohol use, encourage good sleep hygiene, and use behavioral techniques such as relaxation and stress reduction.

Ill-timed or excessive use of coffee, various teas, and soft drinks that contain significant amounts of caffeine or other xanthines can also produce disturbed sleep because of both the stimulant and the diuretic effects of these compounds. When assessing a sleep complaint, especially in elderly patients who may have increased sensitivity to drugs, the clinician must obtain comprehensive information among prescribed medications, over-the-counter medications, and recreational drugs.

SEDATIVE-HYPNOTIC DRUGS AND OTHER SLEEP AIDS

Sedative-hypnotic drugs can be indicated for short-term use to relieve transient insomnia; their long-term use usually results in habituation, loss of efficacy, a drug-dependency insomnia, and rebound insomnia and nightmares when drug use is discontinued. In the presence of undiagnosed sleep apnea, hypnotic drug use can increase the frequency, duration, and severity of apneic episodes. The adverse daytime effects of hypnotic drugs include impaired cognition, slowed psychomotor functioning, and injuries due to falls. A recent National Institutes of Health consensus paper on drugs and insomnia urges great restraint in the use of hypnotic drugs for other than temporary, situational, or intermittent conditions.

Melatonin, a naturally occurring, endogenous hormone, is gaining considerable popularity as a putative sleep aid. Preliminary studies of exogenous melatonin indicated sleep-promoting effects. However, use of melatonin at this time is extremely premature. Several recent clinical trails have failed to confirm a beneficial effect of melatonin on the sleep of elderly patients. Indeed, exogenous melatonin may suppress the endogenous melatonin rhythm. Finally, the adverse effects of chronic use and indeed the optimum dose of melatonin are unknown, and a recent case report documented delirium in a patient taking high doses.

Long-Term Use of Anxiolytic and Sedative-Hypnotic Drugs in Elderly Persons Large European and American surveys have confirmed high rates of long-term anxiolytic and sedative-hypnotic drug use in elderly persons with chronic sleep complaints. While most experts and many elderly insomniacs and their families agree that long-term use of sedative-hypnotic agents is undesirable, pharmacotherapy remains the most frequently used approach in primary care practice. The more important reasons for long-term sedative prescribing are unfamiliarity with either the risk of long-term hypnotic drug use or safe treatment alternatives. Focused, practice-based drug surveillance programs are useful ways to identify both physician targets for specialized education and patients in need of thoughtful clinical reassessment.

Drug reduction strategies, designed to protect elderly patients from the adverse cognitive and motor consequences of long-term drug use and to identify and ameliorate rebound insomnia, have been tested in nursing home populations. Education of caregivers in the effects of sedative-hypnotic agents in geriatric patients can reduce their use.

Use of low-dose sedative antidepressants, such as trazodone (Desyrel), doxepin (Sinequan), and amitriptyline (Elavil) is a popular approach to chronic insomnia in nondepressed older patients but has not been formally tested for safety and effectiveness in controlled trials.

Significant advances have occurred in the nonpharmacological treatment of chronically disturbed sleep in elderly persons. Cognitive-behavioral treatment, sleep-restriction therapy, and relaxation training have all proved acceptable to elderly persons and effective in small controlled trials. All can improve sleep latency and waking after falling asleep, and cognitive-behavioral and sleep-restriction therapies can produce sustained improvement in sleep efficiency. Aerobic exercise is a useful treatment for moderate sleep complaints in healthy, sedentary older adults. Endurance training consisting of low-impact aerobics and brisk walking can also improve sleep quality, as can good sleep hygiene and daytime bright light exposure.

CHAPTER 51. GERIATRIC PSYCHIATRY

51.3 PSYCHIATRIC DISORDERS OF LATE LIFE

51.3C ANXIETY DISORDERS

IRA M. LESSER, M.D.

The clinical presentation of anxiety disorders in elderly populations may not be as dramatic as that of mood, cognitive, and psychotic disorders. However, anxiety symptoms and syndromes in elderly persons are not uncommon, often occur comorbidly with other psychiatric and medical conditions, and are frequently under- or misdiagnosed.

An erroneous belief that anxiety may be a natural accompaniment of aging has probably contributed to a lack of serious attention for these conditions. Relatively few studies have focused specifically on the phenomenology, etiology, and treatment response of anxiety disorders in elderly patients; much of what is known has been extrapolated from studies with younger patients. The prevalence rates of full syndromal anxiety disorders in the elderly are not high; however, subsyndromal anxiety states are very common and like subsyndromal mood disorders, they can adversely affect health and quality of life.

EPIDEMIOLOGY

The Epidemiologic Catchment Area Study (ECA) reported that the prevalence of anxiety disorders in older groups is generally lower than in younger ones, with few subjects reporting an anxiety disorder beginning after age 65. These findings have been confirmed in epidemiological studies in Canada and in England, although differences in instruments, populations studied, and definition of a “case” have led to somewhat different rates. For example, in the ECA study, the prevalence of all anxiety disorders in those over 65 years of age was reported to be 5.5 percent; in Edmonton, Canada, the prevalence was 3.5 percent; and studies in London have found the prevalence rate to range from 1.7 to nearly 10 percent. The low prevalence rates may reflect several factors: the true clinical picture, poorer recall (especially for events such as panic attacks), reluctance to discuss symptoms, or a cohort effect in which the generation of elderly persons may have been at less risk of an anxiety disorder than more-recent generations.

Adults over age 65 years have a lower prevalence of panic disorder than all other age groups; this is true for whites and African-Americans and for men and women. However, for Hispanic women, rates increase linearly with age, while panic is rare for older Hispanic men. New cases of panic disorder in this age group are quite rare, and data show that panic disorder is less likely to be comorbid with depressive disorders and alcohol use disorders in those over 65 years of age than in younger people. For phobias, although individuals over age 65 have lower rates than those in younger age groups, the differences are not as striking, with substantial rates reported in many studies (up to 12 percent of community-residing adults).

For generalized anxiety disorder, rates are lower in older age groups, but there is still a considerable 1-year prevalence rate in persons over 65 years (1 to 7 percent depending upon the strictness used in defining generalized anxiety disorder). Women have a higher prevalence rate than men; the rates are approximately equal for whites and African-Americans, but Hispanics have a low prevalence rate. Obsessive-compulsive disorder has a lower prevalence in the over-65 age group than in those below age 45 and a prevalence approximately equal to that for people between 45 and 65. The lowest prevalence was found in older Hispanic men. Few data exist regarding the incidence and prevalence of posttraumatic stress disorder and social phobia in elders, although symptoms of both disorders may persist into advanced years in those with an earlier onset. There is a suggestion that rates for phobias and general anxiety disorder are higher in nondemented institutionalized adults than in those residing in the community.

ETIOLOGY

Understanding the determinants of an elderly person's anxiety requires giving careful consideration to coexisting medical and psychiatric illnesses. Beyond that, one must search for psychosocial determinants. Some authors have suggested that rather than being a signal affect (warning the individual of intrapsychic conflict), anxiety in the elderly person is largely related to object loss and the fear of depletion of external resources.

The relationship of anxiety to bereavement must be considered. Studies of surviving spouses have shown that they have appreciable anxiety for at least several years after the death of a spouse. To what degree this relates to resulting social isolation or to fears of separation or abandonment is not clear, but the increasing isolation of elderly adults is a major problem. Retirement can be a particularly difficult milestone for elderly persons, leaving them with little direction or definition of self. Real-life burdens such as financial problems, crime and fears for personal safety, caring for an ill spouse, poor housing, and difficulty in obtaining medical care are significant stressors that can precipitate anxiety or worsen preexisting anxiety disorders.

Questions have been raised about the role of death anxiety in this age group. Some authors have suggested that younger people are more concerned by this than their elders, who may have come to a peaceful resignation regarding their mortality. How one deals with this in later life is related to the individual's mastery of earlier developmental phases. In Erik Erikson's epigenetic model, the outcome of the last stage, integrity versus despair, is a culmination of many previous intrapsychic and interpersonal challenges. Many elderly persons, unhappy with their lives and their legacy, may struggle with an existential angst, facing death frightened and alone, yet having difficulty articulating this struggle.

No data suggest that older people are more predisposed to anxiety from a neurobiological perspective. In fact, it has been hypothesized that the lower incidence and prevalence of panic and other anxiety disorders in the elderly population may relate to the reduced activity of several neurotransmitter systems that occurs with aging, thus increasing the threshold for developing panic attacks. There have been no reports of challenge studies using substances such as lactate or yohimbine (Yocon), which have been reported to precipitate panic attacks in panic-prone younger individuals. Likewise, neuroimaging investigations, including studies of cerebral blood flow and metabolism, have not been conducted with older subjects. More biologically based studies of anxiety in elderly patients are needed to understand the contribution of biological factors.

DIAGNOSIS AND CLINICAL FEATURES

One current conceptual approach to anxiety divides symptoms into the cognitive and the somatic. Clinical experience suggests that older patients often focus more on the somatic symptoms than on the cognitive aspects, which may be minimized. Since elderly persons have more physical illnesses than do younger persons, their emphasis on somatic symptoms can cause difficulty in differential diagnosis, particularly for primary care physicians. In the few studies that have compared the symptom profiles and configurations between young and elderly patients with anxiety disorders, occasional small differences were found in severity (e.g., fewer symptoms of panic attacks, less avoidance behavior) rather than in presentation of specific symptoms. Because of the paucity of data, diagnoses of anxiety disorders in the geriatric age group must rest on the use of criteria that have been validated on younger samples, however imperfect the fit may be.

Comorbid Conditions Anxiety disorders often coexist with other psychiatric disorders and with medical disorders. Whether the anxiety disorder preceded or followed the other disorder, the comorbid conditions typically lead to more severe symptoms, a protracted course, and possible poorer response to treatment interventions.

Anxiety typically accompanies serious physical illness, particularly when the conditions are chronic, associated with pain, and possibly terminal. Although data are lacking about the true prevalence of anxiety disorders among physically ill elderly patients, symptoms of anxiety are frequent. Significant comorbid illnesses include central nervous system disorders (e.g., Parkinson's disease, dementia, delirium, stroke), cardiovascular disease (e.g., angina, arrhythmia), respiratory disease (e.g.,

asthma, pulmonary embolus), endocrine disorders (e.g., hyperthyroidism, hypothyroidism, parathyroid disease, diabetes), and sensory impairment. Numerous medications can cause anxiety-like symptoms (e.g., bronchodilators, calcium channel inhibitors, a-adrenergic receptor agonists). Finally, intoxication and withdrawal states from alcohol and other substances (e.g., benzodiazepines, barbiturates) can have anxiety as the presenting symptom. Disentangling the symptoms in these cases can be very difficult, and treatment for one disorder may worsen the other.

> A 65-year-old woman was seen in consultation for episodes of severe anxiety. Several years before, she developed asthma, became steroid dependent, and spent most of her time in a wheel-chair. She had a devoted husband, but having primary custody of their 7-year-old grandchild and severe financial difficulties were major stressors. Soon after the asthma began, she developed classic symptoms of spontaneous panic attacks, with subsequent avoidance behavior. With each panic episode, her respiratory condition worsened; she often needed emergency care. Her physician found it increasingly difficult to ascertain whether she was having a panic attack with ensuing breathing difficulties or an asthmatic attack which frightened her so that she panicked. A further complication was the number of medications she needed to treat the asthma, many of which also could have caused increased anxiety. She obtained moderate relief of her panic episodes with low-dose benzodiazepines; however, ultimately she died of status asthmaticus.

Anxiety disorders frequently present with depressive disorders. Comorbid anxiety symptoms are very prominent in older patients who have depressive disorders. For example, studies have reported that one third to one half of elderly patients with a major depressive disorder have significant anxiety, and elderly patients with phobias or generalized anxiety disorder or both also have a high prevalence of depression. A particularly high comorbidity of anxiety and depression (80 percent) has been noted in institutionalized elderly patients, which suggests that differentiating these two conditions may not be possible in frail elderly patients. Recent data from younger age patients indicate that suicide risk is greater when depression and anxiety occur together than when either occurs alone. As the rates of suicide continue to increase well into the late decades of life, assessment of this co-occurrence is of utmost importance.

Increasing evidence indicates that alcohol-dependent patients have a high prevalence of anxiety disorders, particularly panic disorder and social phobia. Alcohol abuse and dependence in the older population is a significant problem. One-year prevalence rates for alcoholism are over 3 percent for men over 65 years, making it the third most common psychiatric disorder in this group.

Unique to the elderly population is the association of anxiety and states of cognitive decline. Symptoms of anxiety and agitation often accompany the early stages of dementing illnesses and, in some cases, are the major behavioral disturbances that cause families to bring patients for evaluation. Particularly in patients with frontotemporal dementia, early symptoms may be irritability, agitation, and compulsive behavior. For those with age-associated memory impairment and those with early Alzheimer's disease, recognition that memory may be failing and that other cognitive tasks cannot be accomplished easily often evoke feelings of loss of control and anxiety. Because the symptoms of cognitive decline and the behavioral disturbances can be so pronounced, the contribution of anxiety symptoms is easily overlooked.

DIFFERENTIAL DIAGNOSIS

In addition to understanding the relative contributions of comorbid conditions to anxiety disorders, the clinician must consider other conditions in the differential diagnosis. Whenever an anxiety disorder presents for the first time in an elderly person, the clinician must undertake a careful search for medical illness. In the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV), anxiety disorder due to a general medical condition and substance-induced anxiety disorder have replaced organic anxiety disorder. General medical conditions that are thought to be etiologically and temporally related to anxiety conditions would be listed in these diagnoses, along with a specifics indicating the type of anxiety (e.g., anxiety disorder due to hyperthyroidism, with panic attacks). Because patients have more illnesses and take more medications with advancing age, elderly individuals are more prone to have the symptoms of an anxiety disorder be a consequence of their illness or their treatment.

Another new DSM-IV disorder is acute stress disorder. This is related to posttraumatic stress disorder in that a severe stressor must be recognized. In elderly adults, war, concentration camp, refugee, and acculturation experiences as well as early abuse histories are among the stressors that can cause posttraumatic stress disorders. In acute stress disorder, the symptoms are experienced during or immediately after the trauma and last anywhere from 2 days to 1 month (as opposed to a longer time frame for posttraumatic stress disorder). This diagnosis may have considerable relevance to elderly adults, given the many traumas to which they are vulnerable. A diagnosis of mixed anxiety-depressive disorder is included in DSM-IV but is listed as a disorder in need of further study. Its relevance to the elderly population is undetermined. Adjustment disorder with anxious mood should be considered when the anxiety is of short duration and a stressor can be identified. The somatoform disorders, particularly somatization disorder and hypochondriasis, should be considered when the presentation is strongly focused upon somatic symptoms. When the symptoms seem focused upon sleep problems, the primary sleep disorders should be considered. Alcohol and other substance abuse and dependence can be significant problems in elderly adults and should be considered in the differential diagnosis.

TREATMENT

Treatment should follow a thorough evaluation of medical illnesses, and assessments of medications being taken, cognitive function, psychiatric symptoms, current stressors, and characteristic modes of functioning. Whenever possible, the clinician should first use nonpharmacological interventions: education, environmental manipulations, and the full range of psychotherapeutic approaches. Relaxation techniques can decrease anxiety in elderly adults. Preliminary data show that cognitive and behavioral approaches are as successful with the older anxious patient as with younger patients. Traditional psychotherapy or such modifications as the life review or reminiscence can have great benefit. Exploration of the spiritual aspects in an older person's life can also be useful and provide additional support.

Pharmacological treatment can be effective but must be approached with caution in geriatric populations. Altered pharmacokinetics, altered pharmacodynamics, interactions with other medications and with other illnesses, and poor compliance must all be considered. As a general rule, starting with one quarter to one half of the dosage used for a younger patient is a good idea, regardless of the class of medication chosen.

Benzodiazepines may be effective for the short-term treatment of anxiety. Preference should be given to short half-life medications (e.g., alprazolam [Xanax], oxazepam [Serax], lorazepam [Ativan]), particularly those metabolized by direct conjugation in the liver, as they are less likely to accumulate; however, the half-life may still be longer than that seen in younger people. The very short-acting benzodiazepines should probably be avoided because their use in elderly patients has been associated with confusion, anterograde amnesia, and agitation. Short-term use is rarely associated with the need for increasing dosages, but longer-term use may result in dependence. These medications should be used with caution because of possible adverse effects. The major potential adverse effects are those related to sedation, cognitive dysfunction (e.g., reduced short-term memory and attention), psychomotor performance, and cerebellar dysfunction. Taking sedative or hypnotic medications also increases the risk of falling; therefore, caution is indicated when using benzodiazepines. When the medications are discontinued, symptoms of rebound or withdrawal may occur, but these symptoms do not seem to be more severe in elderly patients than in younger patients. Buspirone (Buspar) is reportedly effective in elderly adults, with few adverse effects, but the data are limited.

Antidepressants should be considered, particularly when mixed anxiety-depression or panic disorder are present. Among the tricylic drugs, desipramine (Norpramin) and nortriptyline (Pamelor) are the most widely used for elderly adults. They may have effectiveness in generalized anxiety disorder, panic disorder, and mixed states. Because of an even more favorable side-effect profile, increasing clinical experience suggests the use of the selective serotonin reuptake inhibitors (citalopram [Celexa], fluoxetine [Prozac], fluvoxamine [Luvox], paroxetine [Paxil], sertraline [Zoloft]) for panic disorder, obsessive-compulsive disorder, and mixed states. Limited data exist on treating anxiety disorders with other, newer antidepressants (e.g., bupropion [Wellbutrin], nefazodone [Serzone], venlafaxine [Effexor]). Trazodone (Desyrel) has been used for its sedating properties, although again, no data exist regarding its anxiolytic properties. Although care needs to be taken with their use, the monoamine oxidase inhibitors (MAOIs) can be useful medications and may be tried in refractory patients with panic disorder. There are few studies specific to the elderly population on which to base recommendations.

Antipsychotic medications should not be used routinely in anxious patients unless the anxiety or agitation is secondary to dementia, delirium, or psychosis or is refractory to first-line approaches. If antipsychotic medications are necessary, the best choices are medications in either the high-potency, conventional dopamine receptor antagonists (e.g., haloperidol [Haldol], thiothixene [Navane], fluphenazine [Prolixin]) or the serotonin-dopamine antagonists (e.g., risperidone [Risperdal], olanzapine [Zyprexa], and quetiapine [Seroquel]). Emerging evidence indicates that the novel antipsychotics have the most benign adverse-effect profile regarding extrapyramidal symptoms, are possibly the least likely to cause tardive dyskinesia in elderly individuals, and may have the fewest detrimental effects upon cognitive performance.

SUGGESTED CROSS-REFERENCES

A full discussion of anxiety disorders can be found in Chapter 15. Further discussion of geriatric comorbid states and the differential diagnosis of depression appears in Section 51.3d, of drug and alcohol use in Section 51.3h, of sleep disorders in Section 51.3b, and of dementing disorders in Section 51.3e. Individual psychotherapy for elderly adults is discussed in Section 51.4i, and psychopharmacology for elderly adults is discussed in Section 51.4f.

CHAPTER 51. GERIATRIC PSYCHIATRY

51.3 PSYCHIATRIC DISORDERS OF LATE LIFE

51.3D MOOD DISORDERS

GEORGE S. ALEXOPOULOS, M.D.

Geriatric mood disorders have important medical, social, and financial consequences. Mood disorders cause suffering to elderly patients and their families, exacerbate medical illnesses, and contribute to disability and require expensive support systems. Geriatric mood disorders can be effectively treated in most cases; therefore, it is crucial to identify mood syndromes and treat them appropriately.

Geriatric depression is underrecognized. Clinicians and patients often attribute depressive symptoms to the aging process. Another reason is that older persons emphasize somatic symptoms and underreport depressed mood. Finally, geriatric depression often occurs in the context of medical or neurological brain diseases whose symptoms are similar to the symptoms of depression. In some cases the overlap of symptomatology is such that depression can only be diagnosed after successful treatment with antidepressant medications. In patients at low risk for adverse effects, it is best to offer a trial of antidepressant medications rather than to perpetuate diagnostic ambiguity. The diagnosis of depressive disorder may be difficult in patients who have dementing disorders. Unreliable reports by the patients and fluctuation of depressive symptomatology over time may interfere with diagnosis because the examiner may see the patients during a well period. Caregiver reports can be helpful in such cases because caregivers observe the patients for long periods.

EPIDEMIOLOGY

The Epidemiologic Catchment Area study documented that major depressive disorder is less frequent in elderly compared to younger adults. The overall prevalence of major depressive disorder among persons aged 65 years or older was estimated to be 1.4 percent in women and 0.4 percent in men with an overall prevalence of 1 percent. This prevalence rate is approximately one fourth of that of younger adults. These findings were confirmed by other investigators. Approximately 2 percent of the elderly population suffer from dysthymic disorder and 4 percent have an adjustment disorder with depressed mood. A rather large percentage of elderly persons, approximately 15 percent, have depressive symptomatology that does not meet criteria for a specific depressive syndrome. Although subsyndromic depression is more frequent than syndromic depression, even subsyndromic depression does not appear to increase with age.

The relatively low prevalence of depressive syndromes identified in elderly populations may in part be due to methodological problems, including the tendency of elderly persons to express psychiatric symptoms in somatic terms, reluctance to recall and report psychiatric symptoms, and use of diagnostic categories unsuitable for the elderly. In addition to methodological problems, a cohort effect has been suggested as a reason for the low prevalence of depression in the elderly. It has been observed that the prevalence of major depressive disorder has been increasing in recent birth cohorts compared to cohorts born in the early part of the twentieth century. The cohort effect is also supported by suicide studies showing that white men born after 1922 had lower suicide rates than cohorts born earlier. Depression appears to have an increasingly earlier onset in cohorts born in recent years and there is a narrowing in the differential risk for depression between genders. Finally, depression appears to be more frequent between 1960 and 1975 than in earlier years. This increase in the rates of major depressive disorder over time has recently been confirmed in large cross-national samples.

Depression frequently occurs in medical populations. In patients treated in primary care settings, depression was identified in 17 to 37 percent of patients. Approximately 30 percent of these patients have major depressive disorder while the remainder have a variety of depressive syndromes that could benefit from medical attention. In medically hospitalized patients major depressive disorder occurs in 11 percent, and less severe, yet clinically significant depressive symptomatology is identified in 25 percent of the population. The corresponding figures for patients treated in long-term care settings are 12 percent and 30 percent.

Geriatric depression is associated with female sex, divorced or separated marital status, low socioeconomic level, poor social support, and recent adverse and unexpected life events. Severe impairment in medical health resulting in disability constitutes an important risk factor. Neurological and endocrinological disorders as well as chronic obstructive pulmonary disease, myocardial infarction, and malignancies are associated with an increased incidence of depression.

Depressive syndromes occur in the older geriatric population at a rate lower than that in younger adults. However, very high rates of depression occur in medically ill, disabled, or institutionalized elderly persons. With the increase of the elderly population and the aging of birth cohorts who appear to be particularly prone to depression an unprecedented number of elderly patients are expected to be in need of psychiatric attention.

ETIOLOGY

Although the etiology of geriatric depression remains unclear, some differences have been noted in measures of brain structure and function as well as in neurochemical and neuroendocrine measures in the periphery.

Studies of monoamine metabolites in peripheral fluids yielded relatively inconsistent findings. In mixed-age candidates with depression a significant correlation was noted between age of onset and plasma 3-methoxy-4-hydroxyphenylglycol (MHPG). Studies using agonists of the platelet a $_2$ adrenoreceptor have shown increased binding in mixed age and elderly depressed patients. Increased a $_2$-adrenergic receptor binding was associated with early-onset depression. A weak correlation was also noted between age of onset and secondary MHPG. Geriatrics studies are needed to replicate these findings and examine if low urine and plasma MHPG and high a_2-receptor binding can identify early-onset, perhaps familial, depression from late-onset depression, an entity associated with medical or neurological disorders.

Platelet monoamine oxidase (MAO) activity has been thought to be a marker of vulnerability for bipolar I disorder, alcohol use disorder, and perhaps other disorders. In elderly patients with depression, high platelet MAO activity has been associated with presence of medical illness. Platelet MAO activity appears to be elevated in patients with dementia of the Alzheimer's type with and without depression. Hospitalized women with late-onset depression were found to have higher platelet MAO activity than elderly women with early-onset depression. Studies are needed to examine if high platelet MAO activity can identify subgroups of late-onset depression patients with high medical morbidity or with subclinical Alzheimer's disease. Elevated platelet MAO activity was reported in elderly patients with depression with “reversible dementia” compared to nondemented patients who had depression. Future research may examine if high platelet MAO activity can identify those with reversible dementia who develop permanent dementia on follow-up.

Platelet ^{3}H-imipramine binding is thought to reflect the function of a modulating system of serotonin uptake. With one exception, low platelet ^{3}H-imipramine binding has been found in geriatric patients who have depression compared to controls. Platelet ^{3}H-imipramine binding is lower in primary depressive disorder compared to depressive disorder occurring in the context of medical illness. Furthermore, reduced platelet ^{3}H-imipramine binding is associated with poor response to treatment with antidepressant drugs. Since platelet ^{3}H-imipramine binding is within normal range in patients with dementia of the Alzheimer's type it is important to study if this test can identify patients with clinical or subclinical states of dementia.

Plasma cortisol escape from dexamethasone (Decadron) suppression (abnormal dexamethasone supression test [DST]) is more frequent in geriatric compared to younger patients with depression. Therefore the DST is more sensitive in geriatric than in younger patients. However, abnormal DST occurs in one third of patients with dementia, thus suggesting a low specificity for geriatric depression. Although inadequate geriatric data exist, studies of younger adults suggest that lack of

normalization of DST after adequate clinical response is associated with early relapse of depression.

Blunted thyrotropin response to thyrotropin-releasing hormone (TRH) has been observed in 25 percent of depression patients and this abnormality may be trait-related in at least some patients. Blunted thyrotropin response has been reported in geriatric patients with major depressive disorder but also in patients with dementia of the Alzheimer's type. Therefore, blunted thyrotropin response to TRH is not specific for geriatric depression.

Recent development of brain imaging techniques has allowed studies of brain structure and function. Brain computed tomography (CT) studies observed enlargement of lateral brain ventricles in geriatric depression. Ventricular enlargement is more pronounced in late-onset compared to similarly aged early-onset patients with depressive disorder; the ventricles of late-onset depression patients appear to be comparable to those of patients with dementia of the Alzheimer's type. The biological meaning of ventricular enlargement is unclear but it appears to be associated with poor response to antidepressant treatment, as well as functional abnormalities of depression including hypercortisolemia, hypothyroidism, decreased dopamine beta hydroxylase, and increased concentrations of 5-hydroxyindoleacetic acid (5-HIAA) in cerebrospinal fluid (CSF).

Brain magnetic resonance imaging (MRI) studies showed white matter hyperintensity in elderly patients with depressive disorder. This finding was more frequent and more pronounced in late- compared to early-onset depression and was associated with poor response to drug treatment. Other investigators observed a positive correlation between age of illness onset and cortical atrophy and raised the question whether late-onset depression patients have a high risk for dementia of the Alzheimer's type. This suggestion is supported by the observation that geriatric depressed patients who develop dementia on an average 38-month follow-up had later age of illness onset and more sulcal widening than those who did not develop dementia.

Functional neuroimaging studies of major depressive disorder suggest a prefrontal dysfunction in depression. The prefrontal cortex integrates sensory, emotional, and neuroendocrine functions that often are impaired during depression. The frontal lobe is connected to the basal ganglia through five contiguous, nonoverlapping parallel zones (cortico-striato-pallido-cortical pathways). Studies of major depressive disorder have shown variable results, but most have suggested hypoactivity in the left or bilateral frontal regions, including the dorsolateral, inferior, and medial/anterior cingulate. Some studies have shown hyperactivity in these brain areas suggesting that heterogeneous functional abnormalities may exist in depression. Decreased metabolic rate in the caudate nucleus and left-side decrease in caudate blood flow have been reported.

Three cortico-striato-pallido-cortical pathways may be relevant to depression. Damage of the orbitofrontal circuit may lead to disinhibition, irritability, and diminished sensitivity to social cues. Damage of the anterior cingulate may result in apathy and reduced initiative. Damage of the dorsolateral circuit may result in difficulties in set shifting, learning, and word-list generation. These behavioral abnormalities resemble in part the depressive syndrome. Resting hypoactivity in the left dorsolateral prefrontal cortex and the angular gyrus have been correlated with psychomotor retardation and depressed mood. Increased activity in the posterior cingulate and the inferior parietal lobe has been associated with anxiety. Hyperactivity in the medial prefrontal cortex has been correlated with cognitive deficits in depression.

It has been proposed that cerebrovascular disease may predispose, precipitate, or perpetuate some geriatric depressive syndromes. The vascular depression hypothesis is supported by the comorbidity of depression and vascular disease and risk factors and the association of ischemic lesions to distinctive behavioral symptomatology. Elderly patients with vascular depression have greater overall cognitive impairment and disability than the nonvascular depression group. Fluency and naming are most impaired in vascular depression. Patients with “vascular depression” have more apathy and retardation and less agitation as well as less guilt and greater lack of insight. Disruption of prefrontal systems or their modulating pathways by single lesions or by an accumulation of lesions exceeding a threshold are hypothesized to be central mechanisms in “vascular depression.”

In addition to frontal system's abnormalities, dysfunction in anterior temporal-limbic regions has also been described. Resting single photon emission computed tomography (SPECT) studies of elderly patients with depression have demonstrated reduced global cerebral blood flow (CBF) and one study observed decreased orbitofrontal and anterior temporal regional CBF. A resting positron emission tomography (PET) study of depressed geriatric patients has shown global reduction in CBF as well as reduction in all cortical and subcortical regions studied. Abnormalities in postrolandic cortex have also been described.

DIAGNOSIS AND COMORBIDITY

Depression in Medically Ill Patients Geriatric depression, as a rule, occurs in the context of medical disorders. Sometimes, these conditions predispose or trigger depression, for example, depression occurring after the onset of hypothyroidism or after a myocardial infarction. In other cases the relationship of medical or neurological illness to depression is less clear. However, the overall medical severity and disability appear to be important risk factors for depression. For these reasons, geriatric depression is viewed as a heterogeneous entity.

Depressed medical patients have more medical illnesses than nondepressed patients. A recent study of 15,186 primary care patients showed that the total mean number of medical diagnoses in depressed patients was 7.9 compared to 3 medical diagnoses in nondepressed patients. These differences persisted when the elderly group was examined separately. Depressed medical patients stay in bed more days compared to patients with chronic diseases, such as chronic lung disease, diabetes, arthritis, and hypertension.

In primary care patients, depression is associated with significant functional impairment. Depression impairs social function more than heart and lung disease, arthritis, hypertension, and diabetes, and leads to greater impairment in physical function than arthritis, hypertension, and diabetes. It has been shown that antidepressant treatment can improve mood, physical symptoms, and function in depressed patients with emphysema. Therefore, effective antidepressant treatment has the potential to enhance the quality of life of patients and their families and to lower the cost of care.

In addition to high medical morbidity, depression increases the perception of poor health and utilization of medical services. In primary care clinic populations, 75 percent of distressed overutilizers have clinically significant depressive symptomatology. Depressed patients had almost twice the number of appointments per year compared to nondepressed patients. Depressed patients had more than twice the number of hospital days over the expected length of stay compared to nondepressed patients. Finally, 65 percent of depressed patients received more than five medications compared to 35.6 percent of nondepressed patients. Data from a large health maintenance organization population suggest that the health care cost of depressed medical patients is twice that of nondepressed patients with similar levels of medical morbidity.

Depression is underdiagnosed in primary care settings. However, depression is more often recognized in older compared to younger adults. Even when diagnosed, depression is undertreated in primary care settings. Approximately 11 percent of depressed patients who use primary care services receive adequate antidepressant treatment, while 34 percent receive inadequate treatment, and 55 percent receive no treatment. While primary care physicians appear to identify depression more often in elderly than in young patients, there is little difference in the percentage of treated patients.

Depression in Patients With Dementia Dementia patients develop depression at a rate higher than that of the general population. Depressive manifestations of various intensity occur in approximately 50 percent of demented patients. Reports of the rate of major depressive disorder in patients with dementia of the Alzheimer's type have been highly discrepant, ranging from 0 to 87 percent, with most studies showing a range of 17 to 31 percent. Demented patients attending psychiatric centers as well as patients with mild to moderate dementia syndromes are more likely to report depression. Depressive symptomatology appears to be elicited more often when reports of relatives are used than when evaluation relies exclusively on the interviewer's impressions. There is some evidence that family history of mood disorder predispose these patients to develop depression.

Depression occurs in approximately 25 percent of patients with cerebrovascular disease. Cortical and lacunar infarct have the highest comorbidity with depression. Left hemisphere lesions, especially close to the frontal pole, are most frequently associated with poststroke depression while subcortical atrophy appears to be a predisposing factor. However, some epidemiological studies failed to confirm the high incidence of poststroke depression.

Patients with dementia due to Parkinson's disease appear to develop depression at a rate of up to 50 percent. The severity of depression does not appear to be related to the severity of motor disability.

It has been suggested that depression with onset in late-life includes a large subgroup of patients with neurological brain disorders that may or may not be evident when the depression first appears. This assertion is supported by differences observed between late- and early-onset geriatric depression. Compared to early-onset geriatric depression patients, patients with late-onset depression appear to have a less frequent family history of mood disorders, a higher prevalence of dementing disorders, more impairment in neuropsychological tests, a higher rate of dementia development on follow-up, more neurosensory hearing impairment, greater

enlargement in lateral brain ventricles, and more white matter hyperintensities. Further research may identify clinical and biological parameters that can characterize subgroups of late-onset depression and clarify their pathogenesis.

The similarity of depressive manifestations with symptoms and signs of dementing disorders often poses diagnostic problems. Vegetative features seem to overlap while patients with early-stage dementia of the Alzheimer's type show loss of interest, decreased energy, difficulty in concentration, agitation, or retardation. Apathy, a characteristic of frontal lobe syndrome, may be misidentified as retarded depression. Sad, downcast mood and psychic rather than vegetative features have been found useful in distinguishing depressed-demented patients from patients with dementia alone. It remains unclear whether depression is associated with the degree of cognitive impairment in patients with dementia. These patients may be made to identify and express dysphoric feelings. For this reason, examination should rely on caregiver reports as well as examination of the patient. Identification of depression in dementia patients, Parkinsonian patients, and patients with cerebrovascular disease is important because they may respond to drug therapy or ECT.

Depression With Reversible Dementia Some elderly depressed patients develop a dementia-like syndrome that improves or completely subsides after remission of depression. This syndrome has been termed *pseudodementia of depression*, or *depression with reversible dementia*, and attracted considerable clinical and heuristic interest. Depressed elderly patients who remain with some cognitive impairment even after improvement of depression usually have an early-state dementing disorder whose cognitive manifestations are exaggerated when the depressive syndrome is superimposed. Although some disagreement exists it appears that even patients with more or less complete cognitive recovery develop high rates of irreversible dementia (about 20 percent per year) on follow-up. Many of these patients may even remain cognitively unimpaired for 1 to 2 years before the development of irreversible dementia. The heterogeneity of the course of depression with reversible dementia suggests that patients suffering from this syndrome can be ordered along a continuum. At the one end of the continuum lie cases in whom the cognitive disturbance results predominantly from the depressive syndrome itself. On the other end are cases in whom the intellectual impairment originates from a progressive subclinical dementing disorder, with some contribution by the depressive syndrome. Therefore, identification of a “reversible dementia” syndrome in elderly depressives constitutes an indication for thorough diagnostic work-up and frequent follow-up aimed at the identification of treatable neurological disorders.

Psychotic Depression Psychotic depression occurs in 20 to 45 percent of hospitalized elderly depression patients and in 3.6 percent of elderly depression patients living in the community. As a rule, patients with psychotic depression have delusions whereas hallucinations are less frequent. The usual themes of depressive delusions are guilt, hypochondriasis, nihilism, persecution, and sometimes jealousy. Depressive delusions can be distinguished from delusions of demented patients in that the latter are less systematized and less congruent to the affective disturbance. Sometimes it is difficult to distinguish depressive delusions from overvalued ideas of worthlessness and hopelessness. Nondelusional depressed patients are usually able to recognize the exaggerated nature of overvalued ideas although they are unable to free themselves from their excessive concerns. Psychotic depression requires treatment with combinations of tricyclic drugs and psychiatric medications or ECT since it rarely responds to antidepressant drugs alone.

Geriatric Mania The risk of mania declines in late life. Nonetheless, mania and hypomania affect 5 to 10 percent of psychiatric patients. Late-onset mania often occurs in patients who have had recurrent depression since early life. Cerebrovascular disease and particularly right-sided vascular lesions may predispose to late-onset mania. Steroids may precipitate a late-onset manic syndrome. Unipolar mania is an early-onset disease.

Bereavement Loss of a spouse often is followed by depressive symptoms or syndromes. Significant distress remains during the first 2 years of widowhood. Older persons appear to be at lower risk for developing depressive symptoms or syndromes than younger adults during the first months of widowhood. However, by the end of the second year, older and younger individuals have the same rates of major depressive disorder. The prevalence of major depressive disorder continues to increase during the second year of bereavement. At the end of the second year after loss, 14 percent of bereaved individuals have major depressive disorder, a percentage much higher than the prevalence of major depressive disorder in the elderly community population (1 percent). Bereaved elderly individuals who do not meet criteria for major depressive disorder often have significant depressive symptomatology that can contribute to compromised function, disability, and impaired quality of life.

SUICIDE RISK

Elderly persons have a higher risk for suicide than any other population. The suicide rate for white men over the age of 65 is five times higher than that of the general population. One third of elderly persons report loneliness as the principal reason for considering suicide. Approximately 10 percent of elderly individuals with suicidal ideation report financial problems, poor medical health, or depression as reasons for suicidal thoughts. Suicide victims are demographically different than individuals who attempt suicide. About 60 percent of those who commit suicide are men; 75 percent of those who attempt suicide are women. Suicide victims as a rule use guns or hang themselves whereas 70 percent of suicide attempters take a drug overdose and 20 percent cut or slash themselves. Psychological autopsy studies suggest that most elderly persons who commit suicide have had a psychiatric disorder, most commonly depression. However, often psychiatric disorders of suicide victims do not receive medical or psychiatric attention. More elderly suicide victims are widowed and fewer are single, separated, or divorced than is true of younger adults. Violent methods of suicide are more common in the elderly and alcohol use and psychiatric histories appear to be less frequent. The most common precipitants of suicide in older individuals are physical illness and loss whereas problems with employment, finances, and family relationships are more frequent precipitants in younger adults. Most elderly persons who commit suicide communicate their suicidal thoughts to family or friends prior to the act of suicide.

Older patients with major medical illnesses or a recent loss should be evaluated for depressive symptomatology and suicidal ideation or plans. Thoughts and fantasies about the meaning of suicide and life after death may reveal information that the patient is unable to share directly. There should be no reluctance to question patients about suicide since there is no evidence that such questions can increase the likelihood of suicidal behavior.

COURSE AND PROGNOSIS

Knowledge of risk factors and periods of high risk for particular adverse outcomes enable the clinician to use appropriate diagnostic methods and offer preventive treatments with favorable benefit-to-risk ratios. Despite advances in antidepressant therapies, longitudinal studies of 1 to 6 years duration suggest that 7 to 30 percent of geriatric patients have a chronic major depressive disorder. If partially remitted subjects are considered chronic, the rate of chronicity reaches 40 percent. Chronicity of depression may be predicted by history of a long current episode or long previous episodes, coexisting medical illness, high severity of depression, nonmelancholic presentation, and delusions.

Naturalistic treatment studies of geriatric populations observed a 13 to 19 percent rate of relapse or recurrence at 1 year whereas a 15 percent relapse rate is observed in patients receiving controlled antidepressant treatment. This percentage is lower than the relapse or recurrence rate (34 percent) reported in younger adults. However, if the follow-up of elderly patients with depression is extended to 3 to 6 years, the recurrence rate increases to 38 percent. A 20-year follow-up study of mixed-age depressed patients showed that 95 percent had a recurrence. Relapse or recurrence appears to have different predictors than recovery of depression. The likelihood of relapse or recurrence may be high in patients with history of frequent episodes, late age of illness onset, history of dysthymia, intercurrent medical illness, and possibly high severity and chronicity of the index depressive episode.

Dementia is not an outcome of depression of intact elderly patients. However, a large proportion of geriatric depression patients have cognitive dysfunction or dementia. Approximately 40 percent of geriatric individuals with major depressive disorder consecutively hospitalized in a tertiary care academic psychiatric center also met criteria for dementia. The large percentage of elderly depressed patients with evidence of brain disease suggests that it is clinically meaningful to examine predictors of dementia in these populations. With some exceptions, recent follow-up data observed that the elderly depressed who initially had “reversible dementia” develop permanent dementia at a rate of 9 to 25 percent per year. Presence of an initially “reversible dementia” leads to 2-yearly rate of irreversible dementia that is 2.5 to 6 times higher than that of the general geriatric population. In nondemented depressives late age of depression onset and cortical brain atrophy were significant predictors of development of dementia over a 38-month average follow-up period.

TREATMENT

Depression Geriatric depression can be effectively treated with pharmacotherapy, psychotherapy, or both. Interpersonal therapy and cognitive-behavioral therapy have been found effective in depressed elderly patients. Psychotherapy may play an essential role in the care of bereaved depressed elderly patients or in patients who have significant life crises, lack social support, develop disabilities, or lack coping skills to deal with their life situations. Psychotherapy can be helpful in addressing the hopelessness often experienced by depressed elderly patients, especially those with a history of suicide attempts. Psychotherapy may be helpful in supporting elderly patients to cope with their symptoms and adhere to treatment before antidepressant drugs take effect. Psychosocial therapies should be considered in patients who cannot tolerate biological treatments.

The objectives of geriatric depression treatment include (1) remission of depression and (2) reduction in the risk of relapse and recurrence. Because depression often contributes to disability and excess medical morbidity, clinicians should expect an improvement in both these areas. Appropriate behavioral rehabilitation techniques should be combined with antidepressant treatment in order to enable elderly patients to regain function as the depressive syndrome subsides.

Drugs, medical illnesses, and dementing disorders may lead to depression. Steroids, reserpine (Serpasil), methyldopa (Aldomet), antiparkinsonian drugs, and b-adrenergic receptor antagonists can cause depression. Viral infections, endocrinopathies such as thyroid and parathyroid abnormalities, and malignancies such as lymphoma and pancreatic cancer often are complicated by depression. While it is essential to diagnose and treat the underlying disease, depression may not remit until an antidepressant agent is used. For example, depression in a hypothyroid elderly patient rarely responds to thyroid supplementation alone. Similarly, an antidepressant trial often is ineffective before hypothyroidism is corrected. However, thyroid supplementation and an antidepressant drug offer the highest probability of antidepressant response.

Elderly patients benefit from the same psychopharmacological agents as younger patients. However, the clinician must be aware that aging and medical conditions associated with aging have an impact on pharmacokinetics and increase the sensitivity to adverse effects even at low plasma concentrations of antidepressant drugs. Changes in hepatic metabolism prolong the clearance of most drugs in older people, increasing the likelihood that the parent drugs and their active metabolites will accumulate and cause toxicity. Older patients are more likely than younger patients to develop delirium, constipation, urinary retention, dry mouth, and orthostatic hypotension. For this reason, the dosages of antidepressant medication should be increased at a slower pace in older patients than in younger adults. Four families of antidepressant drugs are available for the treatment of geriatric depression. These are tricyclics, selective serotonin reuptake inhibitors (SSRIs), monoamine oxidase inhibitors (MAOIs), and atypical antidepressants. It is crucial that antidepressant drugs are given at adequate plasma concentrations or dosages for a sufficient length of time. An adequate antidepressant trial in the elderly is longer than that of younger adults and should last at least 7 to 9 weeks.

Tricyclic Antidepressants The secondary amines nortriptyline (Aventyl, Pamelor) and desipramine (Norpramin) are the most frequently used tricyclic antidepressant drugs in geriatric depression. They have lower anticholinergic and sedative effects than the tertiary amines amitriptyline (Elavil), doxepin (Adapin), and imipramine (Tofranil). Nortriptyline appears to have a lower potential for orthostatic hypotension than do other tricyclic antidepressant agents. The plasma concentrations of antidepressant medications required for the treatment of depressed elderly patients are similar to those needed by young adults (nortriptyline plasma concentrations of 60 to 150 ng/mL and desipramine above 115 ng/mL). Elderly patients often develop therapeutic blood concentrations of nortriptyline or desipramine while on low daily dosages. Most elderly patients develop therapeutic plasma concentrations with daily dosages of nortriptyline 1 to 1.2 mg/kg of body weight and desipramine 1.5 to 2 mg/kg. Elderly patients on nortriptyline often develop higher plasma levels of the nortriptyline metabolite 10-hydroxy-nortriptyline than do young adults, even when the plasma levels of the parent compound are similar. The reason for the increased levels of hydroxynortriptyline may in part be due to the lower renal clearance in elderly compared to younger subjects. High 10-hydroxynortriptyline levels may contribute to cardiac conduction defects in elderly patients.

High intellectual functions, orthostatic blood pressure, the electrocardiogram (ECG), and the ability to urinate should be monitored frequently in depressed elderly patients receiving nortriptyline or desipramine. Pretreatment systolic orthostatic hypotension has been found to correlate with antidepressant response to nortriptyline in some elderly patients. Therefore, nortriptyline rather than desipramine should be considered in such patients and orthostatic blood pressure and subjective symptoms of orthostasis (feeling lightheaded upon standing) should be monitored carefully.

Tricyclic medications have anticholinergic properties so these drugs should be avoided in patients with prostatic hypertrophy or patients with narrow-angle glaucoma. Nortriptyline and desipramine have properties similar to those of Type 1_A antiarrhythmic drugs (quinidine-like drugs). When administered to patients with right or left bundle branch block, tricyclic agents may cause second-degree block in approximately 10 percent of cases. For this reason, an ECG should always precede the use of tricyclic drugs in the elderly. The Type 1_A properties of tricyclic medications necessitate cautious use of these drugs in patients with ischemic heart disease. A multicenter study demonstrated that Type 1_A antiarrhythmics increase cardiac mortality in postmyocardial infarction patients. Although tricyclic medications were not used in this study, the Type 1_A antiarrhythmic properties of tricyclic drugs suggest cautious use in patients with depression and ischemic heart disease.

Selective Serotonin Reuptake Inhibitors Studies of elderly outpatients observed that SSRIs are equally effective with tertiary amine tricyclic agents in the short-term treatment of depressive disorder. Recently, sertraline (Zoloft) was shown to be as effective as nortriptyline and fluoxetine (Prozac). It is unclear whether SSRIs can be helpful in hospitalized elderly depression patients with severe, melancholic depression. A study that did not use random assignment suggested that cardiac inpatients with severe, melancholic depression have a poor response to fluoxetine while they have a robust response to nortriptyline at therapeutic plasma concentrations. Although research inpatient studies of SSRIs are lacking, clinical experience suggests that these agents are effective in inpatients with a broad spectrum of depressive syndromes.

The dosages of SSRIs should be increased gradually. The starting daily dosages may be fluoxetine 5 to 10 mg, paroxetine (Paxil) 5 to 10 mg, sertraline (Zoloft) 25 mg, and citalopram (Celexa) 10 mg. For most patients, daily dosages of fluoxetine 20 mg, paroxetine 20 mg, sertraline 75 mg, and citalopram 20 to 30 mg are sufficient, although higher dosages are required by some. The SSRI fluvoxamine (Luvox) may be effective in the treatment of geriatric depression although research data are still sparse. The SSRIs have fewer cardiac adverse effects than tricyclic antidepressant agents and often are used as drugs of first choice, especially in patients with mild, nonmelancholic depression or in patients with cardiac disease. The most frequent adverse effects of SSRIs are insomnia, akathisia, nausea, anorexia, pseudoparkinsonism, and inappropriate secretion of antidiuretic hormone leading to hyponatremia.

Drug interactions should be considered in elderly patients receiving SSRIs. Fluoxetine and paroxetine inhibit the cytochrome P450 (CYP) 2D6 liver cytochrome isoenzyme. Sertraline is a weaker inhibitor of the 2D6 isoenzyme and citalopram has an insignificant inhibiting effect. CYP2D6 isoenzyme is essential for the hydroxylation of nortriptyline and desipramine and the metabolism of antipsychotic agents and Type 1_A antiarrhythmic drugs (encainide, flecanide [Tambocor]), beta-blocking drugs, and verapamil (Calan) whose plasma concentrations may be raised in SSRI-treated patients. Therefore, reduction of dosages and monitoring of plasma levels of tricyclic antidepressant, antipsychotic, and antiarrhythmic drugs is required in patients treated with fluoxetine or paroxetine (Paxil). An exception is the SSRI fluvoxamine, which inhibits the CYP 3A4 and the IA2 cytochrome isoenzyme but does not significantly inhibit the 2D6 isoenzyme. CYP 3A4 is responsible for the metabolism of alprazolam (Xanax), triazolam (Halcion), carbamazepine (Tegretol), quinidine (Cardioquin), erythromycin, terfenazine, and astemizol (Hismanal) and may lead to an increase in the plasma concentration of these agents. These drugs should be avoided in patients receiving fluvoxamine. Similarly, theophylline (Aerolate) should be cautiously prescribed in fluvoxamine-treated patients because fluvoxamine may produce a threefold decrease in theophylline clearance by inhibiting the CYP 1D12 isoenzyme.

MAO Inhibitors Limited information exists on the use of these agents in the old literature. However, MAOIs have been studied in depressed patients who are in their late 60s to early 70s. MAOIs are effective in patients with major depressive disorder; they are also effective in depressed patients with panic attacks. Low dosages of MAOIs, for example, phenelzine (Nardil) 30 to 45 mg daily or tranylcypromine (Parnate) 20 to 30 mg daily, should be used in the elderly. Orthostatic hypotension is the most frequent adverse effect of MAOIs. This adverse effect is of concern in the elderly because it may lead to falls and fractures, especially of the hip or the humerus. Other adverse effects include weight gain, lack of energy, and insomnia; lack of energy and daytime somnolence in phenelzine-treated patients; and nervousness, insomnia, and excessive perspiration in tranylcypromine-treated patients. Peripheral neuropathy occurs in a small percentage of patients on MAOIs and often responds to pyridoxine. Sympathomimetic amines, monoamine precursors, tricyclic antidepressants, SSRIs, venlafaxine (Effexor), concomitant administration of two MAOIs and tyramine-rich food may cause a hypertensive crisis and should be avoided in patients on MAOIs. Drug interactions and dietary restrictions often prevent the use of MAOIs in the elderly.

Other Antidepressant Agents Venlafaxine was found effective in hospitalized depressed patients as well as in drug-resistant depressed patients and in depressed patients with chronic pain. For this reason, venlafaxine should be considered in severe depression and in depression unresponsive to other agents. Elderly patients appear to require dosages comparable to those of younger adults. Daily dosages above 100 to 200 mg are adequate for the majority of elderly patients. Nausea, a rather frequent adverse effect of venlafaxine, can be minimized by a slow increase of the daily dosage. Blood pressure should be monitored, especially in patients receiving dosages above 225 mg daily, since venlafaxine can increase blood pressure. Venlafaxine has limited drug-drug interactions and may be selected in elderly patients who require treatment with drugs interacting with other antidepressant drugs. Venlafaxine needs to be administered in three divided doses daily; for this reason, compliance should be monitored carefully.

Bupropion (Wellbutrin) has comparable efficacy with tricyclic antidepressant agents in younger adults. There is limited research information on the use of bupropion in the elderly. Bupropion has fewer adverse effects than tricyclic drugs, including lack of cognitive impairment or sedation, safety in overdose, and lack of cardiotoxicity. Bupropion was found to be safe in patients with heart disease, and it should be considered in elderly cardiac patients. Bupropion has few drug interactions, but it should not be prescribed in patients receiving MAOIs. Bupropion may exacerbate pre-existing hypertension. For this reason, monitoring of blood pressure is required. Seizures have been reported in 0.4 percent of patients treated with bupropion. The risk of seizures can be minimized by the use of sustained-release preparations,

slow introduction of bupropion (75 mg daily), use of divided daily dosages, and restriction of the total daily dosage to 450 mg. Most elderly patients require 75 to 100 mg of bupropion 3 times daily.

Nefazodone (Serzone) promotes sleep, has anxiolytic effects, is well tolerated, and safe in overdose. Nefazodone does not influence the sleep architecture and does not cause sexual dysfunction. However, sedation and need for two daily doses may be a problem for some elderly patients. A total daily dosage of 300 to 500 mg may be required.

Psychostimulants may be ineffective in elderly patients with primary major depression. However, dextroamphetamine (Adderall) and methylphenidate (Ritalin) appear to improve apathy and anergy in medical patients or cognitively impaired patients. Dextroamphetamine or methylphenidate at doses of 5 to 10 mg in the morning and at noon are sufficient. Psychostimulants have rapid onset of action, minimal adverse effects, limited potential for tolerance, and low risk for addiction.

Augmentation of antidepressant drugs may improve the response of partially remitted geriatric depression. Lithium (Eskalith) may augment tricyclic antidepressant response in elderly patients. The dose of lithium required by depressed elderly patients receiving tricyclics may be one third to one half that of younger adults. In younger patients, combinations of tricyclics with SSRIs have led to an antidepressant response sooner than tricyclics alone. Other augmentation techniques include combinations of tricyclics or SSRIs with thyroid hormones, psychostimulants, bupropion, pindolol (Pindolol), and other agents. Clinical experience suggests that augmentation techniques can be effective in some depressed geriatric patients with incomplete response to a single antidepressant agent. However, the role of augmentation techniques is limited in geriatric depression because elderly patients often are unable to tolerate combination therapies.

Continuation and Maintenance Treatment Following remission of depression, the antidepressant medication should continue to be administered for at least 6 months (continuation phase). Continuation treatment is used to prevent relapse of the episode that the patient most recently suffered. After having been well for 6 months, patients are at risk for a new episode of depression (recurrence). History of three or more episodes is the strongest predictor of recurrence. Other predictors are high severity of the initial episode and persisting anxiety. In mixed-age populations, late age of illness onset is a strong predictor of recurrence. Patient at high risk for recurrence should have maintenance treatment for at least 1 to 2 years. Unlike continuation treatment, which is used to prevent relapse of the initial depressive episode, maintenance treatment seeks to prevent new episodes of depression. The dosage and plasma concentration used for continuation and maintenance treatment should be the same as those used for effective acute treatment of depression.

Compliance Approximately 70 percent of patients fail to take 25 to 50 percent of their medications. Older patients and their families may not understand depression and its course and the importance of taking medications as prescribed. Concurrent medical illnesses can interfere with antidepressant response or attainment of adequate dosages. Alcoholism and other substance abuse may undercut pharmacotherapy. Difficulties accessing health care may hinder the ability of the elderly, especially the functionally dependent elderly, to obtain adequate treatment.

Bereavement The treatment of a bereaved elderly person depends on the severity of symptomatology. If major depressive disorder develops during the bereavement period, antidepressant treatment should be considered. Many clinicians suggest that psychotherapy, antidepressant drugs, or both should be administered if the depression lasts longer than 1 year. The timing of intervention and the decision about drug therapy depend on the severity of symptomatology.

Bereaved persons with depressive symptomatology that does not meet the criteria for major depressive disorder may benefit from brief focused psychotherapy. Interpersonal psychotherapy lends itself well for this purpose because it addresses issues related to loss, depression, and change of roles. Although antidepressant drugs can conceivably be effective in the bereaved elderly who have depressive symptoms, clear guidelines are not available because of a lack of research.

Most elderly bereaved individuals do not develop depressive syndromes or clinically significant depressive symptoms. Therefore, prophylactic treatment is not recommended for the whole elderly bereaved population. However, several interventions may be helpful and they should be considered for individuals with an intense reaction to loss or history of depression. These include self-help groups, counseling, group therapy, and individual dynamic psychotherapy.

Mania The management of late-life mania follows the same principles as that of younger adults. However, geriatric manic patients should be examined for drugs and medical or neurological diseases that can predispose or precipitate mania.

Lithium Lithium is the most investigated drug in geriatric mania. Lithium may be less effective when mania is comorbid with neurological and medical disorders than in uncomplicated mania. Age-associated decline in renal clearance in elderly patients leads to high lithium plasma levels even when low dosages are used. Lithium should be introduced slowly, starting with daily dosages of 150 mg. About one half of the dosage required for young adults is sufficient for the elderly. The half-life of lithium is about 24 to 36 hours in patients who are in their 70s. Therefore, steady-state pharmacokinetics are anticipated 5 or more days after the stabilization of the daily dosage. In some elderly patients, lithium plasma levels of 0.3 to 0.6 mEq/L were found to be effective. However, controlled studies are needed to establish the efficacy of low lithium plasma levels in the elderly. The onset of action of lithium is slow and may require several days or weeks.

The adverse effects of lithium are pronounced in geriatric patients. Elderly patients often develop a fine tremor or myoclonus at lithium plasma levels considered nontoxic in young adults. Lithium can produce Parkinsonian symptoms or worsen pre-existing Parkinson's disease. Delirium can develop at plasma concentrations below the therapeutic range. Psychiatric drugs increase the risk of delirium in elderly patients on lithium. Lithium may worsen cognitive function, especially in patients with dementia. Sinoatrial block may be caused by lithium in predisposed patients; digitalis and beta-blocking agents increase the risk for sinoatrial block. Salt depletion, thiazide diuretics, and nonsteroidal anti-inflammatory drugs may raise the lithium plasma concentrations and result in toxicity.

Anticonvulsants The anticonvulsant valproate (Depakene), divalproex (Depakote), and carbamazepine are effective antimanic agents. Anticonvulsants drugs appear to be effective in both lithium responders and lithium nonresponders. Anticonvulsants may be more effective than lithium in rapidly cycling manic patients and in those with dysphoric mania. Patients of mania with neurological brain disease may be more responsive to valproate than patients without brain disease. Although there is limited research on the use of these drugs in elderly populations, they should be considered especially in patients who are at high risk for lithium toxicity or who have a history of poor response to lithium.

Drowsiness and sedation are frequent adverse effects of valproate and carbamazepine; both are dose-dependent adverse effects. Many patients are habituated to sedation. Therefore, slow introduction of valproate or carbamazepine may reduce this problem. In the elderly, the principal adverse effects of valproate are gastrointestinal distress and ataxia; frequent adverse effects of carbamazepine are ataxia and confusion. Rarely, carbamazepine can cause hyponatremia. Approximately 0.4 of patients receiving valproate and 2 percent of patients receiving carbamazepine develop leukopenia with a white count below 4000/mm ^{3}. Half of the patients who develop leukopenia on carbamazepine have a reduction in their white blood cell count during the first 2 weeks. For this reason, periodic monitoring of the white blood cell count is indicated, especially during the early phases of treatment.

Other Drugs Agitated elderly patients with mania may be treated with low dosages of lorazepam (Ativan). Lorazepam is favored over other benzodiazepines because it undergoes only phase II metabolism (glucuronidation), a process minimally affected by aging. Alternatives to lorazepam are high-potency antipsychotics at low dosages, for example, haloperidol (Haldol) 0.5 to 5 mg daily. These drugs should be used early in the treatment of acute mania and should be withdrawn when the agitation is controlled and therapeutic plasma levels of a mood stabilizer are established.

Electroconvulsive Therapy Electroconvulsive therapy (ECT) should be considered in both geriatric depression and mania because of its efficacy, rapid onset of action, and safety. ECT may be chosen in patients with severe mood syndromes unable to tolerate the long waiting imposed by the gradual introduction of antidepressant drugs or mood stabilizers and the slow onset of drug action in the elderly. Approximately 80 percent of the population in the seventh or eighth decade of life have one or more medical illnesses. Medical illness and depression tend to occur in the same persons. Therefore, the percentage of medical illness in elderly patients with depression is even higher than that of the general population. Cardiac conduction defects, prostatic hypertrophy, glaucoma, and other conditions increase the risk of drug therapy. Moreover, even when antidepressant drugs are tolerated the need for gradual introduction of antidepressants and the slow onset of antidepressant action in the elderly prolong the time during which patients remain depressed, thereby increasing the risk for suicide, debilitation, dehydration, and electrolyte disturbances.

Controlled studies demonstrated that ECT is an established acute treatment for depression and mania. Administration of three ECTs a week appears to produce a more rapid recovery than ECT given twice or once a week. Less frequent ECT is associated with less cognitive impairment, but no differences were found 1 month after ECT completion between the groups that had ECT three times or twice weekly.

It appears that electrode placement and electrical dose influence both efficacy and memory adverse effects. Low–electrical-dose (just above seizure threshold)

unilateral ECT was found less effective than high-dose (2.5 times the threshold) unilateral ECT. However, even high-dose unilateral ECT may not be as effective as bilateral ECT, although disagreement exists. Use of high- or low-dose electrical stimulus does not appear to influence the efficacy of bilateral ECT. Regardless of electrode placement, high dosage increases the speed of improvement. These recent data challenge earlier findings suggesting that long duration of seizures is associated with high treatment efficacy. High-dose unilateral ECT is associated with prolonged time to recover orientation after seizure induction. Bilateral ECT requires longer recovery time than high-dose unilateral ECT. Compared to unilateral ECT, bilateral ECT leads to greater retrograde amnesia within a short period after completion of ECT, but there may not be significant memory differences after 2 months. Most of these observations used mixed-age depressed populations.

Anecdotal literature suggests that ECT is an effective continuation or maintenance antidepressant treatment. Controlled studies of continuation and maintenance ECT are needed since there is evidence of high relapse-recurrence rate in ECT responders who previously had a medication-resistant depressive disorder.

The mortality rate following ECT is 0.01 percent. The majority of deaths (67 percent) related to ECT are due to cardiac complications and occur immediately after ECT or within a few hours from treatment. Compared to younger adults, elderly patients and patients with pre-existing cardiac disease are more prone to cardiovascular events occurring in the context of ECT, including ischemic syndromes, arrhythmias, decompensation of heart failure, and transient severe rise in blood pressure. However, with adequate medical evaluation, monitoring during and after ECT, and appropriate intervention most cardiovascular events related to ECT have a benign outcome.

ECT alters cerebrovascular circulation temporarily. ECT leads to cerebrovascular contraction, heightened blood-brain barrier permeability, and increased brain oxygen consumption. Nonetheless, ECT appears to be reasonably safe 1 month after a cerebrovascular accident. ECT is generally contraindicated in patients with intracranial tumors because it may lead to delirium, major neurological events, or death. However, case reports have documented that patients with small asymptomatic tumors without surrounding edema or obstruction of CSF flow may tolerate ECT.

Geriatric patients require a longer time to recover their memory than younger adults, especially after bilateral ECT. Moreover, geriatric patients sometimes develop prolonged confusion after ECT; falls have been reported in up to 15 percent of patients. However, controlled studies are needed in order to examine whether and to what extent ECT-related confusion is responsible for these falls. The practice of favoring ECT over antidepressant drugs in medically ill depressed patients may have led to inflated reports of ECT-related morbidity. Anecdotal literature suggests that ECT was used uneventfully in patients over 100 years old and in elderly patients with aortic aneurysm cardiac pacemakers, or history of myocardial infarction, stroke, transient ischemic attacks, severe hypertension, and arrhythmias or patients in need of anticoagulant drug therapy.

SUGGESTED CROSS-REFERENCES

Delirium and dementia are discussed in Chapter 10, delusions in Section 13.2, and mood disorders in the general population in Chapter 14. Suicide is discussed in Section 29.1 and Alzheimer's disease in Section 51.3e. Treatment of the elderly is discussed in depth in Section 51.4.

51.3 PSYCHIATRIC DISORDERS OF LATE LIFE

51.3E ALZHEIMER'S DISEASE AND OTHER DEMENTIAS

GARY W. SMALL, M.D.

Alzheimer's disease (called *dementia of the Alzheimer's type* in the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* [DSM-IV]) has received increased attention in recent years, along with the rapidly growing number of elderly persons most vulnerable to it and related dementias. Except for genetic mutations causing the rare early-onset familial cases, the cause or causes of this form of dementia are unknown. Basic and clinical research efforts, however, offer the hope of discovering the cause, which should eventually lead to specific treatments or cures. Until then, accurate diagnosis, symptomatic treatments, and family interventions are essential to minimize the suffering of patients and family members and to maximize the patient's functional level.

DEFINITION

According to DSM-IV, the essential features of dementia include memory impairment, impairment in at least one other cognitive domain (e.g., language and visual-spatial skills), and significant disturbance of work or social functioning or both resulting from cognitive deficits. These features cannot occur exclusively during the course of a delirium. Dementia of the Alzheimer's type is defined as a dementia syndrome that is gradual in onset and progression and without another identifiable and sometimes treatable cause. A definite diagnosis of dementia of the Alzheimer's type can be made only by histopathological examination of brain tissue, generally after the patient's death. A work group on the diagnosis of this disorder established by the National Institute of Neurological and Communicative Disorders and the Alzheimer's Association specified criteria that provide a guide for the diagnosis of possible and probable Alzheimer's disease. Possible Alzheimer's disease includes dementia syndromes in which an additional disease (e.g., tumor or cerebral thrombosis) may be implicated. Probable Alzheimer's disease is similar to progressive dementia of the Alzheimer's type.

HISTORY

In 1906 the German psychiatrist and neurologist Alois Alzheimer first described a middle-aged patient who had suffered from a progressive dementia that affected language, memory, and behavior. After the patient's death at age 55 years, Alzheimer applied new staining techniques to the patient's brain tissue and demonstrated the presence of what is now termed *neurofibrillary tangles* and neuritic plaques in the neocortex and other brain regions. For years, Alzheimer's disease was considered a presenile dementia, partially because some plaques and tangles occurred in elderly persons without dementia and some elderly persons with dementia had few plaques and tangles. Such conflicts were resolved, however, in the late 1960s, when the degree of dementia was shown to correlate with the number of neuritic plaques in neocortical association areas. Moreover, causes of senile dementia other than Alzheimer's disease were also recognized.

EPIDEMIOLOGY

Dementias are the most common causes of psychopathology in elderly persons. Dementia of the Alzheimer's type accounts for about 60 percent of old-age dementias. It is estimated to afflict from 5 to 10 percent of people age 65 and accounts for the most striking rise in dementia incidence in the very old. Dementia of the Alzheimer's type and related dementias cost society each year an estimated $100 billion, which includes both direct costs (i.e., actual dollar expenditures) and indirect costs (i.e., resource losses not involving dollar expenditures). The greatest risk factors for developing dementia is age—the incidence and prevalence of the disease double every 5 years after age 60. An estimated 4 million U.S. citizens suffer from Alzheimer's disease. As the baby-boom generation (born in the 1950s and 1960s) moves into the age group of 60 years and older, Alzheimer's disease will become an even greater public health problem. By the year 2040, 14 million Americans could be affected if current trends remain unabated.

ETIOLOGY

Investigators around the world are searching for possible causes for Alzheimer's disease, which should lead to treatments that may delay or even halt the dementing process. Efforts have focused on various neurotransmitter systems, especially the cholinergic system, because of such findings as loss of cholinergic neurons in the basal nucleus of the forebrain. Some of the latest discoveries have been in the area of molecular biology and genetics. The increased frequency of Down syndrome (trisomy 21) patients who invariably develop Alzheimer's disease neuropathology and dementia by their 40s instigated an initial focus on chromosome 21, and significant linkage to chromosome 21 was discovered in some early-onset families but not in others. Excitement in the area built, however, when the gene coding for the amyloid precursor protein (APP) found in senile plaques was localized to the same chromosome 21 region. APP mutations, however, have been identified in only 20 families. More recent studies have shown that most early-onset pedigrees not segregating APP mutations show mutations of a chromosome 14 gene *(presenilin 1)*. One other form of early-onset Alzheimer's disease is represented by families of Volga German origin. For these families chromosome 1 mutations *(presenilin 2)* have been identified.

Studies of the common late-onset disease (dementia beginning after age 60 years) showed evidence for linkage or association or both for a chromosome 19 region. Apolipoprotein E (APOE) was a candidate Alzheimer's disease susceptibility gene partly because APOE and cerebrospinal fluid bound to immobilized amyloid b peptide and antisera to APOE stain senile plaques and neurofibrillary tangles. In addition, APOE localized to the same region of chromosome 19 identified in linkage studies.

APOE has three allelic variants (2, 3, and 4). Everyone inherits one allele from each parent so that five common genotypes are possible (2/3, 3/3, 2/4, 3/4, and 4/4). The sixth genotype (2/2) is rare. In the general population, approximately 3 percent of persons have the 4/4 genotype, 20 percent have the 3/4 genotype, and most people have the 3/3 genotype. The APOE-4 allele increases risk and decreases age at dementia onset in a dose-related fashion, that is, Alzheimer's disease risk is lowest for the 3/3 genotype, higher for the 3/4 genotype, and highest for the 4/4 genotype. By contrast, the APOE-2 allele has a protective effect so that Alzheimer's disease risk is lower for people with the 2/3 genotype than with the 3/3 genotype. Susceptibility to Alzheimer's disease from APOE affects many races and has been confirmed worldwide.

One strategy used to facilitate searches for causes recognizes that Alzheimer's disease may be a heterogeneous condition. Investigations comparing familial (one or more affected first-degree relatives of proband or large autosomal dominant kindreds) and sporadic Alzheimer's disease patients, as well patients with early-onset (65 years or younger) and late-onset dementia, have found clinical and biological differences among them. Other studies suggest sex differences according to disease expression, cerebral glucose metabolism, and neuroendocrine function and a possible interaction among age at onset, sex, and familiarity. Case-control studies have explored potential risk factors for Alzheimer's disease. Although the studies have demonstrated such risks as prior head trauma and depression, additional study is recommended. Factors that may reduce the risk for developing Alzheimer's disease are also being studied, including higher educational level, larger brain size, and postmenopausal estrogen therapy.

In a sense, research in Alzheimer's disease is like solving a huge jigsaw puzzle: although researchers are beginning to piece together a few corners, the puzzle is far

from solved. In some cases, the cause may be a genetic defect on chromosome 14; in others a mixture of genetic and environmental factors may play a role.

DIAGNOSIS AND CLINICAL FEATURES

The hallmark of dementia is memory impairment. In progressive dementias, short-term memory is affected initially. Patients have particular difficulty in learning new information, as shown by their inability to recall three objects after 5 minutes or even after just two distractions. Long-term memory may be affected, and patients may not recall important past personal information. Other cognitive areas may be impaired, including abstract thinking, judgment, personality, and language. In a typical case of Alzheimer's disease, the onset is so insidious that family members have difficulty estimating when the impairment began.

A complete history from someone who knows the patient well, physical and neurological examinations, and a mental status examination are essential in the diagnostic evaluation. Brief standardized mental status tests (e.g., the Mini-Mental State Examination) are useful to quantify the degree of cognitive impairment, and more extensive neuropsychological batteries provide details on the nature of the cognitive deficits. On examination, the patient may show *apraxia* (inability to carry out motor commands, even though comprehension and motor function are intact), *agnosia* (inability to recognize objects, despite intact sensory function), or difficulties in visual-spatial skills (inability to copy two-dimensional and three-dimensional figures or to assemble blocks). A variety of behavioral changes may accompany the cognitive deficits, including paranoia, agitation, insomnia, anxiety, and depression.

PATHOLOGY AND LABORATORY EXAMINATION

The key histopathological features include neuritic plaques (extracellular deposits of amyloidogenic proteins) and neurofibrillary tangles (abnormal intracellular cytoskeletal filaments). Plaque density has been used as a criterion for the postmortem diagnosis of Alzheimer's disease. Reduction in neuron number and synapses and an accumulation of plaques and tangles occur in the frontal, temporal, and parietal lobes; that finding is consistent with the involvement of association and limbic brain structures. Because of neuronal loss, the brains of Alzheimer's disease patients demonstrate atrophy greater than expected for their ages.

Many clinicians recommend routine use of structural imaging scans (computerized tomography [CT] or magnetic resonance imaging [MRI]) as part of the laboratory evaluation for dementia. Positron emission tomographic (PET) scans can identify patterns of glucose use (the brain's sole source of nutrition in nonstarvation states) that differentiate Alzheimer's type dementia from other dementias (Figs. 51.3e-1 and 51.3e-2), even before the diagnosis can be confirmed clinically. Such parietal and temporal hypometabolism findings observed on a PET scan may be asymmetric and correlate with hemisphere-specific neuropsychological deficits. Moreover, combining genetic risk assessment with PET is a potential strategy for early detection of Alzheimer's disease. Single photon emission computed tomographic (SPECT) scan measures cerebral blood flow and demonstrates biparietal hypoperfusion in Alzheimer's disease, but it has poorer spatial resolution compared with PET.

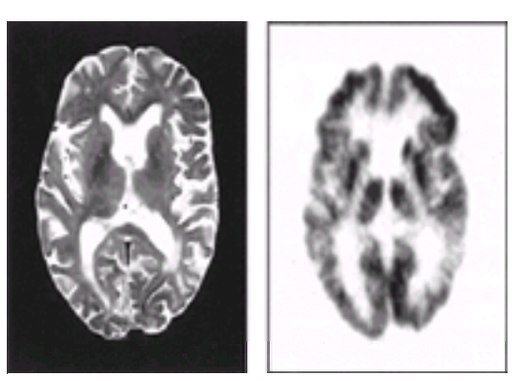

FIGURE 51.3e-1 Brain scans of an 82-year-old woman with a 4-year history of gradual memory loss and a clinical diagnosis of dementia of the Alzheimer type. The MRI (left) shows moderate atrophy with enlarged ventricles and periventricular white matter hyperintensities. The PET (right) shows atrophy but also the temporal hypometabolism characteristic of Alzheimer's disease. Higher planes also showed parietal hypometabolism. The white matter hyperintensities and atrophy are nonspecific findings in this case; by contrast, the parietal and temporal hypometabolism help with the differential diagnosis of dementia.

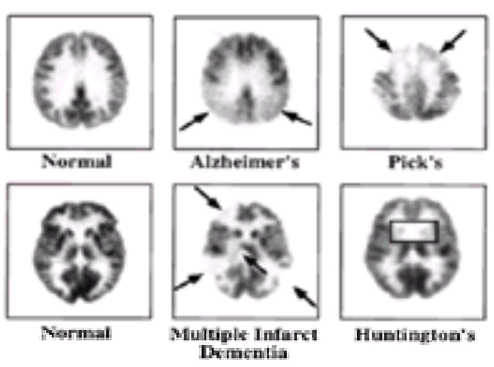

FIGURE 51.3e-2 Characteristic PET patterns (transaxial images) for a cognitively normal person and patients with different dementias. The following metabolic deficits are demonstrated (*arrows*): Alzheimer's disease—bilateral parietal deficits; multiple infarct (vascular) dementia—multiple focal deficits; Pick's disease—frontal deficits with retained parietal metabolism; Huntington's disease—bilateral caudate deficits.

The laboratory evaluation for dementia involves a search for potentially treatable medical conditions. The following blood tests have been recommended as routine: complete blood count; serum urea nitrogen and glucose; serum electrolytes (sodium, potassium, carbon dioxide content, chloride, calcium, phosphorus); serum vitamin B_{12}; thyroid function tests; serological test for syphilis; and liver function tests. The combination of increased tau and decreased beta-amyloid has been found in the cerebrospinal fluid of patients with Alzheimer's disease, but the sensitivity and specificity of this profile has not been studied in large clinical populations.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of Alzheimer's disease can be a problem. Most potential biological markers are still in a development phase, and the clinician is left with conventional methods of evaluation: the patient's history, a physical examination, and laboratory tests. The history provides important information, and several informants should be sought for corroboration. Even with the most thorough evaluation, diagnostic errors do occur. Clinical researchers who have neuropathological confirmation of diagnosis report accuracy rates ranging from 65 percent to more than 90 percent, even though other progressive dementias (such as Pick's disease) can rarely be distinguished on clinical grounds alone.

Vascular dementia is estimated to account for 10 to 20 percent of the dementias of old age. Classically, the disorder is characterized by a sudden onset of illness and stepwise decline in cognitive function, rather than the insidious onset and gradually progressive course of Alzheimer's disease. Focal neurological signs and association with hypertension in many patients may also help differentiate between these two dementias. The clinical signs and symptoms, coded and given weighted scores, have been used widely to help differentiate multi-infarct dementia from dementia of the Alzheimer's type. Although the validity of the scale has been questioned, searching for these features can help clarify the patient's clinical profile (Table 51.3e-1). An expanded scale has been developed aimed at correcting the methodological shortcomings of the early instrument. Nonetheless, the frequent coexistence of these two dementias (estimated at about one third of all dementias) impairs diagnostic accuracy.

Feature	Point Values*
Abrupt onset	2
Stepwise deterioration	1
Somatic complaints	1
Emotional incontinence	1
History or presence of hypertension	1
History of strokes	2
Focal neurological symptoms	2
Focal neurological signs	2

* A score of 4 or more is consistent with vascular dementia.
Adapted from Rosen WG, Terry RD, Fuld PA, Katzman R, Peck A: Pathological verification of ischemic score in differentiation of dementias. Ann Neurol 7: 486, 1980.

Table 51.3e-1 Clinical Features of the Modified Ischemic Score

Even though Alzheimer's disease and vascular dementia constitute the bulk of all dementias, numerous other conditions must be considered and sometimes can be differentiated from Alzheimer's disease by their clinical presentation. For example, frontotemporal dementia is characterized by marked personality changes, relative preservation of visuospatial skills, and executive dysfunction. By contrast, patients with Lewy body dementia may evidence visual hallucinations, delusions, fluctuating mental status, and sensitivity to antipsychotic drugs.

Alcohol and drugs may cause memory loss and other symptoms of dementia. For elderly patients, drugs deserve special emphasis as a cause of memory impairment because of widespread polypharmacy and age-related changes in body function and pharmacokinetics. An elderly person's brain can be extremely sensitive to change in its environment, and almost any physical illness can effect such a change and produce a dementia-like syndrome. Numerous potentially treatable physical and mental conditions must be considered whenever the diagnosis of dementia is entertained (Table 51.3e-2).

Substances
Anticholinergic agents
Antihypertensives
Antipsychotics
Corticosteroids
Digitalis
Narcotics
Nonsteroidal anti-inflammatory agents
Phenytoin
Polypharmacotherapy
Sedative-hypnotics
Psychiatric Disorders
Anxiety
Depression
Mania
Delusional (paranoid) disorders
Metabolic and Endocrine Disorders
Addison's disease
Cushing's syndrome
Hepatic failure
Hypercarbia (chronic obstructive pulmonary disease)
Hypernatremia
Hyperparathyroidism
Hyperthyroidism
Hypoglycemia
Hyponatremia
Hypothyroidism
Renal failure
Volume depletion
Miscellaneous Conditions
Fecal impaction
Hospitalization
Impaired hearing or vision

Table 51.3e-2 Some Potentially Reversible Conditions That May Resemble Dementia

The clinical presentation of geriatric depression may mimic dementia. The earlier term " *depressive pseudodementia*" is no longer considered useful because the dementia is real; instead, the term *dementia syndrome of depression* often is used. The reported frequency of mistaking depressed for demented patients ranges from 5 to 15 percent. Psychomotor retardation, impaired concentration, and apathy characteristic of the depressed patient may be mistaken for symptoms of dementia, especially when these symptoms are accompanied by memory loss. In the dementia syndrome of depression, however, the complaints of memory tend to exceed the actual memory impairment observed on psychological testing. The fact that dementia and depression often coexist further clouds the diagnostic picture. About 30 percent of patients with a progressive dementia also suffer from some form of depression.

Many people in their 50s and older complain of forgetfulness and worry about its meaning. *Age-associated memory impairment*, as defined by a work group convened by the National Institute of Mental Health, applies to healthy persons 50 years and older who have subjective complaints of memory loss and mild deficiencies in memory performance compared to young adults. About 40 percent of persons in their 50s and up to 85 percent of those age 80 and older suffer from age-associated memory impairment. Preliminary data suggest that the condition is stable over intervals of up to 4 years, and thus is presumed to reflect normal aging and does not usually progress to dementia. Although it may take them longer to remember, most elderly people continue to recall information they have learned well and important events from the past.

COURSE AND PROGNOSIS

Dementia of the Alzheimer's type is a progressive disease that eventually leads to death, not directly from the dementing process but usually from intercurrent illnesses. The rate of progression varies, and it is difficult to estimate how rapid a decline a patient may have. Some patients become extremely demented within a year; others experience plateaus for several years.

TREATMENT

The first step in treating dementia is to attempt to identify any underlying illnesses that may be causing memory impairment and other symptoms of the syndrome. If none is found or if the symptoms persist after appropriate specific treatment, then several symptomatic treatments are available.

Psychopharmacotherapy A variety of pharmacological treatments is currently available for Alzheimer's disease (Table 51.3e-3 and Table 51.3e-4). Many of these approaches will diminish symptoms and increase quality of life, but none of them can halt the dementing process. Most pharmacological agents currently available or in development target a specific symptom (e.g., agitation or memory loss) and are derived from the known neurobiology of the disease (e.g., a specific neurotransmitter deficit) or hypothesized antidementia approaches (e.g., anti-inflammation or antioxidation).

Cholinesterase Inhibitors
Tacrine*
Donepezil*
Metrifonate
Galanzamine
Rivastigmine
Sustained-release physostigmine
Eptastigmine
Cholinergic Agonists
Xanomeline
Milameline
Antioxidants
Vitamin E (alpha-tocopherol)
Hormones
Conjugated estrogens
Other Potential Cognitive Enhancers
Nonsteroidal anti-inflammatory drugs (NSAIDs)
Ginkgo biloba
Acetyl-L-carnitine

* FDA approved.

Table 51.3e-3 Medications Used or Under Investigation for the Treatment of Dementia of the Alzheimer's Type

Antipsychotics	**Anxiolytics**
Haloperidol	Buspirone
Thioridazine	Lorazepam
Risperidone	Clonazepam
Olanzapine	**Antiparkinsonian Drugs**
Quetiapine	Selegiline
Anticonvulsants	***β*-adrenergic receptor antagonists**
Carbamazepine	Propranolol
Divalproex sodium	Pindolol
Antidepressants	
Fluoxetine	
Sertraline	
Paroxetine	
Trazodone	

Table 51.3e-4 Some Drugs Used to Treat Behaviors Associated With Dementia

One approach to improving memory function has been to enhance the cholinergic activity in the brain. Autopsies of patients with Alzheimer's disease have found reduced levels of choline acetyltransferase in the brain, a finding consistent with a central cholinergic deficit. Trials of cholinergic agonist agents have temporarily improved memory in young and old normal volunteers. Trials of several agents—including physostigmine (Antilirium), choline (Mega-B), and lecithin (PhosChol) have yielded contradictory results (some effects versus no measurable effects on memory in demented patients) or else have not yet been replicated. The Food and Drug Administration has approved for short-term treatment two reversible cholinesterase inhibitors, tacrine (Cognex) and donepezil (Aricept), which have modest effects on memory and other aspects of cognition. They also may reduce behavioral symptoms in some patients, and prolonged cholinergic therapy may even delay disease progression. Tacrine has the disadvantage of causing reversible elevations of serum transaminase levels. Additional cholinergic agents are under study.

Other promising agents for cognitive enhancement or protection currently under study include vitamin E, deprenyl (Eldepryl), estrogen, and nonsteroidal anti-inflammatory drugs. As scientists uncover the basic pathogenetic mechanisms of Alzheimer's disease, additional antidementia treatments, designed to perform such functions as inhibition of b-amyloid production or accumulation or interference with apolipoprotein E physiology, are likely to emerge. Additional approaches may target other neurotransmitter systems (e.g., noradrenergic) or use drug combination strategies.

Clinical experience suggests that available therapies for behaviors associated with dementia (e.g., depression, agitation, anxiety) are sometimes effective. Patients who have dementia with concurrent depression may improve following treatment with antidepressant medications. Antidepressant drugs with minimal anticholinergic effects (e.g., selective serotonin reuptake inhibitors) are preferred over tricyclic drugs. Lithium (Eskalith) can be an effective antidepressant for geriatric depression and bipolar I disorder. However, patients with underlying neurological diseases have been reported to do poorly with lithium treatment, so it should be used with caution in patients with dementia.

Preliminary data point to the utility of anticonvulsant drugs (e.g., carbamazepine [Tegretol], valproate [Depakene]) for agitation as well. Psychotherapies aimed at enhancing cognition are ineffective for dementia. Clinical experience suggests the efficacy of nonpharmacological approaches such as optimizing sensory input and maintaining daily routines in minimizing agitation.

Antipsychotic drugs are effective in treating psychotic symptoms and agitation, with the choice of a specific agent depending on its adverse effect profile. A meta-analysis of controlled trials of antipsychotic treatment in dementia indicated that antipsychotic drugs had a significantly greater effect than did a placebo, but the degree of the effects was small. Moreover, efficacy differences between such agents as haloperidol (Haldol) and thioridazine (Mellaril) were not found. Those studies, along with clinical experience, seem to support the judicious use of antipsychotic medications in managing some behavioral complications of dementia. Clinicians should be aware of the risk of tardive dyskinesia in elderly patients. One study of elderly psychiatric patients showed that the greatest risk is during the first 2 years of antipsychotic treatment. Because of such adverse effects, alternative drugs have been used to treat agitation, including beta-blocking agents and sedating antidepressant drugs, such as trazodone (Desyrel).

Benzodiazepines have also been used to treat the agitation that accompanies dementia. However, they have undesirable adverse effects, including some particularly noxious to the demented elderly patient, such as confusion, memory impairment, disorientation, dysarthria, and agitation complicated by ataxic gait. Short-acting benzodiazepines that do not require oxidative metabolism in the liver and have no active metabolites are safer than long-acting agents. Long-acting benzodiazepine agents tend to accumulate in the blood and are best avoided, as are very short-acting compounds, which tend to reach high peak levels rapidly. Relatively short-acting benzodiazepines may be useful for treating insomnia, although the clinician should evaluate the specific causes of the insomnia, such as restless leg syndrome, obstructive apnea, urinary frequency caused by prostatic disease, lack of daytime exercise, use of caffeine, and prolonged stays in bed. Moreover, attempts at reducing daytime sleep, avoiding nighttime stimulants, and regulating the timing of meals and activities should be made before using pharmacological agents for sleep.

OTHER INTERVENTIONS

Attention to the Environment Patients with cognitive losses are sensitive to their surroundings and seem to do best with optimal stimulation. Understimulation may cause withdrawal; overstimulation may cause confusion and agitation. Familiar and constant surroundings maximize the patient's existing cognitive functions. Daily routines often increase a patient's sense of security; memory and orientation can be facilitated by prominent displays of clocks and calendars, a night light, checklists, and diaries. Medication schedules should be simplified, if possible. If moves cannot be avoided, it helps to place familiar objects (e.g., photographs and furniture) in the new environment and to create a homelike atmosphere. The availability of newspapers, radio, and television can be useful in maintaining a patient's contact with and awareness of the outside world.

Family Intervention Psychotherapeutic intervention with family members is a critical aspect of treatment. Education and counseling about the nature of the patient's illness help relatives cope with the anger and puzzlement they often experience when the patient with dementia behaves in peculiar, disturbing, and uncharacteristic ways. Relatives may need reassurance that their emotional reactions are common and that talking about them can bring relief. Many relatives also need help in grieving the loss of the patient who now behaves like a stranger rather than the person they once knew. The Alzheimer's Association, a national organization of family members that has local chapters throughout the United States, has been at the forefront of providing educational and emotional support for family members.

Dementia of the Alzheimer's type has captured the attention of the mass media. Consequently, the public's concern and anxiety have led to a heightened awareness of memory changes and a tendency to overinterpret normal age-related memory impairment as dementia of the Alzheimer's type. Family members of Alzheimer's victims are generally the most anxious about any memory changes they observe in themselves, given the likelihood of genetic components in the disease. Sometimes education and a full physical and neuropsychological evaluation allay, at least temporarily, any unfounded anxiety about the disease. At other times, such an evaluation will uncover the early signs of progressive dementia.

In many situations the elderly person with dementia is the identified patient. But interpersonal conflicts among the family members require resolution to help the geriatric patient. Moreover, the adult child often makes the initial contact with the geriatric psychiatrist, and considerable skill and sensitivity are necessary to maintain an alliance with the adult child while respecting the elderly parent's autonomy, dignity, and privacy.

SUGGESTED CROSS-REFERENCES

For additional discussion on differential diagnosis, etiology, and pathology, see Chapter 10 on dementia. Section 51.4f provides details on the use of psychotropic medications for elderly patients. Section 51.6b and Section 51.6c on medical-legal and ethical considerations offer relevant issues for mentally impaired elderly persons. 51.3 PSYCHIATRIC DISORDERS OF LATE LIFE

51.3F SCHIZOPHRENIA AND DELUSIONAL DISORDERS

M. JACKUELYN HARRIS, M.D. AND DILIP V. JESTE, M.D.

Beginning with Emil Kraepelin's description of dementia precox, schizophrenia has usually been considered a disorder with onset during adolescence or early adulthood and a progressively downhill course. Over the past century, most studies of schizophrenia have been restricted to young adult patients. Relatively little research outside the United Kingdom and certain other European countries has examined the possible onset of schizophrenia in middle or old age or evaluated the course of schizophrenia in elderly patients. While the European research in this area has been much richer than that done elsewhere, it is limited by variable terminology and unclear diagnostic criteria. Recent investigations seem to challenge the original Kraepelinian notion of dementia precox in terms of both age of onset and long-term course of schizophrenia.

HISTORY AND COMPARATIVE NOSOLOGY

Psychotic symptoms with onset in middle-age or later life that were not related to a mood disorder or to a mental disorder due to a general medical condition were previously grouped as one disorder (paraphrenia) or as several different disorders (paraphrenia, paranoia, schizophrenia). Kraepelin used the term “paraphrenia” to describe a group of patients who had many of the symptoms of dementia precox but with less disturbance of emotion and volition. The term “paranoia” described a chronic well-systematized delusional state without hallucinations. Manfred Bleuler described late-onset schizophrenia as presenting after the age of 40 and otherwise similar to earlier-onset schizophrenia. The first edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-I) included the category involutional psychotic reaction for psychotic symptoms occurring during the involutional period. Some of the cases were characterized by depression and others by paranoia.

Martin Roth and colleagues used the terms “paraphrenia” and “late paraphrenia” (onset of the disorder after the age of 60). They divided their paraphrenic patients into three groups: (1) those whose symptoms appeared to be an extension of long-standing personality disorders; (2) those who had delusions that seemed related to their particular stressors or circumstances; and (3) those considered to have “endogenous” paraphrenia (i.e., not attributable to a long-term personality disorder or any particular stressors). Kurt Leonhand and other German authors of the time used the term *paraphrenia* to refer to paranoid schizophrenic patients without specifying age of onset. Felix Post categorized nonaffective paranoid disorders beginning after the age of 50 into three groups: (1) paranoid hallucinosis, with no psychotic symptoms other than auditory hallucinations associated with persecutory delusions; (2) schizophreniform syndrome, with somewhat more understandable paranoid symptoms, and (3) schizophrenic syndrome, with Schneiderian first-rank symptoms. The second edition of DSM (DSM-II) used the term “involuntal state” (involutional paraphrenia) to describe a delusional state with onset during the involutional period. No age cutoff was specified for the diagnosis of schizophrenia. The third edition of DSM (DSM-III) stipulated that a diagnosis of schizophrenia could be made only if the symptoms began before the age of 45. It also included the category “paranoid disorder,” which referred to persistent persecutory delusions without prominent hallucinations or other major symptoms of schizophrenia. The revised third edition of DSM (DSM-III-R) recommended the specification of late-onset schizophrenia if the symptoms began after age 45. It replaced the term “paranoid disorder” with the term “delusional disorder,” modified the diagnostic criteria to include a minimum duration of 1 month, and broadened the scope of delusions to include grandiose, erotomanic, somatic, jealous, and unspecified types. The fourth edition of DSM (DSM-IV) neither restricts the age of onset for the diagnosis of schizophrenia nor specifies the subcategory of late-onset schizophrenia. In this section *late-onset schizophrenia* refers to the onset of prodromal symptoms of schizophrenia after the age of 45 years. Notwithstanding the DSM-IV, late-onset schizophrenia is both a clinically and theoretically important condition that may or may not be a neurobiologically distinct subtype of schizophrenia. The criteria for delusional disorder in DSM-IV have not changed from those in DSM-III-R.

Thus schizophrenia and delusional disorder with onset in middle age and later life are considered separate diagnoses, just as schizophrenia is considered to be a separate disorder in younger patients. More research is needed, however, to establish independent diagnostic validity of those two disorders in late life.

LATE-ONSET SCHIZOPHRENIA

Epidemiology The prevalence of late-onset schizophrenia is not known. A 1988 review of studies of late-onset schizophrenia found that approximately 23 percent of patients with schizophrenia were reported to have experienced the onset of the disorder after age 40, with 13 percent in the fifth decade of life, 7 percent in the sixth decade, and 3 percent thereafter. A 1993 study found that 28 percent of first-contact patients (inpatients and outpatients) had onset of illness after the age of 44, and 12 percent after the age of 64. The exact prevalence of schizophrenia in the elderly population is not known. It has been suggested, however, that of the older patients with schizophrenia, approximately 90 percent have had onset during adolescence or early adulthood, while the remaining 10 percent have later-onset schizophrenia.

Studies of late-onset schizophrenia that have included both men and women have consistently found a predominance of women, which contrasts with the preponderance of men among schizophrenic patients between the ages of 15 and 34. It has been suggested that the relative excess of dopamine type 2 (D_2) receptors in young men (compared with young women) and elderly women (compared with elderly men) may help explain the age-related gender differences seen in schizophrenia. Alternatively, estrogen may help delay the onset of schizophrenic symptoms in predisposed women until after menopause. A large proportion of the patients with late-onset schizophrenia are married or were in the past. Many had been satisfactorily employed or had worked as homemakers prior to the onset of their illness.

Etiology The etiology of late-onset schizophrenia remains to be clarified. The data regarding family history of schizophrenia in the late-onset patients are conflicting. Some European studies found that late-onset schizophrenia was more weakly associated with a family history of schizophrenia than the early-onset form. On the other hand, a recent U.S. study reported that the prevalence of schizophrenia was similar in the early-onset and late-onset patients. It is not clear, however, whether the age of onset of schizophrenia in succeeding generations decreases as a function of the age of onset of the proband or whether the relatives also have late-onset schizophrenia. Abnormal premorbid personality traits (especially paranoid and schizoid) have been noted in a sizable proportion of patients with the diagnosis of late-onset schizophrenia. The pattern of impairment on neuropsychological testing is similar in early-onset and late-onset schizophrenia patients when corrected for age, education, and gender, but the late-onset group has less impairment in learning and abstraction and flexibility of thinking. A number of studies have reported an association between late-onset schizophrenia and sensory (visual and auditory) deficits, although sensory impairment has not been shown to be a risk factor for late-onset schizophrenia. A recent study suggested that older psychiatric patients might have difficulty obtaining optimal correction of their age-related visual or hearing deficits. Brain imaging studies have shown nonspecific structural abnormalities such as slightly enlarged ventricles and increased white matter abnormalities. One preliminary study found that older age at onset of schizophrenia was associated with a larger volume of thalamus on magnetic resonance imagery (MRI).

In general, patients with late-onset forms of schizophrenia and those with early-onset form are similar in terms of positive symptoms, the overall pattern of neuropsychological impairment (e.g., relatively normal retention of information), nonspecific abnormalities on structural brain imaging (e.g., slightly enlarged ventricles and increased white matter hyperintensities), chronic course, and qualitative response to neuroleptic drugs. Such similarities support the notion that the patients properly diagnosed with late-onset schizophrenia indeed have a schizophrenic disorder. However, important differences exist between the two forms. For example, patients with the late-onset variety are more likely to be female, be of paranoid subtype, exhibit fewer negative symptoms and less-severe deficits in learning and abstraction, possibly have somewhat different specific structural brain abnormalities, and need for lower daily dosages of antipsychotic drugs than age-comparable early-onset patients. These differences suggest that late-onset schizophrenia is probably a neurobiologically distinct form of schizophrenia.

Diagnosis and Clinical Features Patients with late-onset schizophrenia have symptoms (especially positive symptoms) largely similar to those of patients with early-onset schizophrenia. A comparative study of early-onset (age of onset 44 years or less) and late-onset (age of onset 45 years or more) schizophrenic patients found no difference between the two groups in the prevalence of delusions of reference, bizarre delusions, or lack of insight. Patients with the late-onset form,

however, tended to have more persecutory delusions with and without hallucinations, organized delusions, and abusive auditory hallucinations or hallucinations with a running commentary. The most common symptoms in the late-onset group were delusions, and approximately two thirds had bizarre delusions. Many of the patients have hallucinations, which are usually auditory. Late-onset schizophrenia patients tend to differ from those with earlier onset in having a lower prevalence of looseness of associations, inappropriateness of affect, and other negative symptoms. Consistent with these findings, late-onset schizophrenia patients typically meet criteria for the paranoid or undifferentiated subtype of schizophrenia.

The patient was a 57-year-old divorced white man who required psychiatric hospitalization for the first time at the age of 49, after presenting with a 6-month history of being under surveillance by the police, Central Intelligence Agency (CIA), and detectives who were following him and monitoring his actions. He became very distraught and claimed to have gotten “tired of dodging them” and turned himself in to the police. He was taken by the police to the hospital for admission. He denied hearing voices but reported a ringing in his ears warning him that something harmful would soon happen. The patient admitted seeing faces in pictures that changed from time to time while he looked at them. At the time of admission the patient was working full-time as a painter and lived with his elderly father as he had since his divorce 19 years earlier. He frequently saw his three sons who lived in the area. The family reported no previous history of mental illness in the patient. The patient's hobby was collecting model trains. His medical history was unremarkable, but the family history was significant for a maternal aunt who spent many years in a psychiatric hospital and his mother who required state hospitalization for 7 years for a “nervous breakdown.” The neurological and other physical examination was within normal limits as were routine laboratory tests and MRI of the brain. The patient was treated with haloperidol up to 4 mg a day with resolution of his delusional system except for episodic paranoid ideation and hearing voices. The patient was no longer employed but helped care for his 90-year-old father.

Differential Diagnosis The principal disorders in the differential diagnosis of late-onset schizophrenia include earlier-onset schizophrenia, mood disorders with psychotic features, delusional disorder, psychosis associated with cognitive disorders, psychotic disorder due to a general medical condition, and substance-induced psychotic disorder.

Early-Onset Schizophrenia Dating the onset of schizophrenia can be difficult. Many schizophrenic patients have an insidious onset of symptoms or may have premorbid personality traits that are difficult to differentiate from prodromal symptoms. Earlier onset and thus longer duration of schizophrenia are generally associated with more severe negative symptoms and greater cognitive deficits (especially in the areas of learning and abstraction).

Mood Disorder Major depression and bipolar disorder may be accompanied by psychotic symptoms such as delusions and hallucinations. Some, but not all, studies suggest that psychotic depression is more likely to occur in older patients than in younger ones. Mood-congruent or mood-incongruent psychotic features may occur with either diagnosis, making it difficult to differentiate them from schizophrenia. A careful psychiatric history of symptoms consistent with a mood disorder as well as a past history of mood symptoms may help to differentiate the two conditions. In addition, a positive family history of mood disorder may be helpful but is not necessarily of diagnostic value.

Delusional Disorder Delusional disorder is differentiated from schizophrenia by a lack of prominent auditory or visual hallucinations and an absence of deterioration in areas of functioning outside the delusional sphere. The delusions are necessarily nonbizarre (i.e., they involve situations that may occur in real life, such as theft, suffering from a disease, or spousal infidelity), while those in schizophrenia could be bizarre (e.g., having a computer installed in the patient's brain by a neighbor who wants to read the patient's mind).

Psychotic Symptoms Associated With Cognitive Disorders or Due to a General Medical Condition A patient who presents with psychotic symptoms after the age of 45, particularly if the symptoms present after the age of 60, requires a careful evaluation for underlying neurological and other medical disorders. Dementia is a common disorder in elderly persons, and approximately one third of patients with a diagnosis of dementia of the Alzheimer's type may present with psychotic symptoms at some point during the course of their dementia. Other types of dementia, such as alcohol-induced persisting dementia and vascular dementia, also need to be ruled out. The abuse, and more commonly misuse, of prescription and over-the-counter medications should also be evaluated.

Course and Prognosis Late-onset schizophrenia tends to follow a chronic course, which may be punctuated by partial remissions and exacerbations. The prognosis is somewhat better than that in early-onset schizophrenia. Nonetheless, mortality (especially from suicide) exceeds that in the general population and is probably comparable to that in early-onset schizophrenia.

Treatment Few systematic studies of the treatment of late-onset schizophrenia exist. It is clear, however, that a number of patients with late-onset schizophrenia respond well to low-dose antipsychotic agents. Maintenance therapy is frequently required since many of these patients relapse if they discontinue the medication. Elderly patients are more susceptible to adverse effects such as sedation, anticholinergic toxicity, and extrapyramidal symptoms. Similarly, the risk of neuroleptic-induced tardive dyskinesia is several times greater in older patients. Whereas the cumulative annual incidence of tardive dyskinesia in younger adults is 4 to 5 percent, that in middle-aged and elderly patients is 25 to 30 percent.

Recently, some of the “atypical” antipsychotic agents with serotonergic and dopaminergic blocking activity have been introduced for the treatment of schizophrenia including clozapine (Clozaril), risperidone (Risperdal), olanzapine (Zyprexa), and quetiapine (Seroquel). So far, the data on the use of these drugs in elderly patients are quite limited. These drugs have fewer extrapyramidal adverse effects, and may be more effective against negative symptoms. Some recent data suggest that the newer agents may also carry a lower risk of tardive dyskinesia and have a better effect on cognitive deficits in schizophrenia, although these findings need confirmation. These drugs do have their own adverse effects, and much lower dosages (about a third to a quarter) are recommended for elderly patients than for younger adults.

Psychosocial treatment is a vital aspect of the management of a late-onset schizophrenia patient. Establishing a good therapeutic relationship in a supportive setting is important. Although therapists need not agree with the patients' delusional system, they should convey a sense of understanding and empathy. Clinicians may seek the help of the patients' caregivers, family members, friends, neighbors, and priests or other religious figures in the community to facilitate the overall management. Such a supportive network may result in the early detection and resolution of emergency situations and thus avoid unnecessary hospitalizations as well as legal problems. Therapists may also use social agencies to help patients obtain appropriate financial, medical, nutritional, or transportational assistance. Clinicians may recommend conservatorship or guardianship for patients, with a view to ensuring proper health care and management of the patient's finances.

Course and Prognosis Only a handful of studies have followed the course of early-onset schizophrenia into old age. The findings from these studies challenge the notion implied in the term *dementia precox* according to which schizophrenia is associated with progressive deterioration. Overall, approximately 20 percent of patients with schizophrenia, as they age, begin to experience improvement in both positive and negative symptoms and eventually have psychosocial remission. Another 20 percent of patients have a worsening of symptoms, and the course is relatively unchanged in the remaining 60 percent. Thus, while schizophrenia continues to be symptomatic in older ages in most patients, a possibility of remission exists in a small proportion of the subjects. Accurate prediction of the long-term course of the illness in an individual patient is not possible, but the general factors associated with eventual positive outcome include female gender, later onset of symptoms, paranoid subtype, less severe negative symptoms, and better premorbid functioning.

The required (and tolerated) neuroleptic drug dosage tends to decrease with aging as a result of both pharmacokinetic and pharmacodynamic factors. At the same time, the marked heterogeneity among the elderly patients with schizophrenia indicates the need to individualize dosage regimens.

DELUSIONAL DISORDER

Epidemiology Studies suggest that between 2 and 8 percent of the elderly psychiatric population suffers from some type of paranoid symptoms. One study indicated that although only about 2 percent of elderly psychiatric patients satisfied DSM-III criteria for paranoid disorder, another 13 percent had paranoid ideation. DSM-IV estimates that the population prevalence of delusional disorder is approximately 0.03 percent. Delusional disorder usually first appears in middle-to-late adulthood. The overall prevalence of delusional disorder is slightly higher among women than among men, and the average age of onset is earlier for men (40 to 49) than for women (60 to 69).

Etiology Several factors have been postulated to contribute to development of delusional disorder: a family history of schizophrenia; avoidant, paranoid, or schizoid personality disorder; hearing loss; or being an immigrant or of low socioeconomic status. The available evidence implicating each of these factors needs confirmation. From the viewpoint of psychological defense mechanisms, delusions are generally attributed to an excessive and inappropriate use of projection. The patient tends to hold others responsible for any psychobiosocial losses that may accompany normal aging.

Diagnosis and Clinical Features Persecutory, somatic, or erotomanic delusions in the elderly patient are usually secondary to another neuropsychiatric disorder (e.g., schizophrenia, mood disorder, or dementia). Occasionally, however, a primary delusional disorder is implicated. The conceptualization and study of this disorder, like that of late-onset schizophrenia, has been hampered by inconsistencies in nomenclature and diagnostic criteria.

The essential feature of delusional disorder is a persistent delusion. In addition, the behavior is not obviously bizarre, and auditory and visual hallucinations, if present, are not prominent. The DSM-IV describes the following types of delusional disorder: erotomanic, grandiose, jealous, persecutory, somatic, mixed, and unspecified.

> The patient was a 74-year-old divorced white man referred by his primary care physician for paranoid delusions. The patient reported that a black gang was after him, especially “Mad Dog,” the leader of the 5000-member gang. The patient and his son said that the onset of the patient's concerns began 4 years earlier, and this resulted in the patient changing residences four times during this period and retiring from his job as a sales clerk in a clothing store 2 years ago. He called the police several times to show them the gang's footprints in the grass and to report noise outside his window. The patient denied depressed mood, change in sleep or appetite, memory impairment, or problems with concentration. He denied auditory or visual hallucinations or any past psychiatric history. The patient lived alone in his apartment and took care of his finances and other activities of daily living. He had a high school diploma, was divorced, and had worked as a sales clerk “all his life.” Medical problems were significant for hypercholesterolemia treated with medication. His Mini-Mental State Examination score was 30/30. His physical (including neurological) examination and routine laboratory tests were unremarkable. The patient refused to take the prescribed antipsychotic drug but did come to the clinic to discuss his concerns.

Common types of delusions seen in elderly patients with delusional disorder are skin infestation by insects; organs such as liver are cancerous (despite a lack of evidence); the person is being spied on, followed, or poisoned; and the spouse is unfaithful (without a real factual support).

Differential Diagnosis The considerations in the differential diagnosis of delusional disorder are similar to those for schizophrenia with onset late in life. One study noted more cerebral infarction on computed tomography (CT) scan than in normal control subjects. Another study reported somewhat milder cognitive deficits in older delusional disorder patients than in similarly aged patients with late-onset schizophrenia.

Course and Prognosis The course tends to be chronic, especially in those with the persecutory type of delusional disorder. Others may have partial remissions and relapses. Generally, both intellectual performance and occupational function are preserved, but marital and social functioning is compromised. The data on prognosis are limited, although the likelihood of complete recovery seems very low.

Treatment Antipsychotic agents are often effective, especially in agitated delusional patients, but they must be administered cautiously in the elderly patient. Noncompliance is a common problem in the treatment of patients with delusional disorder. Establishing rapport with the patients is critical for continued treatment.

SUGGESTED CROSS-REFERENCES

Schizophrenia is discussed in Chapter 12, and delusional disorder is discussed in Section 13.2. Antipsychotic drugs are discussed in Section 31.26 on atypical antipsychotics, and Section 31.17 on dopamine receptors antagonists. Psychopharmacological treatment for elderly patients is presented in Section 51.4b.

51.3 PSYCHIATRIC DISORDERS OF LATE LIFE

51.3G PERSONALITY DISORDERS

ROBERT M. ROHRBAUGH, M.D.

Personality disorders are enduring patterns of inner experience and behavior that markedly differ from cultural norms, are pervasive and inflexible, and lead to subjective distress or social and occupational impairment. Longitudinal studies have shown personality functioning, both normal and abnormal, to be remarkably constant across the life cycle; the major change in personality with aging tends to be increased introversion.

EPIDEMIOLOGY

Personality disorders manifest in early adulthood and are thought to be relatively stable over time. Despite this stability over time, cross-sectional comparisons show a lower prevalence of personality disorders in United States and European community samples of older adults than in younger individuals. This decrease in prevalence of personality disorders in the community-dwelling elderly population is subject to a number of interpretations. One factor contributing to the difference may be an age bias in diagnostic criteria; many of the examples of personality disorder in the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) and in commonly administered personality inventories highlight activities like work and sexual function, activities likely to be more prevalent in younger patients than in older ones. Other potential explanations for the decrease in prevalence with age include diminished or biased recall of events by elderly persons, selective mortality due to impulsive acts by individuals with personality disorders, fewer impulsive actions by elderly persons (“burn out”), and other cohort effects caused by different environmental or cultural experiences. The burn-out hypothesis is supported by an analysis by George Vaillant of a 40-year prospective study of male college students that demonstrated that the internal distress and impairment caused by personality disorder diminished by age 60. Other recent studies have suggested that after age 60 some patients with personality disorder may experience an intensification of symptoms. Thus, some patients with minor dysfunction during middle adulthood may become more impaired in late life and require clinical attention for the first time.

Most studies have found that between 15 and 30 percent of elderly psychiatric inpatients have personality disorders; rates in older age inpatient samples appear to be comparable to those in younger age samples. The proportion of elderly inpatients with a personality disorder varies, depending on the Axis I disorder of the patient. A recently published study using criteria from the revised third edition of DSM (DSM-III-R) found that only 6 percent of patients with an organic mental disorder met criteria for a personality disorder, while 24 percent of those with major depression also met criteria for personality disorder.

Comorbidity Much recent research on personality disorders in the elderly population has focused on the relationship between personality disorder and mood disorders. About 25 percent of mixed-age, community-dwelling patients in American, European, and Japanese populations were diagnosed with both major depressive disorder and a personality disorder. While these patients showed improvement in depressive symptoms after treatment, they remained more depressed and had poorer social functioning than the group without comorbid personality disorders. Both Cluster A (in a mixed-age sample) and Cluster B disorders (in an elderly sample) have been reported to predict significantly worse psychosocial and symptomatic outcomes after treatment of major depressive disorder. A prospective study of outpatients initially evaluated in middle age suggested that the negative effect of comorbid personality disorder on outcome of major depressive disorder may continue for 15 to 20 years after the index episode of major depression. However the presence of a comorbid personality disorder has not been shown to affect 1-year relapse rates in a group of elderly patients with major depressive disorder.

Elderly patients with an early age of onset of major depressive disorder have significantly higher scores on avoidant and dependent personality dimensions than do those with late onset of major depressive disorder. Whether a personality disorder predisposes patients to develop early-onset major depressive disorder or is caused by a major depressive disorder early in life is of clear interest to both researchers and clinicians.

Like those with depressive disorders, approximately 20 percent of a mixed-age sample of patients with bipolar I disorder exhibited a comorbid personality disorder. While one small study of elderly patients with bipolar I disorder has suggested a 65 percent prevalence of personality disorder in elderly patients with bipolar I disorder, this finding requires further validation. Like patients with major depressive disorder, elderly patients with bipolar I disorder and a personality disorder were more symptomatic and had poorer social adjustment than patients without a personality disorder.

CLINICAL FEATURES AND COURSE

In DSM-IV the personality disorders are grouped into three clusters based on descriptive similarities. Cluster A consists of odd or eccentric personalities including paranoid, schizoid, and schizotypal personality disorders. Cluster B consists of dramatic, emotional, and erratic personalities including antisocial, borderline, histrionic, and narcissistic personality disorders. Cluster C consists of anxious and fearful personalities including the avoidant, dependent, and obsessive-compulsive personality disorders.

Cluster A While individuals with Cluster A disorders do not appear to become more or less symptomatic from youth to midlife, a number of biological and psychosocial factors may place these patients at risk for becoming more symptomatic after age 60. Cluster A disorders have been identified as risk factors for development of late-onset schizophrenia; the proportion of individuals with Cluster A disorders who develop schizophrenia is not known. Common health problems in the elderly population, such as hearing loss, visual problems, or dementia, may exacerbate underlying tendencies in these individuals to be suspicious or paranoid. Finally, individuals with Cluster A personality disorders typically have significant difficulty tolerating intimacy with others, often reacting with hostility and suspiciousness. These individuals usually have very few supports in the community. If their physical health declines, professional caregivers may be upset by the patient's tendency to respond in an idiosyncratic or suspicious manner or to reject assistance altogether. Further difficulty may ensue if caregivers must provide personal care (e.g., helping the individual bathe) that these patients perceive as an invasion of their personal space. When faced with such activities, the patient may respond with agitation or even frank delusions. Institutional life, with its lack of privacy and forced intimacy, is often especially problematic for these individuals.

> Mr. H. is an 84-year-old single man who, neighbors reported, had always been a loner. Mr. H. worked at a filling station, dressed oddly, and would gruffly say hello when others initiated contact. Neighbors knew of no friends or family contacts. His only previous difficulties had occurred when children in the neighborhood would intrude on his fenced yard; he would become irate and chase them off. His neighbors had notified town officials when they noticed he was no longer taking care of his lawn. When a caseworker came to investigate, Mr. H. refused to allow him to enter, saying that all was well and that he didn't need any help. When the caseworker persisted, Mr. H. became agitated, yelling that the government didn't have any business interfering with his life. On his next visit, the caseworker arrived with a police escort. Mr. H. reluctantly allowed them to enter. The house was filled to the ceiling with newspapers that Mr. H. had saved for the last 20 years. Narrow paths led to the kitchen and bathroom, both of which were in serious disrepair. When asked why he kept the newspapers, Mr. H. replied that he believed if he didn't keep the newspapers he would “lose his luck.” Mr. H. was also found to have severely infected ulcers on his feet, which made it very difficult to walk or care for the house. Mr. H. refused the help offered by the caseworker. Because of the serious health concerns and the presence of a schizotypal personality disorder, a probate court judge granted a petition for a conservator of person and estate. While Mr. H. was hospitalized to treat his medical problems, the conservator authorized repairs to the house. Because Mr. H. continued to refuse entry, housekeeping services were provided by giving the workers a key to the house. With this support, Mr. H. has been able to continue to live in the community.

Cluster B Individuals with Cluster B disorders generally demonstrate improvement, at least through middle age, in the overt, high-energy, impulsivity that is a feature of these disorders. Antisocial personality disorder decreases from a point prevalence of 2 percent in younger community-dwelling individuals to 0.8 percent after age 65. Antisocial personality disorder was diagnosed in 4 percent of a group of male patients older than 65 who were treated in a primary care setting; the high

prevalence of antisocial personality disorder in this population was linked to health problems caused by substance abuse. Follow-up studies of patients hospitalized with borderline personality disorder suggest that these patients may have considerable improvement in both interpersonal and occupational functioning, especially in the second decade after hospitalization; however, after age 60 functioning may again begin to decline.

The core difficulties of individuals with Cluster B disorders include inability to tolerate or modulate strong emotion, fear of abandonment and of being alone, and real or fantasized narcissistic injury. Life events common to aging including bereavement, separation from family or friends, changes in physical appearance, overt health problems, and loss of social or occupational roles that may lead to a resurgence of previous pathological coping mechanisms. These coping mechanisms may be expressed differently by elderly and younger Cluster B patients. Impulsivity in an elderly patient may be manifested by taking unsafe risks like trying to walk shortly after a hip operation or abusing prescription drugs. Identity disturbance may be manifested by an inability to formulate future plans or pursue goal-directed activities. At other times coping mechanisms will be familiar to those who treat younger Cluster B patients. Settings such as prolonged inpatient medical hospitalization or nursing home placement are especially at risk for disruption because of the intense emotions likely to be engendered and the multiple staff working with the patient. Patients with Cluster B disorders may denigrate one group of staff or strongly express how disappointed they are with the quality of the care being provided, while cultivating care from other staff members.

Several studies have investigated the relationship between Cluster B disorders and attempted or completed suicide. Premorbid personality disorders were found in 76 percent of a mixed-age group of completed suicides at psychological autopsy; Cluster B disorders accounted for 82 percent of the personality disorders diagnosed. Patients meeting criteria for more than one personality disorder and those with personality disorder and a mood disorder were at especially high risk for completed suicide. Recent life events, especially interpersonal and financial difficulties judged to result from the individual's own behavior, were more common in a group of mixed-age suicide victims with personality disorders than in a group of age- and sex-matched controls without personality disorders. The association between life events and suicide in patients with Cluster B disorders may be mediated by impulsive reactions to stressful life events. Impulsivity was highly associated with the number of lifetime suicide attempts in a mixed-age population of patients diagnosed with borderline personality disorder.

Mrs. A. was an 80-year-old widowed female who entered a nursing home after developing unstable angina. She reported having had a “perfect life,” always living in the best neighborhoods, having beautiful clothes and jewelry, and having an adoring husband and children. Her children reported that she was emotionally aloof and always demanded “the best,” causing the family to live well beyond their means. While she often talked about her dissatisfaction with having to enter a nursing home, she was pleased that this home was “the best in the country.” She was very critical of certain staff she considered insufficiently attentive to her needs, referring to them as “the stupid ones.” Despite these difficulties she managed relatively well until her private funds were exhausted and she had to move to a semiprivate room. She then became very irritable and depressed, wondering “How am I supposed to live with another person? I've never had to share anything.” She felt that staff tended to the needs of her roommate immediately and forced her to wait for care. She attributed this to the roommate having a “special connection” with someone important at the home, even though there was no evidence this was true. Mrs. A. would loudly complain about having to deal with the physical problems of the roommate while the roommate was in the room. Mrs. A. believed the roommate envied her because of the close relationship she enjoyed with her children. Mrs. A. was quite dissatisfied with the professional staff, feeling they did not have sufficient power to provide her with a private room; she requested a change to the physician who was also the medical director at the nursing home. A change in roommate and treatment with psychotherapy, antidepressants, and antipsychotic drugs were minimally helpful. After finding her at the entrance telling visitors her view of conditions in the nursing home, administrators permitted Mrs. A. to move to a private room. Mrs. A.'s narcissistic need to be recognized as a person worthy of a private room was fulfilled, and the difficulties ended.

Cluster C Avoidant and dependent personality disorder may be more prevalent in older populations than in younger ones, though small sample size and methodological issues severely limit these studies. Moreover, other investigators have posited that the social withdrawal and difficulty with decision making that often accompany mild cognitive impairment from neurological illness may account for the apparent increased prevalence of Cluster C disorders.

Cluster C disorders may also disrupt the elderly patient's ability to interact with the health care system. Individuals with avoidant personality may interpret professional advice as criticism of their behavior and so avoid follow-up. Elderly patients with dependent personality may indefinitely defer making decisions on medical care or exhibit marked passivity in their relationship with health professionals; interestingly, this passive dependent stance may facilitate their adjustment to institutional life. Individuals with obsessive-compulsive personality may have extreme difficulty managing inactivity or changes in their routine caused by convalescence from surgical interventions or medical disability.

Ms. F. was a 77-year-old female who lived with an older sister and her husband. She had never married because she was always uncertain whether she had found the right person. Ms. F. had relied on her older sister to help her make most decisions in her life, even those involving what to wear or what food would be best for her to eat in restaurants. She had worked in relatively menial clerical positions even though she had been offered promotions. After retirement Ms. F. and her sister volunteered at a infant and child care center where the sister would feed and play with the children while directing Ms. F. to clean and change the infants. After her sister died suddenly, Ms. F. became very anxious and fearful about being left alone. Her relationship with her sister's husband, always somewhat conflicted because of her competition with him for her sister's attention, became increasingly problematic. She began to ask his advice on all decisions and to accompany him whenever he went out. Because he had promised his wife he would care for her sister if she were to die, he felt obligated to keep Ms. F. in the house. However, he frequently became irritable and verbally abusive toward her. She became increasingly depressed, anorexic, and withdrawn, rarely leaving her room. Another relative became concerned about Ms. F. and initiated medical consultation. Treatment with an antidepressant helped relieve her depression and anorexia, but she continued to constantly ask her brother-in-law for advice. After some counseling he was able to make the decision to place Ms. F. in a boarding home. She agreed with his decision and felt reassured after meeting the manager of the boarding house, who reminded Ms. F. of her sister.

DIFFERENTIAL DIAGNOSIS

When considering the diagnosis of a personality disorder in an elderly individual, clinicians must attempt to document enduring difficulties typical of the disorder since early adulthood. Failure to do so should prompt the clinician to consider alternative diagnoses. Even if these enduring patterns are reported by the patient or other informants, the clinician must consider whether other disorders may be exacerbating the personality disorder at this time.

Clinicians should carefully assess the elderly patient for medical, neurological, or Axis I psychiatric syndromes that may cause misdiagnosis of a personality disorder. Perceptual disorders such as hearing or vision loss may significantly worsen Cluster A disorders. Medications can produce erratic, volatile, disinhibited behavior typical of Cluster B disorders or the withdrawal and passivity typical of some Cluster C disorders. Personality changes are common in cortical and subcortical dementias and may precede cognitive impairment. Mood and anxiety disorders, including subsyndromal disorders common in elderly patients with medical disorders, should be evaluated closely, as they may mimic personality disorder symptoms or be comorbid conditions with significant added disability. Substance abuse, including prescription drug abuse (increasingly recognized as a major problem in the elderly population) could either be a symptom of a personality disorder or cause behaviors mistaken for a personality disorder, including the suspicious, hostile presentation of many Cluster A disorders.

TREATMENT

Patients presenting with symptoms consistent with a personality disorder should have a full medical evaluation with special attention paid to the neurological and cognitive examinations. Any medical or Axis I disorder should be fully evaluated and treated with somatic therapies before attempts are made to specifically treat the Axis II disorder.

Treatment plans should involve all medical, family, and community supports involved in the patient's care, especially with Cluster B patients, with whom miscommunication can contribute to disrupted care plan implementation. Limited and realistic goals should be set and agreed upon by the patient and collaterals. The treatment plan should be reviewed frequently, especially at the initiation of treatment.

A psychotherapeutic relationship may be useful if the patient can establish a therapeutic alliance. By focusing on the patient's present reality, this relationship may help address the splitting, interpersonal manipulativeness, and denial of unpleasant realities common in patients with personality disorders. At times conjoint meetings with family or caregivers may be useful to clarify aspects of the treatment plan or to moderate the effect of the patient on others; however the therapist must be explicit about issues of confidentiality when interacting with the patient's larger social network.

Pharmacotherapy for elderly patients with personality disorders may be useful, although data supporting the use of medications are largely extrapolated from studies

with younger patients. Antipsychotic drugs have been shown to be superior to placebo in treating the psychotic-spectrum symptoms in borderline personality disorder. A trial with an antidepressant should be considered for patients with prominent mood symptoms. In a group of mixed-age patients with major depressive disorder, fluoxetine (Prozac) significantly reduced the frequency of individual personality diagnoses after 8 weeks of treatment. Lithium (Eskalith, Lithobid) or an anticonvulsant may be indicated for patients with prominent irritability or mood lability. Clinicians considering a medication trial should proceed with caution, given the potential for adverse effects and the lack of data establishing the efficacy of psychopharmacological treatment of personality disorders in the elderly.

While treatment cannot be expected to resolve the sequelae of a lifetime of difficult interpersonal relationships, problematic social functioning, and intrapsychic distress, treatment may facilitate improved relationships with significant others, maximize function, minimize environmental disruption, and reduce the distress the individual feels while contending with the vicissitudes of aging.

SUGGESTED CROSS-REFERENCES

Personality disorders in general are discussed in Chapter 24. Mood disorders are discussed in Chapter 14 and Section 51.3d. The topic of psychotherapy and psychopharmacological treatment of the elderly is discussed in Section 51.4.

CHAPTER 51. GERIATRIC PSYCHIATRY

51.3 PSYCHIATRIC DISORDERS OF LATE LIFE

51.3H DRUG AND ALCOHOL ABUSE

EVE J. WISEMAN, M.D.

DRUG ABUSE

Most elderly drug abusers appear to prefer legal substances used abusively to illicit drugs. Nicotine dependence is the most common substance use disorder in the elderly population in the United States. Elderly people also abuse over-the-counter and prescription medication, especially medications with sedative, hypnotic, anxiolytic, or analgesic properties. Courses of benzodiazepine therapy are considerably longer in elderly persons than in younger ones, and prescription of benzodiazepines for the institutionalized elderly population is widespread. Illicit substance abuse among elderly persons could become a future public health problem, based on the increased prevalence of illicit substance use in current middle-aged people.

Epidemiology Elderly persons are the largest users of legal drugs in the United States, and they tend to use many drugs.

The U.S. Department of Health and Human Services reported that 20.2 percent of men and 18 percent of women between age 65 and 74 were current smokers. Elderly persons in several studies averaged more than four prescriptions and three over-the-counter medications per person. One community program for persons aged 60 or older found prescription drug abuse in 5 percent of cases. Almost two thirds of those identified started abusing prescription drugs before age 65 (early onset), and more than 90 percent had abused prescription drugs for longer than 5 years. They tended to abuse diazepam (Valium), codeine, meprobamate (Miltown), and flurazepam (Dalmane).

The Drug Abuse Warning Network collected data on drug abuse–related emergency episodes (overdoses, unexpected reactions, and chronic effects). Acetaminophen (Tylenol), alprazolam (Xanax), diazepam, and aspirin were the drugs most often reported in suicide attempts. People age 50 and older represented 13 percent of the suicide cases involving benzodiazepines.

Some elderly persons abuse illicit drugs. People who meet the lifetime criteria for alcohol dependence are most likely to have a diagnosis of illicit drug dependence. Elderly abusers of cocaine or heroin are also more likely to be cigarette smokers. Increasing age appears to be associated with a decreased prevalence of opioid abuse and dependence, a phenomenon termed “maturing out.” However, many persons remain opioid dependent for 50 years or longer.

Etiology Altered pharmacokinetics and pharmacodynamics place elderly persons at risk for more frequent and more severe adverse drug reactions. The relative safety of over-the-counter drugs is often established by testing younger people, leaving the elderly population vulnerable.

Advertising of over-the-counter products, the cost of health care, and reclassification of prescription drugs all contribute to drug abuse by elderly persons. A declining percentage of elderly people who abstain from alcohol may reflect an increased willingness to use and abuse drugs, and elderly persons may depend on drugs as a way to solve problems. Benzodiazepines are often prescribed for long-term anxiety and insomnia, and analgesics are prescribed for chronic pain. Illicit drugs may be available even to the institutionalized elderly population: employees of some nursing homes have been caught selling marijuana and cocaine to the more cognitively intact residents.

Diagnosis The clinician's index of suspicion must be high. When medications considered unnecessary or harmful are discontinued (often in an attempt to fulfill federal regulations regarding prescribing), withdrawal reactions can occur. Caffeine intoxication and withdrawal have been associated with irritability in elderly persons, as has nicotine withdrawal. These conditions may first become apparent after admission to a hospital or nursing home.

The phenomenon of sundowning (increased agitation or actual delirium at night) can result from benzodiazepine, anticholinergic, or other drug toxicity. Benzodiazepines produce sedation or paradoxical excitement during intoxication and anxiety during withdrawal. Depending on the drug's half-life, withdrawal symptoms and signs appear within hours or more than a week after cessation of drug use. Benzodiazepine withdrawal may be misdiagnosed as myocardial infarction, hypertensive crisis, or infection.

Severe overdose involving benzodiazepines can be associated with loss of consciousness, respiratory depression, hypotension, and eventual cardiac arrest. Urine and serum drug screens usually confirm the diagnosis. Family members need to list or bring the clinician the patient's medications, including over-the-counter products.

Course Smoking increases the risk of several cancers, vascular disease, chronic obstructive lung disease, peptic ulcer disease, and osteoporosis. Elderly people who continue to smoke also have higher rates of psychiatric symptoms and syndromes. People with previous inpatient treatment for a nonnicotine addiction have an increased cumulative mortality as they age, largely from tobacco-related causes.

The inability of elderly people to manage their own medications frequently causes nursing home admissions, emergency room visits, and hospitalizations. Medications are also implicated in hip fractures and long-term disability (e.g., sedative-, hypnotic-, or anxiolytic-induced persisting dementia).

Over-the-counter drugs can provoke serious complications in elderly persons. Elderly patients with mild dementia have developed delirium after taking a single 25-mg dose of diphenhydramine (Benadryl) for sleep. The combination of diphenhydramine and other medications with anticholinergic adverse effects can cause urinary retention, fecal impaction, confusion, and delirium. The use of ibuprofen (Motrin, Advil) can lead to gastric hemorrhage.

Tolerance can develop from benzodiazepine use, with the concomitant risks of withdrawal. Patients who overdose with benzodiazepines may require intubation, and aspiration pneumonia is a frequent complication. Other complications of benzodiazepine overdose include pressure injury to the skin and muscles, hypoxic brain damage, and irreversible cardiac arrest. Even when administered in therapeutic dosages, benzodiazepines may produce increased sedation and psychomotor impairment in elderly persons. Patients with dementia are more likely to develop intoxication and impaired physiological functioning at lower dosages of sedative, hypnotic, and anxiolytic drugs.

In recent research, cigarette smoking among community-dwelling older persons was associated with albuminemia or progressively lower albumin concentrations. Avoiding or quitting smoking may reduce the likelihood of becoming hypoalbuminemic, which is commonly regarded as a marker of primary protein-energy undernutrition. Cigarette smoking may also be a marker of malnutrition among older persons.

Treatment Cigarette smokers age 50 years and older have often smoked for 40 or more years. Thus, older smokers are usually long-term smokers, and they also tend to smoke more cigarettes per day compared to younger smokers. Although older smokers frequently receive advice to quit during medical visits, they consistently express attitudes unfavorable to smoking cessation. They generally do not think that smoking affects their health, that there is a strong possibility of serious health problems from smoking, that smoking is addictive, that smoke from other people's cigarettes is annoying, or that lung cancer is a terminal illness. Older smokers with realistic health consequences of smoking and those who perceive smoking as addictive may be more likely to be ready to quit. The effectiveness of smoking cessation programs might be improved by including age-sensitive recruitment strategies, program content, and modes of delivery. More emphasis about the consequences of smoking and benefits of quitting may be needed for older adults.

Smoking-cessation strategies include behavioral therapies (rapid smoking and satiation), cognitive therapies, relaxation training, social support, coping skills training, hypnosis, acupuncture, and group or individual counseling. Elderly patients with heart disease, hypertension, or peptic ulcer disease are probably poor candidates for the rapid smoking approach. Nicotine polacrilex (Nicorette) and transdermal nicotine (NicoDerm CQ, Nicotrol) are available as over-the-counter pharmacological treatments to reduce nicotine withdrawal symptoms. Short-term efficacy has been demonstrated for nicotine replacement systems.

Older adults who frequently attend religious services or engage in private religious activities may be significantly less likely to smoke cigarettes, and if they do smoke, may smoke fewer cigarettes per day than less religiously active older people. Religious groups may model prosocial behaviors, proscribe the use of addictive or physically harmful substances, or offer the person an opportunity to form social bonds with others who share positive beliefs concerning health habits. In addition, older adults who participate in religious activities may cope better with stress and experience less of a need to smoke. Research is needed to determine whether older people who participate in secular social group activity where smoking is prohibited report similar differences in smoking to those reported by older people who participate in religious activities.

Sedative, hypnotic, and other psychoactive medications may affect mobility or increase fall risk in older persons. All prescription and over-the-counter drugs should be reviewed routinely in terms of their risks and benefits, especially in frail individuals who may be at great fall risk because of medication adverse effects. Discontinuing unnecessary or ineffective medication may reduce the number of falls among the elderly.

Hospitalization may be necessary to treat acute benzodiazepine-related toxicity and to prevent withdrawal. Flumazenil (Romazicon), a specific benzodiazepine antagonist, may be appropriate for patients with benzodiazepine overdose. Patients with recent overdose frequently require gastric evacuation, lavage, and administration of activated charcoal to prevent further absorption. The airway must be protected during these procedures since elderly patients are at high risk for aspiration. Intensive monitoring for 24 to 48 hours and dialysis may also be necessary.

Gradual benzodiazepine discontinuation (over 4 to 8 weeks) is indicated for benzodiazepine-dependent patients who have not overdosed. Gradual reduction of the benzodiazepine dosage prevents the occurrence of seizures and attenuates withdrawal symptoms. Elderly patients may have more difficulty completing benzodiazepine withdrawal protocols and an increased likelihood of relapse despite completion of a cessation program.

Elderly opioid abusers may benefit from clonidine (Catapres) treatment during inpatient withdrawal. Clonidine reduces withdrawal severity when it is given in gradually decreasing dosages over 2 weeks. However, clonidine has potentially significant hypotensive and sedative effects and has not been specifically studied in elderly patients, so it should be used with caution.

Elderly persons who require opioid medications to control pain may meet criteria for the diagnosis of opioid dependence. They may be at risk to develop opioid withdrawal following either abrupt dosage reduction or administration of an antagonist and should be warned to avoid abrupt discontinuation of the drug. A tapering schedule should be used if treatment cessation is indicated, and opioid antagonist drugs (including mixed opioid agonist—antagonists) should be avoided. The medical use of opioids is very rarely associated with use to achieve euphoria, unsanctioned dose escalation, acquisition of the drug from multiple providers, or use of illicit drugs. Some elderly patients who experience unrelieved pain may manifest drug-seeking behaviors that cease once pain is relieved. Misunderstanding of this phenomenon may lead the clinician to inappropriately stigmatize the patient and to inadequately treat the patient's pain.

The patient and family should be educated regarding the potential complications of drug abuse. Involvement of pharmacists and home health care nurses may resolve medication management issues, and abusers of illicit drugs can be referred to self-help groups such as Narcotics Anonymous.

Pain management, biofeedback, and other nonmedication interventions may be appropriate. The physician should discourage elderly drug abuse by limiting prescriptions for benzodiazepines and analgesics and by regularly monitoring the patient's use of prescription and nonprescription drugs.

ALCOHOL ABUSE

Elderly people with alcoholism are not consistently identified. Chronic, heavy use of alcohol often results in impairments that are not concomitants of normal aging and are reversible with abstinence. Treatment of alcohol abuse and dependence in elderly persons may improve neuropsychiatric function and prevent alcohol-induced persisting dementia.

Epidemiology According to a recent investigation, lifetime prevalence rates for alcohol dependence in people 65 and older were 14 percent for men and 1.5 percent for women. However, these data excluded the homeless, nursing home residents, and hospitalized patients. Higher prevalence rates of alcohol abuse have been noted in elderly medical and psychiatric patients than in the general community. One study of substance abuse in a psychiatric evaluation and admissions unit reported a 40 percent prevalence rate of alcohol abuse in schizophrenic patients and a 65 percent rate in those with major mood disorders. About one fifth of the dual-diagnosis patients were aged 50 or older.

Elderly persons may have abused alcohol for a lifetime, intermittently, or only after a certain age (late onset, usually defined as onset after age 40). Those who meet the criteria for late onset represent 10 percent of the elderly admitted for alcohol treatment and are more likely to be women than men.

Etiology Alcohol is distributed to a smaller volume of blood with aging, so older people may experience problems without altering the amount of alcohol consumed. The aging brain may be more sensitive to the effects of alcohol because of loss of brain mass or impaired cortical blood flow. Inherited factors may regulate the development of tolerance to alcohol as well as susceptibility to the neurotoxic effects of alcohol. Some investigators have speculated that alcohol-related brain changes may contribute to the risk of relapse.

Particular classes of life events may interact with characteristics of the elderly individual and result in increased drinking. Many elderly persons do not classify alcohol as a potentially harmful drug and do not realize that combination of alcohol with medication can produce deleterious effects. Nursing homes may offer happy hours or use wine or beer as appetite stimulants.

Diagnosis Elderly persons with alcohol dependence may display less prominent alcohol use (quantity and frequency of alcohol used), less antisocial behavior, and less impulsivity than younger persons with alcohol dependence. However, older persons with alcohol dependence usually have more levels of cognitive dysfunction, including acquired intellectual impairment, impaired sensorium, self-neglect, and poor concentration. Cognitive impairment in older persons with alcohol dependence may not result solely from a longer duration of alcohol use. In a comparison of older and younger persons with a similar duration of alcohol dependence, the older group still exhibited different cognitive profiles than the younger group, especially in tests of cognitive flexibility.

Older community-dwelling persons with alcohol dependence may utilize health care inappropriately. They seldom seek treatment for alcohol dependence or treatment by a primary care physician, despite frequent emergency room visits and hospital admissions. Alcohol dependence among rural elderly women may be especially underdiagnosed without a thorough and ongoing assessment.

Collaborative sources of information and such indicators as housing problems, falls or accidents, poor nutrition, and inadequate self-care may facilitate the diagnosis. Often family members attribute alcohol-related confusion to advancing age. Because there are no validated instruments for alcoholism screening in cognitively impaired elderly patients, evaluation might include a search for alcoholic beverages at a home visit. The patient may have mental status changes, peripheral neuropathy, ataxia, and elevated values on liver function tests. Computed tomography (CT) and magnetic resonance imaging (MRI) may show cortical shrinkage and ventricular dilatation, which are difficult to separate from aging effects. Positron emission tomography (PET) may show reduced cerebral metabolism, and neuropsychological deficits have been correlated with frontal hypometabolism in PET studies of elderly patients with alcohol dependence. Single photon emission computed tomography (SPECT) scans may reveal perfusion patterns typical of comorbid problems, including head injury, human immunodeficiency virus (HIV) encephalopathy, dementia of the Alzheimer's type, or depression. Brain samples at autopsy may reveal widespread neuronal loss, degeneration of the mamillary bodies, and deficits of cholinergic and aminergic function. Wernicke's encephalopathy is often first recognized at autopsy.

Alcohol withdrawal delirium (delirium tremens [DTs]), Wernicke's encephalopathy, and Korsakoff's syndrome (alcohol-induced persisting amnestic disorder) always require prompt recognition and treatment, especially in frail elderly patients. DTs occur frequently in elderly alcoholic patients, especially in those with a previous history of DTs. The syndrome usually presents 24 to 72 hours after the last drink, but it may occur after as long as a week of abstinence. Characteristically, the patient

is tremulous with elevated vital signs (fever, tachycardia, hypertension) and diaphoresis. Mental status changes include wakefulness, agitation, and hallucinations.

Patients with Wernicke's encephalopathy present with ophthalmoplegia and ataxia, followed by mental status changes. Visual difficulties may include paresis or paralysis of the external ocular muscles with associated nystagmus and dysconjugate gaze. The patient may appear sleepy, confused, and lethargic. If untreated, Wernicke's encephalopathy can evolve into Korsakoff's syndrome.

Korsakoff's syndrome has an insidious onset and a long-term course. The patient is typically alert and responsive, with a profound memory deficit. Amnesia associated with Korsakoff's syndrome has both retrograde (inability to recall the past) and anterograde (inability to retain new information) components. Although the thiamine deficiency causing Wernicke's encephalopathy is probably related to Korsakoff's syndrome, alcohol may also have a direct, toxic role in Korsakoff's syndrome.

Alcohol-induced persisting dementia is generally a diagnosis of last resort. Before the diagnosis can be determined, patients must undergo (1) careful detoxification, (2) serial evaluation of cognitive function after detoxification, (3) nutritional support during detoxification and rehabilitation, and (4) long-term follow-up of cognitive status at regular intervals.

Course Alcohol use disorders in elderly persons are associated with increased mortality from accident, suicide, and illness. Alcohol use is a risk factor for unsafe driving in elderly adults. In a group of elderly psychiatric inpatients with major depression, 13 percent of recent suicide attempters had a diagnosis of alcohol abuse, compared with 2 percent of nonattempters. Medical problems related to alcohol include cirrhosis, one of the leading causes of death in people 65 and older. Alcohol ingestion also increases the likelihood of gastritis, already common in the elderly population, and the concomitant risk of gastrointestinal hemorrhage. Since people with alcohol dependence obtain as much as half of their calories from ethanol, serious deficiencies of protein, thiamine, folate, and niacin can develop.

When DTs occur, it usually lasts 2 to 3 days. Some patients have intermittent episodes of delirium for up to 2 weeks after drinking cessation, and a minority die from DTs. If Wernicke's encephalopathy is identified, ocular palsies improve within hours of treatment and normalize within days or weeks. Confusion from Wernicke's encephalopathy may resolve within a week or persist for as long as 2 months. Most patients with Korsakoff's syndrome show at least a partial recovery of memory with treatment.

As little as one drink a day may increase cognitive impairment in frail elderly persons. Elderly patients with alcoholism tend to have difficulties with memory, information processing, visuospatial analysis, nonverbal abstraction, and set flexibility. Age is the most important risk factor for alcohol-induced persisting dementia; however, prognosis improves with abstinence.

Treatment Hospitalization is usually necessary to detoxify elderly alcohol abusers. Parenteral thiamine administration helps prevent Wernicke's encephalopathy. When the diagnosis of Wernicke's encephalopathy is suspected, the patient should receive 50 to 100 mg of thiamine intravenously before any dextrose-containing solution is administered. Otherwise, carbohydrate metabolism will deplete whatever marginal stores of thiamine exist. Similar daily dosages of thiamine should be administered intramuscularly to all alcoholic patients until a normal diet can be tolerated; then the thiamine should be administered orally.

Patients with DTs require 24-hour monitoring to optimize their medical status and prevent dangerous behavior. Hourly administration of a medication cross-tolerant with alcohol may be required to control agitation. Elderly patients undergoing less-complicated withdrawal may also be confused and must be monitored for wandering and self-care deficits. Short-acting and intermediate-acting benzodiazepines, at one half to one third the middle-aged requirement, prevent withdrawal in elderly patients. A typical geriatric patient with alcoholism may be withdrawn using oxazepam (Serax) 15 to 30 mg up to four times a day and then tapered over a week to 10 days.

The elderly patient may also need hydration, correction of electrolyte imbalances, and nutritional supplementation. An initial workup should include the history, a physical examination, a blood alcohol concentration determination, a drug screening, glucose and electrolyte tests, tests of renal function, liver function tests, an amylase test, a complete blood count with a differential white blood count, a urinalysis, a chest X-ray, an electrocardiogram, and tests for calcium, magnesium, albumin, total protein, and stool guaiac. Brain imaging is essential for patients with a history of falls and neurological findings, since subdural hematomas are frequently diagnosed in elderly patients. Patients with persistent cognitive impairment also need brain imaging, as well as an evaluation of thyroid functions, syphilis screening, vitamin B_{12} and folate concentrations, and possibly assays for heavy metals and HIV.

Coexisting disorders should be addressed with nonaddicting medications. An elderly patient must be abstinent 2 to 3 weeks before a diagnosis of depression, anxiety, or persistent cognitive impairment can be established. Improvement in alcohol-induced memory impairment has been noted when patients were treated with serotonin-specific antidepressants or antidepressants that increase serotonin reuptake. Naltrexone (ReVia) can be used to reduce relapse in conjunction with psychosocial therapy. Naltrexone is contraindicated in opioid-dependent patients and in patients with acute hepatitis or liver failure.

The patient and family should be educated regarding the prognosis of continued drinking. Rehabilitation may include psychotherapy and Alcoholics Anonymous. Some studies have indicated more-favorable treatment outcomes for older patients in groups with similarly aged peers than in mixed-age groups. Programs emphasizing social relationships and positive aspects of an older patient's life have also demonstrated better outcomes than programs using confrontation and focusing on past failures.

Difficulties in getting older persons treatment may include patient denial or refusal, lack of transportation to treatment services, a paucity of local services, or a poor fit with existing services. Treatment programs may be targeted to a younger, healthier, better-educated, and more mobile population. Elderly persons with concomitant medical conditions may be excluded from programs focusing on psychosocial issues.

Although hospitalization is usually recommended for elderly persons undergoing detoxification from alcohol, some may be appropriately detoxified in the outpatient setting. These include older persons with no history of DTs or seizures, no comorbid problem requiring an inpatient level of care, mild to moderate symptoms of withdrawal, a negative breath or blood alcohol level, and adequate social support (assistance with transporation and alcohol-free housing). The preferred detoxification protocol in outpatient settings has been a standard course of benzodiazepine, which is gradually tapered and discontinued. However, older patients may be overmedicated by a standard course of benzodiazepine. Symptom-triggered detoxification, which incorporates a standardized withdrawal scale to determine benzodiazepine requirements during alcohol withdrawal, may be the more appropriate protocol for older persons. This protocol individualizes pharmacotherapy, enabling the clinician to limit the benzodiazepine dosage to the smallest effective amount in older patients.

SUGGESTED CROSS-REFERENCES

Substance-related disorders in the general population are discussed in Chapter 11. Cognitive disorders are discussed in Chapter 10. Neuroimaging is discussed in Section 1.15, Section 1.16, Section 2.13, Section 51.2e, and Section 51.2f.

51.4 TREATMENT OF PSYCHIATRIC DISORDERS

51.4A INTRODUCTION AND OVERVIEW

LISSY F. JARVIK, M.D., PH.D. AND FREDDA L. LEITER, M.D.

Psychopharmacology has become a major form of treatment for psychiatric disorders. In the geriatric age cohort, medications are a readily accepted mode of treatment, and psychotropic medications can be prescribed in the primary care clinic, which enables elderly individuals to obtain treatment without leaving the familiar medical setting. Psychiatrists tend to be involved in more complex situations (e.g., patients failing to respond to medications, developing side effects, presenting diagnostic problems), usually providing consultation to the primary care physician.

PSYCHOPHARMACOLOGICAL AND PSYCHOTHERAPEUTIC INTERVENTIONS

While both psychopharmacological and psychotherapeutic interventions have been shown to be clearly superior to placebo, psychopharmacological interventions have some advantages: they are comparatively inexpensive, reimbursement is easier to obtain, and they act relatively quickly. In depression for example, 50 percent remission of symptoms within 3 to 4 weeks is the standard response, and responders show some improvement of symptoms within 2 weeks. Choice of specific antidepressants is not based on efficacy, as clinical trials fail to reveal differences, but on adverse effects. There are few comprehensive studies of adverse effects in older adults, and the lack of standardized reporting and methodology makes the literature difficult to evaluate. A recent meta-analysis concluded that there is a clear need to supplement the existing database with results derived from well-controlled, rigorously designed, prospective research investigations since there is inadequate evidence with regard to clinically meaningful differences in side effects of antidepressant drugs. Nonetheless, there is a much more robust database for psychopharmacological than for psychotherapeutic interventions; since response rates to existing antidepressants hover around 50 to 60 percent, other approaches are clearly needed.

Psychiatrists may use a wide variety of effective treatments in conjunction with medication. Techniques may need to be altered to take into account physical or cognitive conditions or other issues pertinent to the older individual. Flexibility in location of the treatment setting is essential to provide access for the patient. Nonpsychopharmacological interventions include individual psychotherapy, specifically cognitive-behavioral therapy, family therapy, and group therapy.

A current trend in the treatment of psychiatric disorders in older adults is replacement of psychiatrists with other mental health professionals in an attempt to decrease cost for psychosocial treatments. In the future, mental health professionals may be supplemented or replaced by peer counselors and others with limited training in mental health, as a less expensive and more readily available option. The effects of such substitutions on treatment outcome remain to be evaluated.

ELECTROCONVULSIVE THERAPY

Electroconvulsive therapy (ECT) has been controversial in the United States. It can be the most effective treatment option, with the lowest risk of complications for older individuals with comorbid medical conditions likely to produce drug-disease and drug-drug interactions. ECT can provide a rapid response, which is vitally important in seriously ill patients, those at risk due to malnutrition or agitation related to psychiatric illness, and those at high risk for suicide. Nonetheless, ECT remains a politically charged topic. The current use of general anesthesia and medications to prevent musculoskeletal seizures have changed the procedure so that ECT is now generally considered as safe as, if not safer than, medication for use in frail elderly patients.

ANTIPSYCHOTIC MEDICATIONS

Antipsychotic medications used judiciously are of value in the treatment of elderly patients with psychotic symptoms due to schizophrenia, depression, mania, and dementia. The newer antipsychotics now available provide increased options for treatment with the likelihood of fewer adverse effects. Future research directions include studies on newer antipsychotic agents for the elderly population; inclusion of patients with comorbid medical conditions in studies of efficacy and adverse effects; and further research on the course and treatment of long-term adverse effects such as tardive dyskinesia. Reimbursement policies in both the private and public sectors must be examined to make newer antipsychotics easily available to elderly individuals.

ANTIANXIETY AGENTS

Anxiety is the most frequent mental disorder among persons over the age of 65. However, anxiety disorders and symptoms are not as well recognized in older adults as cognitive and mood disorders. Symptoms of anxiety often coexist with depression in older persons, and for these patients, antidepressants (rather than antianxiety agents) constitute the first-line treatment. Many older individuals are given prescriptions for antianxiety agents in the primary care setting, and education of the primary care physician in the diagnosis, course of illness, and treatment of anxiety and mood disorders is essential. According to a recent survey, antidepressants (specifically the selective serotonin reuptake inhibitors [SSRIs]) have already displaced benzodiazepines as the psychoactive agents most frequently prescribed by primary care physicians. The publication of guidelines for the treatment of mental disorders in the primary care setting is an important advance, and outcome measurement has received increasing attention as a means of assessing guideline implementation.

POSTTRAUMATIC STRESS DISORDER

Posttraumatic stress disorder may not be considered and may thus be missed in older individuals. War veterans may have a long history of undiagnosed posttraumatic stress disorder or may manifest symptoms only later in life, after having experienced multiple psychosocial stressors. Elderly individuals from other cultures who have experienced trauma prior to entering the United States (e.g., Holocaust survivors; refugees from Vietnam, Cambodia, or Eastern Europe) may experience posttraumatic stress disorder. In addition, older persons who have survived disasters such as floods, fires, or earthquakes or who have been the victims of crimes may suffer from unrecognized posttraumatic stress disorder. Research concerned with treatment of these individuals is just beginning.

COGNITION

To effectively prescribe psychotropic medication, the psychiatrist must be skilled in the thorough assessment of the older patient, including evaluation of cognition. Cognitive function may be affected by psychiatric conditions such as depression and may improve with appropriate treatment. Conversely, drug treatments may impair cognitive function because of sedation, slowing of cognitive processing, or other psychopharmacological effects. Dementia may coexist with depression, anxiety disorders, or schizophrenia. Accurate diagnosis facilitates the proper selection and monitoring of treatments.

DEMENTIA

The treatment of dementia can only grow in importance as the population ages. Both the cognitive and the behavioral manifestations of dementias must be addressed, as behavioral symptoms cause significant distress in patients and their families and may hasten institutionalization. Since behavioral symptoms may

reflect the emergence of a medical condition such as myocardial infarction or stroke, a careful medical evaluation is the first intervention for demented patients with an acute change in behavior.

Nonpharmacological Interventions for Dementia Behavioral disturbances include sleep, appetite, and sexual disturbances; incontinence; verbal or physical aggressiveness; restlessness; pacing; screaming; or repetitive requests. The psychiatrist should be familiar with nonpharmacological interventions such as adaptation of the environment to the patient's needs; elimination of excess visual and auditory stimuli; maintenance of a regular schedule; verbal reinforcement of positive behaviors; and minimization of negative behaviors with distractions such as music or other activities. Restraints should be avoided because patients may fall; damage skin, joints, or bone; become deconditioned; become incontinent of urine or feces; or have fecal impaction. Further research is necessary on treatment of behavioral symptoms in both community and institutional settings.

Caregivers often play a key role in the treatment of elderly patients. If the caregiver does not fully understand the plan and its rationale, treatment may be unsuccessful. Caregivers may develop burn-out, medical or psychiatric symptoms, or substance use that compromises the patient's care. Multidisciplinary teams can assess caregivers and harness the necessary psychological, medical, financial and other resources.

PSYCHIATRIST AS A HEALTH PROFESSIONAL

The psychiatrist, primary caregiver and subspecialty physicians, and other appropriate health professionals must be in close communication when treating elderly individuals. Otherwise, older adults may fall through the cracks between multiple systems of care and not receive the proper evaluation, treatment, or follow-up. Any one of the health professionals, including the psychiatrist, may at times have to act as patient advocate, and the geriatric psychiatrist may need to ensure access to treatment and continuity of care in addition to providing psychiatric treatments.

SUGGESTED CROSS-REFERENCES

General principles of psychopharmacology are discussed in Section 31.3, antidepressants in Section 51.4c, antianxiety drugs in Section 51.4d, antipsychotic medications in Section 51.4e, antidementia drugs in Section 51.4f, electroconvulsive therapy in Section 31.31, psychosocial treatments in Section 51.4h, individual psychotherapy in Section 51.4i, cognitive-behavioral therapy in Section 51.4j, family therapy in Section 30.5, and group therapy in Section 51.4l.

51.4 TREATMENT OF PSYCHIATRIC DISORDERS

51.4B PSYCHOPHARMACOLOGY: GENERAL PRINCIPLES

BRUCE G. POLLOCK, M.D., FH.D.

Patients older than age 65 currently represent approximately 13 percent of the U.S. population yet they receive up to 35 percent of all prescription drugs. As many as 20 percent of these patients suffer from multiple health problems and thus require substantial medical treatment. The average older American uses four prescription drugs and an additional four over-the-counter medications, and the typical nursing home resident is taking nine medications. In older patients, the medical complications of pharmacotherapy alone constitute a highly significant, treatable health problem. Adverse reactions to drugs of all types are seven times higher in those aged 70 to 79 years than in those 20 to 29 years old. One sixth of all hospital admissions of patients over the age of 70 have been attributed to adverse drug reactions. By comparison, adverse drug reactions account for only 1 in 35 admissions in the rest of the population. Precise estimates of adverse reactions due specifically to psychotropic drugs are lacking. Nonetheless, psychotropic drugs figure prominently with cardiovascular medications and nonsteroidal anti-inflammatory drugs as a common cause of drug-related problems in the elderly.

Until recently, older subjects, especially those with multiple medical problems, were systematically excluded from clinical drug trials. In 1993, a review of English language publications of any type (including case reports) relevant to treatment of late-life depression identified only 171 patients who were over age 75. An additional limitation in corporate drug trials is that the new entity is usually not compared with a currently recommended treatment standard. For example, amitriptyline (Elavil), which is not considered the antidepressant of choice in older or younger adults, is often compared with new agents in medication trials.

Although elderly patients frequently require lower doses of medications, age alone does not indicate the need for dosage modification. One must consider individual patient characteristics such as cardiovascular or renal function and genetic and acquired differences in body composition or drug metabolism, together with a drug's physicochemical properties. In addition to using rational pharmacotherapy, the physician must form an alliance with patients and their families to ensure adherence to treatment. Noncompliance with therapy is a major problem for psychiatric patients, and this dilemma is exacerbated with age. Age-related health problems combine with physiological changes to increase the probability of adverse effects from medication, which in turn increase the likelihood of noncompliance. Moreover, the complexity of medication regimens, inherent to the multiple illnesses of aged adults, are further complicated by communication difficulties arising from impaired hearing, cognitive impairment, language and cultural differences.

PHARMACOKINETIC CONSIDERATIONS

Pharmacokinetics provides a way of describing and predicting drug concentrations in plasma and various tissues over time. Although single- and multiple-dose pharmacokinetic studies are a standard part of phase I drug development, they are almost exclusively carried out on young, physically healthy, unmedicated males. If pharmacokinetic data are subsequently obtained in aged subjects, they are usually derived from single-dose studies. Single-dose studies are usually not adequate to rule out the possibility of altered pharmacokinetics in elderly adults. This is particularly true if there is systemic illness or interacting medications. Multiple-dose kinetic studies are especially important for high-clearance drugs to detect nonlinear phenomena wherein metabolism is not proportional to dose. Age-associated pharmacokinetic differences may be due to changes in absorption, distribution, metabolism, or elimination of a drug.

Absorption The rates of gastric emptying and intestinal blood flow decrease with age. Most studies evaluating drug absorption, however, have shown no difference in the rate or extent of absorption in geriatric and younger patients. Nevertheless, antacids, high-fiber supplements, and the cholesterol-binding resin cholestyramine (Questran) may significantly diminish the absorption of medications such as tricyclic drugs. Drugs with anticholinergic properties may decrease absorption of levodopa (Larodopa) because of delayed gastric emptying in conjunction with the gastric metabolism of levodopa. The potential gain in compliance achieved by administering medications at the same time should always be weighed against the possibility of drug interactions in the absorption phase.
